Lung biopsy Transbronchial lung biopsy is a sensitive tool for diagnosing sarcoidosis and lymphangitic cancer and may reveal pathologic features suggestive of IPF (i.e., fibrosis and widened alveolar septa with scant inflammatory cell infiltrate). Open lung biopsy is needed to exclude other causes of diffuse disease. It is up to the clinician to decide whether to proceed to open lung biopsy when clinical evaluation and transbronchial lung biopsy are highly suggestive of IPF. Open lung biopsy is advisable when there is any doubt about whether there is an infectious cause. Open lung biopsy should usually be performed in younger patients to establish the diagnosis of the underlying disorder with a reasonable degree of certainty.[5] Older patients with typical clinical features and a compatible transbronchial lung biopsy result may reasonably be spared the morbidity associated with open lung biopsy. In certain cases, it may be reasonable to diagnose IPF without any tissue biopsy. For example, a tissue biopsy may not be needed to diagnose IPF in an elderly patient who has had progressive dyspnea on exertion for many months to years and who has fine, end-inspiratory crackles and clubbing of the digits on examination, bilateral coarse interstitial infiltrates, low-titer serum antinuclear antibody, and no evidence of an environmental or a drug-related disorder.[52]

Prognosis and Treatment

The median survival for patients with newly diagnosed IPF is 2 to 3 years. Most deaths result from progressive pulmonary impairment. Adverse prognostic factors include cigarette smoking, severe dyspnea, low lung compliance, and high numbers of fibroblastic foci in the lung biopsy specimen.[53] Patients with IPF are also at increased risk for carcinoma of the lung.[54]

Corticosteroids have previously been used in the initial management of IPF. However, reviews of the lung biopsies of the patients in the studies supporting steroid use have suggested that the 20% to 30% of patients responding to steroids probably did not have UIP by the current pathologic criteria.[55]

Cyclophosphamide and azathioprine have been used in IPF, often in conjunction with prednisone or in patients in whom prednisone failed. The rationale for the use of these agents is similar to that for the use of steroids. A recent prospective trial found that cyclophosphamide had limited efficacy in a group of IPF patients in whom steroid therapy had failed or had produced unacceptable side effects.[56] Only one study provides evidence that azathioprine has any significant efficacy.[57] Current opinion holds that these drugs are more toxic than beneficial in IPF.[42] Colchicine, a drug thought to have antifibrotic properties, was not found to affect survival in one study.[58] Single-lung transplantation has been used successfully for end-stage lung fibrosis.[59] Patients who are potential transplantation candidates and whose $D_{L_{CO}}$ has dropped below 40% should be referred to a transplant center.[60]

Alternative therapies for IPF have been proposed.[61] A trial of interferon beta was unsuccessful. In a randomized controlled trial, a combination of interferon gamma-1b and low-dose prednisolone given to IPF patients whose condition was unresponsive to steroids or other immunosuppressive agents led to greater improvement in lung function over 12 months than was seen with prednisolone alone.[62] A larger randomized trial of interferon gamma-1b is under way.

desquamative interstitial pneumonia / respiratory bronchiolitis interstitial lung disease

Patients with DIP / RBILD present with cough and dyspnea of insidious onset.[43,63] Clubbing of digits is present in about 50% of cases. The average age at onset of symptoms is the early to middle 40s, which is significantly younger than the age at onset of IPF symptoms. Men are affected twice as often as women. Almost all of these patients are cigarette smokers, suggesting that the disease may be caused or initiated by tobacco use.

The chest radiograph typically shows vague, bibasilar opacities that correlate with ground-glass densities on HRCT. Some studies have found more reticulonodular and linear changes.[43,63]

The lung biopsy specimen in DIP / RBILD is characterized by a fairly homogeneous pattern in which alveolar spaces are filled with pigmented alveolar macrophages. These accumulations of macrophages are often accentuated in peribronchiolar air spaces, sparing the more distal air spaces [*see Figure 9*].[43,63]

Discontinuance of smoking has been associated with im-

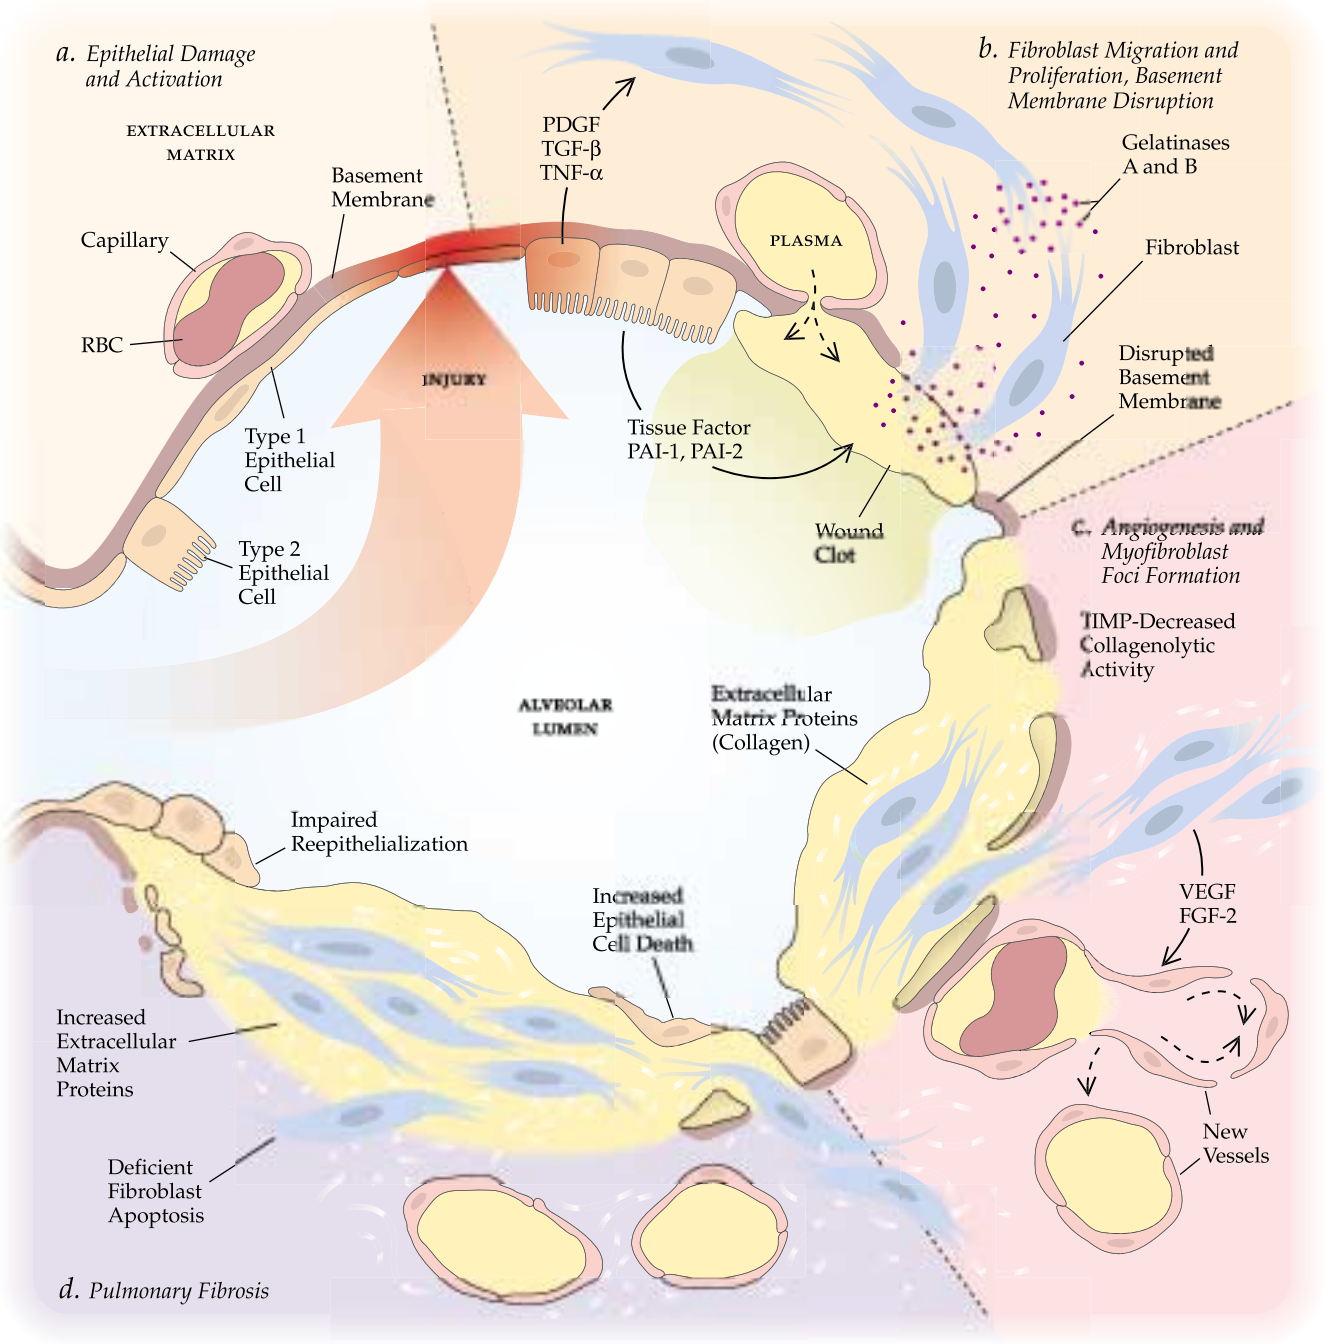

Figure 7 **The current hypothesis is that idiopathic pulmonary fibrosis (IPF) originates with repeated episodes of injury to the epithelium that result in formation of a microscopic lesion—in essence, a wound—in the wall of the alveolus (*a*). A fibrin clot then develops in the alveolar space, and the alveolar cells secrete growth factors (PDGF, TGF-β, TNF-α) that induce migration and differentiation of fibroblasts; in turn, the fibroblasts produce gelatinases that further disrupt the normal extracellular matrix and the basement membrane (*b*). Angiogenic factors (VEGF, FGF-2) induce new vessel formation. Small foci of myofibroblasts appear (*c*). An imbalance between increased synthesis of extracellular matrix proteins, mainly collagen, and decreased collagenolytic activity results in the progressive deposition of matrix, and deficient apoptosis of fibroblasts and increased epithelial cell death impair reepithelialization. The result of this aberrant healing process is pulmonary fibrosis (*d*). (FGF—fibroblast growth factor; MMP—matrix metalloproteinase; PAI—plasminogen activator inhibitor; PDGF—platelet-derived growth factor; TGF—transforming growth factor; TIMP—tissue inhibitor of metalloproteinase; TNF—tumor necrosis factor; VEGF—vascular endothelial growth factor)**

provement. Many patients improve without therapy other than smoking cessation. Steroids have been associated with a beneficial response in about 60%. The mortality is 20% to 30%, and the mean survival is 12 years.

acute interstitial pneumonia

Acute interstitial pneumonia is a distinct idiopathic condition that produces respiratory failure of rapid onset.[43,64] AIP is also known as Hamman-Rich syndrome.

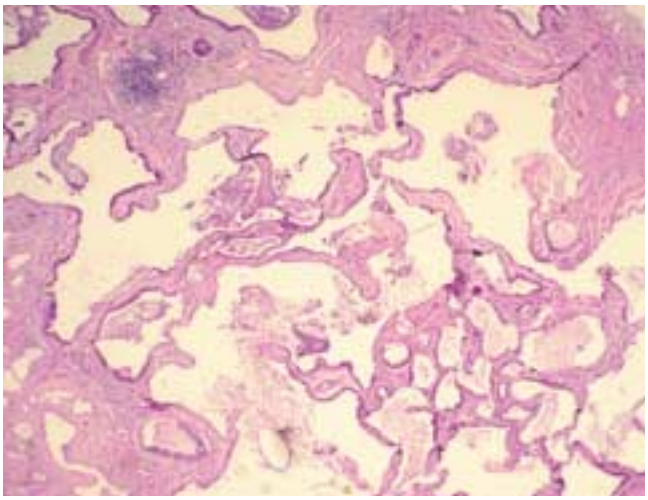

Figure 8 **Usual interstitial pneumonia is characterized by alveolar septal thickening, caused by fibrosis; minimal inflammatory cell infiltrate; honeycombing; and irregular involvement from one region to the next.**

The clinical presentation of AIP is similar to that of ARDS except that, in patients with AIP, no predisposing factor can be identified. A viral prodrome often precedes onset. Over a period of less than 30 days, a symptom complex of dyspnea, cough with mucoid sputum, and fever evolves into respiratory failure. Imaging studies by routine chest radiograph or HRCT show diffuse pulmonary infiltrates with ground-glass changes and consolidation.

The diagnosis is made by the recognition of a clinical illness compatible with ARDS in the absence of a predisposing factor after the exclusion of other alveolar-filling diseases, such as infectious pneumonia (especially PCP), alveolar hemorrhage, and eosinophilic pneumonia. The diagnosis is usually made through bronchoscopy with bronchoalveolar lavage.

AIP is characterized pathologically by the findings of diffuse alveolar damage. It cannot be differentiated from ARDS caused by sepsis, toxins, or shock [*see Figure 10*]. AIP evolves through the same sequence of pathologic patterns as ARDS [*see 14:X Pulmonary Edema*].

Treatment is largely supportive, through use of oxygen with either noninvasive or invasive mechanical ventilation. Steroids are advocated, but their use is not supported by controlled trials.

The mean 6-month mortality is 33% to 78%. Survivors may have recurrences or develop chronic progressive interstitial lung disease.

lymphocytic interstitial pneumonia

LIP is an interstitial lung disease characterized by diffuse or localized lymphocytic infiltration of the alveolar and interstitial areas of the lung.[43,65] This disorder can occur in association with a number of autoimmune processes (especially Sjögren syndrome), dysproteinemias, immunodeficiency (AIDS and common variable immunodeficiency), drug reactions (e.g., to phenytoin), or bone marrow transplantation; or it can occur as an idiopathic process.

LIP occurs more often in women than in men. The mean age at onset is 56 years. Patients present with dyspnea and cough, but the associated disorder may dominate the clinical picture. Rales and lymphadenopathy are common physical findings.

Imaging studies typically show reticulonodular infiltrates. The presence of hilar or mediastinal adenopathy or pleural effusion suggests lymphoma. HRCT will usually show a mixture of interstitial and alveolar (ground-glass) changes. Thin-walled cysts are often present.

Bronchoscopic specimens can be useful, showing a striking lymphocytosis (mostly B cells) on BAL and revealing lymphocytic infiltration on transbronchial lung biopsy [*see Figure 11*]. The pathologist will often need to use special studies to differentiate LIP from neoplastic forms of lymphocytic infiltration of the lung.

Patients with LIP should be treated for any underlying disorder. Some patients respond to steroids, though many require immunosuppressive agents.

nonspecific interstitial pneumonia / fibrosis

NSIP / F has often been confused with IPF. In retrospective analyses of patients who had been diagnosed with IPF, many were found to have NSIP / F and were noted to have a better prognosis than patients with IPF.[43]

NSIP / F occurs in middle-aged adults, with a mean age at onset of 49 years, but it can also affect children and older adults. There is a slight female predominance. Although some cases are idiopathic, many patients have collagen vascular diseases or immunodeficiency (including HIV infection), and some have a history of environmental or therapeutic drug exposures. A few patients have a history of an acute lung injury, such as that caused by pneumonia, ARDS, or surgery.

Dyspnea, cough, and sometimes fever are the dominant clinical features, with imaging studies showing bilateral interstitial infiltrates. HRCT scanning demonstrates bilateral, patchy areas of ground-glass abnormality, but this pattern is also seen with other disorders and therefore does not permit the confident diagnosis of NSIP / F.

NSIP / F can be diagnosed only by lung biopsy. As with IPF, transbronchial lung biopsy is not likely to produce an adequate specimen, so open biopsy is required. Pathologically, NSIP / F is characterized by a temporally uniform mixture of alveolar wall inflammation (mostly lymphocytes and plasma cells) and fibrosis [*see Figure 12*].

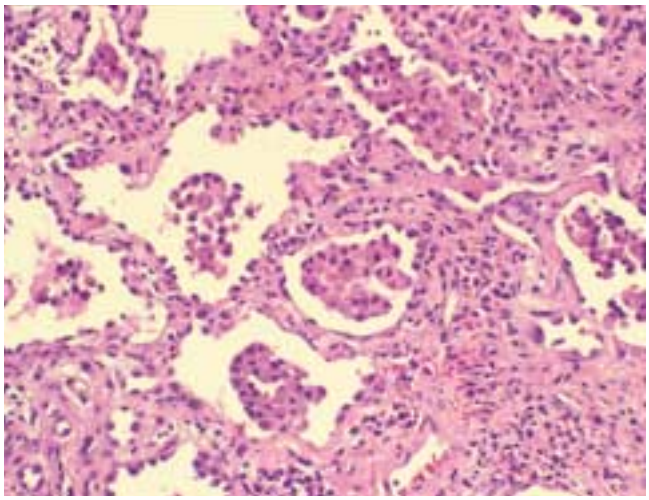

Figure 9 **Desquamative interstitial pneumonia/respiratory bronchiolitis interstitial lung disease. The alveoli and septal walls are filled with macrophages, and no fibrosis is apparent.**

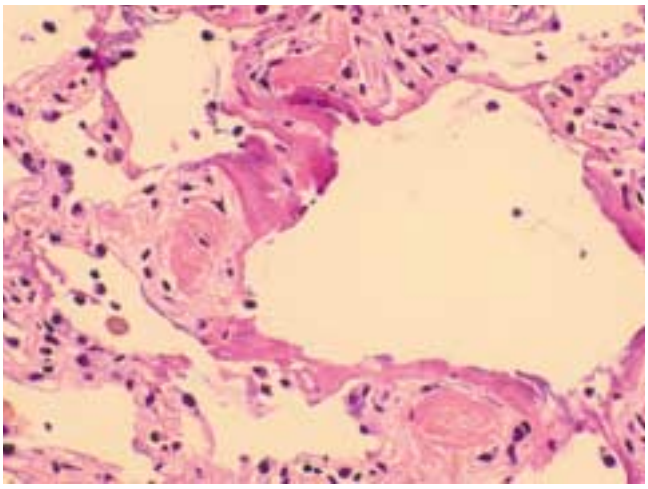

Figure 10 **Acute interstitial pneumonia. The biopsy specimen shows diffuse alveolar damage.**

Steroids appear to provide improvement in more than half of the patients with NSIP/F, and the prognosis for patients with NSIP/F is significantly better than that for patients with IPF.[66] Some patients experience relapses, and a minority have a progressive illness despite treatment.

bronchiolitis obliterans organizing pneumonia

BOOP [*see 14:IV Focal and Multifocal Lung Disease*], also called cryptogenic organizing pneumonitis,[43,67] occurs in the interstitium, within the alveoli, and in the small airways. BOOP is another disorder sometimes incorrectly diagnosed as IPF. The disease may result from any number of secondary causes, including proximal airway obstruction, reaction to drugs or inhalation of toxic fumes (e.g., oxides of nitrogen), viral infections, aspiration, lung transplantation, inflammatory bowel disease, collagen vascular disorders, and other lung diseases, such as eosinophilic lung disease, IPF, and hypersensitivity pneumonitis.

Clinical Manifestations

BOOP occurs in three clinical patterns: symptomatic idiopathic, secondary, and focal asymptomatic.[68] Although a thorough history sometimes identifies one of the secondary causes mentioned above, in some patients with idiopathic BOOP, an open lung biopsy is required to distinguish the disease from other diffuse parenchymal processes.

Clinical onset of BOOP usually occurs at 50 to 60 years of age. The illness frequently begins abruptly and is characterized by dry cough and dyspnea; fever, malaise, and fatigue are more common in BOOP than in IPF. Physical examination sometimes discloses rales that are often associated with wheezes. Clubbing of the digits, which is common in IPF, is absent.

Diagnosis

The diagnosis of BOOP is made by the correlation of the clinical findings with the results of imaging studies, particularly HRCT. Lung biopsy is often required in patients with idiopathic BOOP.

The chest radiograph typically shows bilateral patchy alveolar or ground-glass infiltrates, in contrast to the interstitial infiltrates that occur in IPF. HRCT often shows bilateral areas of consolidation on air bronchograms—involving mainly the lower-lobe subpleural region, the peribronchovascular region, or both—that are quite suggestive of the diagnosis.[6] Pulmonary function tests demonstrate obstruction, restriction, or a mixed pattern with decreased diffusing capacity and hypoxemia.

The lung biopsy in BOOP is characterized by the presence of intraluminal plugs of connective tissue in the bronchioles, alveolar ducts, and alveolar spaces [*see Figure 13*].

Treatment

Treatment with glucocorticoids has been quite successful, and many patients respond dramatically within days after starting therapy. When glucocorticoids are withdrawn, however, many patients experience a relapse, with recurrent systemic symptoms, infiltrates, and hypoxemia. Response to re-treatment is often good in such cases. Patients with focal asymptomatic BOOP do not require therapy.

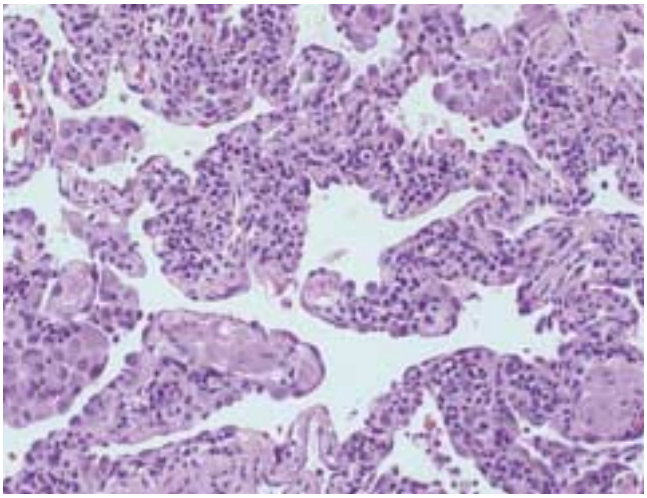

Figure 11 **Lymphocytic interstitial pneumonia. The biopsy specimen shows infiltration of the alveolar walls and alveoli with mature lymphocytes.**

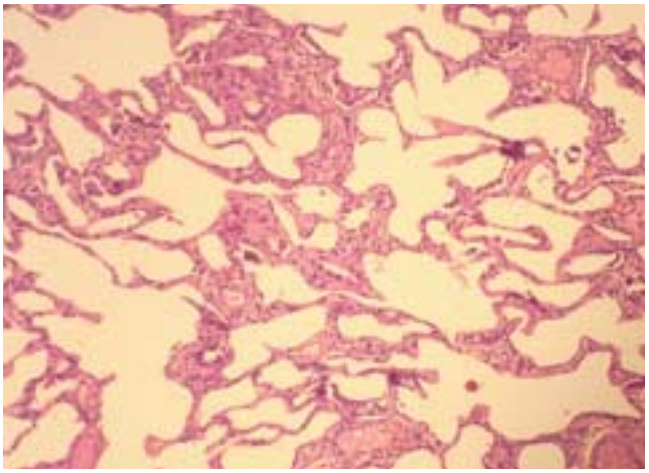

Figure 12 **Nonspecific interstitial pneumonia/fibrosis. The biopsy specimen shows a temporally uniform mixture of alveolar wall inflammation (mostly lymphocytes and plasma cells and fibrosis).**

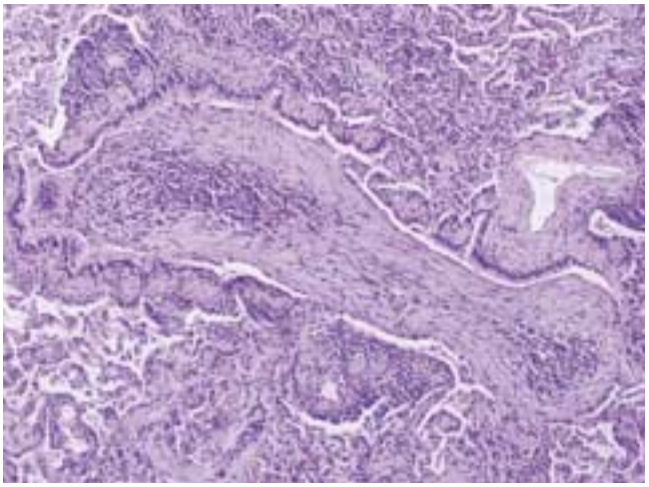

Figure 13 **Bronchiolitis obliterans organizing pneumonia. The biopsy specimen shows intraluminal plugs of connective tissue in the bronchioles, alveolar ducts, and alveolar spaces.**

collagen vascular diseases with associated pulmonary involvement

Collagen vascular diseases commonly affect the lung.[69] As many as two thirds of patients have clinical evidence of pleuropulmonary involvement, and nearly all have abnormal findings at autopsy. The immune mechanism is thought to be immune complex deposition, but the evidence that this mechanism is at work is more convincing in some collagen vascular disorders than in others. Pulmonary function tests in patients with interstitial infiltrates and fibrosis show restriction, small airway obstruction, and reduced $D_{L_{CO}}$ with hypoxemia at rest and worsening hypoxemia with exercise. HRCT of the chest often detects subtle interstitial disease that cannot be seen by routine chest radiography. Although the chronic interstitial disease seen in some of these disorders is pathologically indistinguishable from IPF, patients with a collagen vascular disease seem to have a better prognosis than those with IPF[70]; this is true even for those patients in whom collagen vascular disease develops after IPF.[71] Other patients with collagen vascular disease will have a pathologic pattern consistent with one of the other IPF-like disorders, such as LIP, NSIP / F, or BOOP.

Systemic Lupus Erythematosus

SLE is one of the most prevalent of the collagen vascular diseases, especially in African-American women of childbearing age; however, as many as 18% of cases occur after the fifth decade of life. Drug-induced SLE is a common clinical problem, especially in elderly patients with heart disease. Drugs that commonly cause SLE include hydralazine, procainamide, isoniazid, phenytoin, quinidine, methyldopa, and several of the beta-blocking agents. A few other drugs have been implicated, but the evidence is not as strong.

Pleuropulmonary complications of SLE occur frequently (in 38% to 89% of cases) and often must be differentiated from infections.[69,72] Pleural disease, atelectasis, acute lupus pneumonitis, and chronic intersititial pneumonitis are the most common clinical problems. Less commonly, alveolar hemorrhage or pulmonary vascular disease (acute reversible hypoxemia syndrome, vasculitis, or thromboembolism) may occur. Pleuropulmonary disease is frequently the presentation of patients with drug-induced SLE.

Acute lupus pneumonitis initially presents as sudden onset of cough and dyspnea. Radiographically, it appears as patchy basilar opacities. Occasionally, radiography shows only horizontal linear shadows that have been attributed to small areas of atelectasis; patients in whom this occurs usually respond well to glucocorticoids.

Chronic interstitial pneumonitis occurs as a complication in about 10% of patients with SLE. Many of the patients with chronic interstitial pneumonitis have mild, often asymptomatic disease detectable only by lung function testing and HRCT. Some cases are the result of prior episodes of acute lupus pneumonitis. Pathologically, most of these cases are similar to cases of NSIP / F. Rarely, chronic interstitial pneumonitis evolves into severe pulmonary fibrosis. Steroids and other immunosuppressive agents may be beneficial, but no trials have been performed to investigate this.

Patients with SLE may present with overwhelming alveolar hemorrhage or have occult hemorrhage during the course of their disease. Severe alveolar hemorrhage in SLE is associated with a 70% mortality. The symptoms are cough and dyspnea with or without hemoptysis; chest radiographs show fluffy alveolar infiltrates that may be patchy or confluent. Treatment is similar to that of Goodpasture syndrome and includes corticosteroids, plasmapheresis, and immunosuppressive therapy [*see 10:V Glomerular Diseases*].

Rheumatoid Arthritis

Although the incidence of rheumatoid arthritis is higher in women than in men, pleuropulmonary complications occur more frequently in men than in women.[69,73] Smokers are also at increased risk. Pleuropulmonary complications are clinically apparent in up to 14% of patients within 2 years of presentation[74] and in approximately 50% of patients over the course of the illness; a much higher percentage have pathologic involvement. In occasional cases, thoracic involvement becomes apparent before the articular disease, making diagnosis difficult.

The most frequent pleuropulmonary problems are interstitial lung disease, bronchiolitis, pleural disease, and parenchymal rheumatoid nodules. Less common problems include chronic airflow obstruction, bronchiectasis, BOOP, bronchiolitis obliterans, and pulmonary vasculopathy. These problems are usually associated with active arthritis, high titers of rheumatoid factor, circulating immune complexes, and cryoglobulinemia.

Diffuse interstitial pneumonitis with fibrosis is the most common and serious pulmonary problem in patients with rheumatoid arthritis, seen in up to 58% of patients if sensitive methods of detection are used. Other types of infiltrative lung disease—especially related to drugs commonly used in the treatment of rheumatoid arthritis, such as methotrexate and gold—must be considered. Dyspnea, sometimes with cough, is the most common symptom. Clubbing of the fingers may be present. The chest radiograph evolves from fine nodularity to coarse reticulation and finally to a honeycomb pattern. HRCT shows ground-glass attenuation and basal honeycombing, sometimes associated with pleural disease, bronchiectasis, or emphysema. Results of BAL may be abnormal, demonstrating increased numbers of lymphocytes, neutrophils, eosinophils, or all three; this variability has not been shown to have a bear-

ing on management. The pathologic patterns on open lung biopsy specimens include UIP, DIP, NSIP/F, LIP (in cases complicated by Sjögren syndrome), and BOOP. In patients with interstitial disease that is characterized by increased cellularity in lung biopsy specimens or the presence of progressive symptoms, glucocorticoids should be administered. Other drugs that have been anecdotally reported to benefit these patients include azathioprine, cyclophosphamide, methotrexate, and D-penicillamine.[73]

Rheumatoid (necrobiotic) nodules may be found in many tissues, including the lung parenchyma, endobronchial mucosa, and pleurae; in any of these locations, the nodules may cavitate. These lesions have a characteristic histopathologic appearance on microscopic examination; unless percutaneous transthoracic needle biopsy or open lung biopsy is performed, such lesions can be difficult to differentiate from those of malignancy or tuberculosis. Most rheumatoid nodules do not cause symptoms, and treatment is rarely necessary once a diagnosis is established.

Progressive Systemic Sclerosis

Progressive systemic sclerosis (PSS), also called scleroderma, is a disorder that predominantly affects women in the fourth to sixth decades of life. The prognosis is unfavorable, especially in African Americans, men, and patients with pulmonary disease.

Pulmonary complications, particularly interstitial lung disease, occur in as many as 90% of confirmed cases of PSS.[69,75] The presence of the serum autoantibody antitopoisomerase (Scl-70) is associated with the development of infiltrative lung disease. Interstitial lung disease in PSS is characterized by basilar reticular or reticulonodular fine infiltrates that become coarser as the disease progresses. In addition, radiography may show a loss of lung volume over time, and pneumothorax may occur. Evidence of pulmonary hypertension may be greater than would be expected from the degree of radiographic abnormality or pulmonary function disturbance, especially when Raynaud phenomenon is part of the clinical syndrome.

Glucocorticoids are not useful as therapy for interstitial lung disease associated with PSS; cyclophosphamide may be effective in patients who are shown by BAL to have active alveolitis.[69,75] As a result of esophageal motility disturbance, aspiration of gastric and esophageal contents often occurs; aspiration occurs more frequently when patients are in the recumbent position. Aspiration can be prevented by elevating the upper body to the near-upright position.

CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) is a variant of PSS. Patients with CREST syndrome have prominent pulmonary vascular disease. This pulmonary hypertension may be associated with interstitial fibrosis, as is seen in PSS, or it may occur as an isolated finding [*see 15:V Scleroderma and Related Diseases*].

Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are autoimmune disorders that are characterized by weakness and occasionally by pain in proximal limb and neck muscles, skin rash (dermatomyositis), and neoplasm. The most frequent pulmonary complications of polymyositis and dermatomyositis are respiratory failure caused by respiratory muscle weakness, aspiration secondary to posterior pharyngeal and proximal esophageal weakness, and interstitial lung disease.[69,76]

Interstitial lung disease is seen in a minority of patients and may be associated with anti–Jo-1 antibody, an autoantibody that is specific to the cellular enzyme histidyl-tRNA synthetase. These patients may have BOOP, NSIP/F, UIP, or diffuse alveolar damage. In contrast to the interstitial disease associated with many of the other connective tissue disorders, that associated with polymyositis and dermatomyositis responds well to glucocorticoid therapy. Other immunosuppressive agents, such as azathioprine or methotrexate, are often used concurrently for treatment of the polymyositis/dermatomyositis.

Sjögren Syndrome

Sjögren syndrome comprises the triad of keratoconjunctivitis sicca, xerostomia, and recurrent swelling of the parotid glands and is often (in 60% of cases) associated with other collagen vascular diseases. Sjögren syndrome frequently includes pleuropulmonary problems, but in many cases these problems are secondary to the underlying connective tissue disease. Thoracic complications that may be directly related to Sjögren syndrome include interstitial infiltrates, often lymphocytic in nature (LIP); pleurisy with or without effusion; follicular bronchiolitis; and desiccation of the tracheobronchial tree, leading to impaired tracheobronchial clearance and consequent bronchiectasis and recurrent bronchitis or pneumonitis.[69,77]

Dyspnea is the primary symptom of the interstitial disease associated with Sjögren syndrome, whereas hoarseness and cough that is productive of thick, tenacious sputum are symptoms of laryngeal and tracheobronchial involvement. Chest radiography may show interstitial infiltrates with a prominent nodular component. These infiltrates have a lymphoplasmacytic histology that can be difficult to differentiate from that seen in patients with lymphoma. Results of pulmonary function tests demonstrate restrictive, obstructive, or mixed patterns. The lymphocytic interstitial pneumonitis and bronchiolitis associated with Sjögren syndrome respond to glucocorticoid treatment or immunosuppressive therapy.

Mixed Connective Tissue Disease

Several reports have described patients who have features of SLE, PSS, and polymyositis, often with associated pulmonary disease.[69,78] A hallmark of such mixed connective tissue disease is the presence of high titers of antibodies to extractable nuclear ribonucleoprotein (anti-nRNP). This syndrome is usually a relatively benign disease that responds well to glucocorticoids, although some cases display a less benign course that is associated with fatal diffuse interstitial lung disease or pulmonary hypertension.

eosinophilic granuloma of the lung

Eosinophilic granuloma of the lung, or pulmonary histiocytosis X, is an uncommon cause of diffuse infiltrative lung disease that primarily affects persons who are 20 to 50 years of age.[79] The disease is uncommon in African Americans and extraordinarily rare in Asians. The etiology of eosinophilic granuloma is unknown, but there is a strong association with cigarette smoking. In children and young adults, eosinophilic granuloma is a systemic disease with a similar histologic appearance, and either diabetes insipidus resulting from pituitary involvement or eosinophilic granuloma of bone may be seen in 15% to 20% of patients.

Clinical Manifestations

Most patients with pulmonary eosinophilic granuloma have cough or dyspnea, but as many as 25% of affected persons have only radiographic abnormalities and no symptoms. Between 10% and 20% of patients develop pneumothoraces, and a spontaneous pneumothorax may be the initial manifestation of the disease. The association of spontaneous pneumothorax with radiographic evidence of diffuse interstitial infiltrates suggests a diagnosis of eosinophilic granuloma or AIDS-related PCP.

The patterns seen on chest radiographs and HRCT in eosinophilic granuloma are variable.[6] Nodular and ground-glass opacities with thick-walled cysts are typically present early in the course of the disease. Later, thin-walled cysts, linear opacities, and emphysematous lesions are seen.

Eosinophilic granuloma often causes a reduction in $D_{L_{CO}}$ and vital capacity. However, unlike most other types of diffuse infiltrative lung disease, airflow obstruction is a characteristic feature, particularly in the later stages of the disease. The high incidence of airflow obstruction in eosinophilic granuloma may result from bronchiolar involvement in earlier stages of the disease and from bullae in late-stage disease. Smoking may also be a contributing factor to the high frequency of airflow obstruction in this disorder. Significant impairment of exercise performance is frequent and is greater than that which might be expected from the degree of volume restriction. Increasing wasted ventilation ratio (V_D / V_T) and falling P_aO_2 with exercise result in poor exercise performance in patients with pulmonary vascular abnormalities, which appear to be very prominent in eosinophilic granuloma.[80]

Histopathologic Features

The histopathologic features of eosinophilic granuloma are unique and include the presence of cells that resemble Langerhans cells in the skin. These cells stain positively with anti-CD1a monoclonal antibody and are shown by electron microscopy to contain characteristic inclusions termed X bodies, or Birbeck granules.[79] These cells can be seen in other types of diffuse infiltrative lung disease, but their numbers are much greater in eosinophilic granuloma. In patients with eosinophilic granuloma, $CD4^+$ T cells are in apposition to Langerhans cells, and there are increased numbers of neuroendocrine cells.[81] Granulocyte-macrophage colony-stimulating factor (GM-CSF) and TGF-β are found in the lesions, suggesting that these factors are potential mediators of the stimulation of Langerhans cells and fibroblasts, respectively. These findings suggest that the pathogenesis of eosinophilic granuloma involves interactions among these cells that result in fibroblast stimulation and fibrosis.

Diagnosis

The diagnosis of eosinophilic granuloma can be made most confidently by open lung biopsy. However, it has been suggested that the finding of more than 5% $CD1a^+$ cells in BAL fluid, along with an appropriate clinical and radiographic picture, may suffice for diagnosis.[79] HRCT may prove to be a useful noninvasive technique for diagnosing eosinophilic granuloma.

Treatment and Prognosis

Patients with eosinophilic granuloma have shown improvement after smoking cessation, and treatment with glucocorticoids has been reported to be effective, though no therapy has been sufficiently studied or has produced sufficiently convincing evidence of clinical benefit to justify a definitive recommendation.

Patients with eosinophilic granuloma have a median survival of 12.5 years after diagnosis. Respiratory failure causes a substantial proportion of the deaths. Increased age, airflow obstruction, reduced $D_{L_{CO}}$, and hyperinflation are predictors of a poor prognosis.[82]

alveolar proteinosis

Alveolar proteinosis is a rare disease characterized by the intra-alveolar accumulation of a cellular lipoproteinaceous material that resembles surfactant.[83] The disease can be acquired, congenital, or associated with other diseases.

Pathogenesis

Recent studies appear to have elucidated the pathogenesis of alveolar proteinosis.[83] About 90% of cases are acquired and are caused by autoantibodies to GM-CSF, a protein that is important in controlling the alveolar macrophage clearance of surfactant from the alveolus. In congenital cases, either mutations of surfactant proteins or defects in GM-CSF receptors are at fault. In secondary cases, a disorder that is clinically similar to alveolar proteinosis occurs in persons with lysinuric protein intolerance, acute silica exposure (usually from sandblasting) or other inhalational syndromes, several immunodeficiency syndromes, or any of several hematologic disorders. The potential role of GM-CSF in the secondary cases has not been clearly established.

The lipoproteinaceous material also may inhibit the macrophage's defense against infection, thereby producing the increased incidence of infection with intracellular pathogens that has been observed in patients with alveolar proteinosis.

Clinical Manifestations

Patients with alveolar proteinosis present in one of three ways: (1) without symptoms but with an abnormal chest radiograph; (2) with abrupt onset of cough, fever, and chest pain caused by the disease and complicated by opportunistic infection (with *Nocardia* species, fungi, or *Mycobacterium* species); and (3) with dyspnea and cough (sometimes productive) of gradual onset. Physical findings are often minimal. The chest radiograph or HRCT usually shows patchy or geographic ground-glass opacities with some thickening of the interlobular septa, resulting in a pattern that has been called crazy-paving. In later stages of the disease, coarse interstitial markings resulting from superimposed fibrosis can be seen. An elevated serum lactate dehydrogenase level without elevation of other serum enzyme levels may help make the diagnosis.

Histopathologic Features

The histopathologic changes in alveolar proteinosis include the presence of a granular, eosinophilic material within alveolar spaces that stains positively with the periodic acid–Schiff (PAS) reagent [*see Figure 14*]. Inflammation and fibrosis have been detected in some cases but are usually not prominent features. Electron microscopy reveals that the intra-alveolar substance contains numerous lamellar bodies, similar to those found in type II epithelial cells.

Diagnosis

Diagnosis of pulmonary alveolar proteinosis is made most conveniently by BAL. The effluent appears grossly turbid, and staining reveals large amounts of the PAS-positive material [*see Figure 13*]. PCP causes accumulation of a similar intra-alveolar

substance, and this infection must be excluded by special stains. The lavage liquid should be cultured for *Nocardia* species, fungi, and *Mycobacterium* species.

Treatment

Treatment of alveolar proteinosis is indicated if significant dyspnea is present at the time of diagnosis or if lesser symptoms fail to remit spontaneously after an observation period of several months. Approximately 10% of patients undergo spontaneous remission, so it is preferable to wait several months before instituting treatment. In some cases, however, the degree of hypoxemia and the severity of symptoms necessitate immediate therapy. The current best therapy for pulmonary alveolar proteinosis consists of whole lung lavage with sterile saline. The nonlavaged lung is protected by a double-lumen endotracheal tube. Most patients improve substantially after removal of the alveolar material by lavage, and the contralateral lung can be lavaged at a later date.

Now that the pathogenesis of alveolar proteinosis is known, specific therapy may be on the horizon.[83] In initial phase II trials of subcutaneous GM-CSF in patients with acquired disease, response rates of 36% to 75% have been seen. Further studies are necessary to determine the role of this therapy in relation to whole lung lavage.

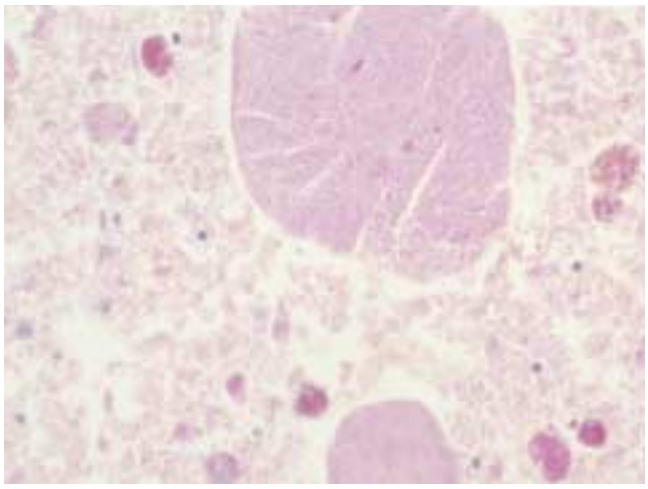

Figure 14 **Bronchoalveolar lavage effluent reveals distinctive periodic acid–Schiff–positive material that is diagnostic of alveolar proteinosis.**

eosinophilic pneumonia

There are seven forms of pulmonary infiltrates with peripheral eosinophilia (PIE): (1) simple pulmonary eosinophilia (Löffler syndrome); (2) prolonged pulmonary eosinophilia without asthma; (3) pulmonary eosinophilia with asthma [*see 14:II Asthma*]; (4) tropical pulmonary eosinophilia; (5) pulmonary vasculitis (allergic granulomatosis and angiitis) [*see 14:IV Focal and Multifocal Lung Disease*]; (6) hypereosinophilic syndrome [*see 5:VII Nonmalignant Disorders of Leukocytes*]; and (7) acute eosinophilic pneumonia.[84] In many of these disorders, substances secreted by eosinophils may help cause injury to the lung parenchyma, airways, or both. Miscellaneous disorders that may also cause pulmonary infiltrates with blood eosinophilia include infections (e.g., tuberculosis, brucellosis, and fungal diseases), neoplastic diseases (e.g., bronchogenic carcinoma, Hodgkin disease, and immunoblastic lymphadenopathy), and immune processes (e.g., rheumatoid lung disease and sarcoidosis).

Simple Pulmonary Eosinophilia (Löffler Syndrome)

Löffler syndrome is characterized by transient and sometimes migratory infiltrates and by mild symptoms lasting less than 1 month. The infiltrates are usually homogeneous in density; either a single infiltrate or multiple infiltrates may occur. Symptoms may be absent, or dyspnea and dry cough may develop. Pathologic examination reveals interstitial and intra-alveolar accumulation of eosinophils, macrophages, and fluid. Löffler syndrome may be idiopathic or may be caused by parasitic infestation (e.g., with *Ascaris* or *Strongyloides*) or a drug (e.g., nitrofurantoin or penicillin). Therapy consists of stopping the offending drug or treating the parasitic infestation; in most cases, no other therapy is required. Occasionally, patients with very symptomatic idiopathic disease require glucocorticoid therapy.

Prolonged Pulmonary Eosinophilia without Asthma

Prolonged pulmonary eosinophilia (chronic eosinophilic pneumonia) is an idiopathic disease that predominantly affects middle-aged women. It is characterized by productive cough, dyspnea, malaise, weight loss, night sweats, and fever associated with progressive peripheral pulmonary infiltrates. HRCT may help in differentiating this disorder from the other PIE syndromes.[85] Hemoptysis and wheezing may be present, which may lead to confusion with other causes of PIE. Pulmonary function test results may be normal or may show either restriction or obstruction.[86] Open lung biopsy specimens show massive, mixed inflammatory infiltrates that have a high eosinophil content. Some pulmonary vessels may contain a few inflammatory cells, but true vasculitis is not present.

Diagnosis is based on the clinical syndrome, chest radiography, and whether or not blood eosinophilia is present. If chest radiography shows typical dense peripheral infiltrates with central sparing, the diagnosis can be made without tissue examination. Usually, confirmatory information can be easily obtained by BAL and transbronchial lung biopsy.

Spontaneous remissions occur in as many as 10% of cases, but respiratory failure can also occur. Treatment with glucocorticoids is rapidly effective. Because relapses are frequent, therapy often must be continued for as long as 5 years.

Pulmonary Eosinophilia with Asthma

Allergic bronchopulmonary aspergillosis can cause pulmonary infiltrates in a patient with asthma [*see 14:II Asthma*].

Tropical Pulmonary Eosinophilia

The diagnosis of tropical pulmonary eosinophilia is suggested by the onset of asthma, fever, and marked blood eosinophilia and the presence of basilar mixed reticulonodular and alveolar infiltrates in a person who has recently traveled to the Far East.[87] This disease probably represents a form of filariasis (caused by *Wuchereria bancrofti* or other organisms). Despite therapy with diethylcarbamazine, many patients with this disorder have persistent inflammation and develop chronic interstitial disease.

Pulmonary Vasculitis (Allergic Granulomatosis and Angiitis)

Allergic granulomatosis and angiitis is a multisystem disorder characterized by vasculitis and necrotizing granulomatous

inflammation that involve the lungs, nervous system, and skin.[88] Although the kidneys, heart, spleen, and GI tract are much less commonly affected, any organ or tissue may be involved. The prominence of eosinophilia and elevated IgE levels suggest that immediate hypersensitivity mechanisms may play an important role in pathogenesis [*see 14:IV Focal and Multifocal Lung Disease*].

Hypereosinophilic Syndrome

Hypereosinophilic syndrome is characterized by a wide range of clinical manifestations that occur when mature eosinophils infiltrate organs [*see 5:VII Nonmalignant Disorders of Leukocytes*].

Acute Eosinophilic Pneumonia

Acute eosinophilic pneumonia is characterized by the acute onset of cough, dyspnea, fever, tachypnea, and rales; patients frequently require mechanical ventilation.[89] There is no clear association with cigarette smoking, environmental exposures, or drug intake, and patients tend to be young. Blood eosinophilia is not seen in most cases and is therefore not useful in diagnosing this disorder. Chest radiography and CT scanning show nonspecific combinations of alveolar (ground-glass) infiltrates and mixed alveolar-interstitial infiltrates that are sometimes associated with pleural effusions. The diagnosis can be made by bronchoalveolar lavage, which shows dramatic increases in the percentage of eosinophils, often to greater than 20% (the normal count is less than 1%). The administration of corticosteroids leads to rapid improvement, and relapses after steroid withdrawal are rare.

diffuse alveolar hemorrhage

Alveolar hemorrhage syndromes are characterized by diffuse parenchymal bleeding in the absence of blood aspiration, coagulopathy, elevation of pulmonary venous pressure, or an identifiable local cause (e.g., pulmonary emboli, cancer, or bronchitis). Frequently, diffuse alveolar hemorrhage is immunologically mediated and is often associated with glomerulonephritis.

The diseases that cause this syndrome are anti–glomerular basement membrane (anti-GBM) antibody disease (Goodpasture syndrome), idiopathic and rapidly progressive glomerulonephritis with or without immune complexes, vasculitis (microscopic polyangiitis, Wegener granulomatosis, and other forms of antineutrophil cytoplasmic antibody [ANCA]–associated capillaritis), SLE and other collagen vascular disorders, antiphospholipid antibody syndrome, certain drugs, and idiopathic pulmonary hemosiderosis.[90] Although each of these disorders has suggestive clinical characteristics, in many cases the diagnosis cannot be made on clinical grounds. In addition, many patients with diffuse alveolar hemorrhage are acutely ill, making a rapid and specific evaluation necessary. A suggested diagnostic approach to such a patient consists of the following steps:

1. Obtain serum to test for anti-GBM antibody, antinuclear and anti-DNA antibody, ANCA, complement levels, and immune complexes.
2. Perform bronchoalveolar lavage with an iron stain of the obtained specimen. If hemosiderin-laden macrophages are present in large numbers, the diagnosis of alveolar hemorrhage is confirmed.
3. If step 1 fails to confirm a diagnosis or the results are not rapidly available, a biopsy of the kidney, lung, or another involved site should be performed. Immunofluorescence and electron microscopy with routine tissue examination should be included.

Almost all cases of alveolar hemorrhage can be rapidly diagnosed if the physician follows this approach. Treatment with high doses of intravenous glucocorticoids should be started while the evaluation is in progress, because alveolar hemorrhage can rapidly become life threatening.

Anti-GBM Antibody Disease

Anti-GBM antibody disease occurs in young men who smoke cigarettes. It is characterized by glomerulonephritis and diffuse alveolar hemorrhage[91] and is caused by cytotoxic antibody against the α3 chain of type IV collagen in glomerular and alveolar basement membranes.

Many patients present with hemoptysis, which can be massive; however, some episodes of hemorrhage occur without hemoptysis. Most patients complain of dyspnea, and gross hematuria is common. Iron deficiency anemia is present in nearly all patients, and renal failure is present initially in 50% of cases.

Chest radiography initially shows fluffy perihilar acinar shadows; later, interstitial changes are seen. Pulmonary function tests demonstrate a restrictive pattern that improves with clinical resolution. $D_{L_{CO}}$ may be increased because of carbon monoxide uptake by extravascular hemoglobin. As the disease becomes chronic, interstitial radiographic changes and restrictive pulmonary function abnormalities may persist.

The diagnosis is confirmed when circulating anti-GBM antibody is detected (95% of patients have anti-GBM antibody) or linear deposits of IgG (occasionally IgA) are demonstrated on the glomerular or alveolar basement membrane. Anti-GBM antibody can also be eluted from the involved tissue.

Current recommendations for treatment include immunosuppressive agents, glucocorticoids, and plasmapheresis. Despite this aggressive therapy, 50% of patients die or require long-term dialysis after 2 years. Death is often caused by massive alveolar hemorrhage that is frequently precipitated by infection.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis, a disorder characterized by recurrent alveolar hemorrhage, occurs primarily in children (usually younger than 10 years) and young adults. When it occurs in adults, men are more often affected than women. Presentation of the disease is similar to that of Goodpasture syndrome except for the absence of renal involvement. Recurrent episodes of clinical and subclinical hemorrhage occur over time, resulting in lung damage that may be obstructive or restrictive in nature. Lung tissue shows changes of acute and chronic hemorrhage, but no vasculitis, immune complexes, or linear-staining deposits are found.

Patients with idiopathic pulmonary hemosiderosis are treated with glucocorticoids. Anecdotal evidence supports the use of immunosuppressive agents and plasmapheresis. Mean survival is 3 to 5 years, but spontaneous remissions and long-term survival do occur.

lymphangioleiomyomatosis

The onset of lymphangioleiomyomatosis (LAM), a rare disease (approximately 100 new cases per year worldwide) that affects women of childbearing age almost exclusively, is often heralded by some combination of dyspnea, cough, hemoptysis, pneumothorax, and chylothorax.[92] At the onset of symptoms, there may be no diffuse radiographic abnormality, though a fine reticular or reticulonodular process, predominating at the lung bases, may be seen. Because of lymphatic obstruction, sep-

tal (Kerley B) lines can be seen. Occasionally, there is a diffuse interstitial pattern in association with hyperinflation. In contrast to most diffuse infiltrative lung diseases, this disorder is often characterized by obstructive physiology with increased lung volumes, which has been attributed to peribronchial smooth muscle hyperplasia. In addition, $D_{L_{CO}}$ is usually decreased.

The diagnosis may be strongly suspected in a young nonsmoking woman with recurrent pneumothorax, chylothorax, fixed airway obstruction, and a diffuse interstitial radiographic pattern.[92] Nuclear ventilation lung scans show a so-called speckled pattern caused by accumulation of radionuclide in the lung cysts. HRCT is diagnostic when it shows homogeneously distributed thin-walled parenchymal cysts, varying from a few millimeters to several centimeters in diameter; these cysts may be associated with retrocrural adenopathy, pleural effusion, thoracic duct dilatation, pericardial effusion, and pneumothorax. Approximately 50% of patients also have renal angiomyolipomas as an associated finding, often first identified on CT scanning. Recently, a high incidence of meningiomas has been noted in patients with LAM.[93] All of these imaging findings are identical to those of tuberous sclerosis (TS). Of patients with TS, about one third of females and none of the males have LAM.[94] The overlap between the two diseases has led to the discovery that patients with LAM without TS may have somatic mutations of the *TSC2* gene, which has been implicated in the pathogenesis of TS.[95]

Open lung biopsy in LAM reveals proliferation of smooth muscle cells along lymphatic, vascular, and bronchial structures; in the alveolar walls; and in the subpleural areas of the visceral pleura. Cyst formation may occur secondary to bronchiolar obstruction. The clinical differential diagnosis includes many of the other infiltrative lung diseases, such as IPF, eosinophilic granuloma (which can produce similar cystic changes on HRCT), and sarcoidosis. Pathologically, the differential diagnosis includes diffuse pulmonary lymphangiomatosis, lymphangiomas, pulmonary lymphangiectasis, metastatic uterine leiomyosarcoma, and benign metastasizing uterine leiomyomata.

More than 75% of patients with LAM survive longer than 8 years.[92] There is some evidence that disease progression may be hormone dependent, because some slowing of progression has been reported with oophorectomy, progesterone treatment, or a combination of the two.[92] Lung transplantation may be considered for end-stage disease. Although transplantation may be lifesaving, there have been cases of recurrence in the transplanted lung, emphasizing the systemic nature of the disorder.[92]

pulmonary alveolar microlithiasis

Pulmonary alveolar microlithiasis is an exceedingly rare, sometimes familial disorder that is most often diagnosed in an asymptomatic patient by a routine chest radiograph. The chest radiograph reveals a strikingly distinct and diffuse scattering of small calcified nodules that, on histopathologic examination, are seen to be calcified spheres (microliths or calcispherites) that occupy the alveolar space.[96] This condition may progress to respiratory failure. A possible response to treatment with disodium etidronate, a bisphosphonate, has been reported in a single patient.[96] Lung transplantation is an option in severe cases.

VI VENTILATORY CONTROL DURING WAKEFULNESS AND SLEEP

KINGMAN P. STROHL, M.D.

Overview

Ventilation is a critical function for eliminating carbon dioxide and acquiring oxygen. At or near sea level, ventilation maintains arterial carbon dioxide tension (P_aCO_2) values in the range of 38 to 42 mm Hg and arterial oxygen tension (P_aO_2) values in the range of 85 to 100 mm Hg. What is remarkable is that P_aCO_2 values vary relatively little over the human life span despite substantial alterations in the mechanical properties of the chest wall and lungs that accompany birth, maturation, and aging. The control system for ventilation not only optimizes gas exchange but also serves a role in acid-base balance, speech, deglutition, defecation, and posture.

The components of ventilatory behavior (i.e., breathing rate and depth) are the result of a feedback control system in which the brain (controller) organizes neuromuscular output to the respiratory muscles of the upper airway, chest wall, and lungs (controlled system). The controlled system alters arterial pH, CO_2, and O_2 in response to impulses from the brain. Specialized sensors located in the respiratory system monitor the rate of gas exchange and send impulses to sensors located in the brain to prompt adjustments in system regulation. A feedback control model of the respiratory system provides insights into the effects of sleep on ventilation and gas exchange [*see Figure 1*].

Genetic factors influence disorders of ventilatory control (e.g., sleep apnea); however, there are adaptive components. One example is the periodic breathing during sleep that occurs with adaptation to high altitude. Such functional flexibility, or plasticity, is an essential feature of development, maintenance, and expression of effective ventilation and is not merely the result of mechanical operation of the lungs and chest wall. Consequently, genes, maturation, and experience all influence the adult phenotype for breathing and sleep and the clinical disorders resulting from this physiology.

This chapter focuses on the respiratory control system and how its elements contribute to sleep apnea and other state-related disorders of ventilation.

Physiology of Ventilatory Control

Inhalation begins with the discharge of inspiratory neural impulses from respiratory centers located in the medulla.[1] This neural network is embedded in a system of adjacent medullary neurons, pontine neurons, and regions such as the nucleus tractus solitarius (NTS) that receive neural impulses resulting from lung inflation, blood pressure, and other afferent systems. Inhalation continues until the respiratory centers receive negative feedback from the adjacent medullary neurons and from peripheral receptors, some of which are activated by lung inflation. The intensity of the activity of medullary neurons is affected by input from chemoreceptors [*see Figure 1*]. Influences from higher centers also adjust inspiratory and expiratory activity for speech and swallowing. With inhibition, inspiration ceases and expiration continues until inhibitory influences wane sufficiently to allow initiation of the next inspiration. Simply put, the rate of inspiration is determined by the intensity of medullary discharge; duration and depth of inspiraton are determined by the timing and intensity of inhibitory influences.

Chemoreceptors are specialized cells that sense O_2 and CO_2 through changes in pH. The peripheral chemoreceptors (i.e., the carotid and aortic bodies) are highly vascular collections of specialized sensory cells.[2] The carotid bodies are located bilaterally at the bifurcations of the common carotid arteries; the aortic bodies are situated anterior and posterior to the arch of the aorta and the left main pulmonary artery. The peripheral chemoreceptors are stimulated primarily by a low P_aO_2, although hypercapnia, acidemia, and possibly hyperthermia may influence an increased response to hypoxemia. Impulses travel from the carotid and aortic bodies to the NTS in the brain stem via sensory ganglia and the afferent nerves that follow along the ninth and 10th cranial nerves, respectively. Increases in P_aCO_2 stimulate cells on the ventral medullary surface (VMS), primarily by lowering the pH of the medullary extracellular fluid.[3] In the steady state, the pH of cerebrospinal fluid reflects the pH of the medullary microenvironment and may differ significantly from blood pH. This discordance is thought to result in transient stimulation of ventilation, even in the presence of a respiratory alkalosis (e.g., in persons who return to sea level after spending several weeks at high altitude).

Specialized sensory cells (i.e., mechanoreceptors) located in the upper airway, chest wall, and lung detect mechanical deformation and temperature changes resulting from inhalation and exhalation.[4] Afferent nerve signals from mechanoreceptors are directed to the medulla (NTS), where information is integrated with chemoreceptor information to influence the medullary timing and volume of ventilation; integrated information is relayed through thalamic connections to the cortex. In the presence of parenchymal lung disease, the information received by the cortex may contribute to perceptions of breathlessness (dyspnea). Thus, lung inflammation and bronchoconstriction will activate unmyelinated pulmonary C fibers, thereby resulting in hyperventilation, tachypnea, and dyspnea. Myelinated fibers from stretch receptors carry impulses that influence the duration of inspiration and expiration. Impulses from stretch receptors and C fibers travel through the pulmonary branch of the 10th cranial nerve. Segmental intercostal nerves carry impulses to the brain stem from the chest wall, muscle spindles, and joint proprioceptors.[5] Mechanoreceptors in these areas are influenced by the position of the rib cage and by the muscular tension required to inflate the lungs, and the rate of change in the afferent neurogram resembles flow rate. This receptor system acts in concert with chemoreceptors to control the timing of exhalation and control ventilation.

Other brain centers (e.g., the hypothalamus and cortex) provide input to pontomedullary respiratory centers.[6] These pathways coordinate neuromuscular outputs with voluntary respiratory acts, such as talking or expulsive maneuvers, and coordinate ventilation with metabolism, posture, and swallowing. Hypothalamic influences are in part responsible for the so-called wakefulness stimulus—the increased activity of medullary neurons in the cortex that occurs during wakefulness, as opposed to the activity that occurs during sleep. Some cortical cerebral path-

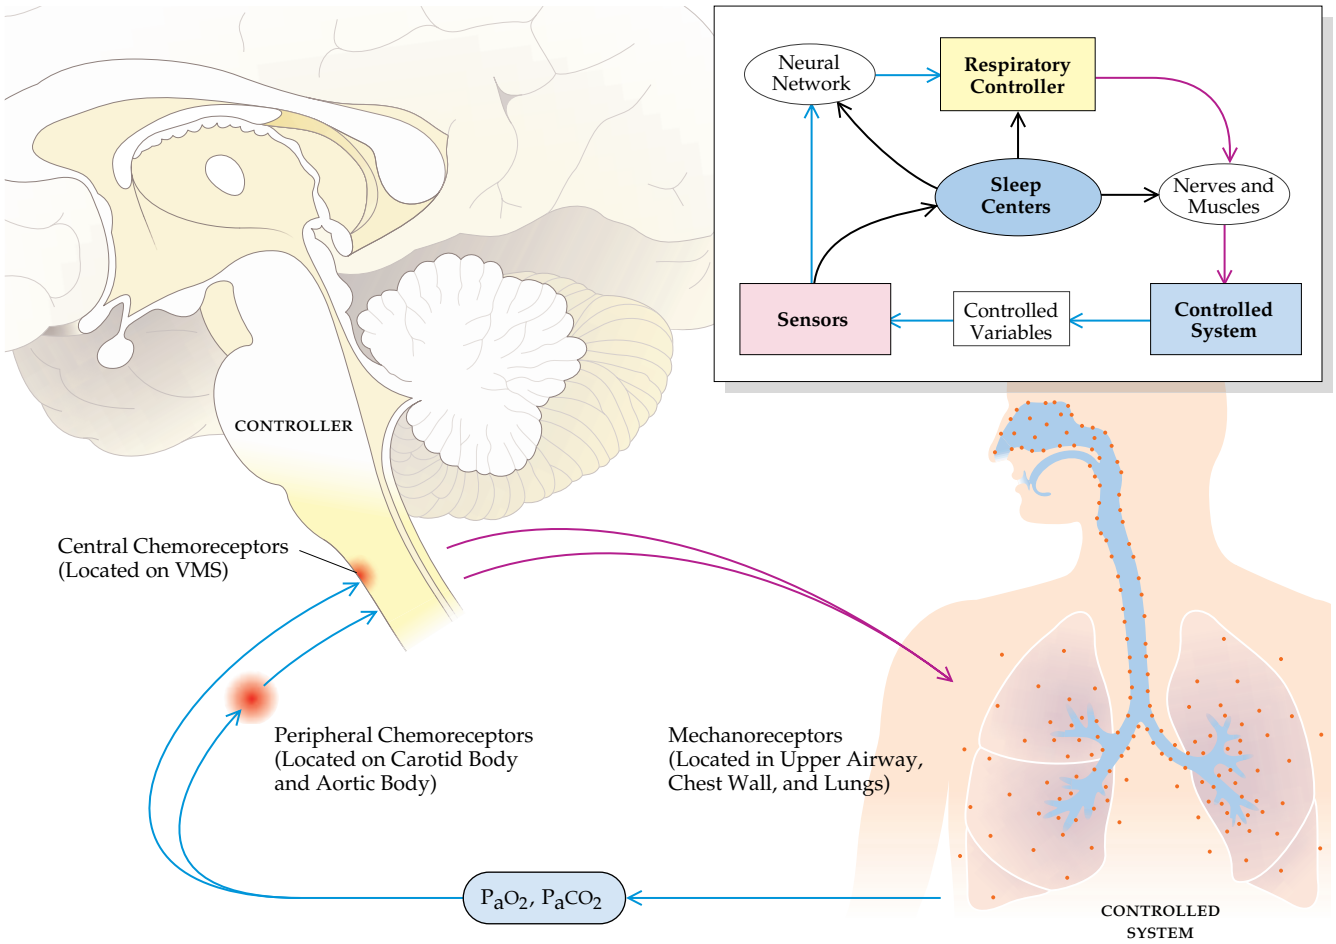

Figure 1 **This schematic representation illustrates the key elements of the respiratory control system—namely, the respiratory controller (the brain regions generating neuromuscular drive), the controlled system (upper airway, lungs, and chest wall), and the specialized sensors that send signals between the two. The controlled system alters arterial pH, CO_2, and O_2 according to signals received from specialized sensors. Peripheral chemoreceptors located on the carotid and aortic bodies are stimulated primarily by decreases in oxygen (P_aO_2) and to a lesser extent by carbon dioxide tension (P_aCO_2) (blue arrows); neural signals received by these chemoreceptors are sent to the brain stem. Central chemoreceptors—for example, those located in the medulla near the ventral medullary surface (VMS)—are stimulated by increases in PCO_2. Information received from the chemoreceptors is integrated in the medulla, and neural impulses from the medullary system (red arrows) travel to the muscles of the upper airway and chest wall to influence timing and volume of ventilation. Peripheral mechanoreceptors in the upper airway, chest wall, and lung detect mechanical deformation and temperature changes resulting from inhalation and exhalation; neural signals from these mechanoreceptors are sent to the central and peripheral chemoreceptors. This scheme of respiratory feedback control is a basic concept for understanding how sleep affects ventilation and gas exchange.**

ways circumvent the medulla and pass directly to respiratory muscles via pyramidal tracts. The cerebellum plays a role in both coordinating and adjusting respiratory neural output to the upper airway and chest wall muscles.

Putative set points for the ventilatory control system help ensure homeostatic control of acid-base balance (pH) and O_2 delivery. One example of a set point is the apneic threshold, which is defined as that level of arterial (or central) CO_2 below which there is little or no inspiratory activation. This set point is higher in sleep.[7] Certainly, brain centers other than the medulla and pons contribute to breathing rate and depth and, to a certain extent, can override brain stem mechanisms for breathing. During sleep, brain centers have less influence and may actively inhibit respiratory activity, unless they are engaged in an arousal response from quiet sleep or triggered by changes associated with rapid eye movement (REM) sleep [*see Figure 2*].

Integration and coordination of neuromuscular activity are most apparent during inhalation. In health, exhalation occurs as a result of the passive recoil of the lungs and chest wall; however, the duration of expiration and the start of a new inspiration are actively controlled events. In a healthy person, breathing is a sequence of inhalations and exhalations that serve to maintain alveolar ventilation at a level that is appropriate for meeting metabolic demands during wakefulness, exercise, and sleep. The increased metabolic requirements of exercise are met by increases in respiratory frequency and tidal volume (and therefore increases in minute and alveolar ventilations). During exercise, activation of abdominal and intercostal muscles during expiration allows more rapid emptying of the lungs at higher tidal volumes.[4,8] Environmental stresses, metabolic disturbances, hormonal changes, drugs, sleep-wake activity, and exercise may influence the output of a normal control system. Excessive respira-

tory suppression results in alveolar hypoventilation (hypercapnia), whereas overstimulation results in alveolar hyperventilation (hypocapnia).

Disorders with Increased Ventilatory Drive

Interstitial lung diseases (e.g., pulmonary fibrosis) increase resting ventilation and lower P_aCO_2 as a result of increased activity of lung receptors (probably C fibers).[9] The hyperventilation that accompanies pulmonary edema, pneumonia, interstitial disease, and the acute respiratory distress syndrome is a rapid, shallow breathing pattern that results from activation of these lung receptors. Hypocapnia with dyspnea may occur in the absence of hypoxemia in this setting. Unilateral vagal interruption in patients with parenchymal lung disease has been shown to reduce ventilation, as well as dyspnea, and may contribute to the improvement in breathlessness after unilateral lung transplantation.[9]

Hyperventilation is regularly produced by exposure to high altitude or other hypoxic environments, metabolic acidosis, pregnancy and other conditions associated with elevated progestational hormones, anxiety states, and mildly toxic doses of salicylates, amphetamines, or other CNS-stimulating drugs. Unlike the hyperventilation associated with parenchymal lung disease, the hyperventilation that occurs during progesterone stimulation (e.g., that which occurs during pregnancy) or metabolic acidosis is associated with an increased tidal volume and little increase in respiratory rate. The hyperventilation characterized by high tidal volume and relatively low frequency that accompanies diabetic ketoacidosis (Kussmaul respiration) is pH mediated and may not be as apparent to an observer as the breathlessness that occurs in interstitial lung disease.

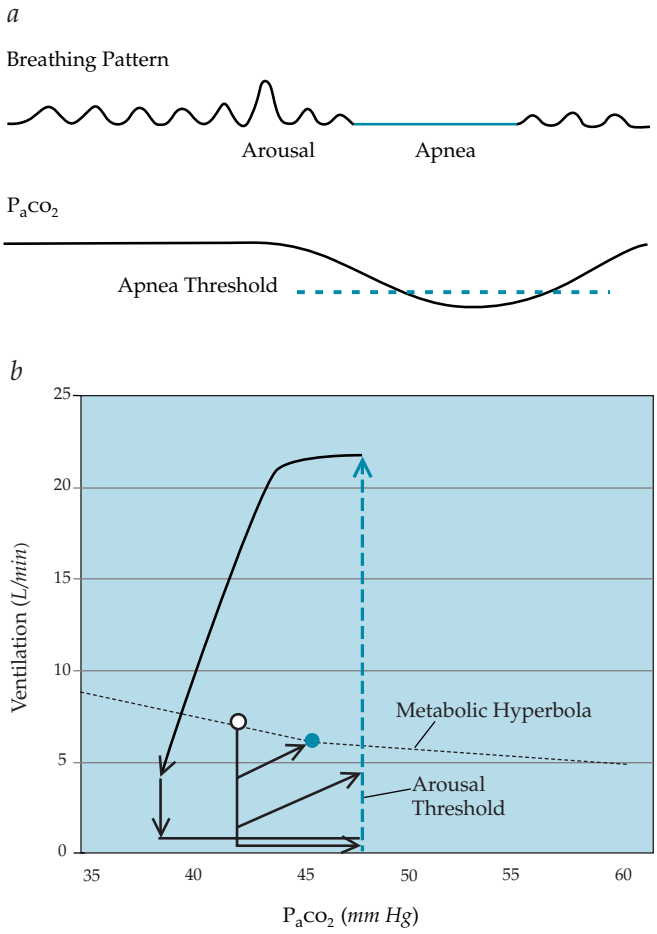

Figure 2 **(*a*) The existence of an apnea threshold (broken line) for arterial carbon dioxide tension (P_aCO_2) during sleep provides an explanation for the changes in breathing that occur at the onset of sleep. A transient increase in ventilation from brief arousal results in a lowering of P_aCO_2 below the apnea threshold. Breathing effort ceases until P_aCO_2 rises above the CO_2 threshold. The effect of lowering P_aCO_2 on ventilation is trivial in awake individuals. Sleep is associated with expression of this apnea threshold and may even raise the threshold, causing hypoventilation and apnea to occur more readily. Conditions that produce frequent arousals and large breaths may result in apneas or hypopneas as sleep resumes after the arousal. (*b*) The graph shows the cycles that occur when the set-point (white circle) is moved from wakefulness to sleep. With snoring, a new set point (blue circle) is established. A small increase in ventilation may lower the P_aCO_2, resulting in reductions in or cessation of breathing. P_aCO_2 will then rise and increase ventilation abruptly as the arousal threshold is reached. The length of an apneic episode depends in large part on the arousal threshold, the recovery mechanisms, and the tendency for sleep to persist without an arousal.**

Disorders with Decreased Ventilatory Drive

Hypoventilation occurs when alveolar ventilation is insufficient to eliminate metabolically produced CO_2. Hypoventilation may be caused by metabolic or mechanical factors. Metabolic causes of hypoventilation may include metabolic alkalosis, deficiency of thyroid hormone, and excess doses of sedative and narcotic agents. In each of these conditions, there is a relatively steady breathing pattern accompanied by a lowered respiratory rate, a lowered tidal volume, or both. Dyspnea is often absent despite an elevation of resting P_aCO_2.

In diseases that mechanically restrain ventilation (e.g., ankylosing spondylitis and chronic obstructive pulmonary disease [COPD]), hypoventilation may occur despite preserved activity of the medullary inspiratory neurons.[10] A perception of dyspnea occurs because of the increased work of breathing and the incongruity between central inspiratory activity and activation patterns detected by mechanoreceptors of the chest wall and lungs. In some persons, ventilation may be reduced to a degree that is out of proportion to the mechanical properties of the lungs or chest wall (possibly because of a genetic predisposition), and dyspnea may be a less prominent feature. As hypoventilation becomes chronic, adaptation of receptors, of central inspiratory neurons, of metabolic alkalosis, or of all three may occur. Adaptation to chronic hypoventilation in sleep apnea, COPD, neuromuscular disease, and chest wall disease may eventually depress responsiveness to CO_2 and depress ventilation during rest. Both resting CO_2 and ventilatory responsiveness to CO_2 may be increased by treatment of sleep apnea or by lowering CO_2 with ventilatory support. Hypoventilation can also be caused by hemodialysis, during which CO_2 removal lowers the P_aCO_2 sufficiently to depress the rhythmic activity of medullary respiratory neurons and produce apneas.

An uncommon condition called primary alveolar hypoventilation can be present at birth (congenital hypoventilation syndrome)[11] or can be acquired as a result of morbid obesity, cerebrovascular accidents, meningitis, encephalitis, bulbar poliomyelitis, or damage to afferent pathways in the cervical spinal cord. In all these conditions, however, no structural abnormality is found at autopsy. Presenting symptoms, which

are a result of blood gas derangement, often include lethargy, somnolence, headaches, and dependent edema. Such patients may not complain of shortness of breath. Physical findings may include cyanosis and evidence of right-sided heart failure. Secondary erythrocytosis is common. In congenital hypoventilation syndrome, alveolar ventilation is improved by exercise, indicating that the disturbance in ventilatory control is functionally determined.

The diagnosis of hypoventilation syndrome is one of exclusion and is considered when hypercapnia cannot be accounted for by disorders of the lungs, chest wall, respiratory muscles, or breathing during sleep. All hypoventilation syndromes worsen during sleep. In extreme cases, breathing occurs only with voluntary efforts and ceases entirely with inattention or during sleep. Management of hypoventilation related to CNS defects includes ventilatory assistance at night with or without respiratory stimulants such as medroxyprogesterone.

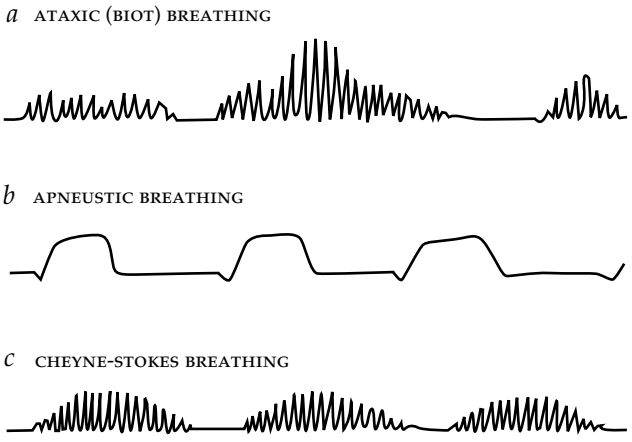

Figure 3 **Irregular breathing patterns may reflect central nervous system disease or an inherent alteration in the apneic threshold. Three examples of irregular breathing are illustrated: (*a*) Ataxic breathing is characterized by an unpredictable sequence of breaths varying in rate and depth and is associated with medullary disease. (*b*) Apneustic breathing involves repetitive gasps, with pauses at full inspiration lasting a few seconds, and is associated with pontine disease. (*c*) Cheyne-Stokes respiration is cyclic, with a crescendo-decrescendo pattern interrupted by apneas.**

Abnormal Breathing Patterns and Sleep Reports

Brain injury and certain drugs and toxins affect breathing patterns during both wakefulness and sleep; however, there is a growing awareness of how abnormal breathing only during sleep may affect health. Periods of cessation of airflow into and out of the lungs (apnea) regularly occur at sleep onset, and episodes of partial upper airway obstruction during inspiration (snoring) are very common. Some irregularity of breathing is considered normal during sleep, including mild CO_2 retention and a reduction in P_aO_2, as well as irregular breathing at sleep onset or with dreaming. As with many biologic phenomena, breathing irregularities that occur during sleep are designated as abnormalities only if they are sufficient in magnitude and frequency to disrupt sleep continuity or impair oxygenation enough to affect a person during wakefulness.

ataxic and apneustic breathing

Ataxic (Biot) breathing is a random pattern of shallow and deep breaths interspersed with irregular pauses [*see Figure 3*]. Ataxic breathing results from disruption of medullary neural pathways by trauma, hemorrhage, or extrinsic compression caused by cerebellar or pontine hemorrhage; it can be seen in terminally ill patients because respiratory control systems are affected by multisystem failure.[12] Complete apnea may ensue, especially in patients given sedative or narcotic drugs. Another disturbance, apneustic breathing, is characterized by an end-inspiratory pause of 2 to 3 seconds before exhalation is begun [*see Figure 3*]. Apneustic breathing is associated with caudal pontine lesions and is sometimes intermixed with ataxic breathing patterns.

Three patterns of apnea, or cessation of breathing, can be observed during sleep. These apneas are defined as episodes of a reduction in airflow of more than 80% occurring for more than 10 seconds.[13] Apneas may be classified as central (or nonobstructive), obstructive, or mixed [*see Figure 4*]. In central apnea, which implies a cessation of respiratory activity at a brain stem level, both airflow and respiratory efforts are absent. During obstructive apnea, respiratory efforts persist, although airflow is absent at the nose and mouth. Obstructive and central apneas are related clinically and pathophysiologically. Many adult patients exhibit mixed apneas in which both central and obstructive patterns occur. In a single apneic episode, there may be a period in which no efforts occur, followed by the appearance of respiratory efforts, also without airflow. In addition, in the same night, patients may have all three types of apneas in varying proportion. If more than 80% of apneas are of a central type, the patient is classified as having central sleep apnea. If apneas are predominantly mixed and obstructive apneas, the patient is classified as having obstructive apnea.[13]

Hypopneas or hypoventilation during sleep may arise by mechanisms similar to those producing apnea. Hypopneas are defined as episodes of a reduction in airflow of 30% to 80% occurring for more that 10 seconds.[13] Hypoventilation (hypopnea) leads to increased CO_2 and decreased O_2 levels in arterial blood and causes arousals from sleep; as with apneas, hypopnea may result from reduction in respiratory efforts or partial upper airway obstruction. Snoring is a form of partial airway obstruction and is called obstructive hypopnea. Snoring is common, but some patients who snore have symptoms similar to those of sleep apnea syndrome even if complete cessation of airflow (apnea) never occurs during sleep. Moreover, such patients may exhibit abnormal sleep and cardiorespiratory changes.

ventilatory behavior in sleep

The transition from wakefulness to non–rapid eye movement (NREM) sleep is accompanied by a reduction in metabolic rate and therefore a reduced need to breathe. Consequences of sleep onset include reduced tidal volume, changes in lung mechanics, reduced activity and upper airway dilators, reduced upper airway caliber, and loss of load compensation [*see* Load Compensation, *below*].[14]

Sleep is accompanied by reduced postural muscle tone. In NREM sleep, the ratio of rib cage displacement to abdominal displacement is greater than it is during wakefulness, whereas in REM sleep it is less.[15] These changes in displacement may affect the distribution of ventilation in the lungs, increasing ventilation-perfusion mismatching and contributing to hypoxia; the development of hypoxia, in turn, may necessitate changes in respiratory output, which may initiate an unstable breathing pattern.

Upper Airway Function

Upper airway caliber is reduced during sleep, and air passage is further impaired by decreased activity of upper airway muscles,[16,17] especially the muscles involved with tonic activity (independent of the phase of respiration), such as the tensor veli palatini muscle.[18] The mechanical consequence of reduced airway caliber is increased upper airway resistance.[19] Because pharyngeal compliance increases during NREM sleep, negative intrathoracic pressures normally produced in the upper airway during inspiration will result in airway collapse. Even in healthy persons, negative intrathoracic pressure during NREM sleep limits inspiratory flow, resulting in an inspiratory plateau that persists in the presence of increasing negative pressure.[19]

Curiously, the retropalatal airway is less compliant during REM sleep, when muscle activity is much reduced, than during NREM sleep.[20] This finding points to the significance of nonneuromuscular factors (e.g., bony and cartilaginous support) in the maintenance of upper airway patency during sleep.

Load Compensation

When the ratio of load to inhalation is increased (whether because of resistive factors or obstructive factors), a concomitant increase in breathing effort is required to restore tidal volume (i.e., load compensation). During sleep, however, immediate and subsequent load compensation is compromised and results in decreased tidal volume and minute ventilation, which thereby results in alveolar hypoventilation. The ensuing elevation of arterial P_aCO_2 restores CO_2 elimination toward normal levels.[7] The inability to perceive and immediately respond to increased loads allows for sleep to continue undisturbed. Thus, the main consequence of sleep is an increase in P_aCO_2 of 4 to 5 mm Hg. Such elevations in P_aCO_2 result in mild acidosis in both healthy persons and in persons with cardiopulmonary disorders but without sleep-disordered breathing (SDB).

Heavy snorers may not arouse from sleep despite continuous generation of subatmospheric intraluminal pressure that is several times higher than that which occurs during wakefulness [*see Figure 5*]. If increased resistance and inspiratory flow limitation are prolonged, the increased work of breathing or hypoventilation, or both, leads to respiratory-related arousals (RERA) from sleep. Partial obstruction of the upper airway (with RERAs) and daytime sleepiness are the features associated with upper airway resistance syndrome (UARS).[21]

The Hypocapnic-Apneic Threshold

In NREM sleep, a highly reproducible hypocapnic-apneic threshold is unmasked, and a central apnea will occur if the P_aCO_2 is lowered, even by a small amount.[22] As a result, hypocapnia is the most important inhibitory factor to breathing during NREM sleep. This threshold level of P_aCO_2 is decreased by hypoxia, possibly by excitation caused by miscellaneous nonchemical stimuli. One major cause of SDB is breathing instability produced by this threshold effect and by arousals, hypoxia, and other factors that alter this threshold over time.

Sleep Effects on Cardiovascular Physiology

The cardiovascular system adjusts to the changes in gas exchange that accompany sleep and to the apneas and hypopneas that may interrupt sleep. Normally, during NREM sleep there is a withdrawal of sympathetic tone, both neural and humoral, and an increase in parasympathetic tone—changes that result in a reduction in heart rate, blood pressure, and cardiac output.[23] The decreased cardiac workload and O_2 demand are accompanied by a diminished ability to provoke an arrhythmia.

Gradual awakening is accompanied by a modest increase in sympathetic outflow without much evidence of parasympathetic withdrawal. In contrast, with an abrupt arousal caused by noise or sleep apnea, there occurs an abrupt increase in sympathetic drive manifested by increases in blood pressure and heart rate and by marked parasympathetic withdrawal.[24]

In REM sleep, cardiovascular and breathing systems are relatively independent of metabolic drive and inhibition of muscle activity. Sympathetic activation increases to levels seen during wakefulness but is often episodic, leading to transient changes in heart rate, blood pressure, and breathing. Such surges in blood pressure may play a part in triggering ischemic events in patients with heart disease or diabetes.[23]

In general, however, sleep is cardioprotective in healthy persons. Sleep apnea disrupts cardiovascular regulation during sleep because of repetitive arousals, hypoxemia, and increased

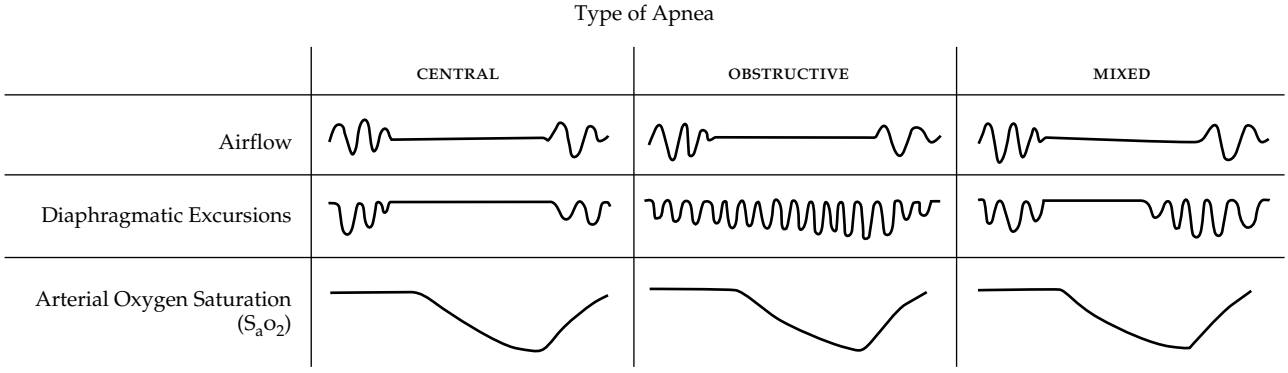

Figure 4 **This schematic representation of the ventilatory signals recorded during a sleep study (polysomnogram) illustrates the different patterns found in central, obstructive, and mixed apneas. In each example, the presence of apnea is confirmed by the cessation of airflow at the nose and mouth (top), and the consequence of apnea—namely, hypoxemia—is demonstrated by the development of oxygen desaturation on the continuous record of arterial oxygen saturation (S_aO_2) (bottom). The three types of apnea are distinguished by the respiratory efforts made during the episode (middle). In central apnea, no respiratory efforts are made; in obstructive apnea, diaphragmatic contractions continue and often intensify during the episode; and in mixed apnea, a period of absent respiratory efforts is followed by active inspiratory muscle contractions against an occluded upper airway.**

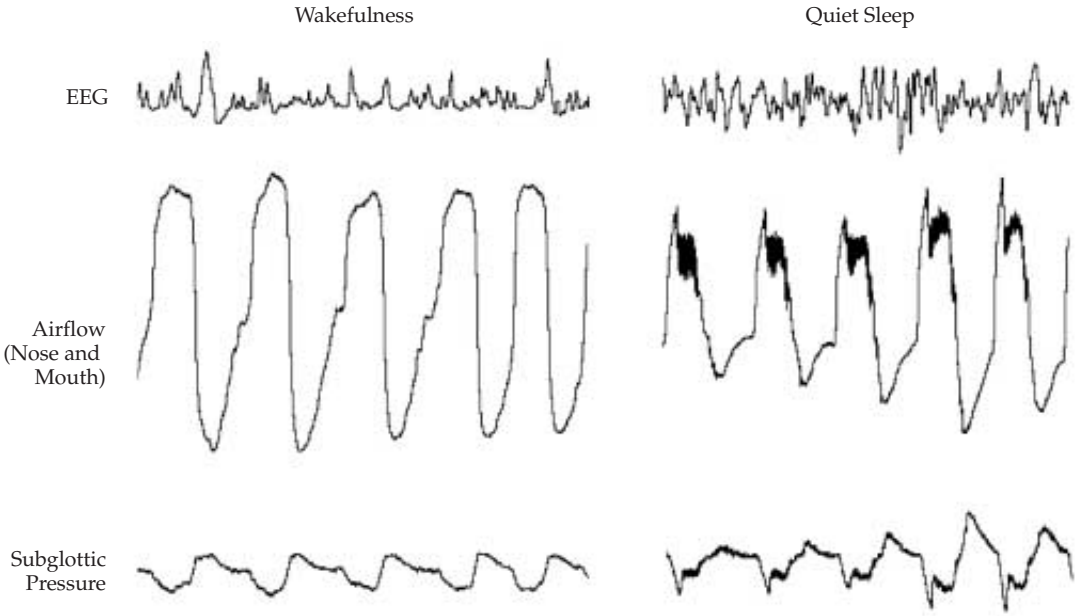

Figure 5 **Several cycles of breathing during EEG-defined wakefulness and sleep are shown for wakefulness (left) and quiet sleep (right) in a healthy person. Flow limitation is present during inspiration, with a chopped-off flow pattern and rapid fluttering of flow indicative of snoring. This pattern can represent a steady-state condition, balancing load compensation and chemical drive.**

intrathoracic pressure changes, which result in preload and afterload effects on the heart.[25]

EVALUATING SLEEP DISTURBANCES

Monitoring a person with electrodes during sleep results in a classification of sleep into two states: non–rapid eye movement, or NREM, sleep and rapid eye movement, or REM, sleep. NREM sleep can be further subdivided into stages I and II (light or transitional sleep) and stages III and IV (deep sleep), depending on the frequency and amplitude of brain waves. States are distinguished by recording electroencephalogram (EEG), electrooculogram (EOG), and electromyogram (EMG) measurements. The combination of these measures and the cardiopulmonary monitoring of airflow, respiratory effort, oxygen saturation, and heart rate—along with identification of body position—constitute polysomnography, which is a common test used to diagnose sleep apnea.

Respiratory Disturbance

Various measurements are used to quantify respiratory disturbances during sleep.[15] The apnea-hypopnea index (AHI) is the total number of apneas and hypopneas occurring during sleep divided by the hours of sleep time. Values of AHI can be computed for the different stages of sleep. Another term for AHI is the respiratory disturbance index (RDI). The term desaturation index, also called oxygen desaturation index, refers to the number of times per hour that O_2 saturation falls by more than 3% to 4%, and it may be reported as an independent measure of cardiorespiratory instability. The snoring index (SI) is the percentage of time spent snoring during sleep.

The arousal index (AI) is computed as the number of transient awakenings per hour, and it is defined by a change in state from sleep to waking that is longer than 2 seconds but less than 3 minutes.[13] This number is used to estimate individual exposure to transient arousals from sleep, and it is distinguished from nocturnal awakenings by the length of the bout of wakefulness. Included in this index are spontaneous brief awakenings caused by external and internal stimuli (e.g., noises and leg jerks, respectively). The AI may differ from the AHI or RDI because many (approximately 20%) apneas or hypopneas are not accompanied by arousals, and because the AI count includes arousals that are not apnea-induced.

Oxygen Saturation

Various measurements of O_2 saturation, as plotted over time, indicate the extent of exposure to hypoxemia during sleep. One measure is the O_2 saturation profile, in which values of O_2 saturation are presented in the frequency domain, which plots the pattern and extent of O_2 deficiency during sleep.[26] Values reported include estimations of the lowest O_2 saturation and the length of time spent below a specific O_2 saturation (e.g., 90%, 85%, 80% O_2 saturation of hemoglobin). In addition, recordings can be examined in the time domain to estimate the degree to which O_2 saturation exhibits periodic behavior.

Hypoventilation

Hypoventilation is not directly measured during routine sleep studies, because tests for arterial blood gases are uncomfortable and incur an unfavorable risk-to-benefit ratio. Markers for $P_{a}CO_2$ include end-tidal values of CO_2 or transcutaneous estimates of CO_2. Both are qualitative. The former makes the assumption of adequate sampling of alveolar gas, and the latter provides trends rather than precise numbers. Neither is used routinely during sleep studies in adults.

Sleep-Disordered Breathing

Healthy individuals may exhibit obstructive or central apneas at sleep onset or during periods of REM sleep.[27] Episodes are usually less than 15 seconds in duration and are not repetitive.

Occasionally, longer periods of apnea (lasting 30 seconds or more) are seen during REM sleep. These episodes may not be accompanied by arousal or sleep-state changes.

Healthy young men have more frequent apneas during sleep than young women, but after the sixth decade of life, respiratory disturbances during sleep increase in number and occur with equal frequency in men and women.[27] Patients with a clinically important sleep apnea may be distinguished from patients with normal respiratory disturbances by the presence of repetitive apneas longer than 10 to 15 seconds that occur during stages I and II of NREM sleep and during REM sleep and that are frequently accompanied by daytime sleepiness. If treated, patients with significant apnea show improvement in daytime symptoms and general performance.

DEFINITION OF SLEEP-DISORDERED BREATHING

In the United States, 9% to 12% of women and 27% to 35% of men may have an AHI greater than 5, a number often quoted as a threshold value for normality; however, many people with an AHI greater than 5 have no clinically apparent illness.[27] If the definition of illness is the presence of daytime sleepiness or cardiovascular complications such as hypertension, it is estimated that about 2% of women and about 4% of men have symptomatic SDB. Studies suggest that patients with symptomatic SDB who drive are at increased risk for vehicular accidents in which they may incur substantial disability. Medical practitioners often fail to recognize the presence of sleep apnea syndrome.

ETIOLOGY OF SLEEP-DISORDERED BREATHING

Predisposing Factors

Snoring is generally considered a predisposing feature in the development of SDB and symptoms of sleep apnea.[28] Snoring increases with age; approximately 45% of men and 30% of women 65 years of age or older are said to snore. Persons who snore are two to three times more likely to have hypertension[29] and 1.5 times more likely to have diabetes than people who do not snore, even after age and obesity are taken into account as risk factors for these diseases.[30]

Genetic Factors

Sleep apnea has a genetic component. Symptoms relating to apnea occur two to four times more often in family members of affected patients than in a control population. Sleep apnea events occur more often in first-degree relatives of sleep apnea patients than in control subjects matched for age, sex, and socioeconomic status. Such studies reveal that the symptomatic sequelae of multiple apneas are quite variable, probably because of an interaction between both genetics and the environment.[31]

Patients with sleep apnea exhibit a twofold increase in a polymorphism for apolipoprotein E associated with cardiovascular disease and Alzheimer disease.[32] Using a statistical approach to estimate inheritance, the Cleveland Family Study found that 27% of the variation in AHI in the community could be accounted for by perhaps only a few genetic factors.[33] Transmission patterns in both the white and the African-American patients were consistent with mendelian inheritance. Adjustment for body mass index (BMI) significantly reduced the significance of a genetic effect in whites but not in African Americans. Thus, an underlying genetic basis for sleep apnea could be independent of the contribution of BMI to the disease in African Americans.

Specific craniofacial morphology (e.g., a short mandible and round head) are predisposing factors for the development of snoring, apneas, or both.[34] It is also known that there are familial traits in hypercapnic and hypoxic sensitivity; these could relate to the tendency to breathe periodically during sleep.[35] In addition, obesity and alcoholism (factors associated with SDB) can be family traits and, to the extent that these factors are causally related to apneas, may account for the familial clustering of sleep apnea. It is not known whether there is a familial trait involving the respiratory coordination of muscles of the chest wall and upper airway. A role for genetic transmission of ventilatory behavior (respiratory frequency, tidal volume, and minute ventilation) is directly supported by reports of nearly absent respiratory depression in several gene knockout models and by studies of inbred rat and mouse strains.[36] Given the current evidence, sleep apnea does not appear to be the result of a single mutation or protein action.

Central Sleep Apnea

PATHOPHYSIOLOGY

The instability of breathing that occurs with central apnea or hypopnea reflects brain stem interplay between the sensitivity to CO_2 and the hypocapnic-apneic threshold. The inhibitory effects of sleep on ventilatory responsiveness are offset by neural mechanisms that stabilize ventilation. One such mechanism is short-term potentiation (STP), or a transient increase in ventilation occurring after a large breath (a sigh) or an apnea. STP may be abolished by prolonged hypoxia, which may explain the development of periodic breathing in patients at high altitudes or in patients with cardiopulmonary disease who have modest hypoxemia. Finally, upper airway obstruction may reflexly inhibit central neural ventilatory output and provoke central apnea in some patients.[37]

The occurrence of a central apnea or, for that matter, any apnea appears to set in motion events that conspire to promote further breathing instability [*see Figure 6*].[38] First, time delays in the ventilatory control system prevent resumption of rhythmic breathing after apnea until arterial CO_2 levels increase by 4 to 6 mm Hg above the set point. Second, central apnea is associated with narrowing or occlusion of the pharyngeal airway.[39] Resumption of ventilation thus requires opening of a narrowed or occluded airway, which involves overcoming mucosal adhesion and gravitational forces. (This narrowing of the upper airway may explain the overlap between central and obstructive apnea, or mixed apnea, and the successful use of nasal continuous positive airway pressure [CPAP] in some patients with central sleep apnea.) Third, a combination of hypoxia, hypercapnia, and transient arousal results in ventilatory overshoot, subsequent hypocapnia, and further apnea or hypopnea.

Mathematical models and studies in humans have focused on statistical correlations between the incidence of periodic breathing and the incidence of hypoxic sensitivity.[40,41] Such periodic breathing during sleep occurs more frequently in individuals with higher peripheral chemosensitivity.[42,43] Alternative explanations for repetitive apneas during sleep are that (1) patients with repetitive apneas have the same oscillations as normal individuals, but excitatory stimuli contribute to a larger amplitude of these oscillations in sleep apnea,[41] or (2) recurrent apneas result from an intrinsic property in the feedback control of breathing in regard to either stability or instability in ventilation over time.[44]

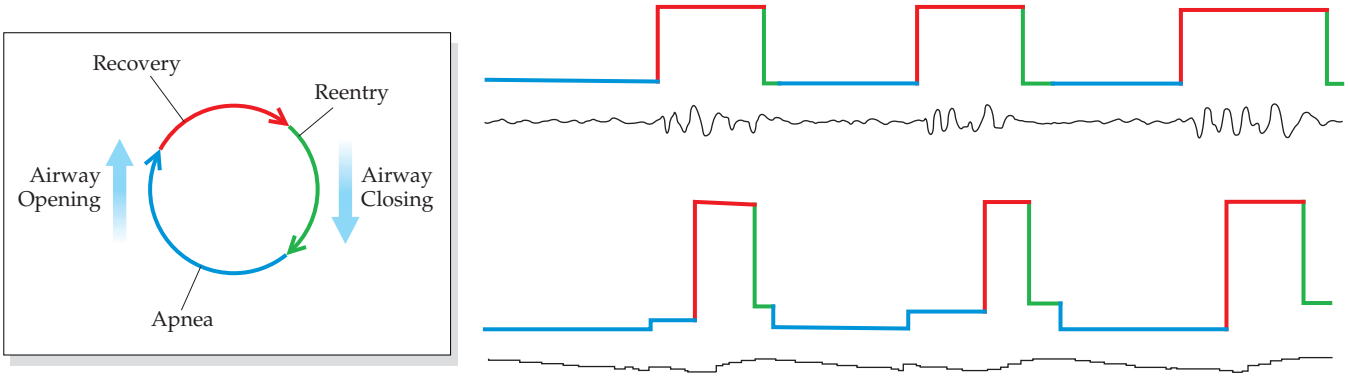

Figure 6 **Apneas can be thought of as a recurrent or "reentry" arrhythmia of ventilation, characterized in this example by a relatively long apnea followed by phases of recovery and reentry. Such periodicity is evident in both airflow and oxygen saturation measurements.**

RISK FACTORS

Several factors predispose persons to sleep apnea, and some of these factors are more selective for central apnea than for obstructive events [*see Table 1*].

Central sleep apnea is also more common in stroke patients than in control subjects matched for age, weight, and BMI.[45] Interestingly, there is no difference between the prevalence of sleep apnea in patients with hemispheric involvement and that in patients with brain stem involvement. Although central sleep apnea is associated with stroke, the natural history and consequences of central sleep apnea in stroke patients remain uncertain. Available data on the effects of sleep apnea on blood pressure and sympathetic motor output suggest that it is prudent to identify and treat sleep apnea in the poststroke period.[46]

Patients with hypothyroidism and renal failure have an unexpectedly high prevalence of both central and obstructive sleep apnea (OSA).[47,48] Similarly, patients with acromegaly have a high rate of central and obstructive apnea, which correlates with higher biochemical markers of disease activity and higher chemoresponsiveness.[49-51]

DIAGNOSIS

Clinical Presentation

Cheyne-Stokes respiration, or CSR, is the signature feature of central apnea. CSR is marked by a crescendo-decrescendo pattern of breaths, followed by central apneas or central hypopneas, some lasting as long as 30 seconds [*see Figure 7*]. Patients are often hypocapnic during wakefulness and sleep. CSR commonly seen in healthy persons at high altitude results from hypoxic stimulation of breathing and resultant hypocapnia. Conditions that promote CSR at normal altitude include hypoxia, decreased lung volume, decreased metabolic rate, renal failure, and cerebrovascular disease.

CSR occurs in 25% of congestive heart failure (CHF) patients. A seemingly minor ventilatory disturbance may initiate an appropriate change in ventilation and overcompensation. Then, a change in ventilation in the opposite direction occurs, with overshoot, and an oscillating breathing pattern is established.

Diagnostic Testing

The severity of central apneas during sleep is determined by a polysomnographic study of the frequency of respiratory events per hour of sleep (i.e., the apnea-hypopnea index or respiratory disturbance index), the severity and frequency of O_2 desaturation or hypercapnia, changes in sleep-stage distribution, and clinical symptoms produced by the disorder.

TREATMENT

Central apneas in otherwise healthy persons are usually not treated. Approximately 25% of patients with CHF, even those who are well compensated, have clinically significant central sleep apnea.[52] CHF patients with CSR have a higher mortality and a greater need for cardiac transplantation than CHF patients without CSR events.[53,54] The clinical management of CSR in the setting of CHF is well documented, and data indicate CPAP as the recommended therapy.

In a randomized study, CHF patients with CSR and central sleep apnea who received treatment with CPAP for up to 6 hours a night had a significantly greater rate of transplant-free survival than control subjects, who did not receive CPAP.[55] In patients with stable chronic CHF who have CSR, CPAP has been shown to reduce CSR, left ventricular afterload, plasma catecholamine

Table 1 Risk Factors for Sleep Apnea with Associations to Apnea Type

Risk Factors	*Apnea Type*
Increasing age	CSA, OSA
Male gender predominance	CSA, OSA
Family history of apnea or snoring	OSA
Head form (craniofacial morphology)	OSA
Poor physical fitness	OSA
BMI	CSA (lower BMI); OSA (higher BMI)
Alcohol ingestion	OSA
Smoking exposure	OSA
Sleep restriction	OSA
Cardiovascular disease	CSA, OSA

BMI—body mass index CSA—central sleep apnea and Cheyne-Stokes respiration OSA—obstructive sleep apnea

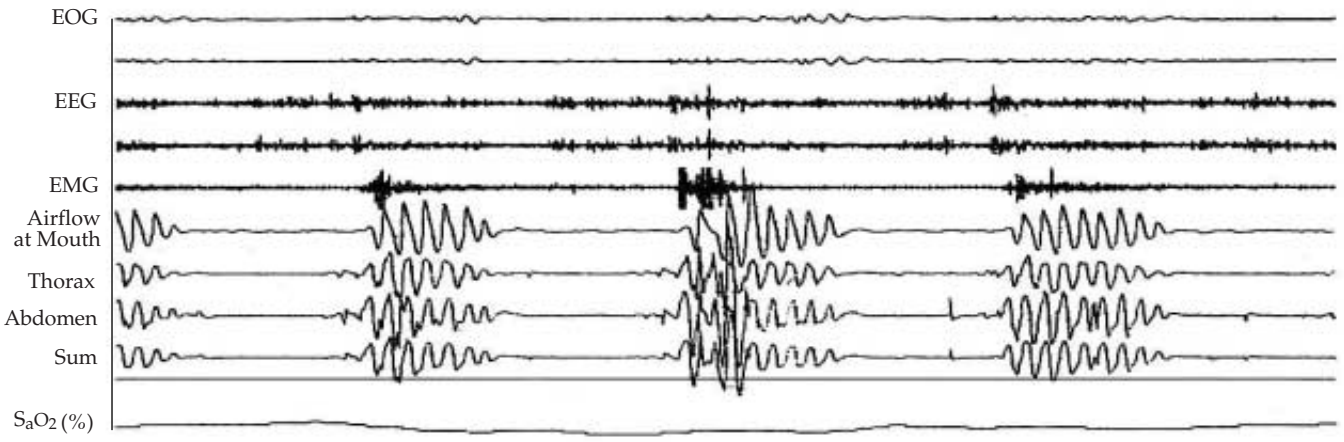

Figure 7 **A fragment of a polysomnogram shows a series of central apnea episodes during slow wave sleep. Each episode of absent flow is accompanied by a cessation of thoracoabdominal efforts. Central sleep apnea has this pattern as its signature.**

levels, and sympathetic nervous system activity and to improve left ventricular ejection fraction and quality of life.[56] Application of CPAP therapy is discussed elsewhere [*see* Obstructive Sleep Apnea, Continuous Positive Airway Pressure, *below*].

Supplemental O_2 has also been shown to reduce the severity of CSR, decrease urinary catecholamine levels, and improve exercise capacity.[57] Theophylline reduces the severity of central sleep apnea[43]; however, long-term use of theophylline is associated with proarrhythmic effects,[58] and sustained benefits are unproven. Thus, further study is necessary before theophylline or O_2 therapy can be recommended over CPAP.

Nonhypercapnic idiopathic central sleep apnea without CSR may improve with supplemental O_2 therapy or treatment with acetazolamide. Treatment for hypercapnic central sleep apnea, a disorder of the ventilatory control system, should be aimed at improving alveolar ventilation. Noninvasive ventilation or tracheostomy and mechanical ventilation should improve P_aCO_2, cor pulmonale, and symptoms of daytime hypersomnolence.

Obstructive Sleep Apnea

The fundamental feature of obstructive apneas and hypopneas, including snoring, is a functional narrowing or collapse of the upper airway. Illness occurs in the context of repetitive events.

PATHOPHYSIOLOGY

The presence of an anatomic abnormality is not sufficient or necessary to produce overt disease. Nevertheless, there is evidence that persons with OSA have a smaller-caliber pharyngeal airway during wakefulness than the airway in persons without OSA. In addition, the pharyngeal airway in patients with OSA syndrome has an elliptical anterior-posterior configuration, in contrast to a more circular configuration in normal persons.[34] This asymmetry seems to predispose patients to anterior-posterior collapse.

A collapsing transmural pressure is generated either by a negative intraluminal pressure or a collapsing surrounding pressure; however, pharyngeal obstruction does not require negative pressure, because complete upper airway collapse occurs during central apnea.[35] The occurrence of upper airway obstruction in the absence of negative intraluminal pressure is consistent with the hypothesis that the intrinsic properties of the upper airway (e.g., stiffness of the pharyngeal wall) will or will not permit collapse to occur.

Another factor in airway collapse is the mechanical interdependence of the upper airway and the thoracic cage and mediastinum. An increased lung volume is associated with increased upper airway caliber in awake humans, independent of muscle dilatation in the upper airway.[59] Caudal traction may stiffen the pharyngeal airway and permit greater dilating force or, at the very least, prevent inspiratory collapse, both of which effects have been demonstrated in model systems. Therefore, a reduction in functional residual capacity could also contribute to a reduction in upper airway patency during sleep.

Proposed mechanisms for the pathophysiology of OSA involve alterations in the neuromuscular control of upper airway muscle, the resting size of the upper airway, and the degree of stiffness of the upper airway wall. The underlying defect is a pharynx that is susceptible to narrowing and collapse. The change in respiratory drive that occurs with sleep onset leads to reduced ventilatory motor output to upper airway muscles, which triggers the cascade of events leading to pharyngeal obstruction during sleep. Upper airway obstruction often occurs during experimentally induced periodic breathing at the lowest point of respiratory drive. Central ventilatory control instability is a key mechanism for repetitive obstructive apnea.[60]

RISK FACTORS

Obesity is the strongest risk factor for OSA [*see Table 1*], and the prevalence of OSA substantially increases with age. OSA has a strong familial component that likely involves multiple genetic influences. Several anatomic abnormalities may predispose a patient to OSA; in men, a large neck size (>17 in) may be a risk factor for OSA.[61] Additional risk factors include ethanol and nicotine use, because these agents promote airway collapse.

OSA-ASSOCIATED MORBIDITY AND MORTALITY

The mortality associated with sleep apnea has not been satisfactorily explained. Early reports suggested mortality from cardiorespiratory failure, pulmonary embolus, and renal failure. Death has been reported to result from sedative drug use, particularly preoperative medications, which suppress breathing and the arousal response to an obstructive apnea. Automobile acci-

dents related to excessive daytime sleepiness may have a substantial impact on morbidity and mortality. Taking a broader view, sleep quantity and quality are associated epidemiologically with hypertension, all-cause cardiovascular risk, and early mortality.[62-64]

The occurrence of sleep apnea with the features of syndrome X—hypertension, obesity, diabetes, and hyperlipidemia—has prompted a call to rename this disorder syndrome Z.[65] This cluster of diseases and disorders may occur through a common set of neuroendocrine factors, genetic predispositions, or both. Both the physiologic plausibility that sleep problems relate to insulin resistance[66] and the epidemiologic association between snoring and cardiovascular risk factors offer a rationale to explore the pathogenesis of OSA as it relates to obesity, race, and cardiovascular disease and the pathogenesis of central apnea as it relates to aging, cardiovascular disease, and stroke. It may be that prevention of disease progression in sleep apnea may be nested within the factors that increase cardiovascular risk—namely, obesity, hypertension, lack of exercise, and alcohol use.

DIAGNOSIS

Clinical Presentation

Self-reported snoring and excessive daytime sleepiness are the major presenting symptoms of OSA. One might suspect that the bed partner rather than the patient would report snoring more reliably; however, reports by the patient and bed partner are similar.[67] Other complaints include apneas, choking during sleep, restless sleep, and, in some patients, insomnia-like symptoms along with excessive daytime sleepiness.

Diagnostic Testing and Imaging

Overnight polysomnography is the current gold standard for the diagnosis of OSA and should be considered in any patient suspected of having this disorder [*see Figure 8*]. Split night polysomnograms provide adequate time for both diagnosis and proper CPAP prescription. Home-based studies provide data comparable to data from laboratory studies; however, devices vary substantially. Oximetry alone cannot be recommended as a screening tool for OSA. Nasal-pressure changes detected during inspiration and expiration reflect changes in airflow with greater accuracy than thermistors.

TREATMENT

OSA patients should be counseled about the risk of sleepiness and offered therapy when it is clinically indicated.[68]

Therapy for sleep apnea is diverse and includes correction of associated medical conditions (e.g., cardiopulmonary disease) and treatment of SDB by specific interventions (e.g., surgery or use of mechanical aids). The principles of management are directed toward improvement in gas exchange, sleep continuity,[15] and chronic cardiopulmonary symptoms during wakefulness. Management approaches start with consideration of mechanical devices; when mechanical devices prove inadequate, surgery to remove nasal or pharyngeal obstruction is considered.

Treatment is customized to the individual patient and may require avoidance of agents that provoke apneic episodes (e.g., alcohol, sedatives, and androgens). Obese patients with OSA who are treated for obesity may show improvement in the severity of sleep apnea, but long-term weight reduction is often difficult to achieve. Dietary management alone is effective in producing long-term weight reduction in a small minority of morbidly obese patients. However, even modest weight reduction achieved by dieting can improve SDB. Gastric stapling can achieve weight reduction in approximately 60% of patients who undergo the procedure, and appears to be effective in improving or reversing sleep apnea in most morbidly obese patients.

Continuous Positive Airway Pressure

Indication CPAP is considered the first choice of treatment for OSA.[69] Treatment with CPAP improves vigilance and cognitive function in persons who report hypersomnolence; however, patients who do not have daytime hypersomnolence may not experience substantial improvement of cognitive function with CPAP.[70] Treatment with CPAP will reduce blood pressure in normotensive and hypertensive patients; in the latter patients, control of blood pressure with drugs may become easier, or

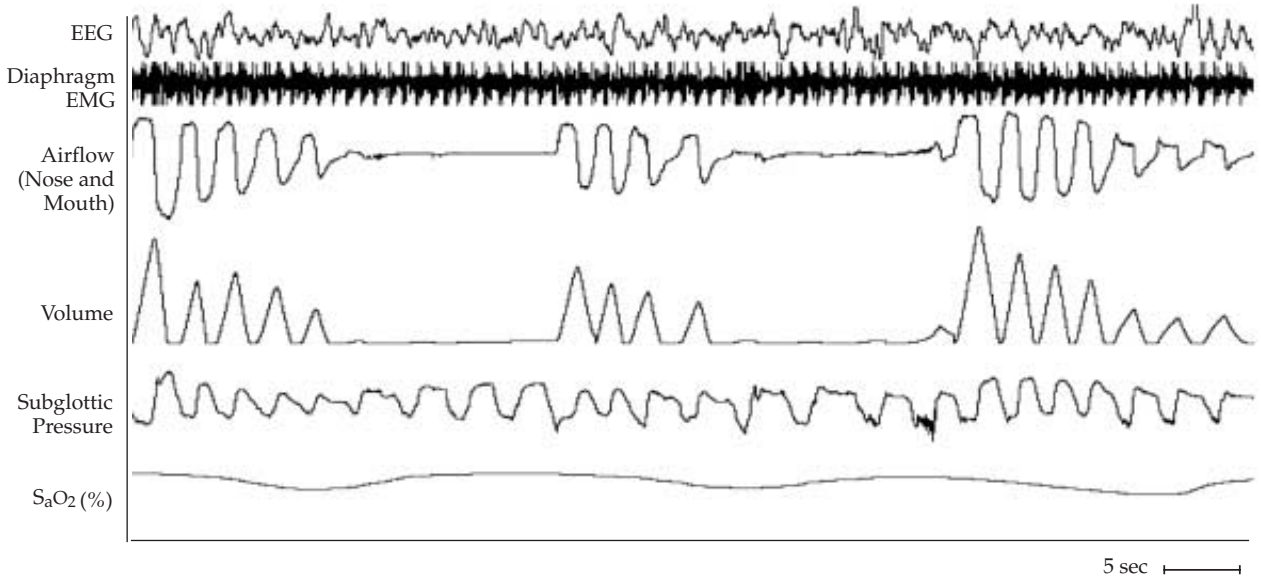

Figure 8 **A fragment of a polysomnogram shows a series of obstructive apneas during sleep. Each episode of absent flow is accompanied by continued thoracoabdominal efforts. Apneas are terminated by arousals. Obstructive sleep apnea has this pattern as its signature.**

drugs may no longer be needed.[71] Contraindications include bronchopleural fistula, acute pneumothorax, and sinus-communicating pneumocephalus. A relative contraindication is nasal or pharyngeal obstruction, which must be managed before CPAP treatment is attempted.

Application Nasal CPAP is immediately effective in reversing airway obstruction in most patients with OSAS. The patient is outfitted with a nasal mask, which is attached to a blower that applies an adjustable positive pressure. The amount of pressure required to relieve upper airway obstruction (usually 5 to 20 cm H_2O) is most often determined empirically during a sleep study. Effective CPAP is defined as the pressure required to prevent inspiratory collapse of the upper airway when the patient is in the supine position and during all stages of sleep. Positive pressure applied to the nose presses the soft palate to the back of the tongue and thereby prevents leakage of air out of the mouth. If the apparatus fails, the patient is free to breathe through the oral cavity. Full-face masks or chinstraps may be needed for patients in whom air escapes through the mouth. Monitoring of pressure can be used to document the hours of use of CPAP and the effectiveness of CPAP in maintaining airway patency. Heated-humidification devices may increase patient compliance and reduce symptoms of nasal obstruction. For patients in whom standard CPAP is unsuccessful or intolerable, bilevel or self-adjusting modes may be attempted.

The routine use of bilevel therapy (i.e., devices that sense inspiration efforts and apply a higher positive pressure during inhalation) does not improve patient adherence; however, bilevel pressure is able to eliminate apneas with lower expiratory pressure and mean airway pressure in patients who are unable to tolerate high pressures. Devices that sense and then automatically triturate pressure to eliminate apneas operate in a way similar to personal titration; the routine use of unattended devices in the home is currently under study.

Oral Appliances

Intraoral devices to reposition the mandible are increasingly being used in the management of sleep apnea, both as primary therapy for heavy snoring and as an alternative therapy for patients who cannot tolerate CPAP.[72] An oral appliance will reduce the apnea-hypopnea index and the arousal index and will improve O_2 saturation even in patients with mild to moderate OSA. Oral appliances are modestly preferred over CPAP; however, CPAP is more effective than oral appliances in reducing the apnea-hypopnea index.[73]

Surgery

Surgical management of OSA encompasses several strategies[74-76]: (1) bypass of the anatomic obstruction by way of tracheostomy, (2) alteration of the bony structural support of the upper airway, and (3) alteration of the soft tissue attachments or deposits to improve airway patency. Of the surgical options, only tracheostomy is routinely effective in eliminating OSA. Central apneas may persist after tracheostomy. Despite the development of a new flap-type tracheostomy and low-profile tracheostomy tubes, local stoma problems are relatively common. Infections, local discomfort, formation of granulation tissue, and the distortions of self-image produced by tracheostomy have limited the use of this procedure to relatively few patients. Adaptation to a tracheostomy often takes a year or more.

Pharmacologic Therapy

Pharmacologic therapy plays a very limited role in the management of upper airway obstructions during sleep. Modafinil is the only drug approved by the Food and Drug Administration for treatment of OSA,[77] and it is effective for the management of residual sleepiness after treatment with CPAP. Use of modafinil may be considered when CPAP compliance is acceptable and other behavioral issues, such as sleep restriction, have been addressed.

Medroxyprogesterone is not effective therapy for OSA in patients with normal levels of P_aCO_2 , but it may be used in the management of obesity hypoventilation syndrome. Acetazolamide therapy is not effective treatment for OSA, but it will reduce the CO_2-apneic threshold and thus may improve central sleep apnea. Protriptyline (a nonsedating antidepressant) increases alertness and may modestly reduce the apnea-hypopnea index, but its anticholinergic side effects limit its routine use. Nicotine may modestly reduce the apnea-hypopnea index in patients with OSA; however, current delivery methods and available doses do not have clinical utility. Serotonin agonists do not generally affect the apnea-hypopnea index or the neurocognitive defects associated with sleep apnea. Thus, these agents are not currently recommended for management of OSA, but they can be used to treat comorbid depression or mood disorder.

Other Conditions Associated with Sleep-Disordered Breathing

ASTHMA

Cough and cough-induced arousals from sleep may be the presenting complaint of patients with reactive airway disease. Cough may be caused by changes in airway smooth muscle tone during NREM sleep and by bronchoconstriction during REM sleep. Gastroesophageal reflux may contribute to awakenings and bronchoconstriction. Nighttime cough occurring in a patient with uncomplicated asthma may indicate inadequate therapeutic effect of asthma medication or exacerbation of airway disease by exposure to allergens [*see 14:II Asthma*]. Morning dipping refers to the fall in lung function that occurs in the early morning hours and represents an extreme form of diurnal variation in lung function present in most patients with airway reactivity. Reports describing morning dipping emphasize that lung function measured at midday may be normal, whereas nighttime values may show moderately severe airway obstruction.

UPPER AIRWAY DISEASE

Patients with disease of the nose, larynx, and pharynx may be disturbed during sleep by apnea or aspiration of secretions caused by excessive production of mucus (e.g., chronic allergic rhinitis) or by impaired swallowing (e.g., bilateral recurrent laryngeal nerve paralysis). In both instances, frequent arousals from sleep are associated with cough or a choking sensation. During sleep, particularly REM sleep, the cough response is less than it is during wakefulness. As a result, greater amounts of secretions are tolerated before a cough ensues. After awakening, this larger amount of material may precipitate paroxysmal cough. Patients who are being treated with hypnotic medications may tolerate greater amounts of secretions before cough-induced arousal from sleep, which increases the likelihood of aspiration injury to the lungs. Hypnotic medications used to manage insomnia should be used with caution in these patients.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with COPD may present with a variety of sleep problems. Nocturnal cough can be related to bronchitis. Insomnia may be the consequence of therapy with methylxanthines (e.g., aminophylline). Hypoxemia during sleep may occur as a consequence of a mechanical airway impairment present during wakefulness that is exacerbated during sleep by the normal fluctuations in gas exchange. Hypoxemia that occurs only during sleep in patients with moderately severe COPD is associated with the development of cor pulmonale. In these persons, complications attributed to hypoxemia and hypercapnia are associated neither with a severe mechanical defect (forced 1-second expiratory volume of less than 1 L) nor with symptomatic apnea. Other diagnostic entities, such as recurrent pulmonary emboli or chest wall muscle weakness, should certainly be considered.

The combination of COPD and sleep apnea is called the overlap syndrome in the European literature, and it is estimated to be present in 20% to 25% of patients presenting with moderate and moderately severe COPD. There is usually historical evidence for snoring, pauses during sleep, and arousals from sleep, and the patient should be treated for OSA [*see* Obstructive Sleep Apnea, Treatment, *above*]. Patients with SDB that is not caused by OSA may experience a good sleep response to supplemental O_2. Symptoms persisting after nocturnal O_2 may warrant a sleep study.

INTERSTITIAL LUNG DISEASE

Respiratory disturbances during sleep for patients with interstitital lung disease include cough and hypoxemia. Patients also may have a concomitant sleep apnea. Sleep hypoxemia may be a factor in the development of pulmonary hypertension. A restrictive defect on pulmonary function testing and interstitial fibrosis on chest roentgenogram may reflect a history of chronic aspiration. In patients with interstitial lung disease, during sleep, the tone of the gastroesophageal junction relaxes, allowing stomach contents to regurgitate to the level of the pharynx. In such patients, it may be useful to measure pH levels in the pharynx and esophagus during sleep.

NEUROMUSCULAR DISORDERS

Respiratory disturbances caused by OSA during sleep may occur because the underlying disease process affects upper airway muscles. Sleep disturbances associated with cough, choking, or aspiration and with SDB may be the first indications of ventilatory problems in patients with neuromuscular disease. Occasionally, sleep fragmentation and the effects of sleep deprivation dominate the clinical presentation of the patient with neuromuscular disease. After treatment for SDB, the clinical manifestations of the primary neuromuscular disorder may not appear so severe.

KYPHOSCOLIOSIS

Treatment of hypocapnic respiratory failure by tracheostomy with or without positive-pressure ventilator support during sleep can reverse cor pulmonale and improve the appearance of the chest roentgenogram.

The author has received grants for clinical research from Respironics, Inc., and the National Institutes of Health.

VII DISORDERS OF THE CHEST WALL

Gerald W. Staton, Jr., m.d.
Roland H. Ingram, Jr., m.d.

The chest wall consists of the parietal pleura, rib cage, and muscles. The abdominal contents and abdominal wall function as part of the rib cage in that they influence the resting position and movement of the diaphragm.

The respiratory pump apparatus is composed of the rib cage and its musculature, including the intercostal muscles, diaphragm, and accessory muscles of respiration.[1] Optimal pumping action requires structural integrity and the synchronized contraction of the intercostal muscles and diaphragm. Respiratory pump function may be impaired by mass loading from obesity, skeletal abnormalities, neuromuscular disorders, or restriction of lung movement from pleural disease. Cervical strap or abdominal muscles may be recruited for assistance when respiratory pump function is impaired. Because the diaphragm is the major power generator for the respiratory pump, loss of rib cage function alone may be insufficient to cause ventilatory failure; ankylosis and paralysis of the rib cage are often associated with a normal resting carbon dioxide tension (P_{CO_2}).

Respiratory Pump Dysfunction

Respiratory pump dysfunction may vary from trivial to severe. Severe dysfunction restricts lung expansion and may cause dyspnea and hypercapnic ventilatory failure because of the small tidal volumes that increase the proportion of wasted ventilation per breath, despite a compensatory increase in the rate of respiration [*see Table 1*]. The result is a decrease in alveolar ventilation with hypercapnia and hypoxemia. Hypercapnia is often most severe during sleep because of a decrease in ventilatory drive and a sleep-associated increase in upper airway resistance. Hypercapnia and the associated hypoxia may in turn cause vasoconstrictive pulmonary hypertension and cor pulmonale [*see 14:XI Pulmonary Hypertension, Cor Pulmonale, and Primary Pulmonary Vascular Diseases*]. Weakness of expiratory muscles from neuromuscular disease may produce ineffective cough and result in recurring atelectasis or infections. Severe respiratory pump dysfunction differs from alveolar and interstitial lung disease, in which ventilatory abnormalities result from alterations in the lung parenchyma [*see Table 2*].

When the respiratory pump is impaired, ventilation will be determined by (1) the efficiency of the inspiratory muscles, (2) the strength of the inspiratory muscles, and (3) the impedance to the pumping action of these muscles. The efficiency of the respiratory muscles is determined by their length and by the resulting mechanical action on the pump apparatus. Shortening of the inspiratory muscles from hyperinflation or chest wall deformity reduces their pumping efficiency. Paralysis of either the chest wall or the diaphragm produces an observable paradoxical movement of the paralyzed component during inspiration; this movement results in inefficiency of the pump apparatus. The strength of the inspiratory muscles may be reduced by neuromuscular disease or metabolic disturbances, such as hypokalemia or hypophosphatemia. Ventilatory ability is proportional to the remaining respiratory muscle strength but may be disproportionately reduced if there are concomitant mechanical problems of the respiratory system. Finally, either increased airway resistance or decreased respiratory system compliance may impede the pumping action of the inspiratory muscles and reduce ventilation. Respiratory system compliance may be reduced by morbid obesity, chest wall deformity, circumferential pleural disease, or parenchymal disease. Patients with a poorly compliant respiratory system must exert more effort than healthy patients to achieve equivalent tidal volumes [*see Figure 1*], so they take smaller breaths to minimize respiratory muscle fatigue but must compensate by increasing their breathing rate.

Obesity and Its Impact on Respiratory Function

Obesity imposes a restrictive load on the thoracic cage, both directly because weight has been added to the rib cage and indirectly because of the large abdominal panniculus, which impedes the motion of the diaphragm when the person is supine.[2,3] In addition, obese patients, particularly males, may experience increased respiratory resistance and resultant airflow limitation that may be related to breathing at lower lung volumes, increases in pulmonary blood volume, or both.[4,5]

Obesity characteristically causes a decrease in functional residual capacity that becomes significant only in the presence of coexisting conditions such as obstructive lung disease, in which airway closure occurs at lower lung volume, leading to hypoxemia.

Obesity in otherwise healthy patients causes little interference with lung function at rest. Generally, vital capacity and total

Table 1 Relations among Tidal Volume, Respiratory Frequency, and Arterial and Alveolar Oxygen Tension

	Volume (L)			V_D/V_T	f	$\dot{V}_A$ (L/min)	P_{aCO_2} (mm Hg)	P_{aO_2} (mm Hg)	$A\text{-}aD_{O_2}$ (mm Hg)
	V_T	V_A	V_D						
Normal respiratory function	0.50	0.35	0.15	30%	12/min	4.20	40	90	10
Restrictive disorder	0.25	0.10	0.15	60%	30/min	3.00	56	70	10*

Note: this table demonstrates how restrictive disorders of the respiratory system resulting from neuromuscular or chest wall disease may produce hypercapnia and hypoxemia by decreasing the amount of ventilation per breath.

*The elevated P_aCO_2 has resulted in arterial and alveolar hypoxia. However, in the absence of atelectasis or another concomitant disease that would increase the ventilation-perfusion mismatch, the $A\text{-}aDo_2$ remains normal.

$A\text{-}aDo_2$—alveolar-arterial difference in oxygen f—respiratory frequency P_aCO_2—arterial carbon dioxide tension P_aO_2—arterial oxygen tension V_A—alveolar portion of the tidal volume $\dot{V}_A$—alveolar ventilation ($f \times V_A$) V_D—dead space portion of the tidal volume V_D/V_T—ratio of functional dead space volume to tidal volume, or the wasted ventilation ratio V_T—tidal volume

Table 2 Respiratory Parameters in Kyphoscoliosis, Neuromuscular Syndrome, and Diffuse Parenchymal Lung Disease

	Kyphoscoliosis	*Neuromuscular Syndrome*	*Diffuse Parenchymal Lung Disease*
Example	—	Amyotrophic lateral sclerosis	Idiopathic pulmonary fibrosis
Chest radiograph	Vertebral deformity	Elevated diaphragms; possible basilar atelectasis	Diffuse reticulonodular infiltrates
Lung volumes:			
Total lung capacity	↓	↓	↓
Functional residual capacity	↓	Normal	↓
Residual volume	↓	↑	↓
Diffusing capacity of the lung for carbon monoxide corrected for alveolar volume (DL/VA)	Normal (except in severe disease, scoliotic angle > 100°)	Normal	↓
Gas exchange:			
Alveolar-arterial difference in oxygen ($A\text{-}aDo_2$)	Normal or slightly ↑	↑ With atelectasis	↑
Arterial carbon dioxide tension (P_aco_2)	↑ As spinal deformity worsens	↑ As inspiratory muscle strength decreases	↓ (↑ Only in late stage as V_D/V_T increases)
Cough	Normal	↓	Normal
Maximal inspiratory pressure	Normal or ↓	↓	Normal

lung capacity remain normal except in the most severe instances of morbid obesity.

In patients with impaired ventilatory drive, the mechanical work load imposed by obesity may not be countered by increased respiratory effort. Under such circumstances, chronic daytime hypercapnia may develop, most commonly in the setting of obstructive sleep apnea but also in the absence of sleep-disordered breathing. The pathogenetic role of obesity in obstructive sleep apnea [*see 14:VI Ventilatory Control during Wakefulness and Sleep and 11:XIII Disorders of Sleep*] may relate in part to fatty encroachment on the upper airways.

Obese patients may experience significant dyspnea during exercise because of the increased work required to move the heavy chest and abdomen and because of overall poor conditioning. The tachypneic shallow breathing pattern during exercise in morbidly obese patients reflects the combined effects of this mass loading and diminished compliance of the respiratory system [*see Figure 1*].

Weight loss is the most important therapy for patients with respiratory problems related to obesity. For patients with associated sleep disorders of breathing, appropriate treatment of obesity may alleviate hypercapnia [*see 14:VI Ventilatory Control during Wakefulness and Sleep and 11:XIII Disorders of Sleep*]. Noninvasive ventilation may help decrease the symptoms of daytime hypercapnia.[6]

Skeletal Abnormalities that Affect Respiratory Function

Deformities of the costovertebral skeletal structures may affect compliance of the thoracic cage, its shape and volume, and, ultimately, pulmonary compliance. Effects vary from undetectable to severe.

KYPHOSCOLIOSIS

The two basic types of costovertebral skeletal deformity—scoliosis, a lateral curvature with rotation of the vertebral column, and kyphosis, an anterior flexion of the spine—are usually found in combination. Approximately 80% of cases of kyphoscoliosis are idiopathic. Idiopathic kyphoscoliosis commonly begins in late childhood or early adolescence and may progress in severity during these years of rapid skeletal growth. The incidence of kyphoscoliosis in females is four times higher than that in males. The remaining 20% of cases of kyphoscoliosis are found in association with neuromuscular disorders (e.g., syringomyelia, neurofibromatosis, or poliomyelitis), congenital vertebral defects (e.g., hemivertebrae), acquired vertebral abnormalities (e.g., tuberculous spondylitis or osteomalacia), or deforming chest wall processes (e.g., sequelae of empyema or as a result of thoracoplasty).

Respiratory Compromise

Of the various chest deformities that produce ventilatory failure, kyphoscoliosis is the most common. The degree to which ventilation is reduced is determined by the severity of deformity

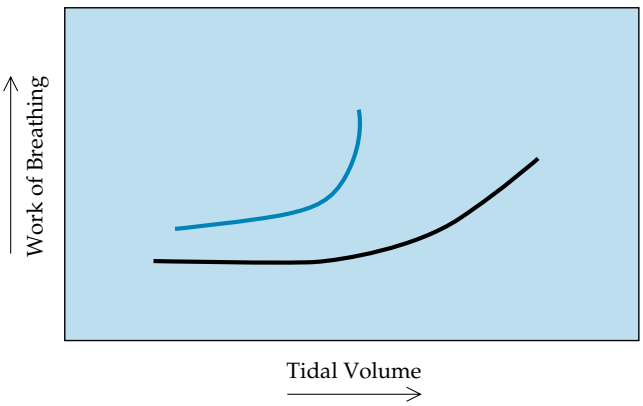

Figure 1 **When the respiratory pump is encumbered by structural changes such as obesity, kyphoscoliosis, or ankylosing spondylitis (blue line), the work of breathing at rest is higher than it is for a healthy person (black line). The work of breathing required to maintain the tidal volumes needed during exercise may be prohibitive for patients with these disorders, forcing them to adopt a shallow tachypneic breathing pattern in response to an increased ventilatory requirement.**

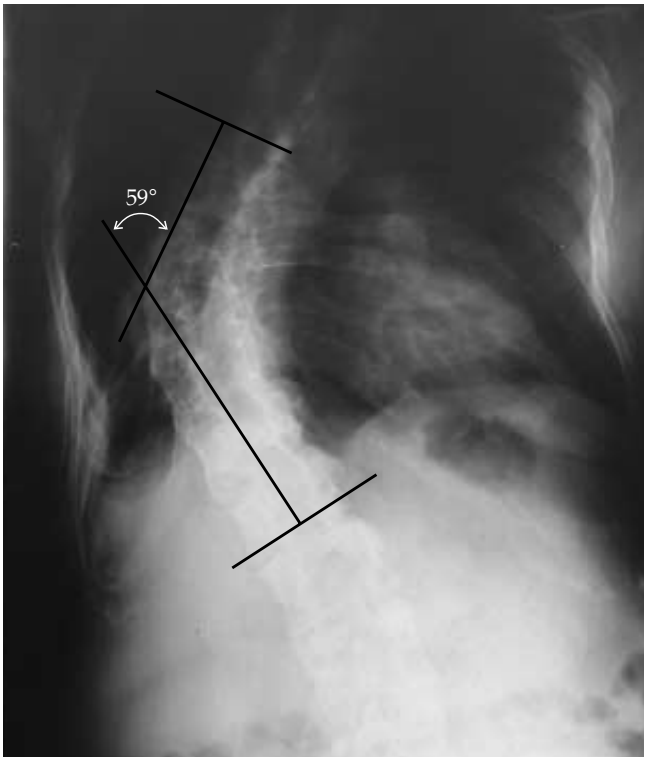

Figure 2 **In this radiograph of the spine in a patient with kyphoscoliosis, straight lines are passed through the upper and lower limbs of the curvature. The angle inscribed by these two lines defines the scoliotic angle.**

and the degree of neuromuscular weakness. A standard technique for measuring the degree of spinal curvature gives an indication of the potential risk for respiratory compromise [*see Figure 2*]. Mild to moderate deformities (scoliotic angle < 60°) are associated with minimal to mild restrictive ventilatory defects.

Dyspnea may occur during exercise and is most often caused by deconditioning and lack of regular aerobic exercise rather than by any alteration of lung function.[7] As the scoliotic curvature worsens, vital capacity and total lung capacity decline significantly, and dyspnea on mild or moderate exertion becomes a common complaint. Kyphoscoliosis may distort the respiratory pump, so that inspiratory power becomes limited even in the absence of a neuromuscular disease, such as poliomyelitis. The severity of hypercapnia is therefore related to both the severity of deformity and the degree of inspiratory muscle weakness.

Severe deformities (scoliotic angle > 100°) can be associated with prominently restricted lung volumes; typically, total lung capacity is reduced to 50% or less of the predicted value. Such restriction may lead to chronic alveolar hypoventilation, hypoxemia, pulmonary hypertension, and, ultimately, cor pulmonale.[8] Long-term follow-up of patients with kyphoscoliosis suggests that those with a vital capacity less than 45% of the predicted value and a scoliotic angle greater than 110° are at the greatest risk for respiratory failure.[9] Kyphoscoliosis of such severity may cause compression of underlying lung tissue, thereby elevating the alveolar-arterial difference in oxygen ($A\text{-}aDO_2$). In most cases of kyphoscoliosis, however, the $A\text{-}aDO_2$ remains at normal or near-normal levels, and significant hypoxemia is present only when hypercapnia develops. These findings contrast with restrictive ventilatory disorders caused by diffuse parenchymal lung disease, in which the $A\text{-}aDO_2$ is characteristically elevated and hypoxemia is often associated with hypocapnia until late in the course of disease.

Treatment

Acute complications Patients with severe kyphoscoliosis may live for many years without succumbing to respiratory insufficiency. Such patients, however, are vulnerable to any respiratory tract infection or central nervous system depressant. Because breathing is chronically restricted, increased central neural output and physical work are required to maintain ventilation; relatively minor insults, such as bacterial or viral bronchitis or pneumonia, may represent an increment in load sufficient to produce frank respiratory failure. In addition, standard doses of narcotics or sedatives may suppress chronically hyperactive control mechanisms to a level sufficient to precipitate acute respiratory failure.

Thus, immunization with influenza and pneumococcal vaccines, early treatment of respiratory tract infections, and strict avoidance of CNS depressants are important in the management of kyphoscoliosis. Episodes of hypercapnic respiratory failure precipitated by reversible conditions respond well to short-term supportive measures, including bronchopulmonary drainage, mechanical ventilatory support, and oxygen supplementation.

Chronic complications Chronic respiratory insufficiency may ensue after several years. Older patients with kyphoscoliosis are at risk for respiratory failure because the angle of curvature typically worsens with age. Although most cases of idiopathic scoliosis stabilize just after puberty, further spinal deformity may result from the osteoporosis, vertebral body weakening, and loss of muscle tone that accompany older age. Surgical procedures to straighten and stabilize the vertebral column usually fail to restore ventilatory capacity. Such procedures are useful early in the course of kyphoscoliosis, when they may prevent progression of the deformity before respiratory compromise develops.[10]

Supportive measures may sustain meaningful life for many years, even in patients with chronic respiratory failure. Many can adapt very well to a state of chronically disordered gas exchange. Chronic hypoxemia accompanied by secondary erythrocytosis, worsening of pulmonary hypertension, and cor pulmonale should be treated with supplemental oxygen administration. Such therapy can be augmented by nocturnal ventilatory support.[11]

Although kyphoscoliosis is not a primary sleep-related breathing disorder, the degree of oxygen desaturation that occurs during sleep is greater than that observed in other types of lung disease, possibly because the baseline hypoxemia and hypercapnia are more severe and lung volumes are smaller.[12] Thus, nocturnal oxygen therapy and mechanical ventilatory support during sleep often improve functional status and symptoms. In fact, many patients who achieve normal levels of arterial carbon dioxide tension (P_aCO_2) during sleep by means of mechanical ventilators can sustain normal or near-normal arterial blood gas levels throughout the day. Devices used for mechanical ventilation in such patients include the iron lung, specially fitted thoracoabdominal negative pressure ventilators, and positive pressure ventilators applied via tracheostomy or nasal mask.[13]

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis may affect the thoracic cage because of arthritic involvement of the costovertebral articulations[14] [*see*

15:III Seronegative Spondyloarthropathies]. The chest may become relatively fixed in a hyperexpanded position, leading to an elevated midposition lung volume. The reduced compliance of the chest wall causes moderate restriction of vital capacity and total lung capacity. A typical physical finding is limited expansion of the chest wall on inspiration, despite normal findings on auscultation and percussion of the chest and normal muscle strength. Nonetheless, the alteration in function is almost never severe enough to produce symptoms, and this deformity does not produce respiratory failure.

DEFORMITIES OF THE STERNUM

Deformities of the sternum and costochondral articulations are potentially dramatic in radiographic and physical appearance and may induce psychological problems, but functional consequences are rare. There are two main varieties of deformity: pectus excavatum, an inward concavity of the lower sternum, and pectus carinatum, an outward protuberance of the upper, middle, or lower sternum.

Respiratory Compromise

Pectus deformity is present in fewer than 0.5% of the general population and appears to be more common in patients with other evidence of structural or connective tissue disease, such as scoliosis, Marfan syndrome, Poland syndrome, or Pierre Robin syndrome. In these circumstances, ventilatory function impairments may result from the underlying disease rather than the pectus deformity. For example, defects in bronchial cartilage development may lead to repeated pneumonia and result in bronchiectasis.

Treatment

In most cases of pectus deformity, no significant functional limitations are caused by the deformity. Lung volumes are preserved, and cardiovascular function is normal. Surgical correction is therefore generally restricted to patients who have severe deformity accompanied by evidence of lung restriction or cardiovascular dysfunction. Although the severity of the pectus deformity may be assessed by determining the ratio of the transverse diameter of the chest to the anteroposterior diameter as measured by computed tomography, it is not clear whether this index predicts improvement in lung function with surgery.[15] A few patients with cardiac compression or with lung restriction from pectus excavatum experience functional improvement after surgical repair. Right and left ventricular end-diastolic volumes also may improve as cardiac compression is relieved.[16]

Surgical correction may result in modest improvements in lung volumes, ventilatory capacity, and exercise capacity in patients with severe pectus deformities but may worsen the condition of patients with good preoperative lung function.[17,18] Surgical correction for only cosmetic reasons may be associated with worsening of lung function. New surgical techniques are being developed that may improve outcome.[19]

FLAIL CHEST

Flail chest is an acute process that may lead to life-threatening abnormalities of gas exchange and mechanical function. Stability of the thoracic cage is necessary for the muscles of inspiration to inflate the lung. In flail chest, a locally compliant portion of the chest wall moves inward as the remainder of the thoracic cage expands during inhalation; the same portion then moves outward during exhalation. Consequently, tidal volume is diminished because the region of lung associated with the chest wall abnormality paradoxically increases its volume during exhalation and deflates during inhalation. The result is progressive hypoxemia and hypercapnia. Multiple rib fractures, particularly when they occur in a parallel vertical orientation, can produce a flail chest. The degree of dysfunction is directly proportional to the volume of lung involved in paradoxical motion. Patient management may be complicated by other manifestations of trauma to the chest, such as splinting of ventilation because of pain, contusion of underlying lung, or hemothorax or pneumothorax. Positive pressure inflation of the lung or negative pressure applied to the chest wall corrects the abnormality until more definitive stabilization procedures can be undertaken.

The pathophysiologic disturbances of flail chest may also result from nonclosure of the wound after median sternotomy is performed. Any dehiscence of the sternal wound will lead to separation, loss of stability, and prominent inward motion during inspiration. The magnitude of the inward motion is directly related to the extent of the sternal separation and to the degree of negativity of inspiratory intrathoracic pressures. This condition is often the cause of difficulty in weaning a patient from mechanical ventilatory support after major cardiac surgery.

Other, rare causes of localized chest wall instability include destruction of the ribs from malignant disease (e.g., multiple myeloma) or from metabolic disorders (e.g., osteitis fibrosa cystica).

Neuromuscular Disorders That Affect Respiratory Function

Processes that interfere with the transfer of central neural output to the muscles that expand the rib cage, such as abnormalities of the spinal cord, peripheral nerves, neuromuscular junctions, or muscles, can lead to ventilatory impairment. Whereas central control problems allow creation of adequate inspiratory pressures by voluntary efforts [*see 14:VI Ventilatory Control during Wakefulness and Sleep*], central neural output abnormalities are characterized by an inability to generate normal respiratory pressures, either automatically or intentionally. Some diseases, such as poliomyelitis, can involve both the central controller and the peripheral neuromuscular apparatus.

OVERVIEW OF NEUROMUSCULAR DISORDERS AFFECTING RESPIRATION

Pathophysiology

Several factors are common to the neuromuscular disorders of the thoracic cage. The respiratory midposition volume is maintained at near-normal levels, whereas total lung capacity decreases (because of inspiratory muscle weakness) and residual volume increases (because of expiratory muscle weakness). Vital capacity is diminished along with maximal static inspiratory pressure.

Because muscle strength and vital capacity can be substantially diminished without causing respiratory failure, the presence of respiratory failure with hypoxemia and hypercapnia indicates either extreme progression of the primary process or the effects of complications such as atelectasis caused by retained secretions from ineffective cough, pneumonia, or pulmonary thromboembolism. Onset of hypoxemia, hypercapnia, or both in the presence of reasonable inspiratory muscle function suggests the presence of a complication rather than progression of the primary process. In the acute setting, the need

to distinguish between a complication and progression makes monitoring of maximal static inspiratory pressures (which assesses muscle strength) superior to measuring serial vital capacity, because vital capacity may be diminished by either a complication or progression.

Neuromuscular disorders that persist for months are associated with chronic decreases in compliance of both the chest wall and the lungs. It is unknown whether the decreases in lung compliance are the result of microatelectasis, altered surfactant, or mild fibrotic changes resulting from recurrent infections. Ventilation-perfusion mismatch occurs in the lungs of patients with these disorders and may lead to hypoxemia that is disproportionate to the degree of hypoventilation. Decreases in chest cage compliance have been attributed to gradual stiffening of the costochondral and costovertebral articulations and to fibrotic changes or spasticity of the muscles of the rib cage.

The diminution in lung volume that occurs in chronic neuromuscular disorders is caused by the combined effects of muscle weakness and secondary alterations in the mechanical properties of the lung and chest wall. Hence, for patients with chronic disease, measurement of vital capacity is a more accurate indicator of the total impact of the disorder than is maximal inspiratory pressure. Attempts to improve lung compliance by periodic hyperinflations with intermittent positive pressure breathing have usually not proved successful.

In contrast to the mechanical disorders of the thoracic cage, which preserve an effective cough, expiratory muscle weakness in the neuromuscular disorders prevents generation of sufficient expiratory velocities for a forceful cough. The extreme example is cervical spinal cord injuries in which paralysis of the abdominal and intercostal muscles severely reduces but does not eliminate spontaneous cough. Ineffective or absent cough eliminates a first-line defense against respiratory tract infection and is particularly troublesome when combined with airway mucus hypersecretion, as occurs in asthma or chronic bronchitis. Pneumonia followed by respiratory failure is a common cause of death in patients with neuromuscular syndromes.

Respiratory Compromise

Patients with neuromuscular disorders must be awake to maintain ventilation. During sleep, hypoxemia and hypercapnia develop or worsen and may contribute to complications such as cor pulmonale. The degree of hypoxemia that develops with sleep is related to the severity of the abnormalities in lung mechanics and to the degree of derangement in gas exchange that is present while the patient is awake.[20]

In the absence of major complications, the patient with neuromuscular involvement is often disproportionately tachypneic in relation to the decrease in tidal volume. The resulting increase in minute ventilation more than offsets the increase in dead space ventilation. Thus, early in the course of the illness, P_aCO_2 is often low. The basis for the tachypnea may be microatelectasis, which also accounts for mild arterial hypoxemia. Microatelectasis probably develops because of the patient's inability to take intermittent deep breaths or sighs, which results in changes in alveolar surface forces. As weakness progresses, tidal volume decreases, dead space ventilation increases, and alveolar hypoventilation with worsening hypoxemia ensues [*see Table 1*]. The decision whether to treat with mechanical ventilatory support must then be made. Long-term results depend on the nature and prognosis of the neuromuscular process and on the potential success of a specific therapy.

Treatment

Whether the primary disorder is acute (e.g., Guillain-Barré syndrome), intermittent (e.g., myasthenia gravis), progressive (e.g., amyotrophic lateral sclerosis), or chronic (e.g., quadriplegia), onset of a pulmonary complication and the accompanying increase in mechanical load and decrease in gas-exchanging ability may precipitate overt and life-threatening respiratory failure [*see Table 3*]. Because the patient is unable to produce an effective cough, even minor causes of increased airway secretions, such as a viral tracheobronchitis, may lead to major respiratory compromise. Maintenance of bronchopulmonary drainage and the early treatment of infections are essential for avoidance of complications. Acute episodes precipitated by such complications usually respond well to specific treatment plus supportive measures, including bronchopulmonary drainage and mechanical ventilation.

DIAPHRAGMATIC PARALYSIS

In the absence of respiratory complications, neuromuscular syndromes rarely progress to the point of hypercapnic respiratory failure unless diaphragmatic weakness or paralysis is present. Thus, quadriplegic patients who have a preserved phrenic nerve and diaphragmatic function (e.g., C7 spinal cord transection) almost never progress to hypercapnic respiratory failure unless a major pulmonary complication supervenes or CNS-depressant drugs are administered. Because diaphragmatic paralysis or paresis uniformly accompanies hypercapnic respiratory failure caused by any of the neuromuscular syndromes, it is not usually considered apart from these disorders. However, because certain forms of diaphragmatic paralysis have distinguishing clinical features, they are best considered as discrete entities.

Bilateral Diaphragmatic Paralysis

Respiratory compromise Bilateral phrenic nerve interruption or injury may result in an isolated partial or complete diaphragmatic paralysis. Causes include cervical and thoracic surgery, cold cardioplegia for cardiac surgery,[21] trauma, multiple sclerosis, and neuralgic amyotrophy.[22] Orthopnea may be a prominent symptom. With the patient supine, the hydrostatic force of the abdominal contents pushes the patient's diaphragm into the thorax. Negative intrapleural pressures generated by the accessory muscles cause the diaphragm to be sucked further into

Table 3 Neuromuscular Syndromes Associated with Respiratory Failure

Site of Lesion	*Disorder*
Spinal cord	Quadriplegia Amyotrophic lateral sclerosis Poliomyelitis Spinal muscular atrophies
Peripheral nerves	Guillain-Barré syndrome Diphtheritic neuropathy
Neuromuscular junctions	Myasthenia gravis Eaton-Lambert syndrome Botulism Drug-induced weakness
Muscles	Muscular dystrophies (e.g., Duchenne dystrophy, myotonic dystrophy)

the thorax during inspiration, producing a paradoxical inward motion of the upper abdomen as the thorax expands [*see Figure 3*]. As a result, mechanical and gas exchange abnormalities similar to those seen in flail chest develop. In the upright position, patients often experience a dramatic increase in vital capacity, improvement in gas exchange, and alleviation of symptoms because the weight of the abdominal contents offsets the negative intrapleural pressures and, therefore, the diaphragm no longer ascends with inspiration. Despite improvements in lung function when in the upright position, patients with bilateral diaphragm paralysis experience a significant reduction in exercise capacity.[23]

Treatment Sleeping in an upright position or nocturnal use of a thoracoabdominal cuirass negative-pressure device can facilitate breathing during sleep. In a limited study, bilateral plication of the diaphragm resulted in improved lung function and allowed patients to sleep in a supine position.[24] The bilateral diaphragmatic pacemaker, although expensive and time consuming to place and stabilize, is an alternative for selected patients.

Unilateral Diaphragmatic Paralysis

Unilateral diaphragmatic paralysis is most often detected as an asymptomatic radiographic finding. The paralyzed hemidiaphragm maintains its normal contour but is displaced cephalad. On fluoroscopy, the paralyzed hemidiaphragm may descend slightly on normal inspiration, mimicking normal contraction. However, with a sudden forceful inspiration (so-called sniff test), the paralyzed portion of the diaphragm ascends further into the thorax, opposite to the direction of the normally functioning side. It is driven cephalad by the sudden increase in intra-abdominal pressure and the sudden fall in intrathoracic pressure occasioned by the sniff. Thus, a fluoroscopic sniff test helps confirm the diagnosis of unilateral diaphragmatic paralysis.

Most cases of unilateral diaphragmatic paralysis are the result of neoplastic invasion of the phrenic nerve. Compression or destruction of the phrenic nerve by surgery, trauma, or enlarging lymph nodes or aneurysmal vessels may also cause the condition. Idiopathic cases, which may stem from an isolated phrenic neuropathy or acute infectious neuritis, appear to be evenly divided between the right and left sides and are usually permanent. Reversible paralysis is a rare complication of acute pneumonia and more commonly follows cardiac surgery in which the phrenic nerve is transiently injured by the ice slurry used to achieve cardioplegia. A thorough history and a CT scan of the thorax usually suffice for the workup of patients with unilateral diaphragmatic paralysis.

Respiratory compromise Vital capacity and total lung capacity are reduced 15% to 20% below normal levels with the patient upright and are reduced significantly more with the patient supine. A modest degree of reduction in exercise capacity is also seen.[23] Nonetheless, in the absence of associated pleuropulmonary disease, most adult patients with unilateral diaphragmatic paralysis but without a coexisting pulmonary disease remain asymptomatic.

Treatment Infants are more dependent than adults on bilateral diaphragm function for adequate respiratory pump function because their more deformable chest wall moves inward with inspiration along with the paralyzed hemidiaphragm. Plication of the diaphragm may be necessary to prevent flail motion in infants with ventilatory failure associated with unilateral diaphragm paralysis. Plication may also improve the lung function of symptomatic adults with unilateral diaphragmatic paralysis.[25]

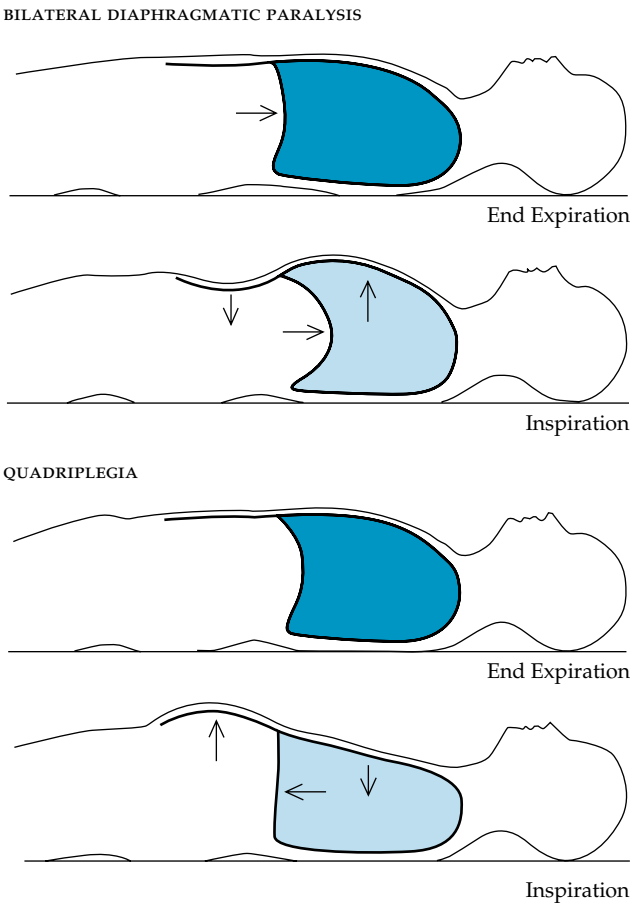

Figure 3 **In a supine patient with bilateral diaphragmatic paralysis (top), at end expiration the weight of the abdominal contents forces the paralyzed diaphragm cephalad. With inspiration, only the accessory muscles contract, elevating the anterior chest wall, creating a negative intrathoracic pressure, and forcing the diaphragm further cephalad. The result is a paradoxical inward motion of the abdominal wall with inspiration. The diaphragm of a supine patient with quadriplegia caused by a spinal cord injury at or below the level of C4 (bottom) contracts and descends normally on inspiration, causing the anterior abdominal wall to protrude. However, because the paralyzed intercostal muscles fail to stabilize the rib cage, the anterior chest wall is pulled paradoxically inward during inspiration by the negative intrathoracic pressure generated by the diaphragm.**

Postoperative Diaphragmatic Dysfunction

A transient form of diaphragmatic dysfunction occurs after upper abdominal surgery. In the hours after surgery, lung volumes and maximal inspiratory pressures fall and A-aD_{O_2} increases. At the same time, tidal volume decreases and respiratory frequency increases. These changes may be caused by irritation of the diaphragm that produces reflex inhibition of phrenic nerve function. As a result of postoperative diaphragmatic dysfunction, atelectasis and hypoxemia occur. Deep breathing that focuses on inspiratory effort, possibly facilitated by incentive spirometry or by direct encouragement, may alleviate these abnormalities.

SPINAL CORD SYNDROMES

Functional Transection

Functional transection, most often caused by trauma from motor vehicle or diving accidents, must be at or below the level of the C4 cervical nerve segment if the patient is to survive. If transection occurs above this level, the diaphragm ceases to function and breathing stops. For the quadriplegic patient, breathing is maintained solely or predominantly by the diaphragm.

Respiratory compromise The degree of compromise of lung function is directly related to the level of injury.[26] Patients with mid- to low-cervical injury are completely dependent on diaphragmatic function, producing problems with several aspects of breathing. Because the diaphragm is active only during inspiration, cough—which requires activity by expiratory muscles, including those of the abdominal wall—is almost totally absent. Intercostal muscles are required to stabilize the upper rib cage against inward collapse when negative intrathoracic pressures are produced by descent of the diaphragm. Thus, with diaphragmatic breathing alone, there is a paradoxical inward motion of the upper thorax during inspiration [*see Figure 3*]. The result is a diminished tidal volume for any level of diaphragmatic activation. Any sparing of the lower cervical segments allows some activity by accessory muscles and diminishes paradoxical motion. Paradoxical motion also diminishes as the condition becomes chronic because of stiffening of the thorax. In patients with injuries of the thoracic spine, inspiratory function is preserved, but expiratory function proves difficult because of abdominal muscle weakness.

Treatment When the quadriplegic patient is upright, the weight of the abdominal contents pulls on the diaphragm, and because abdominal muscle tone has been lost and cannot provide restraining action, diaphragmatic shortening ensues. Thus, the diaphragm is less effective with the patient in this position, and platypnea may result. Abdominal binders serve to replace lost abdominal muscle tone and should be used whenever tidal volume falls with the patient upright. An inflatable anterior air bladder in the binder may be used to assist ventilation in patients with marginal respiratory function. External abdominal compression may be used to help these patients cough. Quadriplegic patients have a mild degree of bronchial hyperresponsiveness caused by parasympathetic tone from the uninjured vagus nerve that is unopposed by sympathetic tone from the spinal cord.[27] Use of an anticholinergic bronchodilating agent or a $beta_2$-adrenergic agonist will reverse this abnormality.[28] Inspiratory muscle training with a resistive device can improve lung function and reduce dyspnea in these patients.[29]

Respiratory failure almost never occurs in quadriplegic patients in the absence of a complication such as pneumonia, atelectasis, septicemia, or pulmonary thromboemboli; therefore, mechanical ventilation is required only during such complications.

Anterior Horn Cell Disease

Amyotrophic lateral sclerosis Anterior horn cell disease is most commonly seen in patients with amyotrophic lateral sclerosis[30] [*see 11:IV Cerebrovascular Disorders*]. Although the disease causes weakness of the muscles of breathing and an associated restrictive abnormality in most patients, only a minority of patients have respiratory symptoms at presentation. Respiratory failure may not be seen until an episode of bronchitis or aspiration pneumonia produces an acute event.

Supportive measures administered during the acute event often return the patient to a stable condition. In most patients, however, respiratory failure caused by diaphragmatic involvement proves fatal within 3 to 4 years of the onset of symptoms.

Poliomyelitis Sporadic cases of poliomyelitis still occur in the United States. When anterior horn cells involving innervation of the diaphragm are affected, the patient may require ventilatory support, either continuously or during acute pulmonary events.

Spinal muscular atrophy Spinal muscular atrophy represents a heterogeneous collection of heredofamilial disorders that primarily involve spinal motor neurons. Patients with the slowly progressive infantile form, Werdnig-Hoffmann disease, may survive until late childhood. With the onset of a rapid growth phase during puberty, kyphoscoliosis develops and complicates the muscle weakness associated with these disorders.

DISORDERS OF THE PERIPHERAL NERVES

Guillain-Barré Syndrome

Respiratory insufficiency that requires artificial ventilation develops in 20% to 25% of patients with Guillain-Barré syndrome[25] [*see 11:II Diseases of the Peripheral Nervous System*]. Duration of ventilatory support averages 2 months, but periods of up to 30 months have been reported.[31,32] Approximately 30% of patients, however, can be extubated within 2 weeks. Mortality is less than 5%; the majority of survivors recover completely. A small minority may have persistent weakness and may be susceptible to recurring episodes of respiratory failure in association with respiratory infections. The chronic form of demyelinating polyneuropathy may account for some of these persistent abnormalities [*see 11:II Diseases of the Peripheral Nervous System*].

Toxin-Induced Neural Dysfunction

Peripheral nerve function may also be impaired by toxins from algae or plankton. Certain fish (grouper and snapper) or shellfish consume and concentrate toxins that may in turn be consumed by humans. Although many of the shellfish-related toxins have been associated with respiratory failure, mortality has been highest in connection with the ingestion of puffer fish, a delicacy in Japan.

Diphtheria

Cardiac and neural toxicity occurs in approximately 20% of cases of diphtheria [*see 7:IV Infections Due to Gram-Positive Bacilli*]. Clinical features and management of the neurologic syndrome are similar to those of Guillain-Barré syndrome.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

Myasthenia Gravis

Myasthenia gravis is the most common disorder affecting neuromuscular transmission. Respiratory failure may occur during myasthenic crisis (acute episode of the basic disease process) or cholinergic crisis (increased weakness caused by an excess of anticholinergic medication), or it may occasionally follow initiation of glucocorticoid therapy. In patients with long-standing myasthenia, myopathy with severe diaphragmatic paresis may

develop and lead to chronic respiratory failure. The principles of respiratory monitoring and ventilatory support for myasthenia are similar to those for the other neuromuscular syndromes.[33]

Myasthenic Syndrome

The myasthenic (Eaton-Lambert) syndrome may be confused with myasthenia gravis. As with other paraneoplastic syndromes, there may be coexistent cerebellar ataxia or carcinomatous neuropathy. The prognosis is not good, and respiratory failure may occur as a terminal event.

Drug-related Muscle Paralysis

Paralysis lasting several hours can occur after a single dose of succinylcholine in patients with reduced functional pseudocholinesterase, as seen in those with severe liver disease, myxedema, or malnutrition; pregnant patients; and patients with a genetic deficiency. A syndrome of prolonged muscle paralysis or weakness can develop after the extended administration of postsynaptic paralytic agents to facilitate mechanical ventilation, especially in patients with renal failure.[34]

A number of other commonly used drugs can interfere with neuromuscular transmission. The mechanism can involve anesthetic-like action at the presynaptic level (e.g., with clindamycin or propranolol), postsynaptic curarelike action (e.g., with lincomycin, polymyxin B sulfate, chloroquine, or procainamide), or stabilization of postsynaptic membranes (e.g., with gentamicin, streptomycin, or neomycin).[35] Delayed recovery from anesthesia and difficulty in withdrawing a patient from ventilatory support should suggest a possible drug effect. Patients affected by these drugs often have mild or latent myasthenia; occasionally, concurrent electrolyte disturbances, such as hypokalemia, hypocalcemia, or hypomagnesemia, combine with drug effects to produce contributory muscle weakness in myasthenic patients. In severe cases, especially those involving antibiotic-induced postoperative muscle weakness, respiratory failure can ensue; ventilatory support, correction of associated electrolyte disturbances, and withdrawal of the drug usually lead to recovery.

Botulism is an uncommon condition caused by ingestion of a polypeptide toxin produced by *Clostridium botulinum* [*see 7:V Anaerobic Infections*]. In addition to specific therapy, careful monitoring and provision of ventilatory support in the event of respiratory failure are required.

DISORDERS OF THE MUSCLES

A number of muscle disorders can produce respiratory abnormalities. Patients with mitochondrial myopathy can present with unexplained dyspnea.[36] A specific abnormality of the diaphragm thought to be myopathic can occur in patients with systemic lupus erythematosus, producing the so-called shrinking-lungs syndrome.[37] Patients with pseudohypertrophic (Duchenne) dystrophy, myotonic dystrophy, and other forms of muscular dystrophy have a more severe disorder and are predisposed to pulmonary complications, and respiratory failure is a frequent cause of death.[38,39] Chronic alveolar hypoventilation caused by inspiratory muscle weakness may develop late in the course of a disease. Expiratory muscle weakness impairs cough in some patients, and accompanying weakness of the muscles of deglutition often leads to aspiration of food, which may precipitate acute deterioration. Chronic alveolar hypoventilation may also develop in patients with adequate muscle strength, which suggests that their disease may involve a defect in central control mechanisms. As with all neuromuscular syndromes, CNS-depressant drugs should be avoided whenever possible or given in minimal doses when necessary. Inspiratory muscle training may delay the onset of chronic respiratory failure.[40] Nocturnal ventilation with noninvasive techniques, such as nasal intermittent positive pressure ventilation or external negative pressure ventilation, may be useful in the later stages of these diseases.[41]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VIII RESPIRATORY FAILURE

MARIN KOLLEF, M.D.

The major physiologic function of the lungs is gas exchange between the pulmonary capillaries and the alveolar space. Oxygen is taken up from the alveolar space onto hemoglobin in red blood cells for transport to peripheral tissues; carbon dioxide is eliminated after it is carried to the lungs via the venous circulation. Acute respiratory failure is the inability of the respiratory system to provide adequate gas exchange. This can take the form of inadequate oxygenation of the arterial blood, insufficient removal of carbon dioxide from venous blood, or both. Acute respiratory failure can be caused by lesions affecting several parts of the respiratory system, including the airways, lung parenchyma, chest wall and respiratory muscles, and neuromuscular processes involved in breathing [*see Table 1*].

Definitions and Pathogenesis

ACUTE HYPOXEMIC RESPIRATORY FAILURE

Definition

Acute hypoxemic respiratory failure is defined as a decrease in the delivery of oxygen from the atmosphere to the blood and, more specifically, as an arterial oxygen tension (P_aO_2) of less than 60 mm Hg. Although somewhat subjective, this value was selected on the basis of the beginning of the descent of the oxygen-hemoglobin dissociation curve at a P_O_2 of 60 mm Hg.

Pathogenesis

The causes of acute hypoxemic respiratory failure are a low inspired concentration of oxygen, impairment of oxygen diffusion, alveolar hypoventilation, ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch, intrapulmonary shunting, and a low mixed venous oxygen content.

Low inspired concentration of oxygen is an uncommon cause of acute hypoxemic respiratory failure. This can occur at high altitudes or when toxic gases are inhaled (e.g., smoke inhalation). In patients with other cardiopulmonary disease processes, an inappropriately low fraction of inspired oxygen (F_IO_2) can contribute to hypoxic respiratory failure. Acute hypoxemic respiratory failure resulting from diffusion impairment is also relatively uncommon. This usually occurs in the setting of acute or chronic interstitial lung disease. Patients with acute respiratory distress syndrome (ARDS) can also have diffusion impairments contributing to hypoxemia, but shunting is the more important physiologic derangement in this disorder (see below). Both low inspired concentrations of oxygen and diffusion impairments usually respond to supplemental oxygen therapy.

Pure alveolar hypoventilation is a relatively rare form of acute hypoxemic respiratory failure that is caused by neuromuscular or central nervous system dysfunction (e.g., opiate overdose). The lung parenchyma is essentially normal. This condition is characterized by an acute reduction in effective alveolar ventilation and a subsequent decrease in the amount of CO_2 that is eliminated by the lungs. Therefore, the arterial carbon dioxide tension (P_aCO_2) and the P_aO_2 are always increased in patients with pure alveolar hypoventilation. Hypoxemia occurs as a result of the displacement of oxygen in the alveolar space resulting from the failure to eliminate CO_2. Calculation of the alveolar-arterial oxygen gradient or difference [A-aD_O_2] is helpful in determining whether acute hypoxemic respiratory failure is from pure alveolar hypoventilation. With pure alveolar hypoventilation, the A-aD_O_2 is in the normal range of 5 to 25 mm Hg when the patient is breathing room air. However, when acute hypoxemic respiratory failure is caused by $\dot{V}/\dot{Q}$ mismatching or an intrapulmonary shunt, the A-aD_O_2 is always increased.

$\dot{V}/\dot{Q}$ mismatching is the most common pathophysiologic cause of acute hypoxemia. It develops when there is a decrease in ventilation to normally perfused regions of the lung, a decrease in perfusion to normally ventilated regions of the lung, or some combination of a decrease in both ventilation and perfusion. Regions of the lung with low $\dot{V}/\dot{Q}$ ratios caused by inadequate ventilation primarily result in arterial hypoxemia. By contrast, regions of the lung with high $\dot{V}/\dot{Q}$ ratios caused by inadequate perfusion result in wasted ventilation, or dead-space ventilation, and are typically associated with hypercapnia when severe. The degree of hypoxemia in patients with pure $\dot{V}/\dot{Q}$ mismatching improves in response to an increase in the F_IO_2. This correction occurs because airways to poorly ventilated alveoli remain patent, and the increased inspired oxygen will eventually reach pulmonary capillary blood. Another clinical use for the calculation of the A-aD_O_2 is to identify $\dot{V}/\dot{Q}$ mismatching, when the measured P_aO_2 is normalized by hyperventilation. For example, a P_aO_2 of 90 mm Hg and a P_aCO_2 of 20 mm Hg when breathing room air would represent significant $\dot{V}/\dot{Q}$ mismatching, as evidenced by the calculated A-aD_O_2 of 35 mm Hg.

Physiologic shunting occurs when venous blood bypasses ventilated alveoli and enters the arterial system. In the normal lung, a 2% to 3% shunt normally occurs because of the bronchial artery circulation and drainage of some coronary venous blood directly into the left ventricle via the thebesian veins. In patients with severe pneumonia, atelectasis, or pulmonary edema, intrapulmonary shunting occurs when pulmonary capillary blood passes next to alveoli that are completely collapsed or filled with edema fluid or inflammatory cells. Shunting can be differentiated from $\dot{V}/\dot{Q}$ mismatching on the basis of the differences in the response to inhalation of 100% oxygen. P_aO_2 levels in patients with shunting who receive 100% oxygen will not improve to normal. In fact, the change in the P_aO_2 level that occurs in response to F_IO_2 values allows the shunt to be estimated as a percentage of cardiac output, assuming normal values for the difference in oxygen content between arterial and mixed venous blood and P_aCO_2 [*see Figure 1*]. With a shunt of 30% or greater, the P_aO_2 rises little, if at all, with increasing F_IO_2. By contrast, the rise in P_aO_2 with oxygen therapy is appreciable even with a severe $\dot{V}_A/\dot{Q}$ mismatch.

Low mixed venous oxygenation can also contribute to hypoxemia. However, it is uncommon for this to be the only factor contributing to acute hypoxemic respiratory failure. Normally, the lungs fully oxygenate pulmonary arterial blood, and mixed venous oxygen tension (P–vO_2) does not affect P_aO_2 significantly. However, a decreased P–vO_2 can lower the P_aO_2 significantly when either intrapulmonary shunting or $\dot{V}/\dot{Q}$ mismatch is present. Factors that can contribute to low mixed venous oxygenation include anemia, hypoxemia, inadequate cardiac output

Table 1 Causes of Acute Respiratory Failure

Acute Hypoxemic Respiratory Failure	*Acute Hypercapnic Respiratory Failure*	*Mixed Respiratory Failure*
Lung parenchymal disease process	Lung parenchymal disease process	Includes many disorders that can be associated with both hypoxemia and hypercapnia
Pneumonia	Emphysema	
Aspiration	Interstitial lung disease (usually end stage)	
Acute lung injury/acute respiratory distress syndrome	Airway disease process (upper and lower airways)	
Asthma	Asthma	
Emphysema/chronic bronchitis	Obstructive sleep apnea	
Smoke inhalation	Vocal cord dysfunction	
Interstitial lung disease	Airway obstruction	
Atelectasis	Chest wall/pleural space disease process	
Radiation injury	Obesity hypoventilation syndrome	
Cardiogenic pulmonary edema	Kyphoscoliosis	
Pulmonary vascular disease process	Pleural effusion	
Pulmonary embolism	Pleural fibrosis	
Fat embolism	Traumatic flail chest	
Air embolism	Pneumothorax	
Airway disease process	Neuromuscular disease process	
Airway obstruction	Brain	
Asthma	Narcotic overdose	
Airway edema (heat injury, allergic reaction)	Cerebrovascular accident	
	Encephalitis/meningitis	
	Spinal cord	
	Amyotrophic lateral sclerosis	
	Poliomyelitis	
	Tetanus	
	Peripheral nerve	
	Phrenic nerve injury	
	Botulism	
	Guillain-Barré syndrome	
	Muscle	
	Electrolyte disorders (hypophosphatemia)	
	Muscular dystrophies	
	Diaphragmatic atrophy (severe emphysema)	

(CO) as occurs in cardiogenic shock, and increased oxygen consumption. Improving oxygen delivery to tissues by increasing hemoglobin or CO usually decreases oxygen extraction and improves P–vO_2 and, subsequently, P_aO_2.

ACUTE HYPERCAPNIC RESPIRATORY FAILURE

Definition

Acute hypercapnic respiratory failure is defined as a P_aCO_2 greater than 45 to 50 mm Hg along with respiratory acidosis. Chronic failure is also marked by elevated P_aCO_2 levels, but in patients with chronic respiratory failure, renal compensation tends to normalize the pH. The distinction of acute from chronic hypercapnic respiratory failure is important, because the two have clearly different prognostic significance and therapeutic implications.

Pathogenesis

Three processes, alone or in combination, can produce acute hypercapnic respiratory failure: a reduction in minute ventilation, an increase in wasted ventilation, and an increase in CO_2 production.

Reduced minute ventilation can occur as a consequence of central nervous system disorders (e.g., brain injury or spinal cord lesions), peripheral nerve diseases (e.g., Guillain-Barré syndrome, botulism, myasthenia gravis or amyotrophic lateral sclerosis), muscle disorders (e.g., polymyositis or muscular dystrophy), chest wall abnormalities (e.g., thoracoplasty or scoliosis), drug overdoses, metabolic abnormalities (e.g., myxedema, hypokalemia), and upper airway obstruction. These disorders normally are associated with a normal A-aDO_2 unless lung disease is also present.

Wasted ventilation is defined as the ratio of the dead space volume (V_D) to the tidal volume (V_T). An increase in wasted ventilation (i.e., an increased V_D/V_T ratio) is caused by overventilation of regions of the lung relative to their perfusion. This may occur in intrinsic lung diseases (e.g., emphysema, asthma, cystic fibrosis or pulmonary fibrosis) and in chest wall disorders associated with parenchymal abnormalities (e.g., scoliosis). Usually, these disorders are also associated with widened A-aDO_2 gradients.

Increased CO_2 production ($\dot{V}CO_2$) in hospitalized patients is usually a result of infection, trauma, burns, or other major stresses that lead to hypermetabolism. Agitation, myoclonus, or other causes of muscle activity can increase $\dot{V}CO_2$ and contribute to the development of hypercapnic respiratory failure. During refeeding, lipogenesis from the oxidation of carbohydrates can increase the metabolic respiratory quotient significantly. The respiratory quotient (i.e., the ratio of the volume of carbon dioxide released to the volume of oxygen consumed), which is normally 0.8, may rise as high as 2.0 in such cases; this basically doubles $\dot{V}CO_2$. In patients who have severe lung disease or are on fixed mechanical ventilation, acute hypercapnia may occur.

Diagnosis

Acute Hypoxemic Respiratory Failure

When the P_aO_2 rapidly falls below 40 to 50 mm Hg, harmful effects may be observed in various organ systems. Patients may experience headache, somnolence, confusion, and seizures. With more severe hypoxemia, permanent encephalopathy may occur. Cardiovascular sequelae from mild hypoxemia, including tachycardia and hypertension, may also develop. With severe hypoxemia, opposite effects may occur, such as bradycardia and hypotension. Patients who have disorders associated with hypoxia (i.e., decreased delivery of oxygen to the peripheral tissues) without concurrent hypoxemia can present with similar clinical signs and symptoms. Causes of hypoxia without hypoxemia include anemia, decreased cardiac output, and carbon monoxide or cyanide poisoning.

Acute Hypercapnic Respiratory Failure

Signs and symptoms of hypercapnia depend not only on the absolute level of P_aCO_2 but also on the rate at which the level increases. A P_aCO_2 above 100 mm Hg may be well tolerated if the hypercapnia develops slowly and acidemia is minimized by renal compensatory changes. However, acute increases in P_aCO_2 levels are associated with several neurologic sequelae, including increased cerebral blood flow and elevation in intracranial pressure.

Acute elevation in P_aCO_2 to 80 to 90 mm Hg may produce many neurologic signs and symptoms, including confusion, headaches, seizures, and coma. A careful neurologic examination of a patient with acute hypercapnia may reveal agitation, coarse tremor, slurred speech, asterixis, and occasionally papilledema. These effects of hypercapnia on the central nervous system are fully reversible, as opposed to the potentially permanent neurologic sequelae that are associated with acute hypoxemia. An elevated P_aCO_2 is also associated with myocardial depression, arrhythmias, hyperkalemia, and gastrointestinal bleeding.

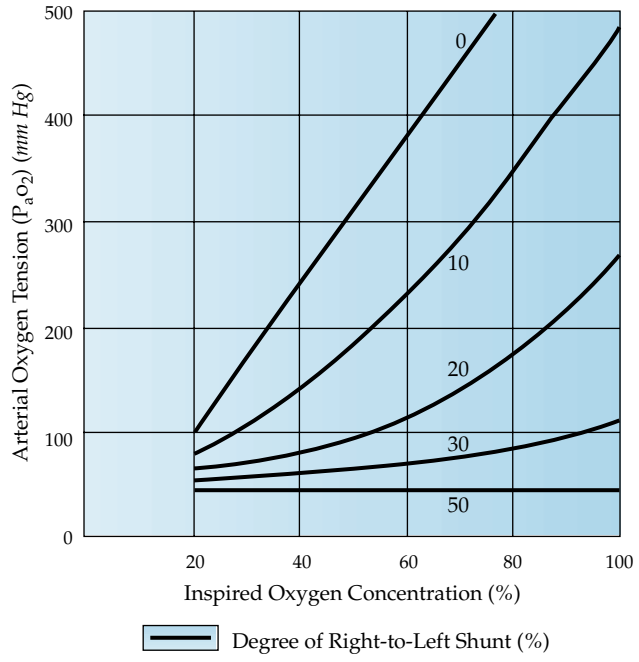

Figure 1 **The oxygen concentration of inspired gas is plotted against arterial oxygen tension (P_aO_2) for right-to-left shunts ranging from 0% to 50% of cardiac output. The arteriovenous oxygen content difference is assumed to be normal. Note that with right-to-left shunts in excess of 30%, there is virtually no increase in P_aO_2 with oxygen enrichment.**

Table 2 Radiographic Appearance of Disorders That Cause Acute Respiratory Failure

Diffuse or Patchy Infiltrates Present	*Relatively Clear Lungs*
Acute respiratory distress syndrome	Acute hypoxemic respiratory failure
Pneumonia	Pulmonary embolism
Cardiogenic pulmonary edema	Air embolism
Atelectasis	Fat embolism
Aspiration	Acute hypercapnic respiratory failure
Interstitial lung disease	Asthma
Pulmonary contusion	Exacerbation of COPD
Alveolar hemorrhage syndrome	Narcotic overdose
Metastatic or lymphatic spread of tumor	Neuromuscular disease
	Obesity-hypoventilation syndrome

COPD—chronic obstructive pulmonary disease

Differential Diagnosis

The many disorders that cause acute respiratory failure can be classified into two categories on the basis of the presence or absence of infiltrates on chest radiographs [*see Table 2*].[1] Most patients with acute respiratory failure have patchy or diffuse infiltrates and primarily develop hypoxemic respiratory failure. In patients whose chest radiographs show infiltrates, the most common causes of acute hypoxemic respiratory failure are pneumonia, cardiogenic pulmonary edema, noncardiogenic pulmonary edema (ARDS), atelectasis, aspiration, progressive interstitial lung disease, pulmonary contusion, and alveolar hemorrhage syndromes (e.g., Goodpasture syndrome, Wegener granulomatosis, and systemic lupus erythematosus).

Acute respiratory failure in a patient with a relatively clear chest radiograph can be either hypoxemic or hypercapnic. Acute hypoxemic respiratory failure in such patients is most often the result of pulmonary embolism or some other form of pulmonary vascular disease. Acute hypercapnic respiratory failure has five principal causes: (1) acute exacerbation of chronic obstructive pulmonary disease (COPD) or asthma, (2) neuromuscular dysfunction, (3) obesity-hypoventilation syndrome, (4) obstructive sleep apnea, and (5) drug overdose associated with a depressed respiratory drive.

Management

The three major steps in the management of acute respiratory failure are to (1) ensure an open airway, (2) restore oxygenation, and (3) maintain or restore ventilation to eliminate CO_2.

ENSURING AIRWAY PATENCY

Airway obstruction may develop in patients with depressed consciousness, dysfunction of the upper airway muscles caused by neuromuscular disease, or an inability to cough and clear secretions. Simple measures such as pushing the mandible for-

Table 3 Procedure for Direct Orotracheal Intubation

1. Administer oxygen by face mask. Ensure arterial oxygen saturation > 95% before attempting intubation, if possible.
2. Gather basic equipment: oxygen source, bag-valve device, suctioning device, endotracheal (ET) tube, blunt stylet, laryngoscope, 20 ml syringe. Have all equipment easily accessible.
3. Place patient on nonmobile rigid surface.
4. If patient is in hospital bed, remove backboard and adjust bed height.
5. Depress patient's tongue with tongue depressor and administer topical anesthesia to patient's pharynx.
6. Position patient's head in sniffing position by placing a small towel under the occiput and extending the head and neck.
7. Administer intravenous sedation and neuromuscular blocker if necessary.*
8. Have assistant apply Sellick maneuver (compressing cricothyroid cartilage against vertebral bodies) to occlude esophagus and prevent regurgitation and aspiration of stomach contents.
9. Grasp laryngoscope handle in left hand while opening patient's mouth with gloved right hand.
10. Insert laryngoscope blade on right side of patient's mouth and advance to base of tongue, displacing tongue to the left.
11. Lift laryngoscope away from patient at a 45° angle using arm and shoulder strength. Do not use patient's teeth as a fulcrum.
12. Suction oropharynx and hypopharynx if necessary.
13. Grasp ET tube with inserted stylet in right hand and insert it into right corner of patient's mouth, avoiding obscuration of epiglottis and vocal cords.
14. Advance ET tube through vocal cords until cuff is no longer visible, then remove stylet.
15. Inflate cuff with enough air to prevent significant air leakage.
16. Verify correct ET tube positioning by auscultation of both lungs and the abdomen.
17. Obtain a chest radiograph to verify correct position of the ET tube.

*Neuromuscular blockade can result in complete airway collapse and airway obstruction; personnel who are skilled in establishment of an emergency surgical airway should be available if paralysis is used.

ward, laying the patient in a lateral decubitus position, or placing a nasal trumpet or oral airway may alleviate upper airway obstruction caused by relaxed upper airway muscles. However, endotracheal intubation should be performed when bronchial secretions are excessive or the patient is at high risk for the aspiration of gastric contents. Emergency cricothyrotomy or tracheostomy is required only if there is glottic or infraglottic anatomic obstruction or if endotracheal intubation cannot be performed for other reasons, such as trauma to the oropharynx.

An endotracheal tube may be passed orally or nasally. The oral route is easier and faster and allows the use of a larger-diameter tube. Proper patient positioning and preparation are required to optimize success with endotracheal intubation [*see Table 3*]. The larger tube facilitates suctioning of secretions and fiberoptic bronchoscopy and decreases the risk of sinusitis.[2] Nasotracheal intubation may be preferable in awake and unanesthetized patients and in patients with limited mobility of the cervical vertebrae, such as that caused by ankylosing spondylitis or rheumatoid arthritis.

Complications of endotracheal intubation attempts occur immediately if the tube enters the esophagus. Other early complications of endotracheal intubation include cervical spine injury in patients with trauma or arthritis and injury to the teeth, nose, pharynx, larynx, and tracheobronchial tree. In addition, both prolonged tracheal intubation and tracheostomy can lead to the serious sequelae of tracheal stenosis or tracheomalacia, which can result from ischemic injury of the trachea by the inflatable cuff of the tube. Such difficulties have been reduced since the advent of high-volume and low-pressure cuffs and can be further reduced by not overinflating the cuff. Tracheostomies and endotracheal tubes are associated with the same long-term complications. Tracheostomy may provide greater comfort and more effective secretion removal and should be considered if mechanical ventilation is needed beyond 2 to 3 weeks.[3]

RESTORING ARTERIAL OXYGENATION

An increase in the F_IO_2 may suffice to restore normal oxygenation. On the basis of the shape of the oxygen-hemoglobin dissociation curve, achieving a P_aO_2 of 60 mm Hg or higher (> 90% oxygen saturation of hemoglobin) is an optimal goal for most acutely hypoxemic patients. In patients with chronic hypoxemia and hypercapnia, a P_aO_2 of 50 to 55 mm Hg may be needed to prevent respiratory depression and worsening hypercapnia.

Supplemental oxygen can be administered by a number of techniques to the spontaneously breathing patient. Nasal cannulas allow patients to eat, drink, and speak during oxygen administration. Their disadvantage is that the exact F_IO_2 delivered is not known, because it is influenced by the patient's peak inspiratory flow demand. As an approximation, the following guide can be used: 1 L/min of nasal-prong oxygen flow is approximately equivalent to an F_IO_2 of 24%, with each additional 1 L of flow increasing the F_IO_2 by approximately 4%. Flow rates should be limited to less than 5 L/min. Venturi masks allow more precise administration of oxygen to be delivered, with calibrated mask F_IO_2 values between 24% and 50%. Often, Venturi masks are useful in patients with COPD and hypercapnia because one can titrate the P_aO_2 to minimize carbon dioxide retention. Nonrebreathing masks achieve higher oxygen concentrations (approximately 80% to 90%) than partial rebreathing systems. A one-way valve prevents exhaled gases from entering the reservoir bag in a nonrebreathing system, thereby maximizing the F_IO_2.

A continuous positive airway pressure (CPAP) mask can be used if the P_aO_2 is less than 60 to 65 mm Hg during use of a nonrebreathing mask and the patient is conscious and cooperative, able to protect the lower airway, and hemodynamically stable. CPAP is delivered by a tight-fitting mask equipped with pressure-limiting valves. Many patients cannot tolerate a CPAP mask because of persistent hypoxemia, hemodynamic instability, or feelings of claustrophobia or aerophagia. In such patients, endotracheal intubation should be performed. Initially, 3 to 5 cm H_2O of CPAP should be applied while monitoring the P_aO_2 or arterial oxygen saturation (S_aO_2). If the P_aO_2 is still less than 60 mm Hg (S_aO_2 < 90%), the level of CPAP should be increased in increments of 3 to 5 cm H_2O up to a level of 10 to 15 cm H_2O. CPAP may improve oxygenation by opening previously closed alveoli and decreasing intrapulmonary shunting. Although the use of CPAP may prevent the need for intubation and mechanical ventilation, it may result in such complications as gastric distention, drying of the eyes from air leaks, and skin breakdown, especially on the bridge of the nose.[4] Bilevel positive airway pressure (BiPAP) is a method of noninvasive ventilation in which inspiratory and expiratory pressure can be applied through a mask during the patient's respiratory cycle. The in-

spiratory support decreases the patient's work of breathing. The expiratory support (CPAP) improves gas exchange by preventing alveolar collapse. Noninvasive ventilation using face or nasal masks may obviate endotracheal intubation and mechanical ventilation in patients with neuromuscular disease, COPD, and postoperative respiratory insufficiency.

In using BiPAP, a pressure-support ventilation (PSV) level of 5 to 10 cm H_2O and a CPAP level of 3 to 5 cm H_2O are reasonable starting points. The PSV level can be increased in increments of 3 to 5 cm H_2O, using the patient's respiratory rate as a guide of effectiveness.

MECHANICAL VENTILATORY SUPPORT

When adequate oxygenation cannot be maintained by noninvasive means or if progressive hypoventilation and hypercapnia with respiratory acidosis occurs, endotracheal intubation and mechanical ventilatory support should be initiated. Mechanical ventilation can produce positive pressure at the airway opening or create negative pressure around the chest wall. Use of negative pressure ventilators (e.g., an iron lung) is generally restricted to patients with chronic neuromuscular weakness or chest wall deformity.

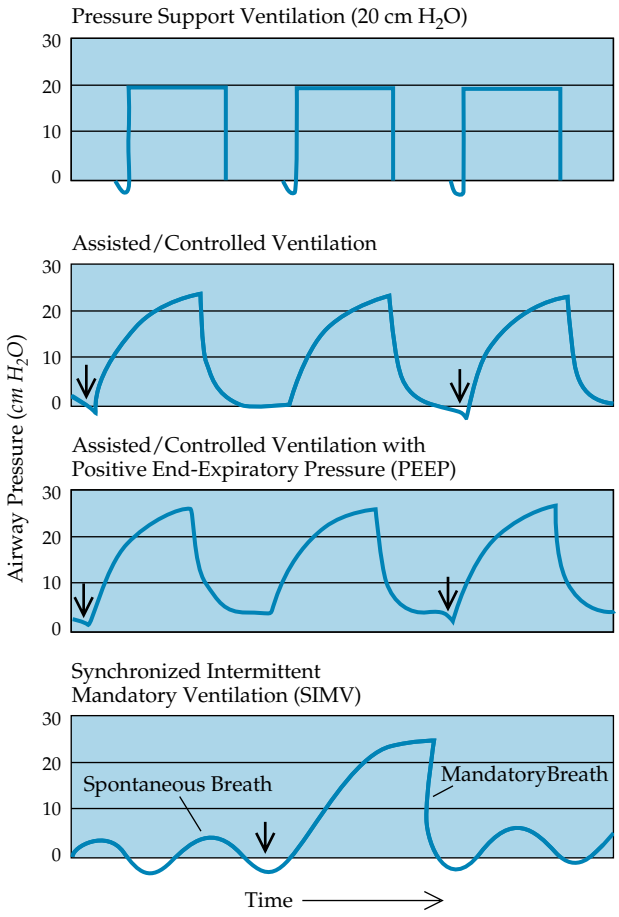

Figure 2 **Pressures measured at the endotracheal tube are shown as a function of time to illustrate the effects of various modes of pressure-preset (top panel) or constant tidal volume (bottom three panels) mechanical ventilation. Supra-atmospheric pressures have positive values, whereas subatmospheric pressures have negative values. Arrows indicate initiation of inspiration by the patient, triggering the ventilator to deliver an assisted breath.**

Volume-Cycled and Pressure-Cycled Ventilation

There are two basic types of positive pressure ventilation: volume cycled and pressure cycled.[5,6] Volume-cycled ventilation, the more commonly used mode in adults, supplies a fixed tidal volume, making inflation pressure the dependent variable. When a volume-cycled ventilator is used, changes occurring in pulmonary impedance are associated with alterations in the airway pressures during inflation. A pressure limit can be set using a pop-off valve that prevents further inflation, avoiding excessive overdistention, and functions as an alarm.

Pressure-cycled ventilation provides gas flow until a preset pressure is reached, so that the tidal volume becomes the dependent variable. With this mode, changes in pulmonary impedance are associated with alterations in tidal volume and therefore minute ventilation.

With volume-cycled ventilation, two primary modes are used: assisted/controlled (A/C) ventilation and synchronized intermittent mandatory ventilation (SIMV) [*see Figure 2*]. In the A/C mode, the ventilator guarantees a preset number of breaths (backup rate) supplied at a preset tidal volume. If the patient desires to breathe at a respiratory rate higher than the preset rate, the ventilator will deliver the entire preset tidal volume every time the patient generates a small negative airway pressure (–1 to –2 cm H_2O). In the SIMV mode, the ventilator also guarantees a preset number of breaths (backup rate) supplied at a preset tidal volume. However, the tidal volume for any additional breath above the preset rate is determined by the effort of the patient. Therefore, the SIMV mode combines a preset number of ventilator-delivered mandatory breaths with the ability to assist intermittent patient-generated spontaneous breaths. Most patients can be effectively ventilated with either A/C or SIMV, and both modes can be used with pressure-controlled ventilators. The A/C mode has certain advantages over SIMV in that the former usually requires less respiratory effort, reduces oxygen consumption, and is more likely to rest respiratory muscles. However, the respiratory muscles may continue to perform considerable work during A/C breathing, especially when respiratory drive and minute ventilation are increased. Potential advantages of SIMV include the exercising of respiratory muscles, the prevention of respiratory alkalemia, and, possibly, improved patient-ventilator coordination. However, a change from A/C ventilation to SIMV does not usually correct respiratory alkalemia caused by an increased respiratory drive.

Pressure-Support Ventilation

PSV is a pressure-targeted, flow-cycled mode that requires the patient to initiate every breath [*see Figure 2*]. During the inspiratory phase, pressures rise rapidly to a preset plateau level. The pressure terminates when the inspiratory airflow created by the patient falls below a certain level. Therefore, the total work of breathing for each breath is usually generated by a combination of patient effort and mechanical support. Intubated patients can be ventilated with pressure support alone, as long as they have an adequate ventilatory drive and are strong enough to initiate a sufficient number of breaths to maintain adequate minute ventilation. When used as the primary mode of ventilation, pressure support can be used with certain amounts of CPAP and generally is well tolerated by patients who are being weaned from mechanical ventilation. The pressure support mode of ventilation can also be used in conjunction with SIMV, in which case the level of pressure support is applied only to patient-generated breaths.

Selecting Appropriate Mechanical Ventilatory Settings

After the patient is intubated, the respiratory rate and tidal volume (in volume-controlled ventilation) should be set to maintain an adequate minute ventilation that will result in an appropriate pH level. The tidal volume should be large enough to prevent microatelectasis and progressive hypoxemia but without causing barotrauma. For most patients, an initial tidal volume between 6 and 10 ml/kg body weight is appropriate [*see* Management of Respiratory Failure in Specific Clinical Settings, Acute Respiratory Distress Syndrome, *below*].

Positive end-expiratory pressure (PEEP) is used to improve oxygenation and reduce the possibility of oxygen toxicity for patients requiring high levels of inspired oxygen. PEEP works by opening or recruiting previously closed alveoli and redistributing lung water from the alveoli to the interstitial spaces. CPAP works in a similar manner for patients who are breathing spontaneously. The benefits of PEEP must be weighed against its deleterious effects, which include decreased cardiac output, increased intracranial pressure, and hyperinflation.

Selecting the appropriate mode, respiratory rate, tidal volume (or pressure, in pressure-controlled ventilation), and amount of PEEP is a dynamic process. No single setting is appropriate for all patients or for a given patient at all stages of acute illness. Optimal ventilatory settings require constant monitoring and numerous readjustments based on acute changes in gas exchange, airway pressures, breathing patterns, and hemodynamics in conjunction with the resolution or progression of the underlying disease process.

During volume-cycled ventilation, peak and plateau airway pressures can be easily seen from most ventilators. Peak airway pressure can be subdivided into three components: (1) flow resistive, (2) elastic distending pressure, and (3) PEEP (either set or intrinsic) [*see Figure 3*]. The plateau pressure is a close approximation of the alveolar pressure and can be subdivided into only two components: (1) elastic distending pressure and (2) PEEP (either set or intrinsic). Because positive pressure is required to overcome the flow-resistive properties of the airway and external apparatus, the peak pressure will always be equal to or greater than the plateau pressure. The plateau pressure is measured by interrupting flow or pausing the ventilator at full inspiration. The static compliance of the respiratory system is computed by dividing the tidal volume delivered to the patient by the change in pressure (plateau pressure minus PEEP). A reduction in the normal static compliance is indicative of a stiffer lung or chest wall.

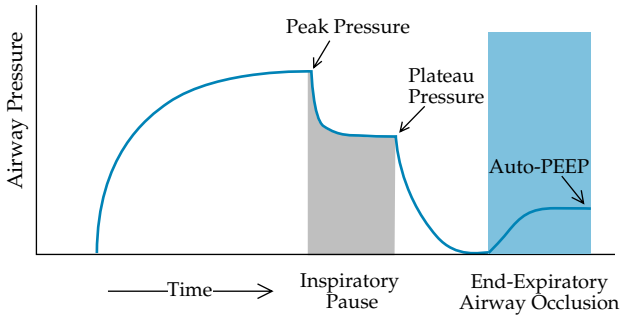

Figure 3 **In volume-cycled pressure ventilation, the total pressure required to overcome flow-resistive and elastic forces and deliver the preset tidal volume is termed peak airway pressure. The plateau pressure is the pressure required to keep the lung and chest wall inflated with the preset tidal volume during a brief period in which there is no flow (inspiratory pause). The difference between the peak and the plateau pressures is a reflection of the flow-resistive component of ventilation and is increased when airway resistance or inspiratory flow rate is increased. The plateau pressure is a function of lung and chest wall compliance and is unaffected by airway resistance and inspiratory flow rate unless auto-PEEP (positive end-expiratory pressure) occurs. Incomplete emptying is associated with auto-PEEP, the magnitude of which can be assessed with end-expiratory airway occlusion.**

During volume-cycled ventilation, changes in airway pressures can be helpful in determining the cause of an acute deterioration in mechanically ventilated patients. A large increase in peak airway pressure (out of proportion to the increase in plateau pressure) signals a change in the flow-resistive properties. This increase is usually observed in patients with airway problems (e.g., kinking of the endotracheal tube, mucous plug, or bronchospasm). Treatment should be directed at improving airway function, including repositioning the endotracheal tube, suctioning the airways, and administering bronchodilator therapy. When an increase is primarily in plateau pressure, the problem is localized to the lung parenchyma or chest wall rather than the airways. This condition can be seen with worsening of pulmonary edema, tension pneumothorax, a large region of atelectasis, or intubation of the right mainstem bronchus.

With both positive and negative pressure ventilators, exhalation is passive and is provided by the elastic recoil of the inflated lungs and chest wall. Exhalation rate depends on the resistance and compliance of the respiratory system. A high resistance is observed in patients who require a prolonged exhalation time, such as those with chronic airway obstruction or asthma. If the subsequent tidal volume is delivered before exhalation is complete, positive airway pressure will be maintained throughout the respiratory cycle, resulting in increases in end-expiratory lung volume and end-expiratory alveolar pressure. PEEP that results from this process of dynamic hyperinflation has been termed auto-PEEP (or intrinsic PEEP). Auto-PEEP increases both peak and plateau pressures and can be measured by briefly occluding the airway at the end of exhalation.[7] When the airflow is interrupted, pressures equilibrate quickly, and the airway-opening pressure rises to the level of the previous alveolar pressure, which is the level of auto-PEEP. The appropriate compliance of the respiratory system can be calculated by dividing the tidal volume by the difference between the plateau pressure and the auto-PEEP.

Management of Respiratory Failure in Specific Clinical Settings

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with severe COPD are often hypoxemic and hypercapnic on a long-term basis and adapt, albeit precariously, to their abnormal state. Acute deterioration is most often triggered by infection, but it may also result from factors such as pneumothorax, congestive heart failure, and increased CO_2 production associated with febrile states. The worsening hypoxemia and hypercapnia that accompany acute deterioration lead to increasing dyspnea, sleep disruption, and, occasionally, alterations in consciousness. Depressed consciousness leads to retention of secretions and further worsening of gas exchange. This cycle can be broken by identifying and rectifying the processes that have precipitated the acute deterioration and by providing

support to improve gas exchange while the underlying disorders are being corrected.

Arterial Blood Gas Analysis

Arterial blood gas analysis is crucial to the proper assessment and management of acute exacerbations. The first priority is to achieve a P_aO_2 level of 50 to 60 mm Hg but no higher. An elevation in P_aCO_2 of 10 to 15 mm Hg is common when oxygen is given to patients with chronic airway obstruction and does not represent a failure of controlled oxygen therapy, provided that there is no critical reduction in blood pH (i.e., ≤ 7.2). Therapy should include promotion of bronchopulmonary drainage by encouragement of cough, administration of inhaled bronchodilators and systemic corticosteroids, and treatment of any underlying infection.[8]

Ventilatory Support

Many patients with severe exacerbations of COPD experience persistent respiratory acidosis and excessive work in breathing even after their initial treatment with bronchodilators. The level for P_aCO_2 at which ventilatory assistance becomes necessary cannot be specified, but ventilatory supports should be considered if hypercapnia is severe enough to cause profound acidemia (pH < 7.2) or if the patient shows signs of altered mental status or respiratory muscle fatigue. Intubation should be performed if hemodynamic instability or somnolence occurs or if secretions cannot be cleared. However, if the hypercapnic patient remains alert and cooperative, delivery of noninvasive positive pressure ventilation through a facial or nasal mask may reverse or prevent fatigue and thereby eliminate the need for conventional mechanical ventilation through an endotracheal tube. In selected patients with severe exacerbations of COPD, noninvasive ventilation decreases the rate of complications, reduces the need for intubation, shortens hospital stay, and may lower mortality.[9,10] Patients who do not tolerate the mask or whose acute exacerbation fails to improve should be intubated. The delay in intubation incurred by an unsuccessful trial of noninvasive ventilation should not pose a significant risk to the patient, provided that personnel skilled in airway management and intubation are readily available and the patient does not have hemodynamic instability or significant underlying cardiac disease. The success rate for noninvasive ventilation is highly dependent on the skill and commitment of the respiratory therapists and nurses who work with the patient.

Noninvasive ventilation The most common method of noninvasive ventilation for patients with airway obstruction is BiPAP. This type of ventilation delivers a specified amount of inspiratory positive airway pressure (IPAP), usually in the form of PSV, that supports each spontaneous breath (usually set at 15 to 20 cm H_2O) in conjunction with a low level of expiratory positive airway pressure (EPAP) (usually set at 3 to 5 cm H_2O). Some patients with acute hypercapnic respiratory failure tolerate a full face mask better than a nose mask because of large leaks that occur with the nose mask. However, securing the mask so tightly that all leaks are prevented may increase discomfort and decrease the ultimate likelihood of success.

Invasive ventilation For exacerbations that require intubation, a reasonable initial ventilator setting is a tidal volume of 8 to 10 ml/kg at 11 to 14 breaths a minute.[11] It is important to remember that P_aCO_2 levels in patients with chronic hypercapnia should not be lowered to the normal range, because this could result in alkalemia, which increases the risk of cardiac dysrhythmias and seizures. In addition, overventilation for more than 2 to 3 days may result in renal restoration of the pH to normal. As a consequence, during subsequent trials of spontaneous ventilation, as the P_aCO_2 rises to the baseline hypercapnic level, the patient becomes acidemic or the patient's respiratory muscles become fatigued because of the greater minute ventilation required for the reset baseline pH and P_aCO_2. To prevent this condition, adjustments in respiratory frequency and tidal volume should be aimed at maintaining the patient's baseline pH and P_aCO_2 or allowing some further degree of tolerated respiratory acidosis.

Dynamic hyperinflation with auto-PEEP occurs frequently during mechanical ventilation of patients with airflow obstruction [*see* Mechanical Ventilatory Support, *above*]. For airflow obstruction, the most critical determinant of the severity of dynamic hyperinflation is the minute ventilation delivered by the mechanical ventilator. Therefore, in addition to the effects on P_aCO_2 and pH levels, excessive ventilation of patients with airflow obstruction increases the risk of pulmonary hyperinflation. The major consequences of excessive auto-PEEP include barotrauma, misinterpretation of central venous and pulmonary arterial wedge pressures, decreased cardiac output secondary to reduced venous return, and increased work in breathing. The effort required to breathe increases because the patient's inspiratory muscles must generate a negative pressure equal to the auto-PEEP before the proximal airway pressure can be lowered to the –1 to –2 cm H_2O required to trigger the ventilator. Auto-PEEP should be suspected in a patient with airflow obstruction when the ventilator does not deliver an assisted breath even though the patient is making obvious inspiratory efforts. Inspiratory effort can be aided by the application of external PEEP at a level equal to or slightly less than the auto-PEEP level. Applying external PEEP causes the ventilator to deliver an assisted breath when the proximal airway pressure is lowered to 1 to 2 cm H_2O below the level of applied PEEP rather than to –1 to –2 cm H_2O. In effect, the application of external PEEP reduces the inspiratory effort required to trigger the ventilator. In patients with chronic airflow obstruction, applied PEEP does not increase lung volume or airway pressures as long as the level of applied PEEP does not exceed the level of auto-PEEP.[12]

ASTHMA

Respiratory failure in children and adults with asthma is usually precipitated by the underlying disease itself, viral or bacterial infection, irritation of the airway from aspiration or inhalation of a toxic gas, or medical noncompliance. Asthmatics usually have a mixed form of respiratory failure with both hypoxemia and hypercapnia.

Ventilatory Support

The goals of ventilatory support in a patient with asthma are to reverse the hypoxemia by administering supplemental oxygen and to reverse the hypercapnia and respiratory acidosis (assuming the patient is not a chronic retainer of CO_2). The approach to ventilatory support is similar to that outlined above for patients with acute exacerbations of COPD. However, patients with asthma may have a greater degree of airway obstruction, which may necessitate additional modes of therapy. The use of inhaled mixtures of helium and oxygen (usually composed of at least 70% helium) can reduce the density of the inspired gases, improving overall ventilation and reducing the pa-

tient's work associated with ventilation. However, in patients requiring increasing supplemental oxygen because of concomitant hypoxemia, the beneficial effects of the helium-oxygen mixture (heliox) may be lost.

ACUTE RESPIRATORY DISTRESS SYNDROME

Hypoxemic respiratory failure in patients with ARDS results in an unacceptably high mortality (30% to 60%). It may occur in previously healthy patients without preexisting lung disease. The pathophysiology, clinical features, and nonventilatory therapies for ARDS are outlined elsewhere[13] [*see 14:X Pulmonary Edema*].

Ventilatory Support

The initiation of mechanical ventilation for ARDS patients clearly has beneficial effects, yet a growing body of evidence indicates that mechanical ventilation can produce pathologic changes in normal lung tissue that are similar to ARDS. Experimentally, large inflation pressures produce capillary leak and, over time, permeability pulmonary edema. Harmful effects of large inflations and subsequent high alveolar pressures have been termed volutrauma.[14] Mechanical ventilation strategies for ARDS patients have been supported by studies that examined computed tomography scans and pressure-volume curves. Although chest radiographs in ARDS patients suggest homogeneous involvement of the lungs, CT scans reveal a markedly heterogeneous pattern.[15] Dependent regions of the lung are consolidated, but more superior regions of the lung appear normal. The inflation portion of the pressure-volume curve of ARDS patients exhibits a lower inflection point, which corresponds to the onset of reopening closed alveoli, and an upper inflection point, which signals the beginning of the overdistention of patent alveoli[16] [*see Figure 4*].

A specific ventilatory strategy that focuses on ventilating patients between the upper and lower inflection points has been proposed for ARDS patients. To limit transpulmonary pressures (plateau pressure of < 30 cm H_2O), low tidal volumes should be used. The subsequent decrease in minute ventilation, which is caused by the use of low tidal volumes and may result in hypercapnia and respiratory acidosis, is termed permissive hypercapnia. This strategy of mechanical ventilation with lower tidal volumes (6 ml/kg) versus traditional ventilation with larger tidal volumes (12 ml/kg) results in decreased mortality and shortens the amount of time that mechanical ventilation is required.[17]

Use of PEEP

PEEP is an effective way to improve oxygenation. However, the optimal amount of PEEP that should be used is controversial. The titration of PEEP to a level above the lower inflection point may decrease the damage to alveoli that would be caused by repetitive reopening and closing of lung units. The application of this level of PEEP, called the open lung approach, was associated with improved mortality when compared with conventional ventilatory strategies.[18] The beneficial effects of PEEP must always be weighed against a possible decrease in cardiac output and increased risk of barotrauma.

Inverse-Ratio Ventilation

One strategy for improving oxygenation without increasing F_IO_2 or PEEP is to prolong inspiratory time by adding an end-inspiratory pause, keeping alveolar pressure briefly at the plateau level.[19] When inspiratory time is prolonged, exceeding expiratory time, the ventilation is termed inverse-ratio ventilation. Inverse-ratio ventilation may improve oxygenation in some ARDS patients; however, prospective studies have found that most patients do not benefit from it.[20] Caution is required in applying inverse-ratio ventilation because barotrauma and hypotension can result from the development of excessive auto-PEEP as expiratory time is shortened.

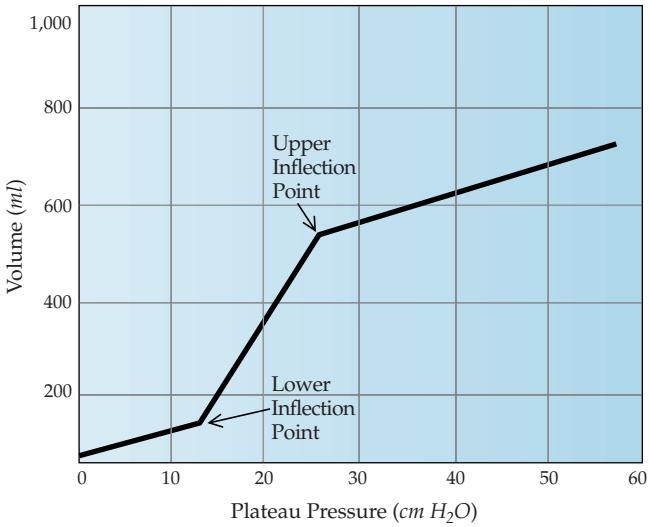

Figure 4 **A static pressure-volume curve can be constructed by plotting the tidal volume versus the elastic recoil pressure of the respiratory system for several different tidal volumes. In patients with acute respiratory distress syndrome, the inflation curve demonstrates a lower inflection point, which corresponds to the onset of reopening closed alveoli, and an upper inflection point, which signals the beginning of the overdistention of patent alveoli.**

Prone Positioning

An effective method for improving oxygenation is to place the patient in the prone position.[21,22] The mechanism by which the prone position improves oxygenation is related to the reduction of shunting and correction of $\dot{V}/\dot{Q}$ mismatching. The recruitment of dorsal atelectatic lung is thought to be produced by a more even distribution of pleural pressure. The transmural distending pressure is greater in the dorsal regions but is not significantly reduced in the dependent ventral region. Studies have found that in 60% to 80% of ARDS patients who are placed in the prone position, the P_aO_2-F_IO_2 ratio improves (from 80 to 200).[22] However, it is not clear whether prone positioning alters mortality for ARDS patients.

Complications of Mechanical Ventilation

PULMONARY COMPLICATIONS

Serious pulmonary complications of intubation and mechanical ventilation can be divided into three categories: (1) infection related to the presence of an endotracheal tube, (2) alveolar overdistention, and (3) atelectasis.

Infection

Mechanically ventilated patients are at high risk (13% to 38%) for nosocomial pneumonia.[23] Early-onset pneumonia, occurring 48 to 72 hours after intubation, is usually the result of aspiration during the intubation process.[24] These infections are most often

caused by antibiotic-sensitive organisms, including oxacillin-sensitive *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. Ventilator-associated pneumonia that occurs more than 72 hours after intubation is frequently caused by antibiotic-resistant pathogens, including *Pseudomonas aeruginosa*, oxacillin-resistant *S. aureus*, *Acinetobacter* species, and *Enterobacter* species. The pathogenesis of ventilator-associated pneumonia usually requires two important steps: (1) bacterial colonization of the aerodigestive tract and (2) aspiration of contaminated secretions into the lower airways. The risk of a ventilator-associated pneumonia appears to be higher in trauma or burn patients, and in all patients, the risk rises as the duration of ventilation increases.[23,25] Diagnosis of ventilator-associated pneumonia may be difficult because many other processes may cause pulmonary infiltrates and fever. Also, cultures obtained by suctioning secretions through the endotracheal tube do not reliably differentiate between pneumonia and bacterial colonization of the trachea. The use of the fiberoptic bronchoscope to obtain specimens with a protected brush or quantitative cultures of bronchial lavage fluid may be helpful in excluding a pulmonary source of infection in intubated patients who have new clinical signs that may be caused by a noninfectious process.[26]

Nonpharmacologic strategies may decrease the incidence of ventilator-associated pneumonia, including adequate hand washing after contact with each patient. Whenever possible, intubated patients should be kept in a semirecumbent position (45° from horizontal), and gastric distention should be avoided to prevent aspiration.[27] In addition, the incidence of ventilator-associated pneumonia can be significantly reduced with the continuous aspiration of subglottic secretions.[28] Several pharmacologic strategies may prevent the development of ventilator-associated pneumonia, such as avoiding the use of unnecessary antibiotics, rotating the class of antibiotics used in the empirical treatment of a suspected bacterial infection, and administering chlorhexidine oral rinse.[29]

Nosocomial sinusitis is strongly related to the nasotracheal route of intubation. In one study, CT demonstrated fluid in the maxillary sinus in 95.5% of patients who underwent both nasotracheal and nasogastric intubation for 1 week, compared with only 22.5% of patients in whom endotracheal and feeding tubes were placed via the oral route.[30] Aspiration of the sinus may reveal nonpurulent mucoid material, but in a significant number of cases, sinusitis will be evidenced by positive stains and cultures of aspirated pus. Treatment of nosocomial sinusitis includes administration of antibiotics, replacement of nasal tubes with oral tubes, and use of decongestants to facilitate drainage.[31]

Alveolar Overdistention

Alveolar overdistention results in two potentially life-threatening problems: hypotension and barotrauma. Ventilator-associated hypotension occurs most often in patients with obstructive airway disease, because the markedly increased lung volume with auto-PEEP impedes venous return. The risk of life-threatening hypotension is greatest at the time of intubation, when preexisting volume depletion and the administration of sedative agents limit the patient's ability to maintain blood pressure. In addition to receiving rapid infusion of intravenous fluids, hypotensive patients who have underlying airway disease should be allowed to reduce the overdistention themselves by interrupting mechanical inflation, before ventilation is resumed at a reduced frequency [*see Figure 5*]. Although less common, ventilator-associated hypotension also occurs in ARDS patients who have high levels of PEEP and when intrinsic PEEP develops with airway obstruction.

Extra-alveolar air caused by positive pressure ventilation is termed barotrauma. Examples include subcutaneous emphysema, pneumomediastinum, pulmonary interstitial emphysema, pneumoperitoneum, arterial gas embolism, and pneumothorax [*see Figure 6*]. Extra-alveolar air usually originates from overdistended alveoli that rupture into the surrounding interstitial space. High alveolar (plateau) pressure and infections that produce lung necrosis increase the risk of barotrauma. Tension pneumothorax is the most common life-threatening manifestation of barotrauma. Tension pneumothorax leads to worsening hypoxemia and decreased venous return with hypotension. Hyperresonance and a reduction of breath sounds on the side of the pneumothorax are common, and inflation pressures are increased. In patients with severe airflow obstruction, differentiat-

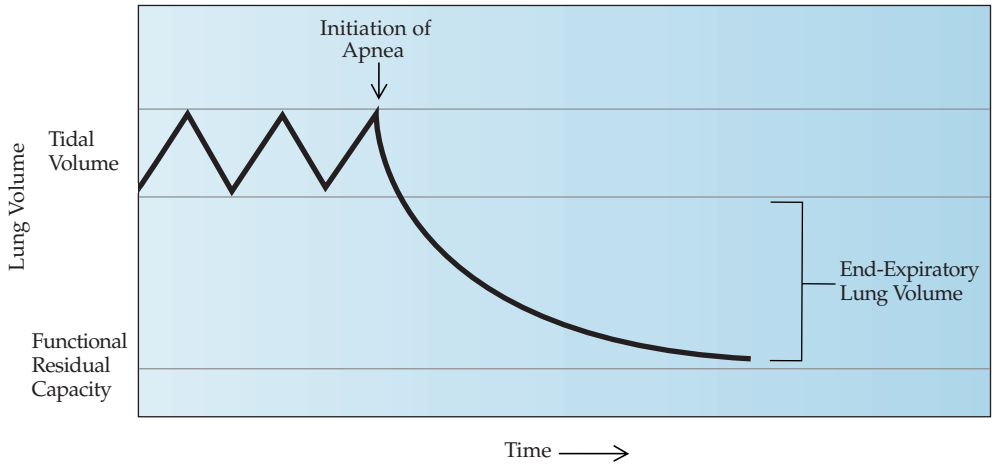

Figure 5 **The degree of pulmonary hyperinflation above the functional residual capacity can be determined by measuring the total exhaled volume during a period of apnea of 20 to 40 seconds. This allows the patient to reach the passive relaxation volume of the respiratory system. The difference between the total exhaled volume and the tidal volume represents the amount of pulmonary hyperinflation or the end-expiratory lung volume.**

Figure 6 **Chest radiograph displays several signs of barotrauma, including subcutaneous emphysema (white arrow) and pneumomediastinum (black arrow).**

ing a tension pneumothorax from hyperinflation as the cause of hypotension may be difficult at bedside. Therefore, it is advisable to allow a period for deflation to determine whether a reduction of hyperinflation improves the blood and inflation pressure [*see Figure 5*].

Atelectasis

Atelectasis is a common cause of severe hypoxemia that develops during mechanical ventilation. Left lung atelectasis may result from intubation of the right mainstem bronchus, a problem that also may lead to overdistention of the right lung signaled by increased inflation pressures [*see Figure 7*]. A common cause of atelectasis is mucoid impaction of the bronchi. The right lung is more easily suctioned because the right mainstem bronchus follows a more direct course. The left lung is more likely to be affected by retained secretions because of the more horizontal course of the left mainstem bronchus. With atelectasis of an entire lung, breath sounds are diminished or absent on the affected side, and the trachea is shifted toward that side. A chest radiograph will reveal increased opacity in the affected hemithorax, together with ipsilateral tracheal shift and elevation of the hemidiaphragm. These findings are crucial for radiographic differentiation of whole lung atelectasis from a massive pleural effusion. Massive pleural effusion should cause the trachea to deviate away from the involved lung. A large region of atelectasis may produce a significant intrapulmonary shunt, giving rise to profound hypoxemia caused by shunting that is refractory to an increase in F_IO_2.

Atelectasis should be suspected when a sudden onset of severe, refractory hypoxemia occurs in the absence of hemodynamic instability. Other causes of profound hypoxemia, such as massive pulmonary embolism or tension pneumothorax, produce concomitant hypotension. Placing the patient in the lateral decubitus position with the atelectatic lung superior may significantly improve oxygenation, because gravity will redistribute blood flow to the dependent lung. Bronchoscopy should be performed to remove excess mucus if it cannot be easily extracted with endotracheal suctioning after chest percussion.[32]

Approach to Pulmonary Complications

Worsening respiratory distress or arterial oxygen desaturation may develop suddenly as a result of changes in the patient's cardiopulmonary status or secondary to a mechanical malfunction. The first priority is to ensure patency and correct positioning of the patient's airway so that adequate oxygenation and ventilation can be administered during the ensuing evaluation. Briefly, note ventilator alarms, airway pressures, and tidal volume. Low-pressure alarms with decreased exhaled tidal volumes may suggest a leak in the ventilator circuit. Disconnect the patient from the ventilator and manually ventilate with an anesthesia bag, using 100% oxygen. For patients receiving PEEP, manual ventilation with a PEEP valve should be used to prevent atelectasis and hypoxemia. If manual ventilation is difficult, check airway patency by passing a suction catheter through the endotracheal tube or tracheostomy tube. Additionally, listen for prolonged expiration continuing up to the point of the next manual breath. This suggests the presence of gas trapping and auto-PEEP. Check vital signs and perform a rapid physical examination, with attention paid to the patient's cardiopulmonary status. Be attentive to asymmetry in breath sounds or tracheal deviation suggesting tension pneumothorax. Note other parameters, including cardiac rhythm and hemodynamics**.** Treat appropriately on the basis of the foregoing evaluation.

Treatment should be specific to the identified problems. If the presence of gas trapping and auto-PEEP is suspected, a reduction in the minute ventilation is appropriate. In some circumstances, periods of hypoventilation (4 to 6 breaths/min) or even apnea for 30 to 60 seconds may be necessary to reverse the hemodynamic sequelae of auto-PEEP (e.g., shock and electromechanical dissociation). Return the patient to the ventilator only after checking its function. Increase the level of support provided by the ventilator to the patient after an episode of respiratory distress or arterial oxygen desaturation. Usually, this adjustment means increasing the F_IO_2 and the delivered minute ventilation unless significant auto-PEEP is present. An acute increase in the peak airway pressure usually implies either a decrease in lung compliance or an increase in airway resistance. At a minimum, considerations that should be entertained as causes of increased airway pressure include (1) pneumothorax, hemothorax, or hydropneumothorax; (2) occlusion of the patient's airway; (3) bronchospasm; (4) increased accumulation of condensate in the ventilator circuit tubing; (5) mainstem intubation; (6) worsening pulmonary edema; or (7) the development of gas trapping with auto-PEEP. Loss of tidal volume, as evidenced by a difference between the tidal volume setting and the delivered tidal volume, implies a leak in either the ventilator or the inspiratory limb of the circuit tubing. A difference between the delivered tidal volume and the expired tidal volume implies the presence of a leak at the patient's airway, from cuff malfunction, malpositioning of the airway (e.g., positioning of the cuff at or above the level of the glottis), or a leak within the patient (e.g., a bronchopleural fistula in a patient with a chest tube).

Asynchronous breathing (so-called fighting or bucking the ventilator) occurs when a patient's breathing coordinates poorly with the ventilator. This difficulty may indicate unmet respiratory demands. A careful evaluation is mandated, with attention focused at the identification of leaks in the ventilator system or

airway, inadequate F_IO_2, or inadequate ventilatory support. The problem can be alleviated by adjustments in the mode of mechanical ventilation, rate, tidal volume, inspiratory flow rate, and level of PEEP. The identification of gas trapping with auto-PEEP may require changing multiple settings to allow adequate time for exhalation (e.g., decreasing rate and tidal volume, increasing inspiratory flow rate, or switching from assist-control to SIMV in selected cases). Measures aimed at reducing the work of breathing with mechanical ventilation also may resolve the problem (addition of flow-by triggering or low levels of PSV to patients taking spontaneous breaths). If these adjustments are unsuccessful, sedation should be attempted. Muscle paralysis should be reserved for patients in whom effective gas exchange and ventilation cannot be achieved with other measures.

NONPULMONARY COMPLICATIONS

Nonpulmonary complications occur in critically ill patients either because of the natural course of the underlying disease or because of iatrogenesis. A major role of the physician is to limit the occurrences of these nonpulmonary complications by anticipating common problems and initiating specific prophylactic measures.

Venous Thromboembolism

Venous thromboembolic disease is a significant cause of morbidity and mortality in critically ill patients. On routine clinical screening, 33% of patients in medical intensive care units have deep vein thrombosis (DVT) and 18% of trauma patients have proximal DVT.[33,34] Specific independent risk factors associated with the development of venous thromboembolism include trauma, underlying malignancy, immobilization, heart failure, and obesity. Prophylaxis is recommended for all high-risk patients and has been reported to decrease the incidence of DVT by 68%.[35] The most commonly used regimen is low-dose unfractionated heparin, 5,000 units administered subcutaneously two or three times daily. Other prophylactic therapies, including intermittent pneumatic compression stockings and graded elastic stockings, can be used for patients who cannot tolerate anticoagulation. In patients with major trauma, low-molecular-weight heparin is more effective in preventing the development of proximal DVT than is prophylaxis with standard unfractionated heparin.[36] In medical patients, however, the use of low-molecular-weight heparin as prophylaxis has not been shown to provide greater benefit than standard unfractionated heparin.[37]

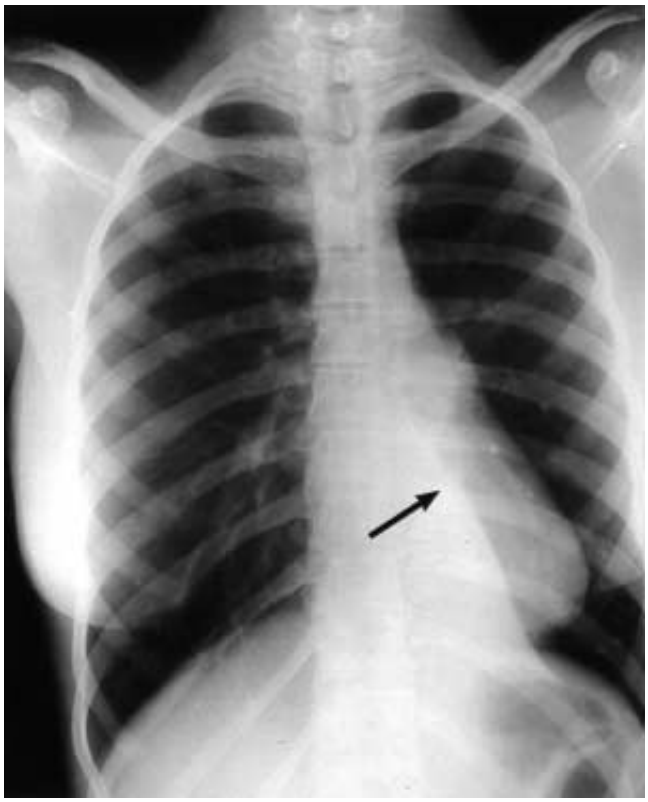

Figure 7 **Chest radiograph shows a collapsed left lower lobe of the lung (arrow).**

Gastrointestinal Bleeding

Gastrointestinal bleeding caused by stress ulceration is another important nonpulmonary complication and occurs in 1% to 10% of all critically ill patients.[38] Patients with coagulopathy, burns, head injury, or respiratory failure requiring mechanical ventilation are at increased risk for clinically significant bleeding. H_2 receptor antagonists should be administered to high-risk patients to reduce the possibility of the development of clinically significant bleeding.[39] Other therapeutic options include the cytoprotective agent sucralfate, which does not alter the gastric pH level and may be associated with a lower risk of late-onset pneumonia.[40]

Pressure Ulcers

Critically ill patients are also at an increased risk for pressure ulcers or localized areas of tissue necrosis that develop when soft tissue is compressed between a bony prominence and an external surface.[41] Pressure ulcers occur in 33% to 56% of patients in the ICU and are a source of infection that can result in bacteremia and osteomyelitis. Prevention programs that include regular repositioning of patients, which reduces the accumulation of moisture on skin, and adequate nutritional supplementation decrease the incidence of pressure sores. Air-suspension beds that redistribute body weight away from bony prominences also reduce the risk of pressure sores in certain critically ill patients.[42]

Neuromuscular Weakness

Patients who undergo mechanical ventilation may be at risk for neuromuscular weakness that persists long after the cause of respiratory failure has been resolved. A common cause of diffuse weakness is critical illness polyneuropathy, an axonal disorder that occurs with sepsis and multiorgan failure.[43] When present, critical illness polyneuropathy may be an important cause of delayed weaning from mechanical ventilation. Use of neuromuscular paralysis may be associated with weakness that persists after the neuromuscular blocking agents have been discontinued. Prolonged neuromuscular blockade can be diminished by appropriate dosing, adequate monitoring of the degree of neuromuscular blockade, and avoidance of medications that potentiate the action of specific neuromuscular blocking agents.[44] Neuromuscular blocking agents may also contribute to the development of acute myopathy, particularly in patients who receive concomitant corticosteroids. The risk of myopathy is not influenced by the chemical structure of the agent that is used to induce paralysis but, rather, is strongly correlated with the duration of paralysis.

Acute Renal Failure

Acute renal failure is a common nonpulmonary complication of patients in the ICU. Despite considerable advances in the management of critically ill patients and renal replacement therapy, the mortality associated with acute renal failure remains greater than 50%. Multiple system organ failure and other comorbidities contribute to the high mortality associated with acute renal failure, but the acute renal failure is also independently associated with an increase in morbidity and mortality.[45,46] In addition, long-term dialysis support is sometimes required for survivors of acute renal failure. Renal dysfunction in ICU patients is usually caused by intrinsic renal disease.[47] Hypotension, sepsis, the use of aminoglycosides, and volume depletion are all risk factors for the development of acute renal failure.

Withdrawal of Mechanical Ventilatory Support

To decrease complications and improve patient comfort, mechanical ventilatory support should be removed as soon as possible. However, premature withdrawal of mechanical ventilation is also associated with adverse events that may further delay appropriate extubation, such as aspiration or severe cardiopulmonary decompensation. Determination of the proper time to extubate a patient is based on several factors, including reversal or improvement of the underlying acute illness, adequate respiratory function, lack of excessive secretions, and ability to protect the airway.

Simple screening criteria have been developed that identify patients who may be ready to be removed from mechanical ventilation. These criteria include a minimal requirement for supplemental oxygenation ($F_IO_2 \leq 0.40$ or $P_aO_2/F_IO_2 < 200$), a PEEP level not exceeding 5 cm H_2O, adequate cough during suctioning, and no infusion of vasoactive agents. Measures of adequate respiratory function that are compatible with extubation have also been proposed, including a measure of rapid and shallow breathing, calculated as the respiratory rate divided by the tidal volume during spontaneous breaths. A threshold of 105 breaths/min/L, measured after 1 minute of spontaneous breathing, provides an excellent means to predict a successful extubation, with a positive and a negative predictive value of 0.78 and 0.95, respectively.[48]

Most patients can be removed rapidly from mechanical ventilation once the acute illness requiring mechanical ventilation has been reversed, and over 75% of patients who meet these initial screening criteria can be extubated successfully.[49] These patients can be quickly identified by a 30-minute to 2-hour trial of spontaneous breathing while they remain connected to the ventilator. Patients who appear comfortable after a trial of spontaneous breathing (respiratory rate < 35 breaths/min; heart rate < 140 beats/min; adequate arterial oxygen saturation; and no evidence of anxiety, diaphoresis, or extreme hypotension or hypertension) will likely be successfully removed from mechanical ventilation. Therefore, the concept of weaning, or slowly removing the patient from mechanical ventilation, does not apply to the majority of patients who require mechanical ventilation.

The remaining 25% of patients who require mechanical ventilation for acute respiratory failure cannot be removed rapidly from the ventilator.[49] There are several options for this group of patients. The three most commonly used modes of weaning are the following:

Table 4 Factors to Consider in Patients Having Difficulty Being Liberated from Mechanical Ventilation

Weaning parameters
$P_aO_2 \geq 60$ mm Hg with an $F_IO_2 \leq 50\%$
PEEP ≤ 5 cm H_2O
P_aCO_2 and pH in the acceptable range for patient's lung function
Spontaneous tidal volume ≥ 5 ml/kg
Vital capacity ≥ 10 ml/kg
Minute ventilation (MV) < 10 L/min
Maximum voluntary ventilation double of MV
Maximum inspiratory pressure (MIP) ≥ 25 cm H_2O
Respiratory rate < 30 breaths/min
Rapid shallow breathing index* < 105
Endotracheal tube
Use largest tube possible
Consider use of supplemental pressure-support ventilation
Suction secretions
Arterial blood gases
Avoid or treat metabolic alkalosis
Maintain P_aO_2 at 60 to 65 mm Hg to avoid blunting of respiratory drive
For patients with CO_2 retention, keep P_aCO_2 at or above the baseline level
Nutrition
Ensure adequate nutritional support
Avoid electrolyte deficiencies
Avoid excessive calories
Secretions
Clear regularly
Avoid excessive dehydration
Neuromuscular factors
Avoid neuromuscular depressant drugs
Avoid unnecessary corticosteroids
Airway patency
Use bronchodilators when appropriate
Exclude foreign bodies within the airway
Wakefulness
Avoid oversedation
Wean in morning or when patient is most awake

*Respiratory rate divided by tidal volume during spontaneous breaths; measured after 1 min of spontaneous breathing and calculated in breaths/min/L
F_IO_2—fraction of inspired oxygen PEEP—positive end-expiratory pressure P_aO_2—partial pressure of oxygen in arterial blood P_aCO_2—partial pressure of carbon dioxide in arterial blood

1. SIMV, which allows spontaneous breathing and diminishing numbers of mandatory breaths per minute until the patient is breathing unassisted.
2. The use of a T-piece circuit, which allows intermittent trials with total removal of mechanical support.
3. Use of decreasing levels of pressure-support ventilation.

Two large studies compared these three methods of weaning. The first one found that a gradual decrease in the level of pressure support was the most effective.[50] The second study found that a daily T-piece trial was associated with the shortest duration of mechanical ventilation.[49] The disparate conclusions of these two studies may in part be the result of differing criteria for extubation. Currently, it appears that both the gradual reduction in the level of pressure support and the use of intermittent T-piece trials are effective methods for weaning, but neither

offers a clear advantage over the other. Gradual reduction in the number of machine-supported breaths by use of SIMV appears to be the least effective method of weaning.

Several other measures can promote successful removal from mechanical ventilation. Daily screening of the respiratory function of patients receiving mechanical ventilation, followed by trials of spontaneous breathing initiated by a respiratory therapist, can reduce the duration of mechanical ventilation.[51,52] Daily interruption of sedative infusions has also been associated with decreased duration of mechanical ventilation and length of stay in the ICU.[53] In addition, it has been shown that fewer diagnostic tests to assess change in mental status are performed in patients assigned to daily interruption of sedative agents. Finally, noninvasive ventilation has been used as a technique to expedite weaning for patients with COPD.[54] Extubation and the application of noninvasive ventilation by face mask attempted after 48 hours has been associated with a significantly shorter mean duration of mechanical ventilation. For patients having difficulty being weaned from mechanical ventilation, a systematic approach to the evaluation of factors contributing to potential weaning failure is required [*see Table 4*].

Extubation

Usually, extubation should be performed early in the day, when full ancillary staff are available. The patient should be clearly educated about the procedure, the need to cough, and the possible need for reintubation. Elevation of the head and trunk to more than 30° to 45° improves diaphragmatic function. Equipment for reintubation should be available, and a high-humidity, oxygen-enriched gas source with a higher-than-current F_IO_2 setting should be available at the bedside. The patient's airway and the oropharynx above the cuff should be suctioned. The cuff of the endotracheal tube should be deflated partially, and airflow around the outside of the tube—indicating the absence of airway obstruction—should be detected. After the cuff is deflated completely, the patient should be extubated, and high-humidity oxygen should be administered via face mask. Coughing and deep breathing should be encouraged while the examiner monitors the patient's vital signs and upper airway for stridor. Inspiratory stridor may result from glottic and subglottic edema. If clinical status permits, treatment with nebulized 2.5% racemic epinephrine (0.5 ml in 3 ml normal saline) should be administered. If upper airway obstruction persists or worsens, reintubation should be performed. Extubation should not be reattempted for 24 to 72 hours after reintubation for upper airway obstruction. Otolaryngology consultation may be beneficial to exclude other causes of upper airway obstruction and to perform tracheostomy if upper airway obstruction persists.

IX DISORDERS OF THE PLEURA, HILA, AND MEDIASTINUM

Gerald W. Staton, Jr., m.d.
Roland H. Ingram, Jr., m.d.

Pleurisy

Pleurisy (also known as pleuritis) is characterized by chest pain that results from inflammation of the pleural surfaces from any cause. The pain originates from the parietal pleura, which derives most of its innervation from the intercostal nerves. The central portion of the diaphragmatic parietal pleura receives phrenic innervation, so that inflammation of the diaphragmatic surfaces causes referred pain to the ipsilateral shoulder. Inspiratory chest pain, however, is not uniquely pleural and may occur with pericarditis or chest wall disease.

Pleuritic chest pain may result from primary involvement of the pleura by neoplasia, infection, trauma, or inflammation or from secondary spread of one of these processes from subjacent lung tissue. Thus, a common cause of pleuritic chest pain is pneumococcal pneumonia, which typically begins at the lung periphery and spreads to the adjacent pleural surfaces. Many middle-aged and elderly persons who report having experienced pleurisy in the past probably suffered from pneumonia.

diagnosis

Pleuritic chest pain is typified by intensification on deep inspiration. It is usually sharp in quality, may be present continuously, and is characteristically made worse by movements of the thorax, as well as by coughing, sneezing, or other sudden respiratory movements. If the pain is severe, inability to take a deep breath without aggravating the pain may lead to the sensation of shortness of breath. Often, pleuritic chest pain must be differentiated from chest wall pain of musculoskeletal origin (e.g., localized muscle strain, costochondritis, or rib fracture) and from the pain associated with pericarditis. Superficial tenderness of the chest wall on light palpation favors chest wall pain, but tenderness on deep palpation does not reliably exclude pleuritis. A pleural friction rub heard on auscultation of the chest establishes the presence of a pleural disorder.

A chest radiograph can be useful in suggesting the underlying cause of pleuritic pain. If the chest radiograph shows the presence of effusions, the causes of pleuritic pain are limited to the processes that produce pleural effusion [*see* Pleural Effusion, *below*]. If the chest radiograph is normal, pleuritic chest pain has a relatively limited differential diagnosis. Major etiologic possibilities include pulmonary embolism, viral pleurisy, and serositis in association with collagen vascular disease, especially systemic lupus erythematosus (SLE). Less common causes of pleuritic chest pain include uremia, sickle cell crisis, and pleuropericarditis that occurs after myocardial infarction or pericardiotomy (Dressler syndrome). Some patients present with an acute illness characterized by low-grade fever, headache, and myalgia; in many such episodes, the cause cannot be determined but is presumed to be viral. These acute illnesses are usually self-limited, resolving within a few days to 1 to 2 weeks. Coxsackievirus B and other enteroviruses cause an epidemic form of viral pleuritis called epidemic pleurodynia, or Bornholm disease, which often affects multiple family members. Relapses may occur after the patient is asymptomatic for several days.

treatment

Idiopathic or viral pleuritis can be treated effectively with nonsteroidal anti-inflammatory drugs and, if necessary, narcotic analgesics. However, the diagnosis is one of exclusion, and pulmonary embolism, a potentially lethal condition, is the most important cause to exclude.

Pleural Effusion

Pleural effusion, the abnormal accumulation of liquid in the pleural space, may affect as many as 800,000 persons in the United States each year. The most common causes are congestive heart failure, malignancy, pneumonia, and pulmonary emboli.

pathophysiology

A number of factors favor pleural effusion, including (1) altered permeability of the pleural membranes; (2) decreased intravascular oncotic pressure and, once a pleural effusion has formed, increased pleural liquid oncotic pressure; (3) increased hydrostatic pressure in the pleural capillaries as a result of heart failure; (4) greater negativity of pressure in the pleural space (e.g., if the lung is unable to expand normally); (5) lymphatic obstruction; (6) migration of ascitic liquid across the diaphragm; and (7) migration of pulmonary edema liquid across the visceral pleura.[1] Pleural effusion produces a restrictive defect that is correlated with the size of the effusion. Because both the air spaces and the pulmonary circulation are compressed and because of pulmonary hypoxic vasoconstriction, there is little shunting and only mild hypoxemia. Removal of a large effusion can result in modest improvement in lung function, but often, the underlying cause of the effusion (e.g., heart failure or lymphangitic carcinoma) causes persistent functional abnormalities. Various mediators are involved in the production of altered permeability and the evolution of pleural effusions.[2,3]

classification and etiology

Various types of liquid may accumulate in the pleural space. Accumulation of serous liquid is referred to as a hydrothorax. If blood accumulates, the condition is referred to as a hemothorax. An effusion composed of lipids is known as a chylothorax. Accumulation of pus is known as a pyothorax, or empyema. Although imaging studies can be helpful, the actual condition can be distinguished only by analysis of the liquid itself.

Hydrothoraces fall into two major categories on the basis of mechanisms of pleural liquid accumulation: transudation and exudation. Transudation of liquid into the pleural space occurs when there is an imbalance between the hydrostatic and the oncotic pressures governing the normal rates of pleural liquid formation and resorption. The most common cause of a transudative pleural effusion is congestive heart failure. Other causes are constrictive pericarditis, superior vena cava obstruction, and the hypoalbuminemic states associated with cirrhosis and the nephrotic syndrome [*see Table 1*]. Pulmonary arterial hypertension and right heart failure usually do not by themselves cause pleural effusions.

Table 1 Causes of Hydrothorax

Transudative
- Congestive heart failure
- Constrictive pericardial disease
- Cirrhosis
- Nephrotic syndrome
- Superior vena cava obstruction
- Ascites (transudative)
- Peritoneal dialysis

Exudative or Transudative
- Hypothyroidism
- Pulmonary embolism
- Trapped lung

Exudative
- Infections (i.e., parapneumonic effusion, tuberculosis)
- Malignant disorders
  - Primary lung cancer
  - Cancer metastases to the lungs or pleura
  - Lymphoma
  - Mesothelioma
- Collagen vascular diseases and vasculitides
- Gastrointestinal diseases
  - Pancreatitis and pancreatic pseudocyst
  - Esophageal rupture
  - Abdominal or retroperitoneal abscess
  - Postabdominal surgery
  - Postendoscopic variceal sclerotherapy

Miscellaneous
- Benign asbestos effusion
- Meigs syndrome
- Dressler syndrome (after myocardial infarction or pericardiotomy)
- Post–coronary artery bypass[97]
- Uremia
- Sarcoidosis and necrotizing sarcoid granulomatosis
- Radiation therapy
- Drugs (e.g., nitrofurantoin, dantrolene, methysergide, all-*trans*-retinoic acid[98])
- Yellow nail syndrome

Exudation of liquid into the pleural space results from any process that disrupts the integrity of the endothelial membrane that lines the pleural capillaries and venules. Obstruction of lymphatic drainage from the pleural space is another mechanism that can cause a protein-rich effusion. Exudative effusions are associated with a broad range of disorders, including a variety of infectious, neoplastic, inflammatory, embolic, and vasculitic diseases. In addition, exudative effusions may be caused by the effects of certain drugs and physical agents [*see Table 1*].

DIAGNOSIS

Clinical Manifestations

A pleural effusion may be suspected on the basis of physical examination. Physical findings include dullness on percussion, diminished or absent breath sounds, decreased fremitus, and egophony at the level of the pleural liquid meniscus.

Imaging Studies

The chest radiograph usually establishes the diagnosis; patients are often further evaluated by other imaging techniques (e.g., ultrasonography and computed tomography).[4]

Radiography When the patient is in the upright position, liquid collects first in the posterior sulcus, the most inferiorly located recess of the pleural space. Blunting of the normally sharp posterior costophrenic angle on a lateral chest radiograph indicates the presence of at least 25 to 50 ml of pleural liquid. As additional liquid accumulates (approximately 150 ml total), the lateral costophrenic angle on a posteroanterior radiograph becomes obliterated. Greater amounts of pleural liquid displace the lung centrally and produce a characteristic homogeneous opacity that forms a concave meniscus with the chest wall [*see Figure 1*].

A massive pleural effusion may opacify an entire hemithorax and displace mediastinal structures to the opposite side of the chest [*see Figure 2*]. Large effusions may reduce venous return and thus cardiac output, creating hemodynamic compromise. The displacement force that is exerted is proportional to the height of the effusion. A contralateral shift of the mediastinum in a patient with massive pleural effusion may go undetected if there is ipsilateral atelectasis of the lung or if the mediastinum is fixed by an invasive tumor or fibrosis. A mediastinal shift toward the side of the effusion indicates almost complete atelectasis of the underlying lung, most often resulting from an obstructing tumor of the mainstem bronchus.

When intense pleural inflammation leads to the formation of adhesions between the visceral and parietal surfaces, localized effusions may collect in the resultant pockets. These loculated effusions may form along any part of the pleural surface and at times may be mistaken for infiltrates or masses within the lung parenchyma [*see Figure 3*]. A radiographic sign that favors the diagnosis of pleural loculation is the oblique angle formed by the chest wall and the margin of the pleural density. A subpleural lung nodule, in contrast, usually forms an acute angle with the chest wall.

An atypical presentation of pleural effusion is the subpulmonary collection of liquid [*see Figure 3*]. For unknown reasons, sizable amounts of pleural liquid sometimes collect between the diaphragm and the base of the lung without significantly distorting the contour of the inferior lung margin. In a patient with a

Figure 1 **This chest radiograph demonstrates the typical configuration of a pleural effusion as seen on posteroanterior projection. The pleural liquid forms a meniscus with the left lateral chest wall.**

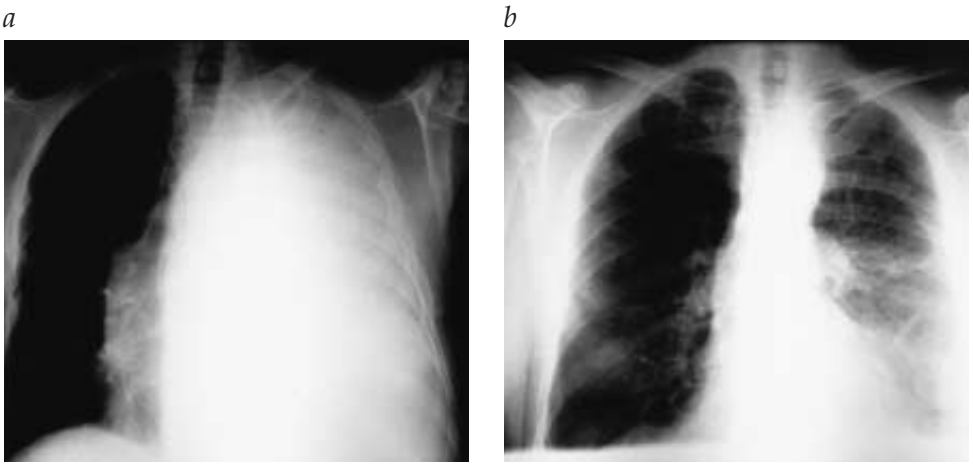

Figure 2 **(*a*) A massive hydrothorax resulting from a subpleural adenocarcinoma of the lung with a malignant pleural effusion is present in this patient. The heart and mediastinum are deviated to the right. Compression of the heart and increased intrathoracic pressure cause a reduction in venous return and resulting tachycardia (heart rate, 120 beats/min). (*b*) The heart and mediastinum return to the midline after evacuation of liquid; heart rate falls to 80 beats/min.**

subpulmonary effusion, it is possible to mistake the superior border of the effusion for the diaphragmatic silhouette, prompting a needless search for causes of an elevated hemidiaphragm. Several radiographic findings suggest the correct diagnosis. First, the contour of the base of the lung is slightly altered by a subpulmonary effusion; the normal domelike curve formed by the diaphragm is replaced by a hockey stick–like shape, with lateralization of the apex of the dome. Second, on the left side, the distance between the base of the lung and the gastric gas bubble is increased. The diagnosis of a subpulmonary effusion is confirmed by a lateral decubitus chest radiograph, which will show layering of the effusion along the lateral chest wall.

In patients with congestive heart failure, pleural liquid may collect between the two visceral pleural surfaces that line the interlobar fissures [*see Figure 4*]. Interlobar effusions, which may be mistaken for tumors of the lung parenchyma, disappear with effective treatment of the heart failure and thus have been called vanishing tumors, or pseudotumors. Interlobar effusions have a characteristic lenticular shape, with the tapered ends oriented in the plane of the fissure.

In some cases of pleural effusion, the only radiograph available for interpretation is an anteroposterior chest radiograph obtained with the patient in the supine position. In this position, a free-flowing pleural effusion spreads along the posterior costal surfaces. The radiograph shows a uniform increase in the opacity of the involved hemithorax, but normal lung markings are visible through the opacity [*see Figure 5*].

On lateral decubitus radiographs, small amounts of pleural liquid can be identified if the patient is positioned carefully. Free-flowing effusions can be distinguished from loculated effusions or thickened pleural tissue by comparing the pleural density with its appearance on a radiograph taken with the patient in the upright position.

Ultrasonography Ultrasonography is also a very sensitive test for detecting pleural effusions. It is particularly effective in cases of loculated pleural effusions because it can identify the precise site on the chest wall where a needle can be introduced to aspirate a sample.

Computed tomography CT scanning is helpful in distinguishing a pleural mass from a loculated effusion and distinguishing a hydropneumothorax from a lung abscess. CT scanning performed with contrast usually shows parietal pleural thickening in patients with exudates and enhancement of the parietal pleura in patients with empyema.[5]

Laboratory Studies

Examination of pleural liquid is useful for diagnosis. Thoracentesis should be performed in virtually all patients with pleural effusions of a significant size and of uncertain etiology. Pneumothorax is relatively common but rarely serious, so routine chest radiography is not necessary after uncomplicated thoracentesis.[6] Occasionally, pulmonary edema develops acutely in the reexpanded lung after rapid removal of large pleural effusions, especially if they have been present for a long time [*see 14:X Pulmonary Edema*]. This complication can be avoided by re-

Figure 3 **This chest radiograph demonstrates two patterns of atypical pleural liquid accumulation. In the left pleural space, a loculated effusion has formed along the lateral chest wall; it is presumably trapped in this position by fibrous adhesions between adjacent areas of visceral and parietal pleurae, preventing free flow of the liquid to the most dependent portions of the pleural space. In the right pleural space, liquid has accumulated in a subpulmonic position, between the base of the lung and the superior surface of the diaphragm. The gas-liquid interface has a shape slightly different from the normal contour of the diaphragmatic silhouette: it is more flattened and curves inferiorly at a point more laterally displaced. A small meniscus sign at the lateral chest wall hints at the presence of this subpulmonic effusion.**

Figure 4 **This anteroposterior radiograph was made in a patient with congestive heart failure. The ovoid or lenticular opacity in the right upper lung zone is an interlobar effusion collected in the minor fissure; such effusions are sometimes mistaken for tumors of the lung parenchyma. Interlobar effusions resolve with treatment of the heart failure; hence, they are sometimes called vanishing tumors, or pseudotumors. The radiograph also demonstrates the presence of osteopenia and scoliosis in this patient.**

moving a limited amount of liquid (1,000 to 1,500 ml) during each drainage procedure or by terminating the procedure if highly negative pressures are required to remove additional liquid.[7,8] The gross appearance of pleural liquid may occasionally provide useful diagnostic information. Gross pus or putrid-smelling liquid is diagnostic of infection. A highly viscous clear liquid reflects the presence of hyaluronic acid elaborated by a mesothelioma, whereas a chocolate-sauce or anchovy-paste appearance suggests a hepatopleural fistula caused by amebiasis.

Three general categories of laboratory tests have been distinguished: (1) those that provide specific information, such as cytologic studies and microbiologic cultures and stains; (2) certain tests that, if the results are abnormal, indicate a limited number of diagnostic possibilities, such as measurements of amylase, glucose, pH (measured by a pH meter, not by dipstick), triglycerides, and antinuclear antibody (ANA) titers and differential cell counts; and (3) those that are useful in distinguishing between transudates and exudates, such as measurements of lactate dehydrogenase (LDH), protein, and cholesterol. Routine laboratory studies pertinent to most cases include total and differential white cell counts, microbiologic stains and cultures, cytologic analysis, pH measurement, and determinations of protein, LDH, amylase, and glucose levels. Measurement of pleural liquid triglycerides or ANA titers may be appropriate in certain patients with pleural effusions. When pleural fluid appears sanguineous, red cell counts may be useful.

Clinical and radiographic findings may indicate whether a pleural effusion is transudative or exudative. Patients who have painful effusions, pleural rubs, loculation of effusion on chest radiograph, or conditions known to produce pleural inflammation (e.g., pneumonia or active lupus) are more likely to have pleural exudates. Patients with cirrhosis and ascites, heart failure, or hypoproteinemia with bilateral free effusions are likely to have transudates. Clinical information may be helpful in designing strategies for pleural liquid analysis [*see Figure 6*].

If a pleural effusion is not pus, chyle, or blood, it is the clinical context that allows categorization as an exudate or transudate. In fact, the gold standards that are used to assess the sensitivities and specificities of the various pleural liquid measurements for differentiating exudates from transudates are based solely on clinical data. Pleural effusions resulting from exudation or obstruction of lymphatic drainage typically have a high protein concentration, usually 3 g/dl or greater. However, four criteria differentiate exudative from transudative pleural effusions more effectively than the absolute protein concentration[9]: (1) a ratio of pleural protein to serum protein greater than 0.5, (2) a ratio of pleural LDH to serum LDH greater than 0.6, (3) a pleural LDH concentration greater than two thirds the upper limit of normal for serum LDH, or (4) a pleural cholesterol level of 60 mg/dl or higher.[10] If one or more of these criteria are met, the effusion is usually exudative or caused by lymphatic obstruction. If none of these characteristics are present, a transudative mechanism would be expected. Although these criteria are extremely useful, they are not absolute, and the results must be considered in the clinical context.

No additional information about the etiology of a transudative pleural effusion can be obtained by further testing of the pleural liquid. However, results of certain laboratory studies can be used to narrow the differential diagnosis of exudative pleural effusions.

Amylase level Determination of the pleural liquid amylase level is warranted in patients with unexplained left-sided pleural effusions, particularly in the presence of coexistent abdominal disease. In patients who have pleural effusions associated with acute pancreatitis or pancreatic pseudocysts, the pleural liquid amylase level typically exceeds serum levels and remains elevated long after the concentration of amylase in the serum has returned to normal. Elevated amylase levels are also commonly seen in patients with malignancy.[11]

Red cell count Most bloody pleural effusions in which the red cell count is greater than 100,000/mm^3 are caused by malig-

Figure 5 **In a chest radiograph obtained with the patient in the supine position, a pleural effusion may be apparent as only a diffusely increased opacity or haze over the affected hemithorax, as seen in the left pleural space of this patient. In this position, the effusion uniformly layers along the posterior chest wall; the x-ray beam penetrates perpendicular to the thin pleural liquid layer, producing a diffuse haze without a discrete meniscus or gas-liquid interface.**

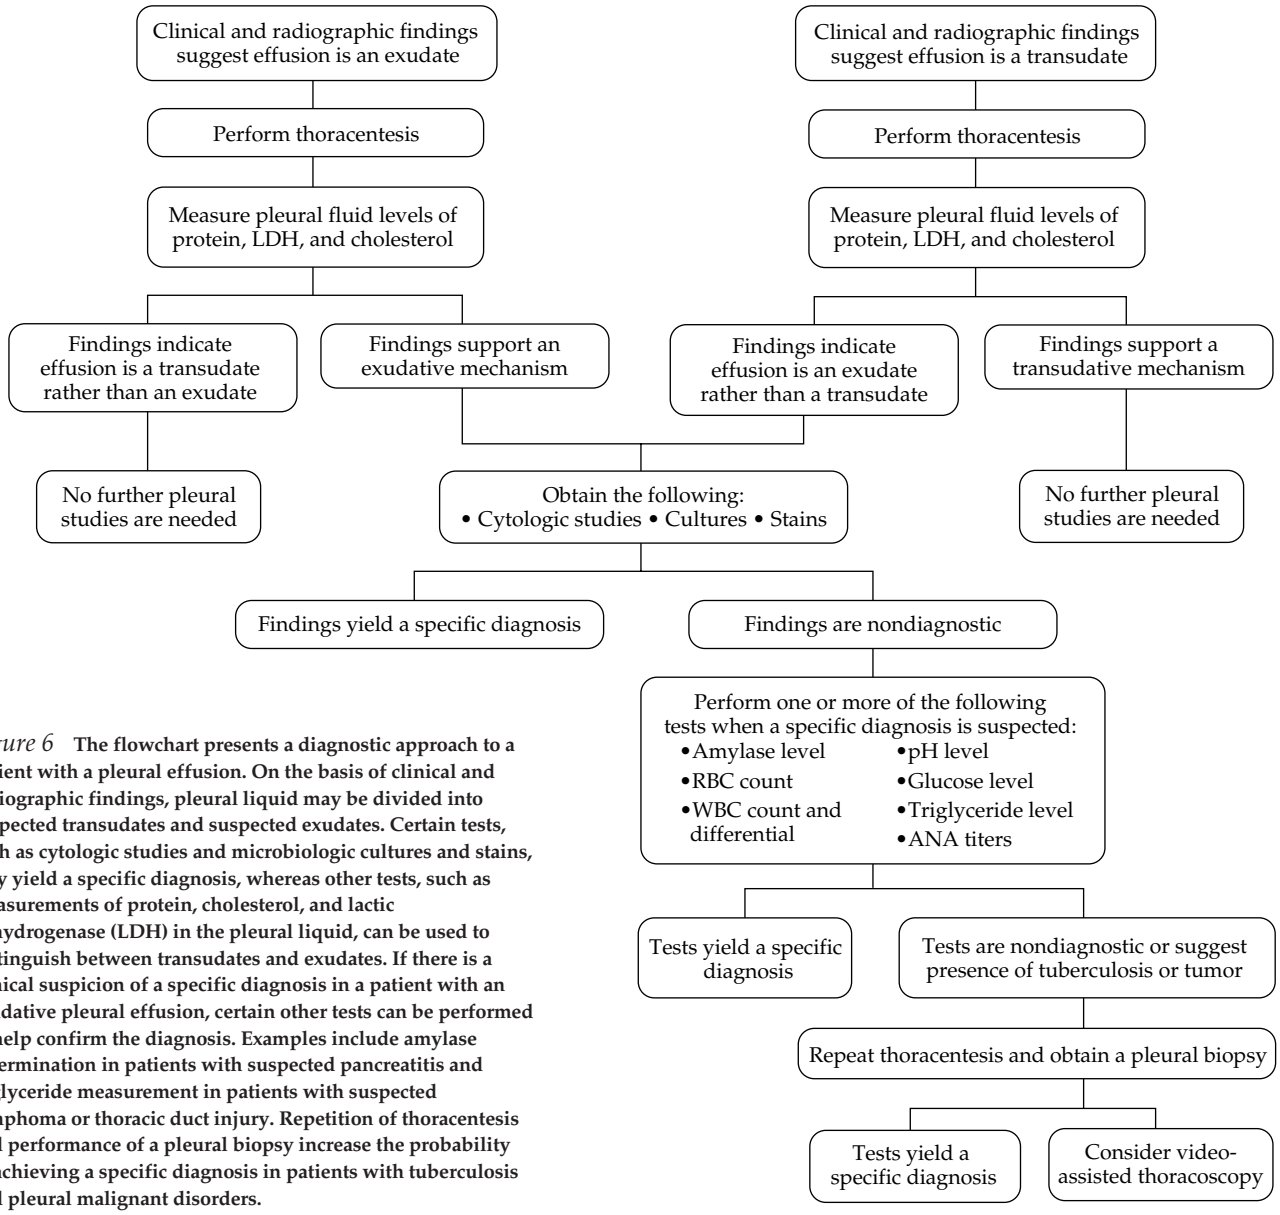

Figure 6 **The flowchart presents a diagnostic approach to a patient with a pleural effusion. On the basis of clinical and radiographic findings, pleural liquid may be divided into suspected transudates and suspected exudates. Certain tests, such as cytologic studies and microbiologic cultures and stains, may yield a specific diagnosis, whereas other tests, such as measurements of protein, cholesterol, and lactic dehydrogenase (LDH) in the pleural liquid, can be used to distinguish between transudates and exudates. If there is a clinical suspicion of a specific diagnosis in a patient with an exudative pleural effusion, certain other tests can be performed to help confirm the diagnosis. Examples include amylase determination in patients with suspected pancreatitis and triglyceride measurement in patients with suspected lymphoma or thoracic duct injury. Repetition of thoracentesis and performance of a pleural biopsy increase the probability of achieving a specific diagnosis in patients with tuberculosis and pleural malignant disorders.**

nant disorders, injuries to the chest, or pulmonary embolism. Other possible causes include tuberculous pleurisy, esophageal rupture, pancreatitis, and benign asbestos effusions. A pleural liquid hematocrit that exceeds half the simultaneous peripheral blood hematocrit indicates frank bleeding into the pleural space and is diagnostic of a hemothorax. On the other hand, the finding that pleural liquid is blood tinged is not diagnostically useful, because as little as 1 or 2 ml of blood added to 1 L of fluid results in a red cell count of 5,000 to 100,000/mm^3 and a serosanguineous appearance. Serosanguineous effusions may be found in transudative and exudative effusions of many different causes.

White cell count Total and differential white cell counts may further narrow the differential diagnosis. Pleural liquid white cell counts exceeding 50,000 to 100,000/mm^3 are usually associated with grossly visible pus; such effusions are by definition pyothoraces or empyemas. Absolute white cell counts below this range cannot be used to differentiate infected pleural effusions from other inflammatory processes. Likewise, a predominance of polymorphonuclear leukocytes in the differential white cell count simply indicates an acute inflammatory process; the etiology may be empyema, parapneumonic effusion, pulmonary embolism, pancreatitis, viral pleuritis, benign asbestos effusion, malignant disease, early tuberculous effusion, or other, less common disorders.

More than 90% of patients with exudates containing a predominance of small lymphocytes have a malignant or tuberculous effusion. Pleural liquid eosinophilia is rarely the result of a fungal or parasitic infection. Much more commonly, the eosinophilia is a nonspecific finding; in some cases, it is thought to result from prior introduction of air or blood into the pleural space. The finding of more than 10% eosinophils in the pleural liquid is relatively uncommon in effusions associated with tuberculosis or malignant disease but does not exclude these diagnoses.[12] Finally, the presence of mesothelial cells in an exudative pleural effusion may be of diagnostic utility because tuberculous pleural effusions, except perhaps at their very onset, almost never contain more than 5% mesothelial cells.

pH level In congestive heart failure, the pH of the pleural liquid is very close to that of the serum (7.35 to 7.45), and in patients who also have acidemia, the pleural liquid pH falls below 7.35 as the serum pH falls. Certain exudative pleural effusions are acidotic (pH < 7.3), presumably because of metabolism of glucose to carbon dioxide and fixed acids (e.g., lactic acid). A pleural liquid pH of less than 7.3 in the absence of systemic acidosis suggests one of the following diagnoses: empyema, malignant disease (usually associated with a pleural effusion of several months' duration), collagen vascular disease, tuberculosis, esophageal rupture, or hemothorax. In patients who have a pleural effusion associated with bacterial pneumonia (parapneumonic effusion), a pleural liquid pH of less than 7.0 is suggestive of an infected pleural space (empyema).[13] A pH of 6.0 or less suggests esophageal rupture.

Glucose level Low pleural liquid glucose values (60 mg/dl) are found in tuberculous effusions, parapneumonic effusions and empyemas, and large or highly cellular effusions associated with malignant disorders. In these conditions, consumption of glucose by microorganisms or by inflammatory or malignant cells is thought to be the cause of the low glucose concentrations. Glucose values are extremely low in effusions associated with rheumatoid arthritis caused by impaired transport of glucose into the pleural space.

ANA and rheumatoid factor titer Identification of lupus erythematosus cells or an ANA titer equal to or greater than that found in the serum is diagnostic of SLE as the cause of the pleural effusion. In contrast, latex fixation titers of rheumatoid factor as high as 1:160 may be found in the pleural liquid of patients who have a pleural effusion related to a variety of conditions other than rheumatoid arthritis.[14]

Repetition of pleural liquid analysis and pleural biopsies increases the probability of achieving a diagnosis in patients with tuberculosis or pleural malignant disorders. When tuberculosis or malignancy is still suspected, thoracoscopy can be used to visualize the pleura and to obtain biopsies of visible lesions.[15] Follow-up in the clinic is indicated in the minority of patients in whom exhaustive evaluation has failed to yield a specific diagnosis. In most of these patients, the disease will have a benign course, with resolution of the effusion occurring over several months.[16]

HYDROTHORAX

Hydrothorax Caused by Congestive Heart Failure

Pleural liquid accumulation may be a relatively early sign of congestive heart failure. A portion of the liquid comes directly from the lung into the pleural space.[1] Radiographic evidence of pleural effusion (i.e., blunting of the costophrenic angles) will appear during the stage of interstitial pulmonary edema formation. Pulmonary venous hypertension, especially in combination with elevated systemic venous pressures, favors the development of transudative pleural effusions. However, at any given level of venous pressure elevation, the likelihood of pleural liquid formation varies widely among individuals; the reason for this variability remains unexplained.

Most often, pleural effusions caused by congestive heart failure form either bilaterally or on the right side only. Successful treatment of congestive heart failure usually leads to clearing of the associated effusions within hours to a few days. The protein concentration of these effusions increases slightly after diuresis, and the resultant protein concentration is occasionally in a range that would be confused with a pleural exudate.[17] In most patients with heart failure, frankly exudative effusions are caused by a process other than congestive heart failure.[18]

Ascites

Liquid that collects in the abdomen from cirrhosis,[19] ovarian tumors, or peritoneal dialysis may migrate into the pleural space. In all these conditions, ascitic liquid is usually evident clinically, and there is a preponderance (60% to 70%) of right-sided effusions. The pressure gradient between the peritoneal cavity (supra-atmospheric pressure) and the pleural cavity (subatmospheric pressure) favors this direction of flow. The transdiaphragmatic migration of liquid appears to occur via lymphatic vessels or physical openings in the diaphragm. Thoracentesis is recommended to establish the diagnosis of hepatic hydrothorax, because a significant proportion of the patients with pleural effusion will have alternative diagnoses (e.g., infection, malignancy).[20] Symptomatic liquid collection may be controlled by diuresis in cirrhosis and by the resection of benign ovarian tumors when these are associated with accumulations in the chest. Repetition of therapeutic thoracentesis is discouraged because this procedure results in protein and volume depletion. A preferable approach to the management of hepatic hydrothorax is to use video-assisted thoracoscopy to close the defects in the diaphragm, which may result in the resolution of the effusions.[21]

Hydrothorax Caused by Malignant Disease

Neoplastic invasion of the pleura, usually involving both the visceral and the parietal surfaces, can cause a pleural effusion.[22] The effusion most often has the characteristics of an exudate. Mediastinal obstruction of lymphatic channels by a tumor frequently contributes to the pathogenesis of pleural liquid formation.

The lung and breast are the most common primary sites from which pleural metastases arise; stomach and ovarian carcinomas are next in frequency. Breast, stomach, and ovarian cancers usually spread to the pleura indirectly from hepatic metastases, although contiguous spread through the chest wall occasionally occurs with breast cancer and spread across the diaphragm occasionally occurs with ovarian or stomach cancer.

Virtually any carcinoma can metastasize to the pleura, and in some cases, pleural carcinomatosis is found with no identifiable primary site.[23] Lymphomas can also cause pleural effusions; the mechanism usually involves infiltration of mediastinal lymph nodes and consequent obstruction of lymphatic drainage from the pleural cavity.

Pleural effusions are a common manifestation of primary pleural neoplasms, such as mesothelioma,[24] a rare neoplasm that can be either localized and benign or diffuse and malignant. Risk factors for the malignant form include exposure to asbestos, zeolite (erionite), and therapeutic radiation. Survival of patients with malignant mesothelioma is poor with all forms of therapy.

Diagnosis Pleural effusions associated with malignant disease typically produce the following pleural liquid findings: (1) the pleural liquid is serosanguineous; (2) protein and LDH concentrations are elevated, characteristic of an exudative effusion; (3) the differential white cell count reveals more than 50% lymphocytes; (4) the pleural liquid glucose level is normal (> 60 mg/dl); and (5) the pleural liquid pH is greater than 7.3. However, none of these findings is consistently present.

Two clinical circumstances in which malignant disease is the likely cause of pleural effusion are (1) massive pleural effusions, in which the pleural liquid opacifies an entire hemithorax,[25] and (2) effusions in which the etiology eludes thoracentesis and closed pleural biopsy.

In a majority of cases of malignant pleural effusion, the diagnosis can be made by cytologic examination. Routine studies include Papanicolaou stain of the centrifuged material and hematoxylin-eosin stain of the paraffin-embedded cell pellet (so-called cell block). When a lymphoma is suspected as the cause of a lymphocytic pleural effusion, special studies of cell surface markers can be of use in differentiating a monoclonal lymphocytic process from a polyclonal inflammatory reaction. Other immunohistochemical studies can assist in the diagnosis of carcinoma or mesothelioma.[26] The greater the amount of material provided for analysis, the higher the diagnostic yield of malignant cells; thus, the number of positive diagnoses increases with the second and third diagnostic thoracenteses. Closed pleural biopsy, which provides samples of parietal pleura 1 to 2 mm in diameter, will identify only an additional 7% of cases of pleural malignancy when repeated thoracenteses have been negative. Image-guided percutaneous biopsy may provide a better yield than traditional closed pleural biopsy.[27] Fiberoptic bronchoscopy is useful in cases that present with clinical features suggestive of bronchogenic carcinoma, such as hemoptysis, a mass, an infiltrate, or atelectasis seen on radiographs.[28] Thoracoscopy is needed for diagnosis in a minority of cases.

Treatment Management of symptomatic pleural effusions should be directed at draining the pleural liquid and, when necessary, obliterating the pleural space. In terminally ill patients with slowly reaccumulating pleural effusions, repetitive thoracenteses may be sufficient to control dyspnea for a few weeks to months.[29] Often, however, a longer-term solution to this problem is needed, in which case chemical pleurodesis may be indicated. This technique requires that the pleural space be drained by a chest tube until a minimal amount of liquid remains, allowing apposition of the visceral and parietal surfaces. Small (14 French) tubes can be used to drain the pleural space, and the procedure can be performed on selected ambulatory patients.[30] In patients with multiloculated malignant effusions, use of an intrapleural fibrinolytic agent may help achieve adequate drainage.[31] Once sufficient liquid is removed, a sclerosing agent (e.g., doxycycline, talc slurry, bleomycin, or iodopovidone[32]) is introduced into the pleural space through the chest tube; during healing of the resultant inflammatory process, a fibrous bond forms between the two pleural surfaces.[33]

Talc is the least costly sclerosing agent available for pleurodesis, and the results with talc are no different from those with doxycycline and bleomycin.[34] When pleurodesis is successful, pleural sclerosis prevents further accumulation of pleural liquid or limits accumulation of liquid to small pockets between pleural adhesions, and the patient experiences remarkably little compromise of ventilatory function. However, pleurodesis will be ineffective if the pleural liquid pH is less than 7.3 or if the lung does not expand to fill the space when pleural liquid is removed. Talc poudrage performed during thoracoscopy is an alternative and possibly more effective technique than pleurodesis.[35] In patients who do not respond to pleurodesis or talc poudrage, implantable catheters or pleuroperitoneal shunts may be useful in controlling pleural effusions.[36,37]

Hydrothorax Caused by Tuberculosis

Pleural effusion is more often a manifestation of primary tuberculosis than of reactivation tuberculosis. Tuberculous effusions occur more commonly in young adults than in children. Typically, the effusion develops 3 to 6 months after initial exposure to *Mycobacterium tuberculosis*. A tuberculin skin test is positive at the time of clinical presentation in 70% of patients; in the remaining 30% of patients, the skin test becomes positive within 6 weeks after an initial negative result. In many cases, pleural effusion is the only abnormality detected on chest radiograph. Tuberculous pleural effusions are thought to be caused by the rupture of a small subpleural focus of infection into the pleural space, with the discharge of tuberculoprotein and viable tubercle bacilli. Widespread granulomatous infection of the parietal and visceral pleurae ensues, as indicated by the high yield of closed pleural biopsy in this setting. In patients with primary tuberculosis, untreated pleural effusions resolve spontaneously in approximately 2 to 4 months. However, active tuberculosis develops in two thirds of such patients during the ensuing 5 years.

Diagnosis Tuberculous pleuritis in patients with primary tuberculosis may present acutely as a febrile illness accompanied by pleuritic chest pain or subacutely as anorexia, weight loss, and dyspnea on exertion. The pleural liquid is usually serous or serosanguineous. In most cases, the differential white cell count reveals a lymphocytosis. A finding of more than 10% eosinophils or more than 5% mesothelial cells suggests a diagnosis other than pleural tuberculosis. In approximately 20% of cases, the pleural liquid glucose level drops below 60 mg/dl and the pleural liquid pH below 7.3. Increased levels of adenosine deaminase and interferon gamma distinguish tuberculous effusions from those of other causes.[38] Use of polymerase chain reaction techniques to analyze pleural liquid for detection of mycobacterial DNA may become the method of choice for identifying tuberculous effusions.[38,39]

Acid-fast bacilli are rarely seen in pleural liquid, and cultures are positive in only 20% to 40% of patients. However, closed-needle biopsy of the pleura reveals caseating or noncaseating granulomas in approximately 70% of cases and provides material that is culture positive in approximately 75% of cases. Thus, the total diagnostic yield, based on histopathology and culture, is 90% to 95%.

Treatment Patients who have pleural effusions from primary tuberculosis should be treated with at least two antituberculous drugs.[40] Treatment schedules should be identical to those used for parenchymal pulmonary tuberculosis. Corticosteroids have not been found to be of benefit[41] [*see 7:VIII Infections Due to Mycobacteria*]. Chest tube drainage is not necessary. On the other hand, in cases of reactivation tuberculosis, infection may spill directly into the pleural space, causing a thick, purulent effusion known as tuberculous empyema. In these cases, chest tube drainage is required, as it is for other forms of empyema.

Hydrothorax Caused by Pulmonary Embolism

Pleural effusion may develop in patients with pulmonary embolism, even though pulmonary infarction (as manifested by a parenchymal infiltrate on chest radiograph) may not be present. In a large series of patients with emboli documented by angiography, 28% of the patients had radiographic evidence of pleural effusion at presentation.[42] Spiral CT scans used for the diagnosis of pulmonary embolism detect pleural effusions in 57% of cas-

es.[43] The precise pathogenetic mechanism for pleural liquid formation in the absence of lung infarction is not known, although increased capillary permeability in the lung and visceral pleura and systemic venous hypertension have been suggested as contributing factors.

Diagnosis In many cases of pleural effusion caused by pulmonary embolism, pleural liquid analysis reveals an exudative effusion that is serosanguineous in appearance (> 10,000 red cells/mm^3). A differential white cell count typically reveals a predominance of polymorphonuclear leukocytes. However, the characteristics of such an effusion are highly variable. The pleural liquid may be serous, may have a low protein concentration and meet the diagnostic criteria for a transudate, and may contain more than 50% lymphocytes. In addition, the total white cell count may vary from less than 100/mm^3 to more than 50,000/mm^3. Thus, none of the findings on routine pleural liquid analysis can be used to exclude a diagnosis of pulmonary embolism.[44]

Treatment Management of pulmonary embolism need not be modified because of the presence of a pleural effusion, even if the effusion is bloody. In this setting, pleural effusions are maximal at their onset and gradually resorb with time, although resolution often requires more than 7 days if the effusion is large and associated with pulmonary consolidation. An enlarging effusion or the subsequent development of a contralateral effusion should raise suspicion of recurrent embolization or another complication, such as empyema.

HEMOTHORAX

Direct hemorrhage into the pleural space most commonly results from trauma to the thorax. The trauma may be either blunt (e.g., sustained in a motor vehicle accident), in which case rib fractures are usually present, or penetrating (e.g., a knife or bullet wound). In a majority of cases, air or alveolar gas enters the pleural space along with blood, causing a hemopneumothorax. Hemothorax may also complicate invasive diagnostic or therapeutic procedures that lacerate pleural or mediastinal blood vessels; such procedures include thoracentesis, pleural biopsy, and cannulation of the subclavian or internal jugular veins. In rare instances, abnormal vascular structures in the mediastinum or lung periphery rupture into the pleural space; examples include hemothorax associated with arteriovenous malformation, pleural endometriosis,[45] and thoracic aortic aneurysm. Rare causes of nontraumatic hemothorax include pleural metastasis and iatrogenic or disease-related coagulopathy.[46]

Diagnosis

When hemothorax is suspected, the hematocrit of the pleural liquid should be measured. It is important to remember that the pleural liquid may appear bloody even when its hematocrit is less than 1%. However, in true hemothorax, the pleural liquid hematocrit exceeds 50% of the peripheral blood hematocrit. Hemothorax, even if it is sterile, may be a cause of transient fever.

Treatment

In a large or rapidly accumulating hemothorax, blood should be promptly drained from the pleural space with a wide-bore chest tube. If rapid bleeding (100 to 200 ml/hr) continues, a thoracoscopy[47] or thoracotomy will be necessary. After bleeding has stopped, intrapleural fibrinolytic therapy to lyse clots not removed by the chest tube may obviate thoracotomy.[48] Potential adverse consequences of undrained pleural blood include empyema and fibrothorax. Empyema may develop because blood provides a rich culture medium for growth of bacteria. Fibrothorax is a late sequela of moderate or large hemothoraces and results from organization of clotted blood into a dense fibrous peel surrounding the lung. A small, self-limited hemothorax associated with minor trauma such as a rib fracture will resolve without drainage or surgery.

CHYLOTHORAX AND PSEUDOCHYLOTHORAX

Chyle is the lipid-rich liquid transported from small intestinal villi—the so called lacteals—to systemic veins in the thorax via the thoracic duct. Disruption or compression of the thoracic duct may lead to leakage of chyle first into the posterior mediastinum and then into the pleural space. Alternatively, an atretic or obstructed thoracic duct may cause reversal of lymph flow through dilated collateral channels. Rupture of these lymphatic channels may also produce chylothorax.

The thoracic duct follows a variable course through the mediastinum. Commonly, it crosses the diaphragm to the right of the vertebral column, entering the chest cavity through the aortic hiatus. It then crosses to the left of the vertebral column between the seventh and fifth thoracic vertebrae, arches above the level of the clavicle, and enters the systemic venous circulation in the region of the left jugular and subclavian veins. Depending on the particular anatomy of a given patient and the level at which the thoracic duct is disrupted, chylous effusions may be left sided, right sided, or, occasionally, bilateral.

Chylothorax

Etiology Various conditions can cause chylothorax. Mediastinal tumors are the most common cause, with lymphomas exceeding metastatic carcinomas in frequency.[49] Trauma is the other major cause of chylothorax in adults. In some cases, major chest trauma has been sustained. In other cases, seemingly minor actions, such as hyperextension of the back, are the only identifiable antecedent events. Thoracic and cardiovascular surgery occasionally results in transection of the thoracic duct and the subsequent development of chylothorax. In addition, chylothorax frequently occurs as a complication of the rare disease lymphangiomyomatosis.[50] Other conditions producing mediastinal lymphatic disruption or obstruction may cause chylothorax. Such conditions include congenital lymphangiectasis, mediastinal irradiation, fibrosing mediastinitis, granulomatous mediastinitis, left subclavian vein thrombosis, and esophageal sclerotherapy.

Diagnosis Chylothorax is usually not suspected until thoracentesis reveals a milky-white pleural liquid. Identification of chylomicrons by lipoprotein analysis establishes the diagnosis of chylothorax and distinguishes it from other causes of an opalescent pleural liquid. However, several less expensive screening tests also may be useful. For example, a chylous effusion remains opaque after centrifugation, whereas the supernatant in empyema is clear. Furthermore, if a chylous effusion sample is allowed to remain undisturbed for 12 to 24 hours, a creamy layer of chylomicrons floats to the top, and the addition of a few drops of ethyl ether rapidly causes the liquid to clear. In most cases of chylothorax, the triglyceride concentration exceeds 110 mg/dl; exceptions usually are limited to patients in whom feedings have been withheld, such as postoperative patients.[49] A CT scan of the chest is indicated in most patients with chylothorax to de-

Table 2 Classification and Treatment of Parapneumonic Effusions and Empyema

Type of Effusion	*Radiographic and Laboratory Findings*	*Treatment*
Typical parapneumonic pleural effusion	> 10 mm maximum thickness on lateral decubitus chest radiograph; glucose level and pH are normal; Gram stain and culture are negative	Antibiotics alone
Complicated parapneumonic pleural effusion	May be nonloculated or multiloculated; no obvious pus; glucose level and pH are low and/or Gram stain and culture are positive	Tube thoracostomy plus antibiotics; if loculated, use intrapleural fibrinolytics; surgery rarely required
Empyema	Free-flowing single loculus or multiloculated; obvious pus present	Tube thoracostomy plus antibiotics; if loculated, use intrapleural fibrinolytics; may require thoracoscopy or decortication

termine if the etiology is carcinoma, and pleural liquid cytology in these patients occasionally yields malignant cells.

Chylous effusions elicit little pleural inflammation and are only very rarely complicated by empyema because of the bacteriostatic properties of chyle. The major consequence of chylous effusions is the rapid and recurrent accumulation of liquid in the pleural space. Normally, the thoracic duct transports chyle at a rate of 1.5 to 2.5 L/day. In patients with chylothorax, much or all of this liquid may enter the pleural space.

Treatment Repeated thoracenteses or chest tube drainage can avert lung compression caused by pleural liquid buildup. However, these procedures may result in large losses of protein, fat, and circulating lymphocytes, rapidly leading to malnutrition and possible immunosuppression.

Definitive treatment of chylothorax varies with the specific etiology. Radiation therapy, with or without chemotherapy, is frequently effective for patients with mediastinal malignant disease, especially lymphomas. Thoracotomy, with oversewing of the thoracic duct leak or ligation of the duct below the leak, is curative in cases of accidental or intraoperative trauma. Pleurodesis [*see* Hydrothorax Caused by Malignant Disease, *above*] may prevent reaccumulation of chyle in patients with unresponsive malignant disease or in other poor operative candidates.

Pseudochylothorax

Occasionally, in patients with long-standing pleural effusions, cholesterol crystals collect in the pleural liquid, causing a milky-white appearance that is indistinguishable from chylothorax on gross inspection.[51] Such pseudochylous, or chyliform, effusions can usually be readily differentiated from true chylothorax on the basis of the clinical setting. Pseudochylous effusions typically occur as a complication of rheumatoid or tuberculous effusions that have been present for several years and are associated with extensive pleural thickening. Chyliform effusions have been reported with paragonimiasis. These effusions should be drained and the underlying process treated.

Parapneumonic Effusions and Empyema

Thoracic empyema most often results from contiguous spread of infection from an underlying region of pneumonia and occasionally from a lung abscess or bronchiectasia. Bacteria are the most common pathogens, although any microorganism capable of causing pneumonia may also cause empyema. In a report from an inner-city municipal hospital, as many as 7% of patients admitted with acute pneumonia had empyema on presentation.[52]

The pleural space may also become infected as a result of seeding of pathogens after thoracic surgery, penetrating trauma, thoracentesis, or tube thoracostomy. Direct spread of infection from a subdiaphragmatic site, hematogenous spread of infection during septicemia, and embolic spread during septic thrombophlebitis are other mechanisms by which the pleural space may become infected. Finally, empyema may occur as a complication of spontaneous pneumothorax, mediastinitis, or esophageal rupture.

Etiology Microorganisms causing empyema have changed considerably during the past 50 years, largely because of the introduction and increasingly widespread use of potent broad-spectrum antibiotics. In the 1930s and 1940s, *Streptococcus pneumoniae* (pneumococcus) and hemolytic streptococci were the pathogens most frequently isolated from empyemas. In the 1950s and 1960s, *Staphylococcus aureus* and gram-negative bacilli (e.g., *Escherichia coli, Haemophilus influenzae, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*) became the predominant pathogens found in empyemas. Some series, employing modern techniques for culturing anaerobic bacteria, have found a preponderance of anaerobes, either alone or in combination with aerobic bacteria.[53] Fungi have been isolated from empyemas more frequently in recent years, particularly in hospitalized patients with significant comorbidities who are immunocompromised.[54]

Diagnosis The most common presenting symptoms of empyema are fever, chest pain, cough, and dyspnea. These symptoms, however, are not specific enough to distinguish patients who have pneumonia and empyema from those who have pneumonia alone. Patients with anaerobic empyema are more likely to have an indolent presentation, characterized by low-grade fever, anorexia, weight loss, or anemia. Between 10% and 15% of patients with empyema do not have fever or an elevated white cell count.

In patients with pneumonia and pleural effusion, it is important to determine whether the effusion is a typical parapneumonic effusion (formerly known as a sympathetic effusion), a complicated parapneumonic effusion, or an empyema. These three types of effusion can be distinguished on the basis of the radiographic appearance and characteristics of the pleural liquid obtained at thoracentesis [*see Table 2*].

Treatment In general, very small pleural effusions (maximum thickness < 10 mm as measured on lateral decubitus chest radiograph) in the setting of acute pneumonia will resolve with

appropriate antibiotic treatment of the pneumonia and do not require further investigation by thoracentesis. However, most larger effusions require thoracentesis. Loculations on radiographic studies, low pleural liquid pH and glucose concentrations, high LDH, or positive Gram stain and cultures indicate the presence of a complicated parapneumonic effusion (in cases in which there is no obvious presence of pus) or empyema (in cases in which there is obvious presence of pus). A pleural liquid pH of 7.2 or higher favors the diagnosis of typical parapneumonic effusion. Pleural liquid pH values between 7.0 and 7.2 are considered to be indeterminate (borderline complicated pleural effusion) and necessitate repeated thoracenteses, often from different sites, to determine whether a parapneumonic effusion is typical or complicated.

Systemic antibiotic therapy and prompt drainage of the pleural space are key.[55] In general, antibiotics penetrate the pleural space well and should be given systemically rather than intrapleurally. The choice of antibiotics should be guided by the results of a Gram stain and culture of pleural samples, blood samples, sputum samples, or a combination of these. For anaerobic empyema, clindamycin is the drug of choice because as many as 10% to 15% of the anaerobic isolates are penicillin-resistant *Bacteroides fragilis*.

Pleural drainage usually requires prompt placement of a chest tube because complicated parapneumonic effusions and empyema liquid reaccumulate rapidly after thoracentesis. In addition, continuous drainage is required to sterilize the pleural space, and drainage prevents the formation of loculi. In some patients with complicated parapneumonic effusions and empyema that do not resolve radiographically after placement of a chest tube, intrapleural streptokinase or urokinase[56] may allow adequate drainage and obviate the use of multiple chest tubes or surgical drainage, although the evidence for this approach is not strong.[57] Urokinase may be preferred over streptokinase because urokinase is associated with less frequent febrile reactions.[58] Use of intrapleural fibrinolytic agents may also allow small-bore pigtail catheters to be placed into loculi with CT or fluoroscopic guidance.[59] This approach may be unsuccessful with thick pleura, multiple loculi, or both.[60] Early thoracoscopic therapy may be more cost-effective than attempts at drainage and the use of fibrinolytic agents in such cases.[61]

With appropriate treatment, most patients will become afebrile within 4 days, and peripheral white cell counts will return to normal within a week. In a minority of cases, adequate pleural drainage cannot be achieved, and fever and leukocytosis persist; in such cases, a surgical procedure, either video-assisted thoracoscopy (early stage) or thoracotomy (late stage), is usually required.[62] Stripping the adherent inflammatory peel from the pleural surfaces and removing the purulent exudate from the pleural cavity (i.e., decortication and empyemectomy) is a demanding surgical procedure. In elderly or severely debilitated patients, a more conservative surgical procedure may be used in which a partial rib resection is performed to create an open pleurocutaneous tract.[63] The chronic empyema cavity that is formed can then be managed in the same way as any other chronic open wound and eventually may close spontaneously or can be closed by reconstructive surgery.

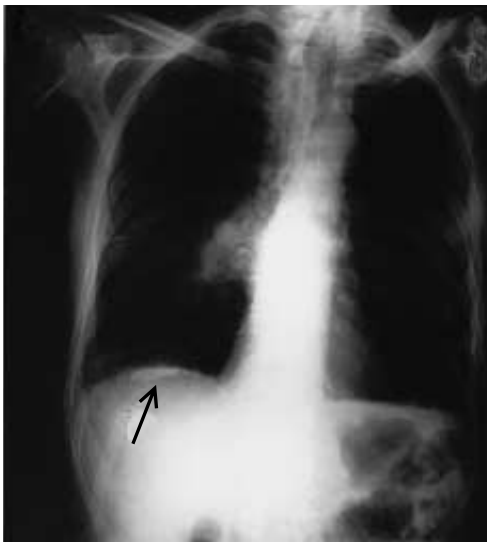
If left untreated, empyema can lead to septic shock. Other complications of untreated empyema include localized dissection of infection and consequent rupture through the skin (empyema necessitatis) or into the bronchial tree (bronchopleural fistula).

Pleural Plaques, Diffuse Pleural Thickening, and Pleural Calcification

PLEURAL PLAQUES

Pleural plaques are asymptomatic collections of collagenous connective tissue that form on the parietal pleura. They usually occur as a consequence of heavy exposure to asbestos fibers. In rare cases, plaques may form in response to inhalation of inorganic fibers other than asbestos, or they may arise in association with hyaloserositis or other conditions. Pleural plaques are discrete lesions that are covered by a layer of normal mesothelium and are clearly demarcated from normal surrounding pleura. They vary in diameter from a few millimeters to several centimeters and have an average thickness of approximately 0.5 cm. They typically form on the lateral and posterior pleural surfaces and the central (aponeurotic) portion of the diaphragm, sparing both the costophrenic sulci and the upper third of the thorax. They are often difficult to identify on chest radiograph unless their orientation is tangential to the x-ray beam, and only a small percentage of noncalcified pleural plaques identified at surgery

a



b

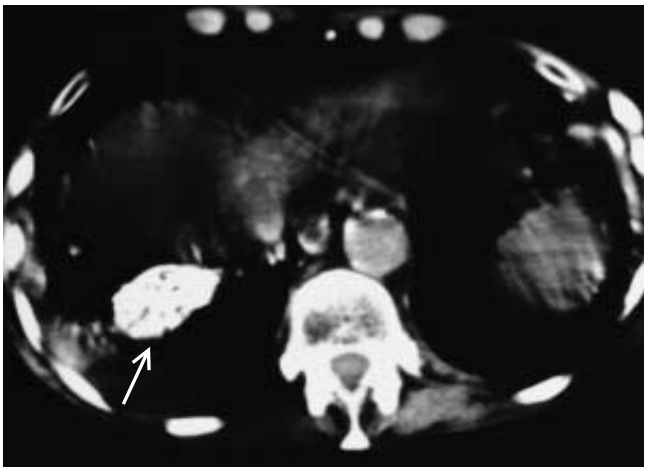


Figure 7 **(*a*) Dense, white linear opacity along the left diaphragm (arrow) represents calcification of the parietal pleura in a patient with long-standing asbestos exposure. (*b*) CT scan shows area of dense calcification along the central dome of the diaphragm (arrow).**

Figure 8 **Radiograph reveals a so-called trapped lung, which was caused by marked thickening of the visceral pleura from a chronic empyema. Despite the application of a highly negative pressure to the pleural space, the right lung does not expand. A pyopneumothorax is present in the right thorax because evacuated pus has been replaced by air. There is no bronchopleural fistula (air leak from the lung). Obstruction of the mainstem bronchus may also cause a trapped lung.**

or postmortem examination are recognized radiographically. CT scanning is more sensitive than plain films of the chest for detection of plaques. After several years, pleural plaques calcify, causing a radiographically distinct image [*see Figure 7*].

Pleural plaques develop slowly over a period of many years, and they usually do not become apparent until 20 years after initial asbestos exposure. After 40 years, as many as 50% of persons who had occupational exposure to asbestos have pleural plaques. These hyaline plaques do not degenerate into neoplastic disease, but minimal changes in lung function may be associated with their presence.[64] Their main significance is as a marker of probable asbestos exposure.

Other processes that resemble plaques include metastases, callus formation surrounding rib fractures, and normal areas of muscle insertion or fat accumulation. The distinction can usually be made easily by overpenetrated oblique views on radiograph or, if necessary, by CT scanning.

PLEURAL THICKENING

Pleural thickening develops when pleural inflammation of any cause heals with the formation of fibrous tissue involving the visceral or parietal pleural surfaces. The costophrenic angle is most frequently involved, causing blunting of the normal recess. Localized pleural thickening over the apex of the lung—the so-called apical pleural cap—usually involves fibrous scarring of the apical lung merging into the adjacent visceral pleura. Although apical pleural thickening was once thought to be indicative of granulomatous disease from tuberculosis, more recent studies have documented the absence of any correlation with tuberculosis. The etiology of this asymptomatic finding is unknown.

Pleural thickening may be bilateral or unilateral. Extensive bilateral pleural thickening, extending along the lateral margins of the chest and even to the apex of the lung, is frequently the result of exposure to inorganic fibers—most often asbestos and, occasionally, talc. Other causes of bilateral pleural thickening include uremia and collagen vascular diseases, especially SLE and rheumatoid arthritis. Diffuse unilateral pleural thickening usually results from one of three causes: hemothorax, bacterial empyema, or tuberculous pleurisy.

Diffuse pleural thickening may be sufficiently dense to entrap the underlying lung, preventing its full expansion and impairing gas exchange [*see Figure 8*].[65] This condition is referred to as fibrothorax. During the months immediately after hemothorax or empyema, inflammatory pleural thickening may gradually resorb. However, once an organized fibrous peel has formed, surgical decortication is the only available therapy. If the underlying lung tissue is relatively normal, resection of a thick pleural peel may result in significant improvement in ventilatory function.

In rare cases, localized or diffuse pleural thickening can entrap a small region of lung, producing a masslike lesion termed rounded atelectasis. It can be difficult to differentiate such lesions from other, more serious mass lesions (e.g., neoplasm).[66]

PLEURAL CALCIFICATION

Diffuse, sheetlike calcification may develop in patients with hemothorax, bacterial empyema, or tuberculous pleurisy. Unlike the pattern of calcification that is observed in asbestos-related pleural plaques, calcium deposition after these conditions always takes place along the visceral pleura, thereby outlining the inner margin of the pleural thickening. In addition, calcification is generally found at the level of the midthorax, sparing the diaphragmatic pleural surface.

Pneumothorax

ETIOLOGY

Pneumothorax, the presence of gas within the pleural space, indicates that disruption of the visceral or parietal pleura has occurred.[67] The gas that enters the pleural space may come from various sources. For example, in a penetrating injury involving the chest wall and parietal pleura, the gas enters from the outside environment. Alternatively, the gas may come from a gas-filled gastrointestinal structure; this situation might arise as a result of a ruptured esophagus, or it could arise from a ruptured intra-abdominal viscus and subsequent escape of gas across the diaphragm from a pneumoperitoneum. Most commonly, the source of the gas is the lung—after alveolar or tracheobronchial injury, after blunt or penetrating trauma, or as a complication of invasive diagnostic and therapeutic procedures, such as thoracentesis, attempted percutaneous cannulation of a central vein, acupuncture, or intercostal nerve block.

Pneumothorax caused by disruption of the visceral pleura may also result from focal pulmonary processes. Focal destructive processes may involve the visceral pleura as a primary site or may extend to the pleura from adjacent lung tissue. Examples of focal pulmonary processes that cause pneumothorax include bronchogenic carcinoma, rheumatoid lung nodule, thoracic endometriosis,[45] necrotizing pneumonia, and pulmonary infarct. In the past, tuberculosis was frequently implicated as a cause of pneumothorax. *Pneumocystis carinii* pneumonia, a complication of AIDS, has become a common cause of pneumothorax, particularly in patients receiving aerosolized pentamidine, those who smoke cigarettes, and those with pneumatoceles seen on chest radiograph or CT scan.[68]

Diffuse diseases of the lung parenchyma can also cause pneumothorax. Such diseases can greatly distort the lung architecture, resulting in an uneven distribution of ventilation within the lung. In this setting, localized alveolar overdistention, along with weakened alveolar walls, leads to an increased incidence of associated pneumothorax. The most common of these diffuse processes are the obstructive lung diseases, specifically emphysema, asthma, and cystic fibrosis.[69] Rarer conditions that also carry an increased risk of pneumothorax include pulmonary lymphangiomyomatosis,[50] tuberous sclerosis, eosinophilic granuloma, scleroderma, and congenital disorders of connective tissue. In some cases, the visceral pleura remains intact but alveolar gas gains entry to the pleural space via the mediastinum. When perivascular alveoli rupture, alveolar gas can dissect centripetally along the bronchovascular interstitium to the mediastinum, entering the pleural space through the mediastinal parietal pleura.

CLASSIFICATION OF PNEUMOTHORAX

A commonly used classification of pneumothorax recognizes traumatic pneumothorax and iatrogenic pneumothorax as distinct clinical entities and lumps all other causes of pneumothorax under the somewhat misleading label of spontaneous pneumothorax. When spontaneous pneumothorax occurs in patients with underlying pleural or parenchymal disease, it is called secondary spontaneous pneumothorax. When no underlying lung disease is evident, it is called idiopathic spontaneous pneumothorax. Although patients with idiopathic spontaneous pneumothorax are otherwise healthy, most have subpleural apical blebs, frequently associated with more diffuse centrilobular emphysema detectable by CT scan[70]; during surgery, the blebs are often found to have ruptured into the pleural space. These abnormalities may have a genetic etiology.[71] Secondary spontaneous pneumothorax is a more serious problem than idiopathic spontaneous pneumothorax because patients with secondary spontaneous pneumothorax typically have impaired lung function.[67]

EPIDEMIOLOGY

Secondary Spontaneous Pneumothorax

The incidence of secondary spontaneous pneumothorax depends on the underlying disease process. The incidence of pneumothorax in patients with chronic obstructive lung disease is approximately 26 per 100,000 per year, and the incidence is directly related to the severity of obstruction.[67] Pneumothorax will develop in 5% to 8% of cystic fibrosis patients at some point in their lifetime; however, it occurs in 16% to 20% of cystic fibrosis patients older than 18 years. Pneumothorax occurs in 2% to 6% of HIV patients and is almost always associated with *P. carinii* pneumonia.[67] Twenty-five percent of patients with eosinophilic granuloma and 80% of patients with pulmonary lymphangiomyomatosis have pneumothorax at some point in their disease course, and pneumothorax can be a presenting manifestation in both diseases.[67]

For most underlying lung diseases, the rate of recurrent pneumothorax is similar to that of idiopathic spontaneous pneumothorax (39% to 47%),[67] although patients with cystic fibrosis have a much higher recurrence rate (68% to 90%).[69]

Idiopathic Spontaneous Pneumothorax

Idiopathic spontaneous pneumothorax has an incidence of approximately 4.3 cases per 100,000 patient-years. The peak incidence is in persons between 20 and 30 years of age, and the male-to-female ratio is approximately 5:1. Patients often have a tall, thin stature[72] and very frequently are cigarette smokers. The precise mechanism whereby male sex, asthenic habitus, and cigarette smoking predispose to apical pleural bleb formation or rupture is unknown. One study detected anomalies of the bronchial tree in the majority of patients with spontaneous pneumothorax, suggesting associated congenital abnormalities of lung structure.[73] How these anomalies may relate to the occurrence of pneumothorax is unclear. Common misconceptions are that strenuous physical activity is frequently a trigger for the development of pneumothorax and that patients are at increased risk during airplane travel. In fact, most studies have found that the onset of symptoms of pneumothorax usually occurs at rest or during light activity, and a study of pneumothoraces among pilots in the United States Air Force found that very few episodes occurred during flight.[74]

DIAGNOSIS

The most common symptoms of pneumothorax are chest pain and dyspnea. The pain may be a dramatic, severe, stabbing unilateral chest pain with a sudden, explosive onset, sometimes radiating to the ipsilateral shoulder or scapular area. In other cases, the discomfort may be more modest and more easily tolerated. Often, patients will recall previous transient episodes of pain that were similar to, although milder in degree or shorter in duration than, the one that finally caused them to seek medical attention. Dyspnea develops in most patients. The dyspnea is more severe when the pneumothorax is large and when there is significant underlying lung disease (i.e., secondary spontaneous pneumothorax).

Secondary Spontaneous Pneumothorax

In a patient with secondary spontaneous pneumothorax associated with underlying emphysema, the diagnosis is particularly difficult to make on the basis of physical findings. Decreased lung elastic recoil and residual hyperinflation keep the lung from fully collapsing and limit changes in the size of the thoracic cage. In addition, in patients with emphysema, physical findings such as hyperresonance and diminished breath sounds may be found over the contralateral lung. In a patient with chronic airflow obstruction, the sudden onset of chest pain and worsened dyspnea should raise the suspicion of pneumothorax. Confirmation of the diagnosis of pneumothorax usually requires a chest radiograph.

Idiopathic Spontaneous Pneumothorax

Characteristic physical findings on the involved side include expansion of the hemithorax (caused by release of the ipsilateral chest wall from the recoil forces of the lung), hyperresonance, diminished fremitus, diminished transmission of voice sounds, and distant or absent breath sounds.

As gas collects in the pleural space, the lung recoils from the chest wall toward the hilum. The presence of a pneumothorax can be identified on a chest radiograph by visualization of a thin (=1 mm) linear shadow made by the visceral pleura as it passes along a plane tangential to the x-ray beam. This linear shadow, marking the outer rim of the lung, follows the contour of the inner aspect of the chest wall, and no lung markings (i.e., bronchovascular shadows) can be seen peripheral to it. In cases in which the pneumothorax is small and gas collects over the apex of the lung, it may be difficult to distinguish the visceral pleural line from superimposed rib margins. When the chest radiograph

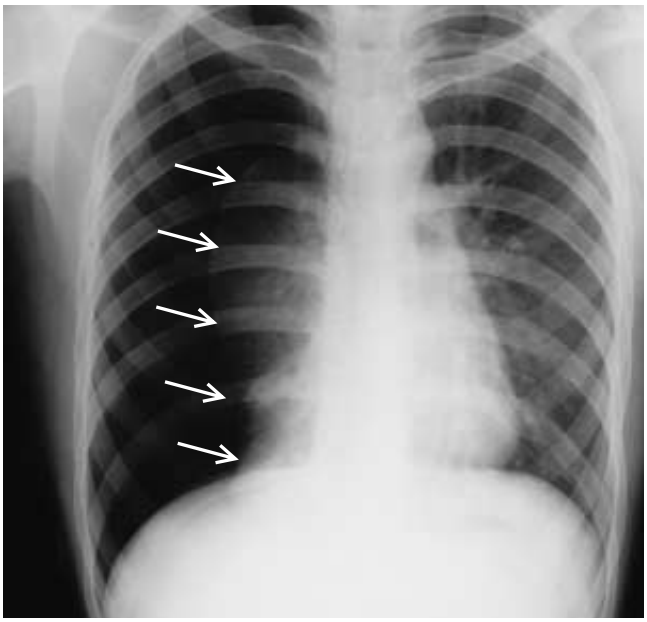

Figure 9 **This chest radiograph of a patient with pneumothorax demonstrates virtually complete collapse of the right lung. There has been a slight shift of the mediastinum toward the contralateral side. The visceral pleura (arrows) can be clearly identified because gas is present on both sides.**

is taken with the patient in the supine position, a pneumothorax will collect along the costophrenic sulcus rather than along the apex of the lung. This so-called deep sulcus sign may be useful in identifying occult pneumothorax in hypotensive patients in whom upright chest radiographs are inadvisable. Chest radiographs taken during full expiration have not been shown to enhance the detection of pneumothorax.[75] Pitfalls in the radiographic diagnosis of pneumothorax include confusion regarding two other causes of curvilinear shadows in the chest: (1) extrathoracic skin folds and (2) intrapulmonic cysts or bullae.

It is difficult to accurately estimate the size of a pneumothorax relative to the size of the hemithorax by casual inspection of the chest radiograph. As a rough indicator, a collection of gas around the lung that has an average thickness of 1 in. represents a 30% pneumothorax. When collapse of the lung is complete (100% pneumothorax), the lung forms a fist-sized opacity near the hilum, and the mediastinum may shift slightly toward the contralateral lung; the diagnosis is obvious on x-ray [*see Figure 9*].

A small pleural effusion is commonly present in pneumothorax. It is detected on radiograph by blunting of the costophrenic sulcus. The pleural liquid is usually bloody. The effusion is probably formed as a result of the rupture of small blood vessels within pleural adhesions.

TREATMENT

Secondary Spontaneous Pneumothorax

Because initial or recurrent episodes of secondary spontaneous pneumothorax can be life threatening, aggressive treatment is required.[67,76] Patients should be hospitalized and a chest tube placed for drainage; observation and simple aspiration are not adequate treatment. The methods for preventing recurrence of secondary spontaneous pneumothorax are the same as those of idiopathic spontaneous pneumothorax (e.g., thoracotomy, video-assisted thoracotomy, pleurodesis) (see below), although many experts feel that application of such methods should be utilized on the first occurrence of secondary spontaneous pneumothorax.[76]

Idiopathic Spontaneous Pneumothorax

Treatment of idiopathic spontaneous pneumothorax is directed in part at allowing the collapsed lung to expand fully again and in part at preventing recurrences.[67] In mildly symptomatic patients with moderate pneumothorax, simple aspiration of the pneumothorax may be successful in 60% to 70% of cases.[77] A patient with a small (15% to 20%) pneumothorax who is asymptomatic or minimally symptomatic can be safely observed, and the pneumothorax can be allowed to resorb spontaneously. Complete resolution of a pneumothorax usually requires approximately 10 days, provided there is no further air leak. Resolution can be accelerated by the administration of supplemental oxygen. Supplemental oxygen lowers the nitrogen content of blood, thereby increasing the pressure gradient for nitrogen that favors transfer of gas from the pleural space into the venous end of the pleural capillaries. Strict bed rest does not hasten resolution and is not necessary. A large pneumothorax in a symptomatic patient should be evacuated promptly with an intercostal small-bore (14 French) or large-bore (28 French or greater) chest tube passed cephalad into the apex of the chest. The air leak from the lung may seal immediately or may persist for 3 to 5 days until the tear in an apical bleb heals. An air leak from the lung that persists for more than 7 days is considered by many physicians to be an indication for surgical intervention; at thoracoscopy or thoracotomy, the blebs can be oversewn or excised by wedge resection and the pleura abraded or pleurodesis performed.

Incidence of recurrence Idiopathic spontaneous pneumothorax often recurs. At least 20% to 30% of patients with idiopathic spontaneous pneumothorax will experience an ipsilateral recurrent pneumothorax within the ensuing 5 years; most recurrences occur within a year after the initial event. According to some reports, the rate of initial recurrence may be as high as 50%. Recurrences are more common in women and taller men and are reduced by smoking cessation.[78] Ninety percent or more of recurrences are ipsilateral, despite the fact that the underlying abnormality (i.e., apical subpleural blebs) is bilateral in more than half the cases.[79] Simultaneous bilateral idiopathic spontaneous pneumothoraces are fortunately infrequent, occurring in approximately 1% of cases; surprisingly, when they do occur, they are rarely fatal. After the first ipsilateral recurrence of a pneumothorax, subsequent recurrences become increasingly likely.

Management of recurrence There is debate regarding the best method of preventing recurrences and the optimal timing for such an intervention.[76] Because half or more of patients with idiopathic spontaneous pneumothorax will never suffer a recurrence, it seems reasonable to withhold preventive treatment until after a recurrence. At that point, the probability of further recurrences is quite high, and the discomfort and inconvenience associated with recurrent pneumothoraces would have become increasingly apparent to the patient. Traditional and definitive treatment for prevention of recurrences involves thoracotomy: apical blebs are oversewn or excised by wedge resection, and adhesions are induced between the lung and chest wall by abrasion of the pleural surface with dry gauze or by partial parietal

pleurectomy. Recurrent pneumothorax occurs after this procedure in 0% to 2% of patients. Video-assisted thoracoscopy has allowed these procedures to be performed without thoracotomy, resulting in less pain and shorter hospital stays.[80] Attempts have also been made to achieve pleurodesis without thoracotomy via a chest tube. This technique is the same as that used for the management of pleural effusions in patients with malignant disease [*see* Hydrothorax Caused by Malignant Disease, *above*]. Recurrence of spontaneous pneumothorax is reduced after doxycycline administration or talc pleurodesis.

TENSION PNEUMOTHORAX

Occasionally, gas enters the pleural space during the inspiratory phase and is prevented from escaping during expiration, presumably because an airway or tissue flap acts as a one-way valve. Under these circumstances, there is a progressive increase in the amount of pleural gas, and the pleural gas is under increased pressure (i.e., tension). This situation is referred to as tension pneumothorax. Tension pneumothorax occurs in only 1% to 2% of the cases of idiopathic spontaneous pneumothorax. However, it is a more common manifestation of the barotrauma that may occur as a complication of positive pressure mechanical ventilation.

Diagnosis

Tension pneumothorax is a medical emergency. Patients are often dyspneic at rest and gasping for breath. Cyanosis and hypotension are common. The diagnosis cannot be established by a plain chest radiograph, although a marked contralateral shift of the mediastinum and depression or inversion of the ipsilateral hemidiaphragm are suggestive.

Treatment

If there is acute distress, immediate action must be taken to remove gas from the pleural space. Introduction of a small-bore plastic catheter together with a needle through an intercostal space may suffice for emergency relief if delay in placing a full-sized chest tube is anticipated. In patients with tension pneumothorax, the gas that is under pressure will rush out of the chest through the open catheter. If a Heimlich flutter valve, which allows one-way passage of gas, is attached to the catheter, a series of coughs or Valsalva maneuvers will allow almost complete evacuation of the remainder of the pneumothorax that is not under tension. Because of the life-threatening nature of tension pneumothorax, a procedure to prevent recurrence should be undertaken after the first such event in cases involving idiopathic spontaneous pneumothorax.

Hilar and Mediastinal Disorders

NORMAL ANATOMY OF THE HILA AND MEDIASTINUM

The mediastinum is the intrathoracic compartment situated between the two lungs. It is bordered anteriorly by the sternum, posteriorly by the vertebral column, and laterally by parietal pleura. It extends from the thoracic inlet to the superior surface of the diaphragm. Several important structures are contained within or pass through the mediastinum, including the heart and great vessels, the esophagus, the trachea and mainstem bronchi, lymphatic vessels and nodes, and nerves.

It is convenient to divide the mediastinum into three parts on the basis of imaginary coronal sections [*see Figure 10*]. The anterior mediastinum (i.e., the portion anterior and superior to the anterior surface of the pericardium) contains the thymus, lymph nodes, and mesenchymal tissue. The middle mediastinum consists of the heart and pericardium, the major vessels as they enter and leave the heart, the trachea and main bronchi, lymph nodes, and portions of the phrenic and vagus nerves. Between the posterior aspect of the pericardium and the vertebral column lies the posterior mediastinum, which contains the descending aorta, the esophagus, the thoracic duct, lymph nodes, and a portion of the vagus nerve. The sympathetic nerve chain, which runs in the costovertebral gutter, is conventionally included in the posterior mediastinum.

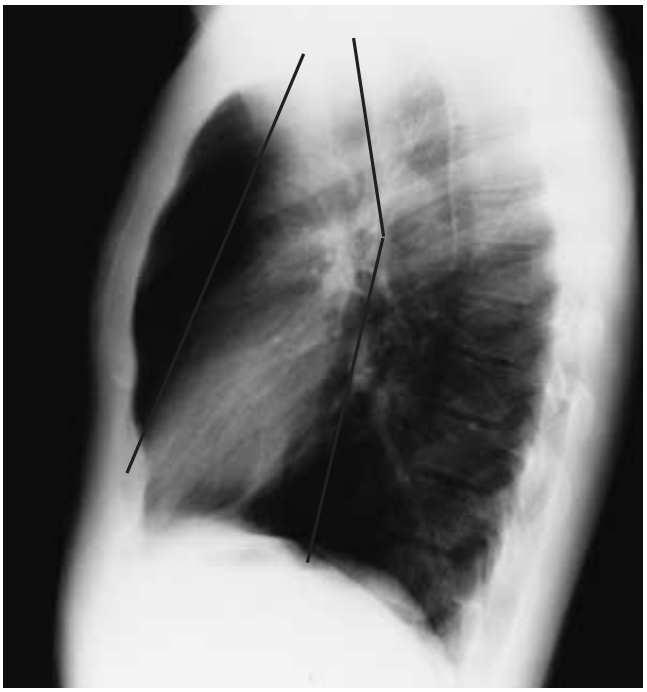

Figure 10 **Lines drawn on this normal lateral chest x-ray mark the theoretical division of the mediastinum into anterior, middle, and posterior compartments. Focal abnormalities of the mediastinum can be identified as occurring predominantly in one compartment or another, facilitating differential diagnosis.**

As blood vessels, airways, and nerves leave the mediastinum and pass into the lungs, they form the pulmonary hila. On chest radiographs, the hilar shadows are composed primarily of branches of the pulmonary arteries. The right pulmonary artery bifurcates just before entering the hilum as the truncus anterior artery (superior branch) and the right interlobar artery (inferior branch). The left pulmonary artery divides within the hilum into superior branches and the larger left interlobar artery. In 97% of normal persons, the left hilum is positioned superior and posterior to the right hilum; displacement from this normal position may be caused by mass lesions or lobar atelectasis. Central bronchopulmonary lymph nodes that are important for drainage of the lung parenchyma are situated within the pulmonary hila along the bronchial tree, especially within bifurcations.

HILAR ENLARGEMENT

The most common causes of enlargement of the hilar shadows on chest radiographs are vascular engorgement and adenopathy.

Enlargement Caused by Vascular Engorgement

Vascular engorgement may result from increased blood flow in the pulmonary circulation, as in atrial septal defect with left-to-right intracardiac shunt, or from pulmonary arterial hypertension of any cause. The caliber of the pulmonary arteries can be assessed by measurement of the transverse diameter of the right interlobar artery on a posteroanterior radiograph; in normal persons, this value is usually less than 16 mm. In rare cases, localized aneurysmal dilatation of the pulmonary arteries occurs; this condition is referred to as the Hughes-Stovin syndrome.

On plain chest radiographs, it is sometimes difficult to distinguish vascular from nodal enlargement of the hila. Pulmonary angiography was formerly needed to make this distinction. Currently, however, contrast-enhanced CT scanning of the chest can effectively identify vascular structures in the hila without the need for invasive procedures. Occasionally, there is a strong contraindication to the use of intravenous contrast agents in some patients; in such cases, magnetic resonance imaging, which does not require the use of contrast agents, can be used.

Enlargement Caused by Adenopathy

Hilar lymph node enlargement may be unilateral or bilateral. Unilateral lymphadenopathy may accompany virtually any pneumonia, although it is most characteristic of granulomatous infections (e.g., tuberculosis and atypical mycobacteriosis, histoplasmosis, and coccidioidomycosis) and certain atypical pneumonias (e.g., *Mycoplasma* infections, tularemia, pertussis, and psittacosis). Neoplastic enlargement of hilar lymph nodes usually results from spread of bronchogenic carcinoma; extrathoracic cancers that metastasize to the hilar and mediastinal lymph nodes include cancers of renal cell origin, which are implicated especially often, and cancers of the breast and GI tract. Hodgkin disease and other lymphomas may also cause unilateral or asymmetrical hilar adenopathy. Finally, about 1% to 3% of patients with sarcoidosis have unilateral hilar adenopathy.

A common diagnostic challenge is the evaluation of a patient with bilateral hilar adenopathy. This condition is often found in association with mediastinal adenopathy and sometimes in association with parenchymal infiltrates. Nonspecific symptoms of cough, chest pain, dyspnea, or malaise may have prompted the chest radiograph, or bilateral hilar adenopathy may have been detected incidentally on a chest radiograph obtained for unrelated reasons. The most common etiology, especially in patients between 20 and 40 years of age, is sarcoidosis. The differential diagnosis of bilateral hilar adenopathy includes the following: (1) lymphoma, which is usually accompanied by extrathoracic manifestations, such as systemic symptoms, peripheral adenopathy, and anemia; (2) metastatic cancer, in which the primary malignant disease is most often known; (3) chronic granulomatous infections, such as tuberculosis or histoplasmosis, in which the adenopathy is more commonly unilateral; and (4) berylliosis, which can precisely mimic sarcoidosis but which can be readily diagnosed with a careful occupational history.

In a retrospective analysis of 100 cases of bilateral hilar adenopathy not caused by infection, it was found that patients who were asymptomatic and had a normal physical examination or those who had erythema nodosum or uveitis as the only manifestation of their disease invariably had sarcoidosis. On the other hand, it was found that patients who were symptomatic or patients with other abnormal physical findings (e.g., peripheral adenopathy, hepatomegaly, or splenomegaly) in some cases had sarcoidosis and in other cases had neoplastic node involvement.

The approach to diagnosis in patients with bilateral hilar adenopathy depends on the relative likelihood of the various diagnostic probabilities, as determined by clinical assessment. Patients strongly suspected of having sarcoidosis may be observed with serial chest radiographs or may undergo transbronchial lung biopsy via the fiberoptic bronchoscope for tissue confirmation (i.e., identification of noncaseating granulomas). In patients with granulomatous infection, CT scanning can indicate the presence of active infection when areas of low attenuation (necrosis), peripheral rim enhancement, and larger nodes are seen, whereas inactive infection is suggested by smaller nodes, homogeneous density, and calcification.[81] When lymphoma is suspected, lymph node biopsy by mediastinoscopy should provide diagnostic material. In patients suspected of having carcinoma of the lung, an increase in the uptake of fluorodeoxyglucose by the thoracic lymph nodes, as shown through use of positron emission tomography, indicates high risk of malignancy.[82] The definitive diagnosis of cancerous lymph nodes can be determined with a high yield by needle aspiration of the hilar mass under fluoroscopic, CT, or transesophageal endosonographic guidance.[83] It should be noted, however, that direct histologic analysis of hilar lymph nodes, which might be necessary in cases of lymphoma in which there is no mediastinal involvement, requires at least a limited anterior thoracotomy to obtain a tissue sample of adequate size.

Enlargement Caused by Calcified Lymph Nodes

Calcified hilar lymph nodes most often indicate previous granulomatous infection, especially tuberculosis or histoplasmosis. Hilar and mediastinal lymph node calcification in patients with silicosis may appear in a highly characteristic pattern referred to as eggshell calcification, in which calcium outlines only the perimeter of the lymph nodes. Sarcoidal lymph nodes rarely become calcified.

ACUTE MEDIASTINITIS

Acute bacterial mediastinitis usually occurs as the consequence of esophageal perforation and the subsequent release of acidic gastric juices, often along with anaerobic bacteria, into the mediastinum. Rupture of the lower esophagus from violent vomiting is referred to as Boerhaave syndrome; free gas in the mediastinum (i.e., pneumomediastinum) and pleural effusion or pneumothorax (which is usually left sided) are common manifestations of this syndrome. Esophageal rupture may also occur as a complication of foreign-body ingestion, esophageal carcinoma, penetrating or blunt chest trauma, and medical procedures that dilate the esophagus. Occasionally, infection spreads to the mediastinum from adjacent sites; empyema, lung abscess, pericarditis, and retropharyngeal abscess[84] may all be complicated by acute mediastinitis. Mediastinitis can also be a complication of sternotomy for cardiac or thoracic surgery.[85] Finally, a mediastinal bronchogenic cyst may become infected and discharge its contents into the mediastinum.

Patients who have acute mediastinitis are usually acutely and severely ill. Symptoms of the disorder include fever, dysphagia, and a lancinating chest pain. The chest radiograph may reveal, in addition to mediastinal widening, such abnormalities as the presence of pneumomediastinum and pleural effusions.

Treatment consists of the administration of broad-spectrum antibiotics, including antibiotics that are effective against anaerobic bacteria, because the infections are usually polymicrobial.[86] In addition, open surgical drainage is required in most cases.[87] Per-

cutaneous catheter drainage may be successful in some cases of limited esophageal leakage.

MEDIASTINAL WIDENING AND MASS LESIONS

A great diversity of benign and malignant lesions may cause the mediastinum to have an abnormal appearance on the chest radiograph. Occasionally, a specific set of findings may prompt a search for a mediastinal lesion. For example, the muscle weakness of myasthenia gravis may prompt a search for associated thymomas. Alternatively, the constellation of abnormalities suggesting the superior vena cava syndrome (e.g., headaches, jugular venous distention, engorgement of the head and neck, and a prominent collateral venous pattern across the upper thorax) may prompt a search for an obstructing lesion [*see 12:VIII Lung Cancer and 12:XII Oncologic Emergencies*]. In some patients, the mediastinal disorder induces nonspecific symptoms referable to the thorax, such as cough, dyspnea, chest pain or pressure, hemoptysis, dysphagia, hoarseness, or wheezing. Most often, however, diagnostic evaluation is prompted by an asymptomatic radiographic finding.

The differential diagnosis of abnormal radiographic opacities within the mediastinum includes benign and malignant neoplasms, cysts, vascular abnormalities, ectopic thyroid tissue, granulomatous diseases, and several other disorders.[88] It is useful to distinguish abnormalities that cause diffuse widening of the mediastinum from those in which the abnormality is confined primarily to the anterior, middle, or posterior mediastinum [*see Table 3*]. Selected examples of each category will be presented.

With the use of intravenous contrast agents, CT scanning can distinguish vascular structures, fat density, cysts, and calcifications from soft tissue density. Often, benign mediastinal lesions can be identified with reasonable certainty by the CT image alone; nonneoplastic lesions include those associated with mediastinal lipomatosis, congenital cysts, vascular aneurysms, diaphragmatic hernias, and intrathoracic goiters. In other cases, CT scanning can be used with a high degree of sensitivity and specificity to guide the biopsy of suspected malignant lesions.[89] MRI may provide advantages over CT in cases suspected to be vascular.[90]

Diffuse Mediastinal Widening

Diffuse mediastinal widening may occur acutely or chronically. Acute widening of the mediastinal shadows may result from an acute mediastinitis or from mediastinal hemorrhage. Important causes of chronic mediastinal widening include mediastinal lipomatosis and mediastinal granuloma and fibrosis.

Mediastinal Lipomatosis

Mediastinal lipomatosis is a consistently asymptomatic condition in which excess fat tissue is deposited between and around mediastinal structures; it is found in some patients with Cushing disease, iatrogenic Cushing syndrome, or obesity. The only significance of mediastinal lipomatosis is that it must be distinguished from other, more serious causes of mediastinal widening. CT scanning of the thorax readily establishes the diagnosis by identifying material of fat density deposited diffusely through the mediastinum.

Mediastinal Granuloma and Fibrosis

Mediastinal lymph node involvement is common in patients with chronic granulomatous infections, such as histoplasmosis and tuberculosis. Infrequently, an excessive fibrotic response develops around a caseous focus within lymph nodes. In some cases, fibrosis causes a capsule 2 cm or greater in thickness to form around a caseous focus, giving rise to a mediastinal mass that is usually situated in a subcarinal or right paratracheal location. In other patients, the fibrosis invades or compresses adjacent structures and at times extends diffusely through the mediastinum. The latter condition, called fibrosing mediastinitis, is the most common nonmalignant cause of superior vena cava syndrome.[91] Depending on which structures the fibrosis impinges, patients may also exhibit bronchial obstruction, pulmonary arterial or venous obstruction, or esophageal obstruction.[91]

In some cases of fibrosing mediastinitis, histologic examination of a surgical or postmortem specimen reveals only dense fi-

brosis. In other cases, a small caseous focus of infection can be identified, almost always caused by infection with *Histoplasma capsulatum*.[91] The presumed mechanism in all cases is rupture of caseous material into the mediastinum, leading to an intense inflammatory reaction that heals with fibrosis.

Even when viable fungal organisms can be identified, the therapeutic response to amphotericin B is poor, and corticosteroids are generally ineffective as well. Some studies have suggested that ketoconazole may be helpful.[92] In some patients, surgical extirpation of the fibrotic mass is possible. Endovascular balloon angioplasty and placement of stents have been successful in the management of superior vena cava and pulmonary artery obstructions. In general, progression of the fibrosis is slow, and long-term survival is possible.

Anterior Mediastinal Masses

In addition to lymphomas, common causes of masses found in the anterior mediastinum are thymomas, teratomas, dermoid cysts, and retrosternal goiters.[88]

Thymomas Thymomas may be found in adults of any age. They may arise from epithelial or lymphocytic cell lines. Most thymomas are benign, but some behave as malignant lesions and exhibit local invasion into adjacent structures. Reports of distant metastases are rare. Calcification may be present at the perimeter of or throughout the thymoma, but its presence does not necessarily signify that the lesion is benign. As many as one quarter to one third of patients with thymomas have myasthenia gravis, and some of these patients will experience a remission of symptoms after removal of the tumor. Other rare paraneoplastic syndromes that are associated with thymomas include red cell aplasia, Cushing syndrome, Graves disease, carcinoid syndrome, and hypogammaglobulinemia. Because of their malignant potential, suspected thymomas should be surgically excised in most cases. Other thymic lesions include thymic carcinoma, thymic carcinoid, thymolipoma, and thymic cysts.

Dermoid cysts and teratomas Germ cell tumors are most common in young adults 18 to 25 years of age. They originate from germ cell rests that were deposited in the mediastinum during embryogenesis. Dermoid cysts are usually benign cystic tumors composed of epidermal and dermal tissue; on occasion, hair, bone, or teeth form within these lesions. Teratomas consist of cells from all three embryonic origins (i.e., ectodermal, mesodermal, and endodermal) and may be cystic (usually benign) or solid (usually malignant). As with thymomas, calcification may be present along the periphery of the tumor. A potential complication of dermoid cysts and cystic teratomas is rupture and subsequent discharge of the cyst contents into the mediastinum or tracheobronchial tree. Surgical excision is the treatment of choice. Other germ cell tumors of the mediastinum include seminoma and nonseminomatous malignant tumors.

Goiters Cervical goiters may extend inferiorly into the thorax.[93] On occasion, masses within the mediastinum, usually located anteriorly, that have no palpable cervical connection prove to be intrathoracic goiters. These lesions are usually nodular colloid goiters that arise from the lower pole or isthmus of the thyroid gland and extend down into the chest; occasionally, such lesions prove to be adenomas or malignant tumors.

Most patients with nodular colloid goiters are asymptomatic, but some lesions grow sufficiently large to compress the trachea, causing dyspnea and stridor. Dysphagia, vascular compression, and vocal cord paresis or paralysis are other potential presenting manifestations. Uptake of radiolabeled iodine by a mediastinal mass on thyroid scan is diagnostic, but this is a relatively infrequent finding because most of these lesions are nonfunctioning goiters. Certain characteristic features of the CT image, including anatomic continuity with the cervical thyroid gland and particular patterns of calcification, have proved useful in identifying intrathoracic goiters. Patients with small, asymptomatic intrathoracic goiters can be observed or possibly given suppressive thyroid therapy; however, symptomatic patients require thyroidectomy, which can usually be achieved with a suprasternal incision.

MIDDLE MEDIASTINAL MASSES

Mediastinal bronchogenic cysts usually originate near the main carina of the tracheobronchial tree, but they may extend into any of the three mediastinal compartments.[88] They are lined with respiratory epithelium and contain a milky-white or brown mucoid material. Direct communication with the tracheobronchial tree is rare, although the potential exists for infection within the cyst and subsequent rupture into the airways or mediastinum. Bronchogenic cysts are usually discovered during childhood or early adulthood; in the latter age group, related symptoms are uncommon. Surgical excision is warranted for infected bronchogenic cysts or for cysts communicating with the tracheobronchial tree.

POSTERIOR MEDIASTINAL MASSES

Neurogenic tumors are the most common primary neoplasms of the posterior mediastinum.[88] They are round or oval masses in the paravertebral sulcus. Most patients are asymptomatic, although in some patients, chest or back pain or symptoms of bronchial compression develop. Tumors that arise from the nerve sheath (schwannomas) are usually benign; tumors derived from nerve cells may be benign (ganglioneuromas) or malignant (neuroblastomas or ganglioneuroblastomas). Neurofibromas derive from all nerve elements, including axons, sheath cells, and connective tissue; most are benign. Mediastinal neurofibromas may represent an isolated finding or may be part of generalized neurofibromatosis (von Recklinghausen disease). A rare tumor arising from paraganglionic cells is a mediastinal pheochromocytoma, which may be hormonally active.

Even benign neurogenic tumors may erode into an adjacent rib or cause pleural effusion. Some neurogenic tumors, most commonly neurofibromas, may extend into the spinal canal, causing widening of the intervertebral foramen; as a result, such tumors may assume a dumbbell shape. CT and MRI have for the most part supplanted myelography in the assessment of spinal extension of these so-called dumbbell tumors, which often require a coordinated thoracic and neurosurgical approach for resection.

Pneumomediastinum

Gas outside of normal GI structures may enter the mediastinum by several routes. First, it may collect in the mediastinum after esophageal or tracheobronchial rupture. Second, it may dissect into the mediastinum along fascial planes from the neck or oropharynx above (e.g., after dental extraction or tracheotomy) or from the retroperitoneum below (e.g., after colonic rupture or duodenal perforation). Third, after alveolar rupture,

gas may track along the perivascular interstitium in the lung and enter the mediastinum at the pulmonary hilum. This third pathway is the likely route of gas entry in patients subjected to barotrauma from mechanical positive pressure ventilation or in those who suffer pneumomediastinum as a complication of bronchoscopy. Pneumomediastinum occurring in the setting of mechanical ventilation may be associated with the more serious complications of barotrauma, which include pneumothorax, gas embolization, and pneumopericardium. Most often, however, pneumomediastinum occurs independently of traumatic or iatrogenic causes, in which case it is referred to as spontaneous pneumomediastinum.

Etiology

Spontaneous pneumomediastinum occasionally occurs as a complication of pneumonia or asthma, but most often, it is found in young and otherwise healthy individuals.[94] Symptoms are typically abrupt in onset and usually follow exaggerated respiratory efforts. Presumably, distended marginal alveoli rupture into the interstitium when the transpulmonary pressure is high; the elevated transpulmonary pressure would occur, for example, when a person inhales deeply or when a scuba diver holds his or her breath during ascent from an underwater depth. Thus, events that commonly precede spontaneous pneumomediastinum include parturition, cough, emesis, and straining at stool. In addition, numerous reports have appeared describing spontaneous pneumomediastinum after cocaine or marijuana use.

Diagnosis

Typical symptoms are retrosternal chest pain and dyspnea. The chest pain mimics that of pericarditis in that it is improved by sitting up and leaning forward; coughing, swallowing, and deep inspiration generally aggravate the pain.[94] Because the free mediastinal gas often escapes cephalad into the subcutaneous tissues of the neck and supraclavicular area, patients may also complain of neck pain and sore throat, dysphagia, or a peculiar swelling and crepitation in the upper chest and neck. Physical findings may include a crunchlike sound heard in synchrony with the heartbeat (Hamman mediastinal crunch), diminished dullness on percussion of the heart, and subcutaneous emphysema. The last finding, which is detected by palpation of crepitations resulting from the formation of gas bubbles just below the surface of the skin, may in extreme cases of pneumomediastinum extend as far down as the arms, abdominal wall, and genitals. Gas in the mediastinum may also decompress into the pleural space, leading to a concomitant pneumothorax, usually on the left side.

The diagnosis is established with chest radiography.[95] On posteroanterior view, a lucent zone of up to a few centimeters in width separates the cardiac silhouette from the medial border of the parietal and visceral pleurae. Gas may be seen outlining the aortic knob and extending in linear streaks up into the neck. On lateral view, gas collects between the sternum and the anterior border of the heart and outlines the aorta and other mediastinal soft tissue structures. In more subtle cases, lateral views of the neck reveal gas in the pretracheal fascia**.** In mild cases, CT may be necessary to detect the air in the mediastinum.[96]

Treatment

Spontaneous pneumomediastinum in spontaneously breathing adults resolves without specific therapy within a few days, and recurrences are uncommon. In contrast to spontaneous pneumothoraces, spontaneous pneumomediastinum is not recurrent. Thus, other than treating any underlying lung disease, management consists of reassurance, avoidance of strenuous activities, and use of analgesics if needed. Breathing-enhanced concentrations of oxygen may accelerate the rate of gas resorption. In adults, it is exceedingly rare that gas within the mediastinum is of sufficient pressure to compress vascular structures; therefore, surgical decompression of the mediastinal space by techniques such as tracheotomy is not indicated.

X PULMONARY EDEMA

Gerald W. Staton, Jr., m.d., f.a.c.p.

Acute pulmonary edema can be divided into two categories: edema caused by increased capillary pressure (hydrostatic, or cardiogenic, edema) and edema caused by increased capillary permeability (noncardiogenic pulmonary edema, or acute respiratory distress syndrome [ARDS]). In some cases of pulmonary edema, both pressure and permeability are increased.

Pathogenesis

Pulmonary edema is an abnormal, diffuse, extravascular accumulation of liquid in the pulmonary tissues and air spaces. It is the most common noninfectious, diffuse parenchymal lung disease. The pathogenesis of pulmonary edema can be best understood by examination of the Starling equation, which defines the determinants of liquid flux across the pulmonary capillary membrane:

$$Q = K[(P_{cap} - P_{int}) - \sigma(\pi_{cap} - \pi_{int})]$$

where Q is liquid flux; K, the filtration coefficient, which is directly proportional to the endothelial surface area and inversely proportional to alveolar capillary wall thickness; P_{cap}, the intravascular (capillary) hydrostatic pressure; P_{int}, the interstitial hydrostatic pressure; σ, the reflection coefficient for protein (i.e., the degree of permeability to macromolecules); π_{cap}, the plasma oncotic pressure; and π_{int}, the interstitial oncotic pressure. In this equation, $P_{cap} - P_{int}$ represents the hydrostatic force, and $\pi_{cap} - \pi_{int}$ represents the colloid osmotic force.

An alteration in any of the factors in the Starling equation could conceivably lead to an increase in transvascular liquid flux. However, in clinical practice, only two of these factors commonly lead to pulmonary edema: (1) an increase in capillary pressure, which leads to cardiogenic, or hydrostatic, pulmonary edema, and (2) a decrease in the reflection coefficient, which leads to noncardiogenic, or permeability, pulmonary edema.

The primary defense against pulmonary edema is provided by the lymphatic system. Normally, liquid that is filtered across the capillary membrane is removed by the lymphatic vessels. The lymphatic reserve is such that even a fourfold to sixfold increase in transcapillary liquid flux can be tolerated without an increase in lung water. A secondary defense mechanism and pathway for the removal of edema liquid is the active transport of Na^+ with passive osmotic water reabsorption in type II alveolar lining cells.[1]

Once the liquid removal reserve is overwhelmed, lung water increases, first in the interstitium around the airways, then in the interstitium around the alveoli, and finally within the alveoli. Clinical or radiographic evidence of pulmonary edema therefore implies a large increase in transcapillary liquid flux.

Approach to the Patient with Suspected Pulmonary Edema

Because of the different therapeutic approaches in cardiogenic and noncardiogenic pulmonary edema, it is important to differentiate between these conditions, though this is sometimes difficult, and some patients have components of both. The patient's history provides some important clues [*see Table 1*]. Patients with cardiogenic pulmonary edema often have a history of cardiac disease or hypertension, whereas patients with noncardiogenic edema may have a history of alcoholism or other problems that increase the risk of infection. The patient with cardiogenic pulmonary edema may have symptoms of a new cardiac event (ischemic chest pain) or a hypertensive emergency. The patient with noncardiogenic pulmonary edema will almost always have a clear precipitating event, such as sepsis, trauma, aspiration of gastric contents, multiple transfusions, or pneumonia.

The symptoms and signs are similar in the two forms of pulmonary edema, with some important exceptions [*see Table 1*]. Although both groups of patients experience dyspnea, patients with cardiogenic pulmonary edema have cool, diaphoretic skin

Table 1 Cardiogenic versus Noncardiogenic Pulmonary Edema

Clinical Features	*Cardiogenic Pulmonary Edema*	*Noncardiogenic Pulmonary Edema*
Clinical setting	Prior MI, hypertension, cardiomyopathy, MI, hypertensive emergency, dietary indiscretion, others	Alcoholism, immunosuppression, sepsis, trauma, aspiration, pneumonia, others
Symptoms	Dyspnea, cough productive of pink sputum	Dyspnea, cough
Signs	Tachypnea, tachycardia, weak pulse, hypertension, cool skin, diaphoresis, central or peripheral cyanosis, wheezing, rales, LV heave, gallop	Tachypnea, fever, hypothermia, bounding pulse, warm skin, central cyanosis, hyperdynamic precordium
Findings on chest radiography	Venous cephalization, wide vascular pedicle, increased cardiothoracic ratio, perihilar infiltrates, Kerley B lines	Diffuse infiltrates, air bronchograms
Findings on echocardiography	Decreased LV ejection fraction, diastolic dysfunction, valvular disease, segmental wall motion abnormalities	Hyperdynamic LV, RV dilatation, pulmonary hypertension
Findings on pulmonary artery catheterization	Increased PCWP, normal or decreased CO, increased pulmonary arterial pressure with normal PVR, increased SVR	Normal or low PCWP; when sepsis is present: increased CO, increased pulmonary arterial pressure with increased PVR, decreased SVR

CO—cardiac output LV—left ventricular MI—myocardial infarction PCWP—pulmonary capillary wedge pressure PVR—pulmonary vascular resistance RV—right ventricular SVR—systemic vascular resistance

with evidence of left ventricular (LV) dysfunction (LV heave, gallop); by contrast, most patients with noncardiogenic pulmonary edema have warm skin and show evidence of a hyperdynamic circulation.

Pulmonary edema of either type is typically manifested by bilateral, symmetrical alveolar opacities that involve all four quadrants, as seen on a standard anteroposterior chest radiograph [*see Table 1*].[2] A predominantly perihilar distribution is common, and occasionally, there is a very sharp demarcation between the central area of pulmonary edema and the lung periphery, leading to a so-called bat's-wing or butterfly pattern. This pattern is more typical of cardiogenic pulmonary edema than noncardiogenic pulmonary edema [*see Figure 1*]. This sharp line of demarcation does not correspond to any anatomic boundaries but may be caused by physiologic gradients of ventilation, perfusion, and lymph flow from the central to the peripheral portions of the lung. Less often, the edema is markedly asymmetrical or entirely unilateral. Asymmetrical pulmonary edema can occur as a result of the patient's lying on the involved side as the edema develops, or it may result from vascular obstruction (thromboembolism) or attenuation (emphysema) in the more radiolucent regions of the lung. However, the reasons why some cases are asymmetrical and others are unilateral are often impossible to determine.

Ancillary features that can be routinely visualized on an anteroposterior chest radiograph made with a portable x-ray machine may help differentiate cardiogenic from noncardiogenic pulmonary edema. A widened vascular pedicle and an increase in the cardiothoracic ratio suggest increased pulmonary capillary pressure[3]; distinct air bronchograms are more common with noncardiogenic pulmonary edema. The presence or absence of pleural effusions have less value in making the differential diagnosis. Unfortunately, cardiogenic and noncardiogenic pulmonary edema often cannot be confidently differentiated using bedside radiography, owing to anteroposterior exposure and lack of full inspiration, both of which magnify the cardiac silhouette.

Bedside echocardiography can be very useful in differentiating cardiogenic from noncardiogenic pulmonary edema [*see Table 1*]. In patients with cardiogenic pulmonary edema, echocardiography can detect and quantitate the abnormal left ventricular function and can be used to diagnose many of the causes (e.g., valvular dysfunction, diastolic dysfunction, cardiomyopathy, and focal wall motion abnormalities). In patients with noncardiogenic pulmonary edema, a normal or hyperdynamic left ventricle is seen.

If differentiation of cardiogenic from noncardiogenic pulmonary edema is not possible with the noninvasive evaluation outlined above, placement of a pulmonary arterial catheter may be considered. Pulmonary capillary wedge pressure (PCWP) is the most helpful measurement, but other measurements can support the diagnosis and may help in treating the patient [*see Table 1*].[4]

Despite the logical appeal of the use of pulmonary arterial catheters, no beneficial effect on outcome has been attributed to their use. A study of a large number of patients in intensive care units has suggested that patients who had pulmonary arterial catheters had a higher mortality at a higher financial cost than patients who did not undergo catheterization.[5] The report has been criticized but is currently the only published analysis of the effect of the use of these catheters on the outcome of patients in the ICU.

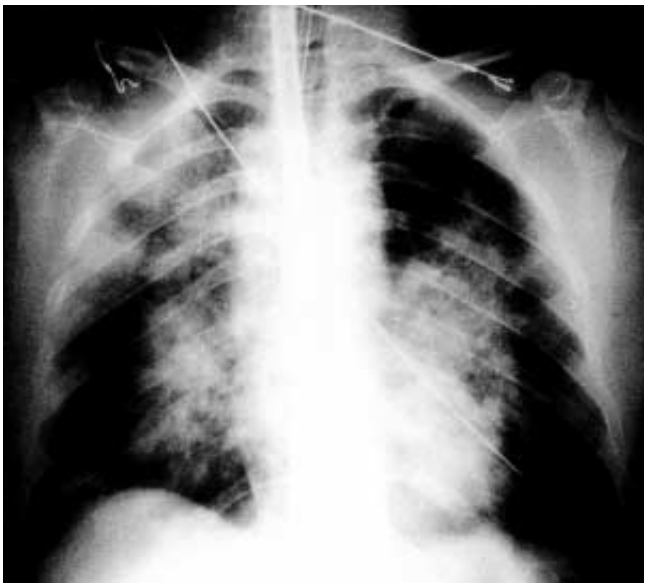

Figure 1 **Bat's-wing pattern characteristic of acute pulmonary edema is evident in this chest radiograph.**

Cardiogenic Pulmonary Edema

PATHOGENESIS

Pulmonary edema caused by increased capillary pressure can occur as a result of systolic or diastolic dysfunction of the left ventricle, mitral valvular disease, hypervolemia associated with normal left heart function (as might occur in a patient with renal failure), or pulmonary venous obstruction. The most common cause of cardiogenic pulmonary edema is left ventricular dysfunction. In congestive cardiomyopathy, the systolic performance of the left ventricle is impaired, the ventricle is dilated, and left ventricular end-diastolic pressure (LVEDP) is increased. The rise in LVEDP leads to an increase in pulmonary capillary pressure. Other types of heart disease can also increase LVEDP, despite normal systolic function and euvolemia, by reducing left ventricular compliance and producing diastolic dysfunction.[6] Reduced compliance may be persistent (as seen with left ventricular hypertrophy or restrictive cardiomyopathy from infiltrative heart disease) or transient (as from myocardial ischemia). Increased capillary pressure despite normal LVEDP is uncommon but does occur with mitral stenosis or as a result of obstructed flow in the pulmonary veins (pulmonary venoocclusive disease).

DIAGNOSIS

The salient clinical features of cardiogenic pulmonary edema are extreme breathlessness, tachypnea, and signs of increased sympathetic activity, such as tachycardia, hypertension, and diaphoresis [*see Table 1 and* Approach to the Patient with Suspected Pulmonary Edema, *above*]. Hypotension is uncommon but may occur if pulmonary edema results from a large myocardial infarction. Breathlessness is rarely alleviated by correction of hypoxemia, suggesting that the cause may be activation of intrapulmonary stretch receptors rather than hypoxemia. In cardiogenic pulmonary edema, central cyanosis may be observed if there is profound arterial hypoxemia; more often, cyanosis is peripheral and results from intense cutaneous vasoconstriction and a decreased cardiac output. Use of accessory muscles of res-

piration is common because of the marked increase in the work of breathing. The effort required to breathe is often so great that endotracheal intubation and mechanical ventilation are required to correct or prevent the development of frank hypercapnic respiratory failure. Early in the acute course, there may be wheezing caused by airway edema and intraluminal liquid; later, diffuse coarse rales are heard.

TREATMENT

Supplemental oxygen should be given by mask or nasal cannula. If hypoxemia cannot be corrected by establishing maximum oxygen flow rates and by use of reservoir bags, mechanical ventilation with a mask[7] or endotracheal tube will be required [*see 14:VIII Respiratory Failure*]. The positive intrathoracic pressures created by the ventilator open collapsed alveoli and impede venous return. While hypoxemia is being treated, one or more of several therapeutic options should simultaneously be exercised, depending on the underlying pathophysiologic processes [*see Table 2*]. The proper combination of therapeutic measures depends on the pathophysiology. For example, when pulmonary edema occurs as a complication of malignant hypertension, vasodilators and diuretics may suffice. In the case of a causative or strongly contributing tachyarrhythmia, antiarrhythmic therapy may be the key intervention. Specific interventions for causative cardiac conditions are described elsewhere [*see Section 1 Cardiovascular Medicine*].

OUTCOME

Patients with acute cardiogenic pulmonary edema often are elderly and have multiple medical problems, including ischemic heart disease, diabetes, and valvular heart disease. As a consequence, the mortality for these patients ranges from 6% to 30%.[8] Of those patients who survive to discharge, approximately 70% will survive 1 year, and 50% will have relatively good functional status for longer periods.[9]

Noncardiogenic Pulmonary Edema: Acute Respiratory Distress Syndrome

ARDS is characterized by diffuse pulmonary endothelial injury, which leads to pulmonary edema as a result of an increase in capillary permeability to water, solutes, and macromolecules.[10,11] The pulmonary edema seen in patients with ARDS is characterized by a higher concentration of protein in the edema liquid than is seen in patients with cardiogenic pulmonary edema. In patients with ARDS, this concentration is often as high as 80% to 90% of the plasma protein. Furthermore, in ARDS patients, the underlying inflammatory response causes high levels of neutrophils and their secretory products in bronchoalveolar lavage liquid; this characteristic distinguishes noncardiogenic edema from cardiogenic edema.

Table 2 Treatment of Cardiogenic Pulmonary Edema

Effect Sought	*Therapeutic Approach*
Decrease venous return	Venodilator
Decrease impedance to ventricular systole	Arteriolar dilator
Decrease intravascular volume	Diuretic agent
Stimulate the myocardium	Inotropic agent
Correct arrhythmias	Antiarrhythmic agent, pacemaker
In the Presence of Coronary Arterial Occlusion	
Alleviate ischemia	Angioplasty, thrombolytic agent, coronary bypass
Prevent clot propagation	Aspirin, other antiplatelet agent, anticoagulant

Table 3 Causes of ARDS[11]

Condition	*Examples*
Direct Lung Injury	
Diffuse pulmonary infection	Bacterial, viral (including SARS[53]) or fungal pneumonia; *Pneumocystis carinii* pneumonia; tuberculosis
Chemical pneumonitis caused by aspiration	Aspiration of gastric contents or of water in near-drowning
Inhalation injury	Inhalation of smoke, chlorine, or nitrous oxide
Direct pulmonary trauma	Automobile accident
Indirect Lung Injury	
Systemic reaction to nonpulmonary infection	Bacteremias, nonbacteremic sepsis, toxic-shock syndrome
Systemic reaction to nonpulmonary tissue inflammation or injury	Pancreatitis, trauma, fat embolism, amniotic fluid embolism
Transfusion reaction	Red cell transfusion
Drug toxicity	Salicylates, cytotoxic agents
Reperfusion injury	Cardiopulmonary bypass, post–lung transplantation
Other	Marathon running

SARS—severe acute respiratory syndrome

Many clinical disorders are associated with the development of ARDS [*see Table 3*], which may arise from direct injury to the lung or from extrapulmonary processes that injure the lung indirectly.[10,12] A patient's risk of developing ARDS varies with the predisposing disorder, and the risk increases as the number of predisposing disorders increases.[11] The risk of ARDS may be further increased in patients with a history of alcohol abuse[13] or cigarette smoking,[14] or it may be increased by the presence of low serum pH or hypoproteinemia[15] at the time of the insult. Genetic factors may also play a role in predisposition.[16]

PATHOGENESIS

Diffuse alveolar damage is a descriptive term for the nonspecific but predictable sequence of changes that characteristically occur in patients with ARDS.[17] The causative agent or process usually cannot be determined from the histopathologic pattern. In addition, the abnormalities may resolve at any point in the clinical course.

The histologic appearance of diffuse alveolar damage varies during the period between the precipitating event and the biopsy or autopsy, progressing through the following three phases: an acute exudative phase (days 0 through 7); a subacute proliferative, or organizing, phase (days 7 through 14); and a chronic phase (after day 14).[17]

The earliest part of the acute exudative phase is characterized by interstitial and intra-alveolar edema, neutrophil infiltration, hemorrhage, and fibrin deposition. A mixture of fibrin and cellular debris is deposited in the alveolar space to form the so-called hyaline membranes that are prominent 3 to 7 days after injury. Sloughing of the cells of the alveolar lining leaves a de-

nuded basement membrane, which plays an important role in subsequent repair or fibrosis. An interstitial infiltrate of inflammatory cells becomes more pronounced around day 7 and persists throughout the proliferative phase.[17]

Denudation of the basement membrane causes type II pneumocytes to proliferate (days 3 through 7), producing a pattern of hyperplasia in the cells of the alveolar lining. In patients in whom the syndrome resolves, these proliferating cells ultimately differentiate into type I pneumocytes, restoring the epithelial side of the alveolocapillary wall and returning gas exchange to normal.[17]

The proliferative phase of ARDS is characterized by inflammation and fibroblast proliferation, initially in the interstitium. The fibroblasts invade the alveolar spaces through basement membrane defects, a process that produces regions of intra-alveolar fibrosis. During this phase, the hyaline membranes disappear as a result of phagocytosis or of organization involving the incorporation of the exudate into intra-alveolar plugs of proliferating fibroblasts.[17]

The chronic phase of ARDS is characterized by regions of intense fibrosis, focal regions of overexpansion, and pulmonary vascular obliteration. Histologically, this phase of the disease can be similar to idiopathic pulmonary fibrosis; in contrast to idiopathic pulmonary fibrosis, however, the chronic phase of ARDS may improve with time.[17]

Extensive investigations have led to a better understanding of the mechanisms that lead to ARDS[10,17,18] [*see Figure 2*].

DIAGNOSIS

Clinical Manifestations

The major clinical signs of noncardiogenic pulmonary edema overlap those of cardiogenic pulmonary edema [*see Table 1 and* Approach to the Patient with Suspected Pulmonary Edema, *above*]. In noncardiogenic pulmonary edema, however, there is often less sympathetic activity[19]; cyanosis, if present, is often caused by arterial hypoxemia. The skin may be warm (rather than cool, moist, and pallid), and the pulse may be racing.

Imaging Studies

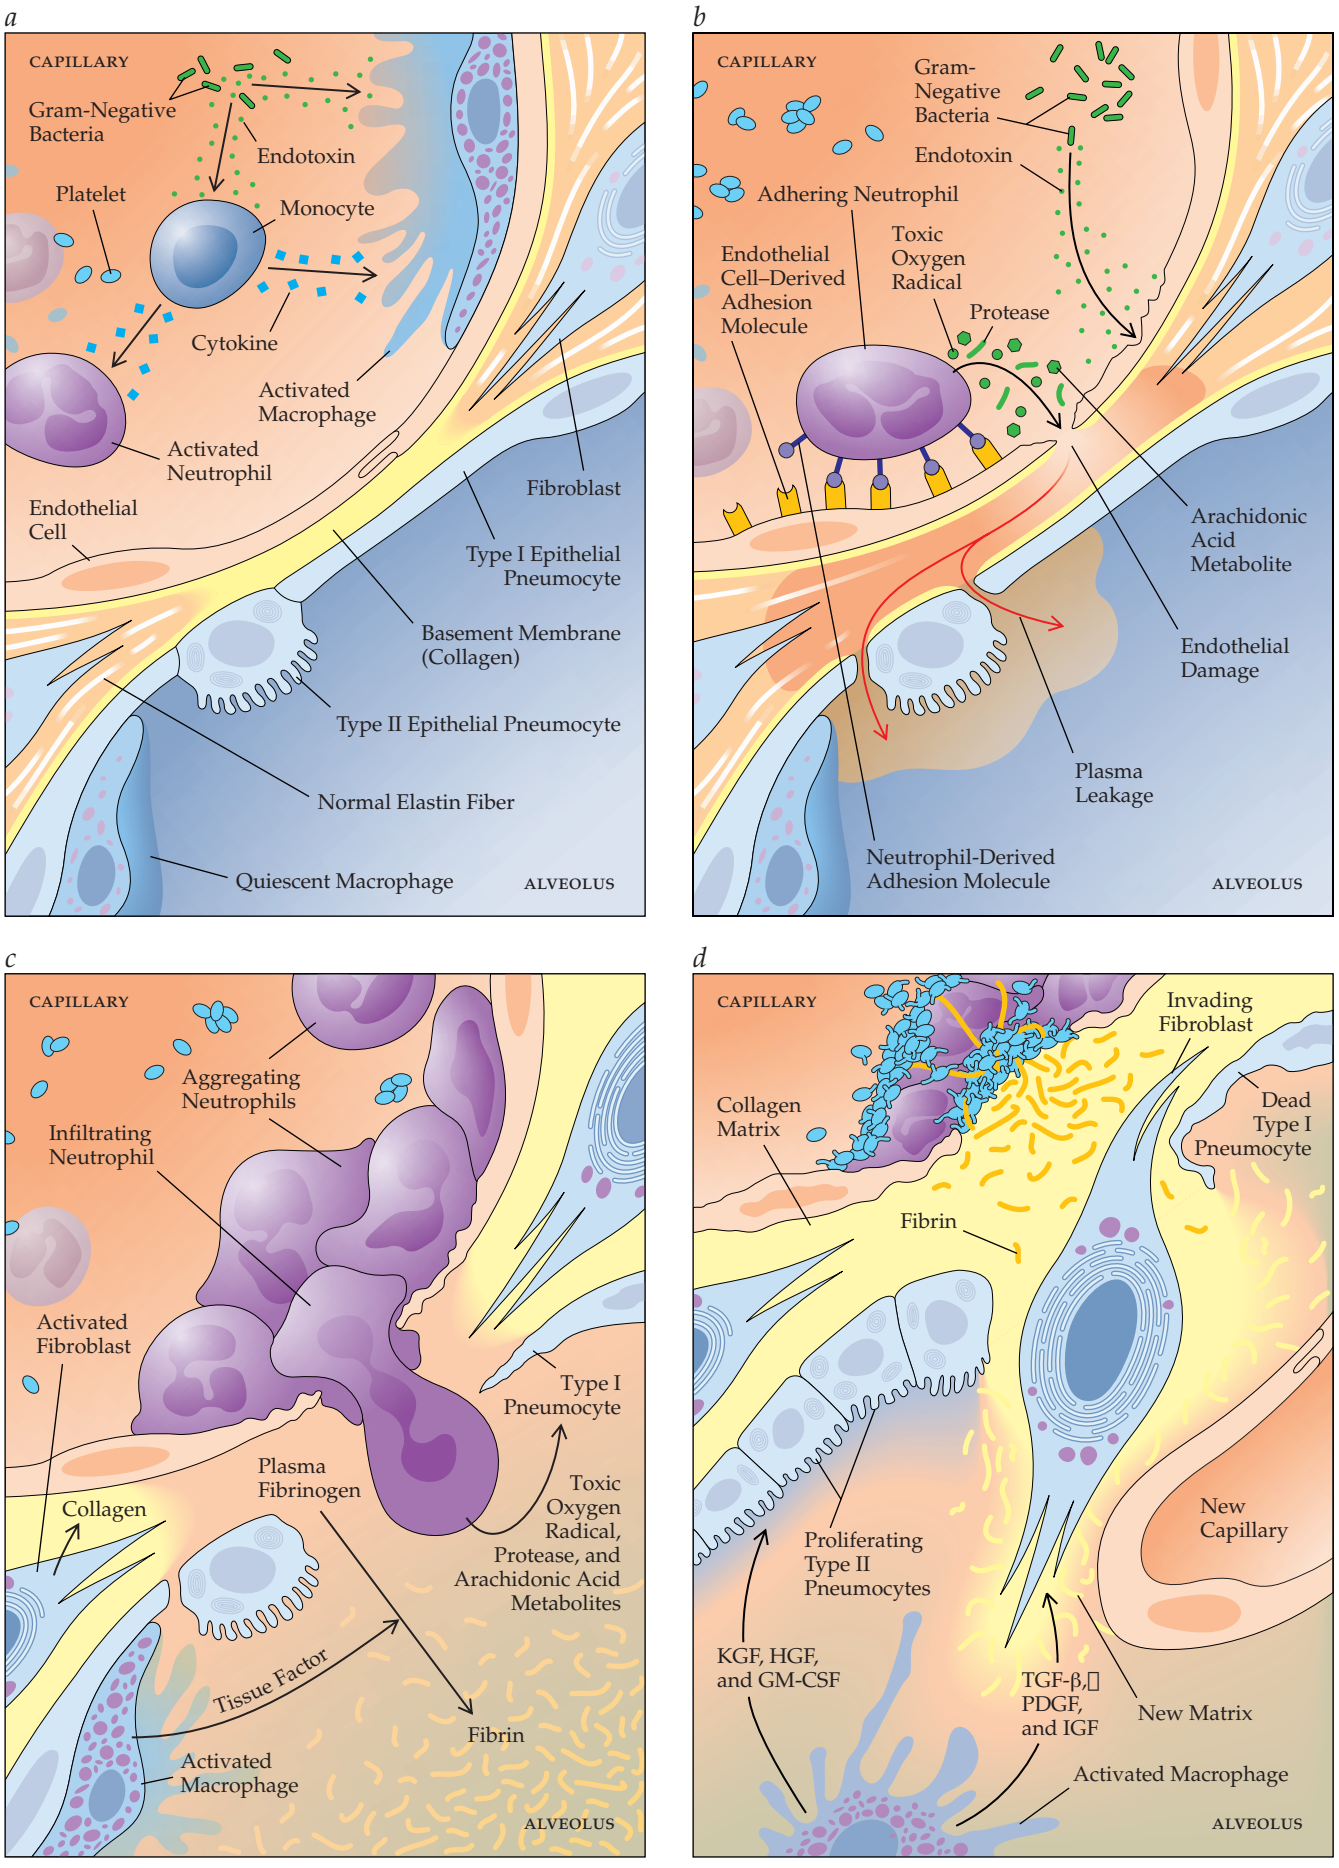
Typically, portable anteroposterior chest radiography reveals a diffuse and homogeneous alveolar filling process.[20] When examined by computed tomography, however, the air-space filling pattern frequently appears less homogeneous. Radiographs with the patient in the supine position typically show a greater degree of consolidation in posterior lung zones than in anterior lung zones; this distribution, however, may be reversed by placing the patient in the prone position for a few hours. With the patient in the prone position, the anterior regions become more consolidated, because of the influence of gravity, and the posterior portions of the lung show improved aeration. This finding demonstrates the contribution of Starling forces (i.e., capillary pressure) to the severity of edema in the setting of increased permeability.

Physiologic Testing

Gas exchange in ARDS is characterized initially by hypoxemia that is refractory to increasing concentrations of inspired oxygen, implying the presence of increased intrapulmonary shunting. Intrapulmonary shunting is primarily a consequence of diffuse alveolar filling, collapse, or both, with microatelectasis. Diffuse alveolar collapse is believed to be caused by abnormalities in surfactant, a substance that normally helps maintain alveolar distention by lowering the surface tension in the air-liquid interface of the lung.

Initially, arterial carbon dioxide tension (P_aCO_2) is either low or in the normal range with only a modest increase in minute ventilation. However, the ratio of dead space to tidal volume (V_D/V_T) tends to increase over time, so that increasing amounts of minute ventilation are required to achieve a normal P_aCO_2.[21] In some cases, the increase in V_D/V_T is so extreme that hypercapnia cannot be avoided even when minute ventilation is increased to the maximal achievable level. This increase in physiologic dead space results from damage to the pulmonary capillary bed, which creates regions of high ventilation relative to perfusion. A secondary cause of the increased minute-ventilation requirement in ARDS is the presence of increased carbon dioxide production from hypermetabolism. The high V_D/V_T in ARDS is slow to resolve; this, together with the reduction of lung compliance (which imposes a burden on spontaneous breathing), accounts in part for the frequent need for mechanical ventilatory support for prolonged periods. Such support often must be continued even though hypoxemia has improved sufficiently to make only a modest increase in inspired oxygen concentration necessary.

Figure 2 **(*a*) The first site of injury in ARDS is the endothelium of the pulmonary capillaries. In ARDS caused by sepsis, endotoxin stimulates the production or release of several proinflammatory mediators such as activated complement fragments, coagulation factors, platelet activating factor, eicosanoids, and cytokines/chemokines (e.g., tumor necrosis factor-α [TNF-α], interleukin-1 [IL-1], IL-6, IL-8, and other cytokines), as well as anti-inflammatory substances such as IL-10, IL-11, cytokine receptor antagonists, anticytokine autoantibodies, antioxidants, and antiproteases.[51] Release of some of these mediators may be induced by the mechanical ventilation that is often required in such cases, and these mediators may play a role in inducing the systemic inflammatory response syndrome and multiorgan failure.[52] If there is an imbalance in favor of the inflammatory mediators, the mediators act as primers and secretagogues for neutrophils and other monocytes/macrophages, resulting in aggregation and embolization of these cells in the pulmonary vasculature. (*b*) The neutrophils adhere to the endothelium by way of specific receptors on the neutrophils (integrins and L-selectin) and receptors on the endothelium (intercellular adhesion molecule–1 [ICAM-1] and E- and P-selectin) and release injurious oxidants, proteolytic enzymes, and arachidonic acid metabolites, resulting in endothelial cell dysfunction and destruction and in denudation of the endothelial side of the basement membrane. Endotoxin may also injure endothelial cells directly. Increased permeability of the alveolocapillary membrane allows plasma to enter the interstitial spaces of the lung and, ultimately, the alveoli. (*c*) The second site of injury is the alveolar epithelium. Neutrophils penetrate the alveolocapillary membrane and, along with activated macrophages, release oxidants and proteolytic enzymes. As a result, type I pneumocytes die, denuding the alveolar side of the basement membrane. Macrophages produce procoagulant substances, such as tissue factor and factor VII, that produce fibrin, and the alveolus becomes filled with proteinaceous exudate and cellular debris. (*d*) In response to the death of the type I pneumocytes, type II pneumocytes, under the control of growth factors (keratinocyte growth factor [KGF], hepatocyte growth factor [HGF], and granulocyte-monocyte colony-stimulating factor [GM-CSF] from macrophages), begin to proliferate and attempt to cover the denuded basement membrane. If the injury to the epithelial cells and the basement membrane is severe, progressive interstitial and intra-alveolar fibrosis ensues. Fibroblasts, which are controlled by growth factors (transforming growth factor–β [TGF-β], platelet-derived growth factor [PDGF], and insulinlike growth factor [IGF]) derived from macrophages, invade the exudate, where they proliferate and synthesize collagen (type I), elastin, and other new matrix components. The normal lung architecture is progressively replaced at this point (approximately 2 weeks from onset) by fibrous tissue that severely impairs gas exchange.**



Lung mechanics in ARDS is characterized primarily by a reduction in lung compliance (increased lung elastance); thus, high transpulmonary pressures are required to achieve normal tidal ventilation. Early in ARDS, when edema predominates, much of the distending pressure needed to inflate the lung is expended in opening collapsed alveoli. Indeed, lung compliance (i.e., the slope of the pressure-volume curve) may be in the normal range if it is measured after these collapsed alveoli have been opened. However, there is a significant reduction in compliance as the disease process evolves or when alveolar fibrosis becomes predominant. This apparent reduction may be caused by a diffuse thickening of the alveolocapillary membrane as a result of fibrosis or by the loss of a large percentage of the alveolocapillary units that are available for ventilation. It has been suggested that in patients with ARDS, lung mechanics is best conceptualized by regarding the lung as being small rather than stiff.[22] Increased airway resistance that responds to inhaled bronchodilators is also seen in ARDS.[23]

In addition to their effect on V_D/V_T, the pulmonary vascular changes in ARDS result in increased pulmonary vascular resistance and pulmonary hypertension.[24] Indeed, the pulmonary arterial pressure is elevated in nearly all patients who have moderate to severe ARDS. The etiology of pulmonary hypertension in ARDS is likely to be multifactorial; however, a major underlying cause seems to be the presence of small pulmonary arterial thrombi. The pathogenesis of the thrombi in ARDS is unknown, but it is likely that they are formed in situ.

Many patients with ARDS have certain markers of accelerated intravascular coagulation.[25] However, despite the apparent importance of thrombosis in producing pulmonary hypertension, it has not been determined whether traditional anticoagulation benefits patients with ARDS.

TREATMENT

The treatment of ARDS includes addressing the precipitating cause of ARDS, general ICU support (e.g., nutrition), prevention of complications in the ICU (e.g., stress ulcer prophylaxis), and management of edema[26] [*see Table 4*]. Ventilatory and cardiorespiratory issues in the management of respiratory failure in patients with ARDS are discussed in detail elsewhere [*see 14:VIII Respiratory Failure*].

Treatment of the cause of ARDS, when feasible, should be instituted as soon as possible. For example, in patients with ARDS that is associated with sepsis, appropriate antibiotics should be started immediately, and the source of the infection should be identified and treated (e.g., abscesses should be drained).

The initial management in the ICU should include several general measures. Prevention of stress ulceration and associated gastrointestinal bleeding, as well as prevention of deep vein thrombosis and pulmonary embolism, is indicated. Activated protein C (drotrecogin alfa [activated]), an endogenous protein with antithrombotic, profibrinolytic, and anti-inflammatory properties, should be administered to patients with sepsis who are not at risk for bleeding.[27] In septic patients with adrenal insufficiency, replacement doses of corticosteroids are indicated.[28] Attempts to reduce nosocomial infection, particularly ventilator-associated pneumonia, through the use of topical and systemic antibiotics have had favorable results,[29] but concerns about the induction of resistant organisms have made this type of therapy controversial. Enteral feeding is indicated if the GI tract is functioning; otherwise, parenteral nutrition should be provided. Special enteral formulations enriched with "immunonutrients" (e.g., arginine, glutamine, omega-3 fatty acids, and nucleotides) have been found to reduce length of hospital stay, infection rates, and duration of mechanical ventilation, but not mortality.[30]

The treatment of ARDS is focused on reducing existing pulmonary edema, preventing further edema, and modifying the evolution of the disease. Once the patient is hemodynamically stable, fluid restriction, diuresis (possibly with albumin infusion), or both are indicated.[31] Numerous attempts have been made to reduce the inflammatory response in ARDS. Except in patients with relative adrenal insufficiency, use of corticosteroids early in the course of disease has no beneficial effect; however, steroids given 7 to 14 days later may modify the fibroproliferative phase.[32] Numerous other agents have not been found to modify the disease process or improve outcome [*see Table 4*].[33,34]

OUTCOME

Although the prognosis of patients with ARDS is related to the degree of lung injury, other parameters more accurately predict outcome; this is not surprising, because ARDS is frequently part of a systemic inflammatory response syndrome. The cause of the syndrome is often unclear, but the possibilities include bronchopneumonia, translocation of bacterial products across the intestine, and persistent release of endogenous mediators in the absence of ongoing infection. Sepsis, which is often associated with vasodilatation that is unresponsive to vasoconstrictors, is the most common cause of death during the course of illness. As a result of state-of-the-art ventilatory-support techniques, respiratory failure is the cause of death in less than 20% of cases—a fact that highlights the importance of dysfunction of other organ systems (e.g., hemodynamic failure with refractory shock or progressive renal failure) in causing morbidity and mortality. Data suggest that the outcome of patients with ARDS may be improving, possibly because of improvements in therapy.[10,19]

One way to predict mortality is by the number of organ systems that fail. Mortality increases with the number of failing organs and the number of days of failure [*see Figure 3*].[35] There is a further increase in mortality in patients who are older than 65 years. For example, in patients younger than 65 years who have single-organ malfunction for 5 days, mortality is 27%, whereas in patients with single-organ malfunction who are older than 65 years, mortality is 48%. Likewise, the failure of two organs for 2 days results in a 47% mortality in patients younger than 65 years and a 73% mortality in patients older than 65 years. The failure of three or more organs for 5 days in patients of any age is associated with a 97% mortality.[35] These data provide a useful guide for decision making for patients with catastrophic illness and their families.

If patients survive the acute illness that causes ARDS, the prognosis for return of lung function is good. Factors associated with poor pulmonary functional outcome are severity of ARDS, lowest measured compliance, and duration of positive pressure ventilation.[10] Lung function improves rapidly over the first several weeks, then more slowly over a period of as long as 2 years. Common symptoms and signs include exertional dyspnea, cough, wheezing, and persistent rales. Pulmonary function tests may demonstrate the presence of restrictive disease; obstructive disease, often with increased airway reactivity; or decreased diffusing capacity. CT may show a persistent reticular pattern in 85% of patients.[36] One year or more after the onset of ARDS, more than 75% of patients either have normal respiratory function or suffer only mild impairment. However, many will suffer

Table 4 Treatments of ARDS That Do Not Involve Ventilation[26]

Treatment	*Purpose*	*Evidence Grade*	*Is This Treatment Recommended?*
Stress ulcer prophylaxis	Prevent stress ulcers and GI bleeding	A (studied in ICU patients)	Yes, gastric acid neutralization allowable
Prophylaxis of deep vein thrombosis and pulmonary embolism	Prevent deep vein thrombosis and pulmonary embolism	A (studied in ICU patients)	Yes
Activated protein C	Antithrombotic, profibrinolytic, anti-inflammatory	B	Yes, for patients with sepsis without risk of hemorrhage
Corticosteroids, replacement doses	Relative adrenal insufficiency	B	Yes, for patients with sepsis with relative adrenal insufficiency
Topical plus systemic prophylactic antibiotics	Prevent nosocomial infections	A (studied in ICU patients)	Controversial; evidence favors
Enteral nutrition	Prevent malnutrition	Ungraded	Yes, if GI function satisfactory
Parenteral nutrition, with low carbohydrate and high fat	Prevent malnutrition	Ungraded	Yes, when GI function inadequate
Immune-enhancing nutritional formulations (e.g., omega-3 fatty acids)	Alter immune system and prostenoids	B	Controversial; evidence favors
Early fluid restriction and/or diuresis, possibly with albumin infusion	Prevent or reduce edema	B	Yes, if hemodynamically stable, trial under way
Corticosteroids (high dose) early in course of disease	Reduce inflammation	A	No
Corticosteroids (high dose) late in course of disease	Prevent or reduce intra-alveolar fibroproliferation	B	Controversial; one randomized clinical trial reports benefit when given at 7–14 days; large randomized clinical trial is in progress
Exogenous surfactant	Prevent alveolar collapse	B	No; no trials under way
Acetylcysteine, procysteine	Antioxidant	B	No
Ketoconazole	Inhibit thromboxane and leukotriene synthesis	A	No
Ibuprofen, other NSAIDs	Reduce inflammation	B	No
Alprostadil (prostaglandin E_1)	Inhibit neutrophil activity	B	No
Pentoxifylline, lisofylline	Inhibit cytokine secretion	A	No
Antiendotoxin and anticytokines	Prevent ARDS	A	No
Inhaled nitric oxide	Improve $\dot{V}/\dot{Q}$ balance; reduce hypoxemia	A	No
Nebulized prostacyclin (epoprostenol)	Improve $\dot{V}/\dot{Q}$ balance; reduce hypoxemia	C	No
Inhaled beta-adrenergic agonists	Reduce airway resistance, speed edema resorption	D	Yes

ARDS—acute respiratory distress syndrome GI—gastrointestinal NSAIDs—nonsteroidal anti-inflammatory drugs $\dot{Q}$—perfusion $\dot{V}$—ventilation

neuropsychological sequelae such as impaired memory, attention, and concentration; decreased mental-processing speed; or all four effects.[37] Patients also experience reduced quality of life because of impaired physical functioning that results from muscle wasting and weakness.[19,38,39]

Miscellaneous Causes of Pulmonary Edema

NEUROLOGIC INSULTS

Pulmonary edema can occur as a result of various insults to the central nervous system, including grand mal seizures, head trauma, subarachnoid hemorrhage, intracerebral hemorrhage, and subdural hematoma. The common denominator for these CNS insults is that they are severe and occur acutely. Most often, pulmonary edema is acute, occurring minutes to hours after the CNS event. Occasionally, there may be a more delayed onset and gradual progression over several days. The pathogenesis of neurogenic pulmonary edema is not well understood. The acute form, which is more common, may result in large part from intense sympathetic activity associated with systemic hypertension and central pooling of blood volume. This combination of factors can lead to extraordinary, albeit transient, increases in pulmonary capillary pressure and a predomi-

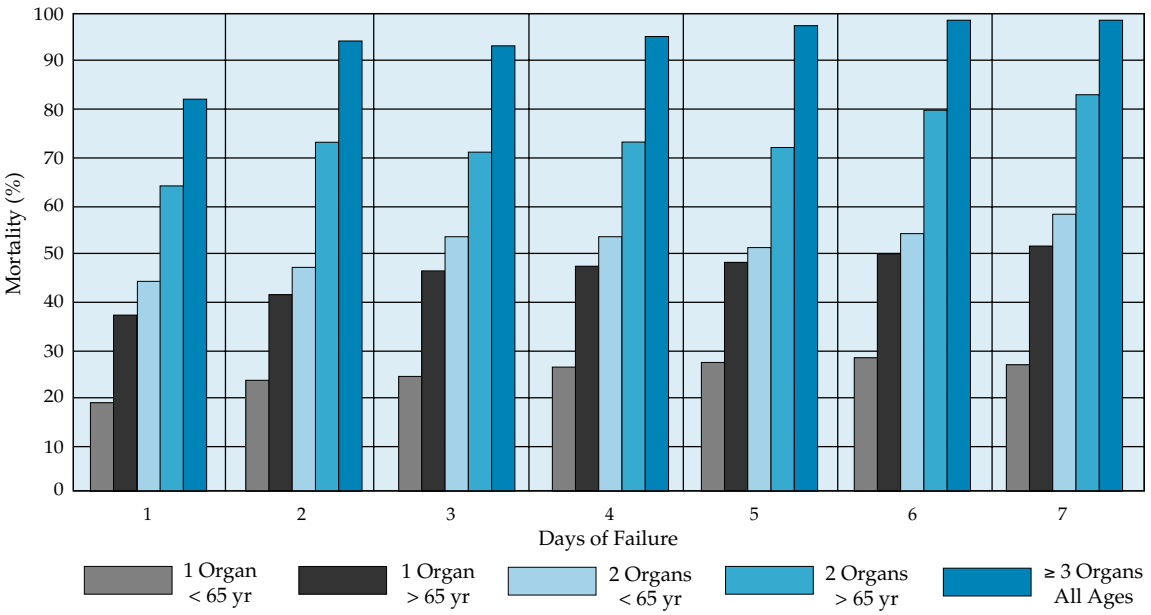


Figure 3 **In patients with ARDS, the number of failing organs and the patient's age have a greater influence on mortality than does the number of days of failure.**

nantly cardiogenic pattern of pulmonary edema. Increased permeability caused by pressure-induced mechanical injury to pulmonary capillaries or possibly by CNS control over pulmonary capillary permeability is also believed to play a role in neurogenic pulmonary edema.[40]

Clinically, neurogenic pulmonary edema is usually diagnosed through its association with a rather dramatic preceding CNS insult. The major differential diagnosis is aspiration injury to the lungs. Unlike neurogenic pulmonary edema, chemical pneumonitis resulting from aspiration frequently persists for more than a few days and is often complicated by secondary bacterial infection. If the pulmonary process clears rapidly (i.e., over a few days), the likely diagnosis is neurogenic pulmonary edema. The management of neurogenic pulmonary edema is basically supportive. Diuretics should not be used in the absence of hypervolemia because of the risk of hypovolemic hypotension, which could aggravate the CNS injury in the setting of increased intracranial pressure.

EXPOSURE TO HIGH ALTITUDE

High-altitude pulmonary edema (HAPE) has been reported to occur at heights of 2,500 to 5,000 m (8,202 to 16,404 ft), with an incidence of 0.5% to 15%; greater risk is associated with young age, male sex, more rapid ascent, heavy exertion, and cold environment.[41] HAPE can also occur in persons residing at high altitude who return from a few days' stay at a lower altitude. Persons with previous episodes of HAPE have a 60% chance of recurrence.

Symptoms are cough, which is sometimes productive of pink or bloody sputum, dyspnea on exertion, and fever; onset of symptoms is often gradual but typically occurs within 48 to 96 hours at high altitude.[41] Fulminant pulmonary edema may be preceded by the less severe symptoms of acute mountain sickness. The edema may be diffuse, yet patchy, or quite asymmetrical.

The primary pathophysiologic abnormality underlying high-altitude pulmonary edema is increased capillary permeability, yet the mechanism of the increased permeability is uncertain. It has been suggested that pronounced hypoxia-induced pulmonary vasoconstriction may lead to overperfusion of the less obstructed portions of the vascular bed and subsequent endothelial injury that results in fluid leakage.[41] Evidence for this mechanism comes in part from the observation that persons who have experienced HAPE have more exaggerated hypoxic pulmonary vasoconstriction than those who have not. Several mechanisms have been examined as contributing factors in this process. Exaggerated release of vasoconstrictors (e.g., endothelin-1) or impaired production of vasodilators (e.g., nitric oxide) may play a role.[41,42] Edematogenic mediators released from endothelial or inflammatory cells may also be involved.[41] In addition, impaired activity of alveolar NA+,K+-ATPase may contribute to slowed clearance of alveolar fluid.[43]

The risk of HAPE can be decreased by ascending slowly and steadily to high altitudes. In addition, nifedipine has been found to prevent HAPE in susceptible persons.[32] Inhaled β-adrenergic agonists may also prevent HAPE.[43] Descent to a lower altitude when symptoms of acute mountain sickness develop should also reduce the risk of pulmonary edema. Once full-blown pulmonary edema has occurred, administration of oxygen, continuous positive airway pressure, nifedipine, and prompt descent are useful treatments.[41] Descending even only a few hundred meters may be beneficial. Inhalation of nitric oxide has been shown to improve arterial oxygenation and may be useful in patients who cannot be evacuated to a lower altitude.[44] Persons who have experienced HAPE are at increased risk for its recurrence and should be advised to avoid high altitudes.

REEXPANSION OF COLLAPSED LUNG

Rapid reexpansion of a collapsed lung may lead to ipsilateral or, occasionally, bilateral pulmonary edema.[45] The risk of reexpansion pulmonary edema after evacuation of a pneumothorax or pleural effusion is related to the amount of air or liquid in the pleural space, the duration of collapse, the rapidity of reexpansion, and the suctional pressures required to reexpand the lung. The development of highly negative pleural pressure during removal of pleural air or liquid, with resultant marked reduction in interstitial hydrostatic pressure, may be important in the

pathogenesis of reexpansion pulmonary edema. The high protein concentration in the edema fluid suggests enhanced membrane permeability. This increased permeability could be caused in part by mechanical stretching and deformation of endothelial pores or by generation of toxic oxygen radicals during reperfusion of the rapidly expanded lung. Depletion of surfactant in the collapsed lung may play a role in the genesis of the reduction in interstitial hydrostatic pressure during reexpansion. The risk of reexpansion pulmonary edema is very low during evacuation of a pneumothorax that has been present for a day or less. For a pneumothorax that is thought to have been present for longer than a day, evacuation under water seal, rather than by application of negative pressure, may reduce the risk of edema. Evacuation of pleural liquid does not usually lead to pulmonary edema unless more than 1.0 to 1.5 L of liquid is removed rapidly. It has been suggested that any amount of pleural liquid can be removed safely as long as pleural pressure is maintained at a level higher than –20 cm H_2O. It is not certain, however, whether this approach will always prevent reexpansion pulmonary edema; therefore, it is advisable to remove very large effusions gradually over several hours whenever possible. Treatment of reexpansion pulmonary edema is supportive. There is no evidence that treatment with diuretics is beneficial.

UPPER AIRWAY OBSTRUCTION

Pulmonary edema has been reported to occur after episodes of upper airway obstruction caused by postextubation laryngospasm, tumors, strangulation, or obstructive sleep apnea.[46] The pathogenesis is thought to be related to the development of highly negative intrapleural pressure (–50 to –100 cm H_2O) caused by vigorous inspiratory efforts against an obstructed airway (Müller maneuver). The highly negative intrapleural pressure decreases the interstitial hydrostatic pressure, increases venous return, and imposes an afterload on the left ventricle. In addition, such pressure may lead to intense sympathetic activation, systemic hypertension, and central pooling of blood volume. These factors together can lead to acute pulmonary edema by increasing the transcapillary pressure gradient (i.e., the difference between the capillary pressure and the interstitial hydrostatic pressure). The condition resolves rapidly after the obstruction is removed.

DRUGS

Acute noncardiogenic pulmonary edema can occur after administration of a number of drugs [*see Table 5*]. Acute pulmonary edema can occur after intravenous injection of heroin or other narcotics.[47] Because the edema fluid has a high protein concentration, it has been suggested that a permeability defect could be a pathogenetic factor, but this finding could result from a transient, extreme increase in capillary pressure produced by a so-called neurogenic mechanism. Onset usually occurs within a few hours after narcotic use, but occasionally, it may be delayed for as long as 24 hours. In addition to the clinical and radiographic features of pulmonary edema, typical signs of narcotic intoxication are present, such as pupillary constriction, decreased respiration, and altered mentation. Fever and leukocytosis do not necessarily indicate the presence of infection. As with neurogenic pulmonary edema, the primary differential diagnostic consideration is aspiration, because of the altered level of consciousness.

Management is supportive and should generally include intubation with mechanical ventilation, both to guarantee adequate ventilatory support and to provide airway protection against aspiration. The role of naloxone is uncertain. Certainly, a patient who has overdosed on narcotics and is experiencing life-threatening hypotension or bradycardia should be given naloxone. Likewise, if naloxone is given to an unresponsive and hypopneic patient who does not necessarily require mechanical ventilation for pulmonary edema, the patient may be spared intubation. In contrast, for a patient who is intubated on an emergency basis because of acute pulmonary edema and who becomes clinically stable without hemodynamic compromise, better management may be to allow the narcotic intoxication to reverse gradually rather than precipitously. There is no evidence that naloxone helps speed resolution of narcotic-induced pulmonary edema. In fact, naloxone has been reported to cause pulmonary edema.[32] Furthermore, acute reversal of narcotic intoxication in a long-term addict could result in agitation, with marked sympathetic activation and a less stable clinical course.

Cocaine causes acute pulmonary edema, usually when used as free-base cocaine.[48] The pathophysiology is uncertain. Like heroin, cocaine leads to a high-protein pulmonary edema that suggests endothelial cell injury and increased capillary permeability. However, as has been suggested with heroin, cocaine could lead to extreme sympathetic activation with a steep, extreme increase in capillary pressure that could produce a transient increase in protein leakage across the capillary membrane. Cocaine also causes coronary vasoconstriction, with acute myocardial ischemia or infarction, resulting in pulmonary edema.

LUNG RESECTION

Pulmonary edema can occur as a complication after lung resection, especially pneumonectomy. The clinical picture is consistent with acute lung injury or ARDS and occurs in approximately 6% of pneumonectomies, 3.7% of lobectomies, and 1% of minor resections. Mortality in these cases is 64.5%.[49]

The pathogenesis of post–lung-resection pulmonary edema is multifactorial. Perioperative fluid overload, impaired lymphatic drainage from lymph node dissection, damage from high concentrations of oxygen, and ischemia and reperfusion injury are probably involved.[50]

Management of post–lung-resection pulmonary edema includes mechanical ventilation, with particular attention paid to airway pressures, and fluid restriction.

Table 5 Drugs Associated with Acute Pulmonary Edema

Narcotics	Intrathecal methotrexate
Cocaine	Bleomycin
Salicylates	Dextran
Nonsteroidal anti-inflammatory drugs	Contrast media
Naloxone	Ethchlorvynol
Amiodarone (after general anesthesia)	Phenothiazines
Thiazide diuretics	Colchicine
Tocolytic agents	Interleukin-2
Protamine	Insulin
Cytarabine	All-*trans*-retinoic acid[54]

XI PULMONARY HYPERTENSION, COR PULMONALE, AND MISCELLANEOUS VASCULAR CONDITIONS

LEWIS J. RUBIN, M.D.

Pulmonary hypertension is a hemodynamic abnormality that is caused by a variety of disorders. It can be classified into four broad categories: (1) pulmonary arterial hypertension; (2) pulmonary venous hypertension (e.g., left ventricular dysfunction and mitral valve disease); (3) pulmonary hypertension associated with disorders of the respiratory system, usually with hypoxemia (e.g., chronic obstructive and restrictive lung disease); and (4) pulmonary hypertension caused by chronic thrombotic or embolic disease [*see Table 1*].[1] This chapter covers the processes that chronically affect the pulmonary vasculature directly as well as the common features of acute and chronic cor pulmonale, irrespective of cause.

Pulmonary Hypertension

Pulmonary hypertension is defined as a mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg with exercise. Pulmonary hypertension may be suggested when estimated pulmonary arterial systolic pressure exceeds approximately 40 to 50 mm Hg (tricuspid regurgitation velocity of 3.0 to 3.4 m/sec), as assessed by echocardiography. The prevalence of pulmonary hypertension is difficult to measure precisely, but it is very common; most patients with heart failure have some degree of pulmonary hypertension.[2]

PHYSIOLOGY

The normal pulmonary circulation is capable of accommodating the entire cardiac output at perfusion pressures that are one fifth of those in the systemic circulation, even when cardiac output increases severalfold during exercise. The pulmonary circulation accomplishes this by dilation of the vasculature already receiving the cardiac output and recruitment of unused vasculature (i.e., arterioles and capillaries); by these mechanisms, the pulmonary circulation minimizes increases in perfusion pressure and maximizes gas exchange surface area. There are two unique characteristics of the pulmonary vasculature. First, the effect of gravity on blood flow through the lungs is greater than its effect on ventilation, which results in diminishing zones of perfusion from base to apex in the upright position. Upstream pressure, such as the filling pressure from the left side of the heart, also increases pulmonary arterial pressures by distending and recruiting vasculature. Second, there are two portions of the vasculature that are influenced in opposite directions by changes in lung gas volume. Alveolar vessels are lengthened and narrowed monotonically with increases in lung volume; this in turn produces an increase in their resistance to blood flow. In series with the alveolar vessels are the extra-alveolar vessels that are tethered by the lung parenchyma; their size increases with increases in lung gas volume. The result of this interplay of these two characteristics is a rise in pulmonary vascular resistance both when lung volume decreases below usual levels and when it increases above usual levels [*see Figure 1*].

Accordingly, the major responses of the normal pulmonary circulation to upstream and downstream vascular pressures and to changes in lung volume are generally passive responses. Neural and humoral vasomotor responses are normally modest, in keeping with the paucity of vascular smooth muscle.

PATHOGENESIS AND PATHOPHYSIOLOGY

Pulmonary hypertension can be caused by narrowing of the precapillary vessels (arteries and arterioles), loss of vascular surface area, or passive back pressure from the postcapillary vessels [*see Table 2*].

Precapillary pulmonary hypertension can be produced by several mechanisms. Embolic material, such as venous thrombi, can lodge in the pulmonary artery, producing acute obstruction

Table 1 Revised Nomenclature and Classification of Pulmonary Hypertension (2003)[1]

- Pulmonary arterial hypertension (PAH)
  - Sporadic (IPAH)
  - Familial (FPAH)
  - Conditions associated with PAH
    - Collagen vascular disease
    - Congenital systemic to pulmonary shunts (large, small, repaired or nonrepaired)
    - Portal hypertension
    - HIV infection
    - Drugs and toxins
    - Other (glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy)
    - Significant venous or capillary involvement
      - Pulmonary veno-occlusive disease
      - Pulmonary capillary hemangiomatosis
- Pulmonary venous hypertension
  - Left-sided atrial or ventricular heart disease
  - Left-sided valvular heart disease
- Pulmonary hypertension associated with hypoxemia
  - Chronic obstructive pulmonary disease
  - Interstitial lung disease
  - Sleep-disordered breathing
  - Alveolar hypoventilation disorders
  - Chronic exposure to high altitude
- Pulmonary hypertension due to chronic thrombotic and/or embolic disease
  - Thromboembolic obstruction of proximal pulmonary arteries
  - Thromboembolic obstruction of distal pulmonary arteries
  - Pulmonary embolism (tumor, parasites, foreign material)
- Miscellaneous
  - Sarcoidosis
  - Histiocytosis X
  - Lymphangiomatosis
  - Compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

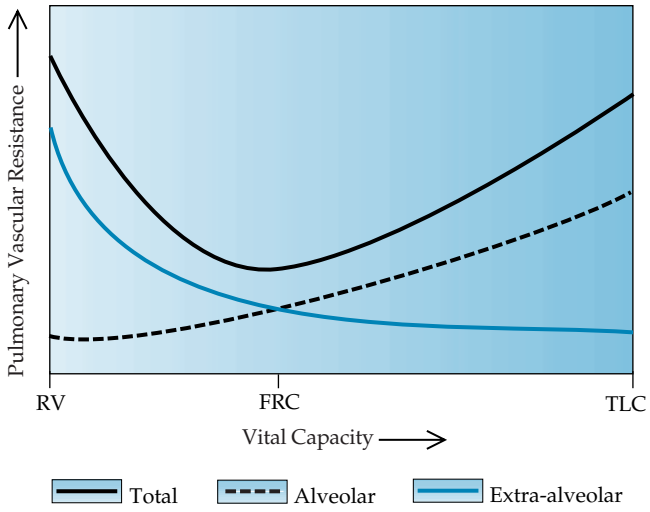

Figure 1 **Effects of lung volume on vascular resistance in alveolar, extra-alveolar, and total pulmonary circulation. The total vascular resistance is lowest at functional residual capacity (FRC) and is higher at low lung volume (residual volume [RV]) and high lung volume (total lung capacity [TLC]).**

or, if unresolved and organized into the vessel wall, chronic obstruction. In situ thrombosis can also occur. Chronically increased blood flow, as seen in large left-to-right intracardiac shunts, is associated with remodeling of the pulmonary arterial walls to vessels that resemble systemic arteries and arterioles; this results in an increase in pulmonary vascular resistance and, ultimately, reversal of the shunt (a condition known as Eisenmenger syndrome). Remodeling of the pulmonary arterial and arteriolar walls as a result of inflammation or endothelial dysfunction can also occur, for example in idiopathic pulmonary arterial hypertension (IPAH) or pulmonary arterial hypertension (PAH) caused by connective tissue diseases.

Loss of the pulmonary vascular bed as a result of destructive processes such as emphysema or interstitial fibrotic disease will increase resistance to blood flow and produce pulmonary hypertension. Hypoxia-induced pulmonary vasoconstriction and vascular remodeling further augment the degree of pulmonary hypertension in this setting.

On rare occasions, the pulmonary veins can be obstructed by a primary process (pulmonary veno-occlusive disease) or during passage of the pulmonary veins through the mediastinum (neoplasm or mediastinal fibrosis). Any process that increases left atrial pressure (mitral stenosis or regurgitation) or increases left ventricular end-diastolic pressure (LVEDP) will also increase pulmonary arterial pressure, with less dramatic increases in intrinsic pulmonary arteriolar resistance.

Regardless of the etiology, when pulmonary hypertension occurs, the vasculature responds by undergoing changes that further increase its resistance [*see Figure 2*].[3] The patterns of histopathologic change seen in pulmonary hypertension are medial hypertrophy, intimal thickening, plexogenic pulmonary arteriopathy, thrombotic pulmonary arteriopathy, and veno-occlusive disease.[4] Historically, these patterns were felt to be specific for the different causes of pulmonary hypertension. However, more recent studies indicate that these changes likely represent a final common pathway of response to pulmonary vascular injury and persistent pulmonary hypertension.

DIAGNOSIS

The diagnostic evaluation of pulmonary hypertension [*see Figure 3*] begins with a careful history and physical examination.

Many of the clinical features of pulmonary hypertension are similar regardless of the underlying cause.[5] Early in the process, the symptoms of pulmonary hypertension may be minimal and nonspecific. Dyspnea, weakness, and fatigue are common; these symptoms are sometimes associated with chest pain that can mimic angina pectoris. Syncope, which is often exertional, occurs late in pulmonary hypertension; it is a sign of poor prognosis because it implies an inability to augment cardiac output during exertion. Hoarseness caused by compression of the recurrent laryngeal nerve (Ortner syndrome) and hemoptysis related to rupture of hypertensive, atherosclerotic small pulmonary vessels could occur. Signs and symptoms of right ventricular failure, such as edema and ascites, occur relatively late in the disease; as with syncope, these symptoms indicate a poor prognosis.

Physical Examination

During physical examination, the jugular veins may be distended, and there may be prominent A waves, signifying decreased right ventricular (RV) compliance. Also, increased V waves may indicate tricuspid regurgitation. Palpation of the chest may detect an RV heave in the parasternal area or, in patients with COPD, in the subxiphoid area. On auscultation of the heart, there may be an increased P_2, an RV S_4, an RV S_3, a pulmonic ejection click, the murmur of tricuspid regurgitation at the lower right sternal border that is increased with inspiration, and, occasionally, pulmonic regurgitation (Graham Steell murmur). Hepatomegaly, ascites, and lower extremity edema are each extrathoracic indicators of right ventricular failure.

Table 2 Relation between Site, Pathogenesis, and Disorders of the Pulmonary Circulation

Site	*Pathogenesis*	*Disorders*
Precapillary	Intravascular obstruction, increased blood flow, vascular remodeling or inflammation, vasospasm, increased blood viscosity	Pulmonary emboli or in situ thrombosis, left-to-right shunt, alveolar hypoxia, vasculopathy caused by collagen vascular disorder or primary pulmonary hypertension, polycythemia
Capillary	Destruction of capillary bed	Emphysema, interstitial lung disease, surgical removal
Postcapillary	Passive back pressure from pulmonary venous obstruction, high left atrial pressure, high LVEDP	Pulmonary veno-occlusive disease, pulmonary venous obstruction in the mediastinum, mitral regurgitation or stenosis, left ventricular failure

LVEDP—left ventricular end-diastolic pressure

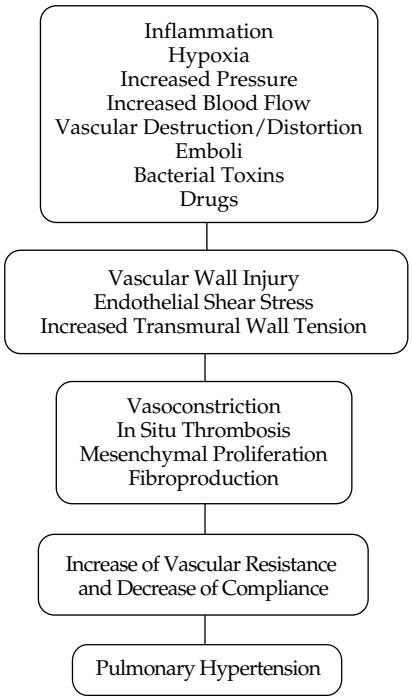

Figure 2 **Mechanisms of pulmonary hypertension. Irrespective of the initiating event or events, pulmonary hypertension worsens over time because of vascular wall injury, endothelial shear stress, and an increase in transmural wall tension. These processes result in vasoconstriction, vascular wall remodeling, and in situ thrombosis.**

Initial Imaging and Physiologic Testing

Chest radiography The chest radiograph can provide clues to the diagnosis and etiology of pulmonary hypertension. Symmetrical enlargement of the pulmonary arteries, with rapid tapering of the distal vessels (pruning) and enlargement of the right ventricle, can be found but usually is not seen until later stages of the disorder. Asymmetrical enlargement of the central pulmonary arteries may be seen in patients with chronic thromboembolic pulmonary hypertension (CTEPH). Radiographic findings that suggest the underlying cause of pulmonary hypertension include pulmonary venous congestion (e.g., LV failure), hyperinflation (COPD), and interstitial lung disease (e.g., interstitial pulmonary fibrosis).

Electrocardiography In mild cases of pulmonary hypertension, the electrocardiogram may be normal. In more severe cases, the ECG will show changes of right ventricular hypertrophy and right atrial enlargement. These changes are to be contrasted with the typical ECG findings seen in COPD, which largely reflect the hyperinflation of the lungs and low diaphragms.

Transthoracic echocardiography Transthoracic echocardiography with Doppler estimation of pulmonary arterial pressure is the noninvasive method of choice in screening populations of patients with a high incidence of pulmonary hypertension; such patients include those with the scleroderma spectrum of disease, those who have a family history of pulmonary artery hypertension, patients with HIV, and patients with cirrhosis who are being evaluated for liver transplantation. Transthoracic echocardiography is also useful in evaluating patients with symptoms suggestive of pulmonary hypertension. Findings indicative of pulmonary hypertension include hypertrophy, enlargement of the right ventricle and atrium, and abnormal motion of the septum [*see Figure 4*]. In some patients, transesophageal echocardiography may be necessary to detect congenital defects. If hypoxemia suggestive of a right-to-left intracardiac shunt is present, injection of saline filled with air bubbles during the echocardiogram will allow detection and localization of the shunt.

Tests to Diagnose Underlying Cause of Pulmonary Hypertension

It is often necessary to perform additional testing to determine the etiology of pulmonary hypertension. The sequence for this testing generally begins with noninvasive studies, followed by more invasive studies as needed.

Pulmonary function testing Measurements of pulmonary function can be useful in evaluating patients with pulmonary hypertension. Detection of severe obstructive or restrictive defects may indicate that all or a portion of the pulmonary hypertension is caused by intrinsic lung disease. By contrast, isolated reduction of the diffusion capacity or minimal reduction in the lung volumes can be seen in any of the causes of pulmonary vasculopathy. Arterial blood gases at rest and pulse oximetry with exercise detect complicating resting or exercise hypoxemia that should be remedied therapeutically with supplemental oxygen. The finding of hypercapnia is most compatible with severe chronic airflow obstruction, sleep apnea, or restrictive chest wall disease.

Polysomnography Patients suspected of having a sleep disorder of breathing that may be causing or contributing to pulmonary hypertension should undergo nocturnal polysomnography.

Ventilation-perfusion lung scanning Ventilation-perfusion lung scanning is a critical test in evaluating patients with pulmonary hypertension, especially when chronic thromboembolic pulmonary hypertension is suspected. Patients with chronic thromboembolic pulmonary hypertension will have multiple, bilateral perfusion defects of different sizes (usually interpreted as indicating a high probability of pulmonary embolism), whereas patients with other causes of pulmonary hypertension will have either homogeneous or mildly mottled perfusion [*see Figure 5*]. The presence of radioactivity in the head or kidney suggests a right-to-left intracardiac or intrapulmonary shunt.

Computed tomography Computed tomography of the chest using spiral or helical or electron-beam techniques can visualize central pulmonary thromboemboli. High-resolution CT of the chest can detect emphysema or interstitial lung disease not seen on routine chest radiography and may also provide clues to the presence of pulmonary veno-occlusive disease.

Cardiac catheterization and pulmonary arteriography Right heart catheterization, with pulmonary arteriography and/or left heart catheterization as clinically indicated, should be performed to confirm the presence of pulmonary hypertension and determine its severity and to exclude congenital heart disease, proximal or peripheral pulmonary arterial stenosis, and valvular or ventricular left sided heart disease. Because of the increased risk of complications, experienced angiographers should perform pulmonary arteriography in this situation. In those patients who are thought to have PAH, vasodilator testing with such agents as ni-

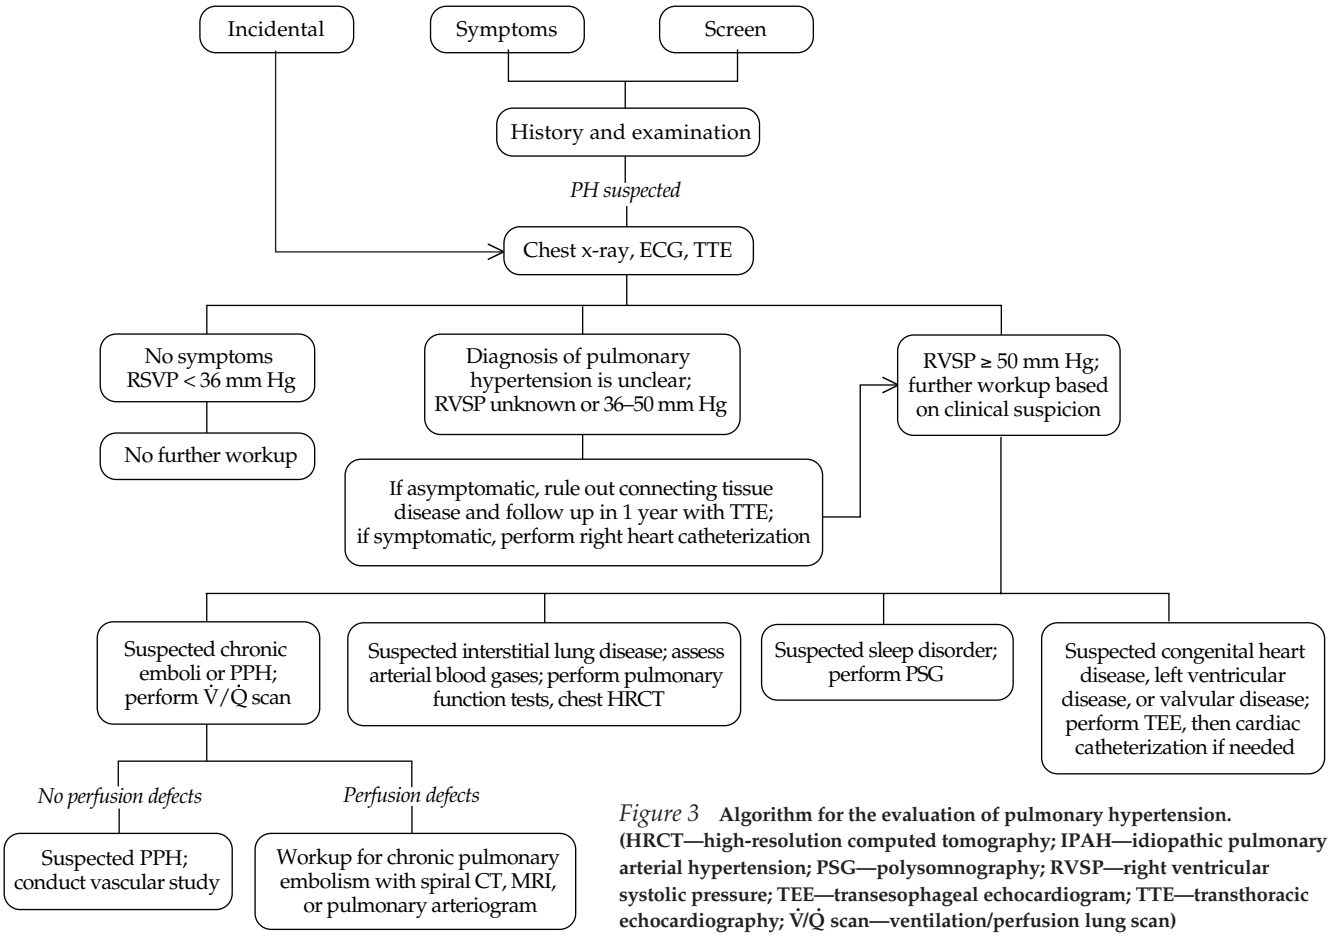

Figure 3 **Algorithm for the evaluation of pulmonary hypertension. (HRCT—high-resolution computed tomography; IPAH—idiopathic pulmonary arterial hypertension; PSG—polysomnography; RVSP—right ventricular systolic pressure; TEE—transesophageal echocardiogram; TTE—transthoracic echocardiography; V̇/Q̇ scan—ventilation/perfusion lung scan)**

tric oxide, prostacyclin, and adenosine, with monitoring of gas exchange and pulmonary hemodynamics, should be performed.[5]

Lung biopsy It is very uncommon that a lung biopsy is required to establish the cause of pulmonary hypertension. The only exceptions would be in patients in whom one of the interstitial lung diseases or pulmonary arteritis is suspected as a cause of pulmonary hypertension. Bronchoscopic lung biopsy is contraindicated in patients with severe pulmonary hypertension; in such cases, open or video-assisted biopsy is the technique of choice. Such a biopsy poses a greater risk for patients with pulmonary hypertension than for patients without pulmonary hypertension.

TREATMENT

Treatment of pulmonary hypertension depends on the underlying cause. Disorders that affect the pulmonary circulation acutely (e.g., pulmonary embolism, pulmonary edema, and the acute respiratory distress syndrome) are covered elsewhere [*see 1:XVIII Venous Thromboembolism and 14:X Pulmonary Edema*], as are valvular heart defects [*see 1:XI Valvular Heart Disease*], congenital heart defects that can cause pulmonary hypertension [*see 1:XV Adult Congenital Heart Disease*], and diseases that affect the lung airways and parenchyma, such as COPD and the interstitial lung diseases [*see 14:III Chronic Obstructive Diseases of the Lung and 14:V Chronic Diffuse Infiltrative Lung Disease*].

Cor Pulmonale

DEFINITION

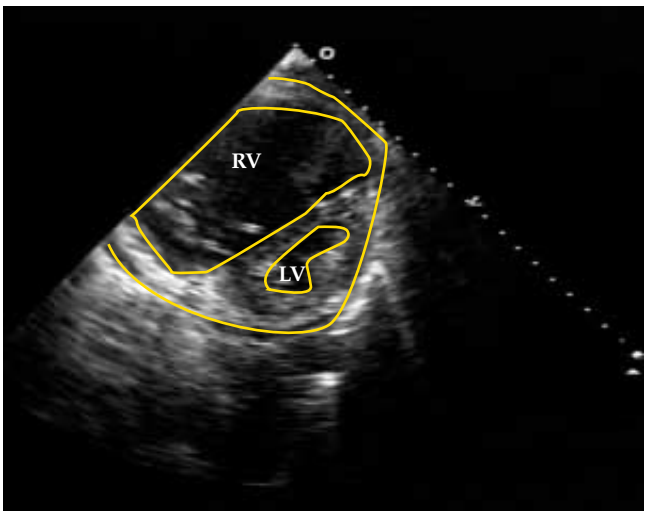
Cor pulmonale is the term used for pulmonary hypertension resulting from disorders of the pulmonary parenchyma, the thoracic cage, or the neuromuscular system, excluding congenital heart disease and disorders of the left side of the heart. Cor pulmonale can occur acutely in settings of rapid-onset right ventricular overload, or chronically with the slow onset of pulmonary hypertension.

ACUTE COR PULMONALE

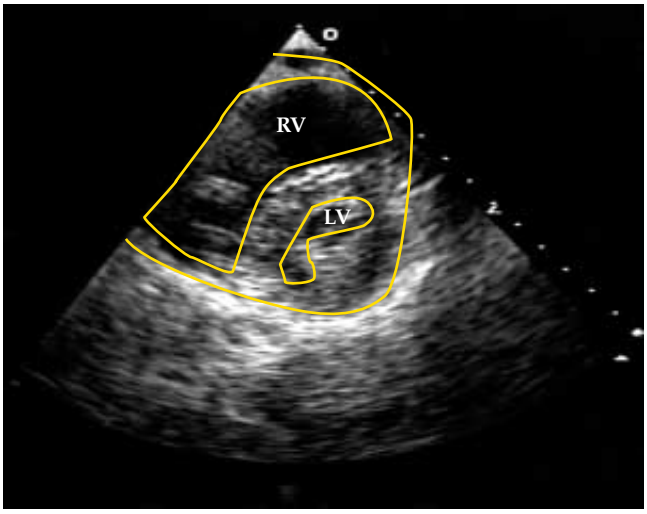
Pathogenesis

The right ventricle normally pumps against a low afterload, even when cardiac output is dramatically increased by exercise. In response to an acute increase in pulmonary vascular resistance, the right ventricle distends, producing an increase in right ventricular systolic and diastolic volume, but is unable to generate high pressures (the maximal pressure generated is usually approximately 40 mm Hg). If the right ventricle cannot adequately compensate, increases in right ventricular end-diastolic pressure (RVEDP) and right atrial pressure occur, producing acute right heart failure. Additionally, the reduced cardiac output from the right ventricle to the left ventricle and the shift of the interventricular septum toward the left ventricle cause a re-

a



b



c

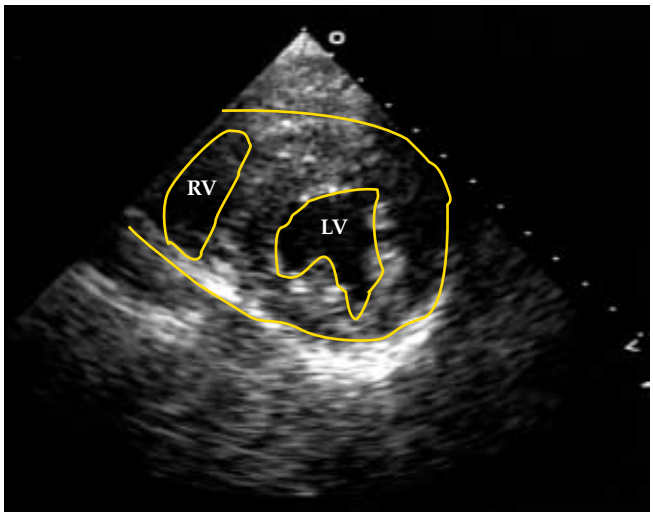


Figure 4 **(*a*) Echocardiogram of a patient with chronic pulmonary hypertension. (*b*) Echocardiogram of a patient with acute pulmonary hypertension. (*c*) Echocardiogram of the patient shown in Figure B after clot lysis. (LV—left ventricle; RV—right ventricle)**

duction in left ventricular filling, resulting in systemic hypoperfusion. Decreased coronary perfusion caused by low systemic diastolic pressure further reduces the ability of the right ventricle to overcome the added resistance, producing a rapid decline to death.

The disorders that cause acute cor pulmonale are diseases that produce sudden obstruction of the pulmonary vasculature, such as massive pulmonary thromboembolism[6]; acute embolism caused by other materials, such as air, bone marrow, fat, amniotic fluid, or tumor; or obstruction of the microvasculature caused by high airway pressure or destruction, as is seen in acute respiratory distress syndrome.[7]

Diagnosis

In the setting of acute respiratory failure or shock with evidence of acute right heart failure, immediate bedside echocardiography can demonstrate acute cor pulmonale. Features that are seen include pulmonary hypertension (usually mild), right ventricular dilatation without hypertrophy, tricuspid regurgitation, septal flattening or paradoxical septal motion, and left ventricular diastolic dysfunction [*see Figure 5*].[8]

Treatment

Rapid recognition of acute cor pulmonale and relief of the pulmonary vascular obstruction, if possible, are key to survival for patients with acute cor pulmonale. For example, thrombolytic therapy for patients with acute massive pulmonary embolism may result in complete resolution of the acute cor pulmonale [*see Figure 6*].[9]

CHRONIC COR PULMONALE

Pathogenesis

In response to a chronic increase in pulmonary vascular resistance, the right ventricle will distend and undergo hypertrophy. When the ability of the right ventricle to compensate is overwhelmed, increases in RVEDP and right atrial pressure occur, resulting in right heart failure.

The pulmonary hypertension that characterizes chronic cor pulmonale is produced by increased pulmonary vascular resistance caused by varying combinations of pulmonary vascular destruction or obstruction, dynamic vasoconstriction caused by hypoxia or acidosis, and remodeling of the pulmonary vasculature. Some of these changes (e.g., hypoxic vasoconstriction and some remodeling) are reversible with therapy, whereas others (vascular bed destruction) are not.

Diagnosis

Early detection of chronic cor pulmonale may be difficult because the manifestations of the underlying lung disease dominate the clinical picture. The clinical features and evaluation are the same as those described for pulmonary hypertension [*see* Pulmonary Hypertension, *above*] Echocardiography has become the most useful means of detecting right heart changes caused by pulmonary hypertension.

Treatment

The nature and severity of the underlying lung disease determine the outcome of patients with chronic cor pulmonale. For example, cor pulmonale secondary to sleep apnea may be entirely reversible with treatment directed at the underlying ventilatory disorder, whereas cor pulmonale caused by idiopathic pul-

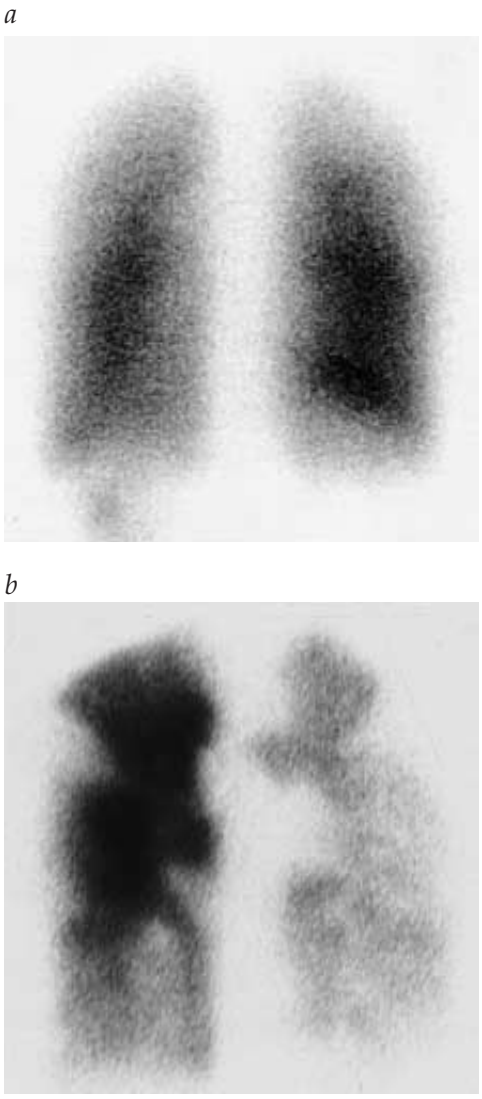

Figure 5 **Perfusion lung scans of a patient with primary pulmonary hypertension showing homogeneous perfusion (*a*) and of a patient with chronic thromboembolic pulmonary hypertension, showing large bilateral perfusion defects (*b*)**

monary fibrosis is often irreversible. In patients with COPD, an increased incidence of right ventricular involvement may correlate with increasing severity of lung dysfunction.

The most important treatment of chronic cor pulmonale is the treatment of the underlying lung disease [*see 14:III Chronic Obstructive Diseases of the Lung, 14:V Chronic Diffuse Infiltrative Lung Disease, 14:VI Ventilatory Control during Wakefulness and Sleep, and 14:VII Disorders of the Chest Wall*]. In patients with hypoxemia, controlled-flow supplemental O_2 should be given at rest, during exercise, and during sleep to maintain O_2 saturation above 90%. Patients should be monitored for acute increases in arterial carbon dioxide pressure (P_aCO_2).

Diuretics are useful in reducing the edema, ascites, and liver congestion associated with cor pulmonale, but these agents must be used carefully to avoid reducing right ventricular filling pressures, which may lead to decreasing cardiac output. Phlebotomy in patients with secondary polycythemia[10] and noninvasive mechanical ventilation of patients with chronic respiratory failure[11] may also improve hemodynamics.

Although vasodilator agents such as calcium channel blockers block hypoxic pulmonary vasoconstriction and cause pulmonary vasodilatation, the impairment in gas exchange in patients with chronic cor pulmonale negates any potential positive effect of these drugs. Epoprostenol (prostacyclin) and three of its analogues have been studied in several types of chronic pulmonary hypertension and are approved for use in PAH, but they have not been studied extensively in cor pulmonale.[12] Except in cases of coexistent left ventricular failure, clinical studies do not support the use of digitalis in patients with cor pulmonale; in addition, use of digitalis may be associated with greater toxicity.

Intrinsic Pulmonary Vascular Diseases

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Idiopathic pulmonary arterial hypertension (IPAH), formerly known as primary pulmonary hypertension (PPH), is a condition in which the pulmonary vasculature is the exclusive site of the pulmonary hypertension.[1,13] By definition, other causes of pulmonary hypertension are excluded.

Epidemiology

IPAH is rare, having an estimated incidence of 1 to 2 per million people a year. Although the disease can occur at any age, the mean age at diagnosis is 36 years.[13] The disease is more frequent in females than in males (ratio, 1.7:1 to 3.5:1) and is equally represented in all races. Approximately 6% to 12% of cases are familial, now termed familial pulmonary artery hypertension (FPAH).[1,14]

In the United States, the mortality from IPAH rose substantially from 1979 to 1996, possibly because of the introduction of anorexigens (see below).[15]

Etiology and Pathogenesis

The cause of IPAH is unknown, although there are several clinical conditions associated with its development. For example, the ingestion of certain drugs or other materials has been associated with IPAH.[16] In the 1960s and again in the 1990s, ingestion

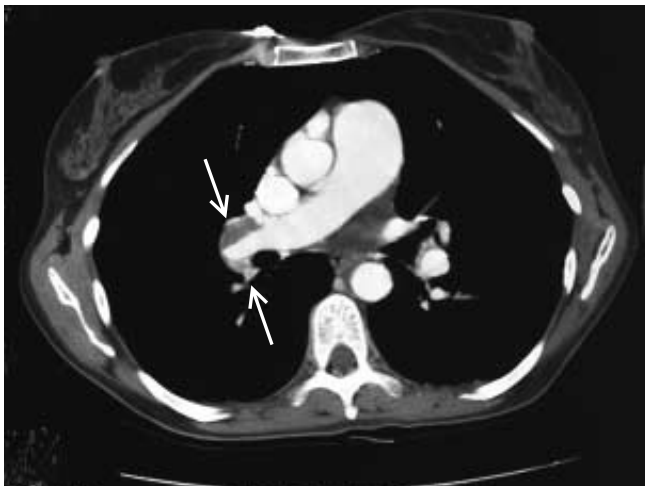

Figure 6 **Spiral CT scan of the chest of a patient with chronic thromboembolic pulmonary hypertension showing large defects in the right main pulmonary artery (arrows).**

of appetite suppressants such as aminorex, fenfluramine, and dexfenfluramine were associated with an increased incidence of pulmonary hypertension.[17] Additionally, ingestion of contaminated rapeseed oil, L-tryptophan, amphetamines, and cocaine are associated with IPAH.[16] Other conditions associated with IPAH are splenectomy/asplenia, portal hypertension, and HIV infection.[18,19]

As is true of many diseases, it is thought that PAH in general, and IPAH in particular, results from an inciting factor in a genetically susceptible individual. Studies of inheritance have suggested an autosomal dominant pattern with markedly reduced penetrance in FPAH. The gene for familial pulmonary hypertension, *PPH1,* has now been identified as heterogeneous germline mutations of the gene coding for the bone morphogenic protein receptor 2 (BMPR2).[20] The exact mechanisms accounting for how abnormalities of this receptor produce pulmonary hypertension are being investigated.[21]

Studies of the pulmonary vasculature in IPAH suggest endothelial injury and dysfunction occur early in the process.[22] In IPAH, expression of endothelial nitric oxide synthetase is reduced (nitric oxide is a pulmonary vasodilator) and expression of endothelin 1, a potent pulmonary vasoconstrictor and a mitogen, is increased. There is an excess of thromboxane (a vasoconstrictor and potent stimulus for platelet aggregation) relative to prostacyclin, a pulmonary vasodilator. Other vasoactive mediators, such as serotonin, another pulmonary vasoconstrictor, may also play a role, especially in pulmonary hypertension associated with appetite suppressants, which inhibit serotonin reuptake and increase expression of its transporter. Abnormal α_1-adrenoceptor affinity and responsiveness may produce downstream signaling events that cause defects in ion channel activity and control of intracellular calcium and could contribute to vasoconstriction and to smooth muscle proliferation and growth.[23] As a consequence of the endothelial dysfunction and resultant pulmonary vasoconstriction, intimal proliferation, smooth muscle hyperplasia and hypertrophy, and other remodeling phenomena occur, further increasing pulmonary vascular resistance.[19] In situ thrombosis may also play a role in endothelial injury and vascular obstruction.

Diagnosis

The diagnosis of IPAH can be made when clinical findings (e.g., raised pulmonary artery pressure, dyspnea, evidence of right heart failure) [*see* Pulmonary Hypertension, *above, and Figure 3*] are present and other causes of pulmonary hypertension have been excluded.[13]

Treatment

Medical therapy Current treatment options slow the progression of the disease but do not halt it. Patients with IPAH should receive long-term warfarin anticoagulation therapy to achieve an INR (international normalized ratio) of 1.5 to 2.5, and they should avoid medications that interfere with warfarin metabolism.[13] Medications that worsen pulmonary hypertension or right heart function (e.g., decongestants, beta blockers) should also be avoided. Symptom-limited physical activity should be encouraged. Pregnancy is poorly tolerated and should be prevented (oral contraceptives should not be used, because they may increase the risk of thrombosis). Invasive medical procedures should be avoided whenever possible. Oxygen should be used for resting or exercise-induced hypoxemia or if the patient will be exposed to high altitudes, such as on an airplane flight. Diuretics are useful to help control edema and ascites. Use of digoxin is controversial.[24] Vasodilators may be helpful for only a select portion of patients with pulmonary hypertension who have evidence of significant vasoreactivity, generally considered to be 10% of those with IPAH and very few with other forms of PAH. For patients who have an acute vasodilator response to the agents used (i.e., inhaled nitric oxide, inhaled iloprost, intravenous epoprostenol, or intravenous adenosine), a trial of a calcium channel blocker, such as nifedipine or diltiazem, should be initiated. The patient should be monitored closely during this time because some patients will deteriorate despite this therapy. If the patient responds, the therapy can be continued and titrated to maximum benefit. Patients should be warned that abrupt withdrawal of therapy can lead to rebound pulmonary hypertension that can be fatal.[24]

Patients who do not show a vasodilator response during right heart catheterization should be started on one of the other available agents, including the oral endothelin receptor antagonists (e.g., bosentan), subcutaneous or intravenous treprostinil, inhaled iloprost, or intravenous epoprostenol.[13,25-27] Epoprostenol must be given intravenously and, because of its 3- to 5-minute half-life, delivered by continuous infusion. Abrupt discontinuance of therapy may be required because of drug-delivery system malfunction or I.V. access infections. Minor side effects include headache, jaw pain, rash, diarrhea, and joint pain. The dose must be gradually increased over time to maintain maximum benefit. Epoprostenol appears to have effects that go beyond vasodilation and may include the decreased production of endogenous vasoconstrictor substances and antiplatelet and antiproliferative properties that seem to ameliorate what previously appeared to be irreversible vascular changes.[28] Bosentan is administered orally twice daily. The major toxicity is hepatic, which necessitates monthly monitoring of liver function. Treprostinil administered subcutaneously produces site pain that often limits its usefulness. Inhaled iloprost obviates the need for intravenous delivery of prostanoid medication; however, it must be administered by nebulization six to nine times daily.

Surgical therapy Creation of a small interatrial communication by percutaneous balloon atrial septostomy may result in decompression of the right ventricle and improvement in symptoms related to right heart failure.[29] Indications include recurrent syncope and right heart failure despite maximum medical therapy, deterioration despite maximum medical therapy while the patient is awaiting transplantation, and exhaustion of all other options. Because right-to-left shunting at the atrial level occurs, hypoxemia worsens but is usually well tolerated in patients without severe preprocedure hypoxemia.

Lung transplantation Lung transplantation is indicated for patients in whom IPAH has progressed despite optimal medical and surgical therapy. In most centers, heart-lung transplantation is no longer performed because it was found that the right ventricle recovered both form and function when pressure fell after even single-lung transplantation. Indications for referral for transplant evaluation include New York Heart Association (NYHA) functional class III or IV despite medical therapy[29]; failure of epoprostenol therapy and the occurrence of severe side effects from epoprostenol are additional indications for referral for transplant evaluation. These guidelines take into consideration the course of the disease and the waiting time for transplantation.

The surgical mortality for patients with IPAH is higher than that for patients receiving lung transplantation for other forms of pulmonary disease,[30] partly because of the greater complexity of the transplant surgery. The 1-year survival for patients receiving lung transplantation for IPAH is 65%; the 3-year survival is 55%; and the 5-year survival is 44%. No randomized study of medical therapy versus transplantation has been performed. Comparison of survival data from different studies suggests that survival may be higher with medical therapy than with transplantation, although it is likely that only the more severely ill patients received lung transplantation.[31] Recurrences of IPAH after lung transplantation has not been reported.

Prognosis

A National Institutes of Health (NIH) registry of patients with IPAH in the 1980s defined the natural history of the disease.[32] The mean life expectancy from diagnosis was 2.8 years, and the 5-year survival was 22% to 38%. Patients younger than 14 years and older than 65 years had lower survival, as did patients with more severe symptoms. Patients with acute responses to vasodilators had a better prognosis. This study also developed a formula, utilizing data from right heart catheterization (right atrial pressure, cardiac index, and mean pulmonary arterial pressure), that predicted survival of patients before the current era of efficacious medical therapy and lung transplantation. With these new therapies, the natural history of the disease has changed. A recent evaluation study identified African-American and Asian descent as factors associated with an increased risk of death in patients with IPAH; cardiac function and acute reactivity of the pulmonary vascular bed remained strong independent predictors of outcome.[33]

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Epidemiology

The epidemiology of chronic thromboembolic pulmonary hypertension (CTEPH) is unknown. An estimated 0.1% to 4% of patients with acute pulmonary embolism will experience chronic pulmonary hypertension, suggesting that several thousand cases occur each year in the United States.[34] There are conflicting data on the male-to-female ratio. The disease has been seen in adults of all ages, but more than 50% of patients are younger than 45 years. The reason for the development and lack of resolution of pulmonary emboli in these patients is unknown. A minority of the patients is found to have hypercoagulability states, such as deficiencies of protein C or S or of antithrombin III. About 10% will have circulating lupus anticoagulant.[35] The incidence of factor V Leiden and other hypercoagulable syndromes has not been adequately studied. Abnormalities of the fibrinolytic system have been sought, but no consistent patterns have been detected.[35] Embolization of so-called aged clot, lack of therapy for the initial episode of embolism, and recurrent emboli have all been hypothesized. Medical conditions that may be associated with an increased risk for the development of CTEPH are splenectomy, ventriculo-atrial shunt for the treatment of hydrocephalus, and chronic inflammatory disorders such as osteomyelitis and inflammatory bowel disease.[36]

Pathogenesis

CTEPH results from the organization (rather than lysis) of the clots from a single massive episode of pulmonary embolism or multiple episodes of pulmonary embolism. As a consequence of obstruction and distortion of the proximal pulmonary vasculature, the pulmonary vascular resistance is increased, and over time, pulmonary hypertension develops and right ventricular function worsens.[35]

Diagnosis

Clinical manifestations Patients with CTEPH usually present months or years after the initial (and often asymptomatic) embolic event(s) with symptoms of pulmonary hypertension.[35] The initial event may have been diagnosed as an episode of embolism (in only 50% of cases) or may have been undiagnosed or misdiagnosed as pneumonia or another clinical entity. The reason for the delay in onset of symptoms is unknown, although it is suspected that organization of the clot and the increased pulmonary arterial pressure result in progressive remodeling of the obstructed and unobstructed pulmonary vasculature, gradually worsening the pulmonary hypertension and finally resulting in right ventricular failure.

Physical examination A pulmonary arterial flow murmur is the only finding on physical examination that is characteristic of chronic thromboembolic pulmonary hypertension. It is best heard over the lung fields while the patient holds his or her breath.

Imaging and physiologic testing The chest radiograph may be normal or may show abnormalities suggestive of pulmonary hypertension. Findings that suggest chronic thromboembolic pulmonary hypertension include asymmetrical enlargement of the pulmonary arteries, regions of hyperperfusion and hypoperfusion, and focal fibrotic areas of old infarction that may be associated with local pleural thickening or cavitation.

The electrocardiogram may be normal or have changes of right ventricular hypertrophy or strain, right atrial enlargement, and right bundle branch block.

Pulmonary function tests will most commonly show no abnormality of lung volumes or of spirometry measurements, although about 20% of patients will have restriction, probably related to previous infarction.[35] Frequently, carbon monoxide diffusion in the lung is mildly reduced; this reduction is thought not to be proportional to the degree of obstruction. Hypoxemia is common and is often worsened by exercise. The hypoxemia is the result of a combination of ventilation-perfusion inequality, low cardiac output, and, sometimes, a patent foramen ovale with a right-to-left shunt.[35]

The ventilation-perfusion lung scan is the best method of screening patients with pulmonary hypertension to identify those in whom the disorder may be caused by chronic thromboembolism.[35,37] Patients with chronic thromboembolism will have at least one segmental or larger perfusion defect [*see Figure 5*]. This pattern can also be seen with tumor or fibrosing mediastinitis. In chronic thromboembolism, the degree of obstruction is underestimated by the defects seen on the perfusion scan.[35]

When large perfusion defects are seen on the ventilation-perfusion scan, additional testing is needed to confirm that the defects are caused by chronic thromboembolism. Spiral CT is a noninvasive imaging technique that can allow identification of proximal chronic clots and detect other causes of pulmonary vascular obstruction [*see Figure 6*].[35] However, pulmonary angiography is needed to accurately assess the full extent of pulmonary vascular obstruction and determine candidacy for pulmonary thromboendarterectomy.

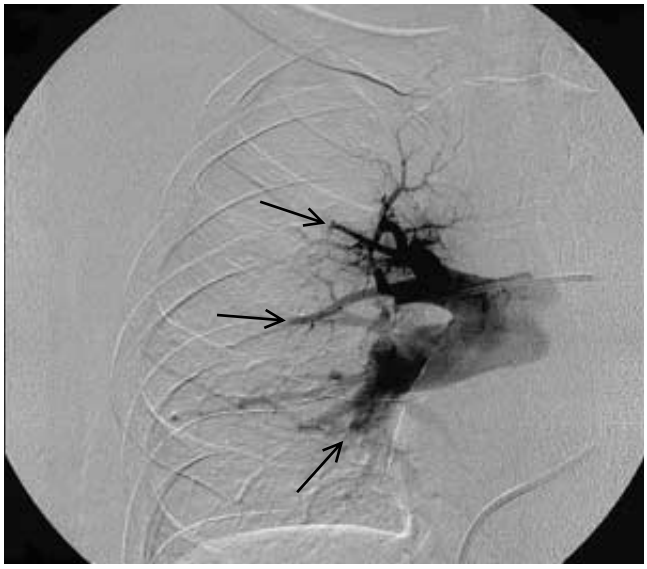

Figure 7 **Pulmonary arteriogram of a patient with chronic thromboembolic pulmonary hypertension showing multiple abrupt terminations (arrows) of the pulmonary arterial branches, with no distal flow characteristic of chronic pulmonary embolism.**

The use of pulmonary angiography in patients with pulmonary hypertension has been thought to be associated with a significant risk of death or adverse outcome. Use of oxygen, small amounts of nonionic contrast dye, and a limited number of injections has reduced the risk dramatically.[35] Results of pulmonary angiography must be interpreted with the understanding that the patterns of pulmonary hypertension are different from those of acute embolism [*see Figure 7*].[35] In some cases, direct visualization of the pulmonary vasculature by pulmonary angioscopy is useful to confirm the presence and extent of obstruction.[35]

Treatment

There is no effective medical therapy for CTEPH. Vasodilators, angioplasty of the obstructed areas, and thrombolytic therapy have been investigated in small studies and have limited utility. Preoperative anticoagulation is needed to prevent further embolism and in situ thrombosis. Placement of an inferior vena cava filter is recommended.[35]

Surgery for CTEPH is pulmonary endarterectomy, a procedure that is associated with significant risk and therefore should not be considered unless the patient meets criteria for surgery. The criteria used in the centers with expertise are: an elevated pulmonary vascular resistance (> 300 dynes·sec·cm^{-5}), severe disability (at least NYHA class III), and surgically accessible disease.[35] Contraindications or factors that increase risk include significant comorbid disease, especially renal disease, inoperable coronary artery disease, other lung disease, and massive obesity. At highly experienced centers, survival has continued to improve over time: before 1990, mortality was 15.8%; from 1998 to 2002, mortality was reduced to 4.4%.[38]

Pulmonary thromboendarterectomy is performed through a median sternotomy, with cardiopulmonary bypass, deep hypothermia, and periods of complete arrest (because of the brisk backbleeding from the increased bronchial collateral circulation), allowing better visualization in a bloodless field.[35] Dissection of the pulmonary artery starts in the proximal vessels and extends into the subsegmental branches, including the intima and some media. If an atrial septal defect or a patent foramen ovale is found, it is corrected.

Besides experiencing the usual complications associated with cardiac surgery, these patients have some specific problems, including reperfusion pulmonary edema in the previously obstructed areas, resulting in hypoxemia caused by shunting of blood from the previously unobstructed but remodeled pulmonary arterial bed into these newly opened areas.[35] Altered mental status is very common and seems to relate to the total circulatory arrest time.

Patients who are not candidates for pulmonary thromboendarterectomy may be considered for medical therapy with drugs used to treat other forms of pulmonary hypertension, although experience to date is limited.[39-41]

Prognosis

Without surgery, the survival rate for patients with CTEPH is poor. In patients whose mean pulmonary arterial pressure is 40 to 50 mm Hg, 5-year survival is 30%; in those whose pulmonary arterial pressure is greater than 50 mm Hg, 5-year survival is 10%.[35]

Mortality associated with pulmonary thromboendarterectomy ranges from 5% to 24% and is lowest in the institutions with the greatest experience. The patients who survive have improvement of functional status from NYHA class III or IV to NYHA class I or II.[35] The right heart recovers quickly, and the pulmonary arterial pressure may continue to fall for up to 1 year after surgery. Many patients are able to return to work.

CONDITIONS ASSOCIATED WITH PULMONARY ARTERIAL HYPERTENSION

Collagen Vascular Diseases

Pulmonary hypertension with little or no parenchymal lung disease is a life-threatening manifestation of the collagen vascular diseases.[42] The clinical course and pathologic changes are similar to those of IPAH. The pathophysiology is unknown, although autoantibodies, immunoglobulin, and complement have been found in the vessel walls, suggesting involvement of immune complexes.[43] Patients with scleroderma, particularly those with CREST syndrome (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasias) have a high incidence of pulmonary hypertension; the incidence ranges from 2% to 35% in patients with scleroderma to 50% in those with CREST syndrome. The incidence in patients with other disorders varies from 23% to 53% in those with mixed connective tissue disease to 0.5% to 14% in those with systemic lupus erythematosus; it is rare in those with rheumatoid arthritis, Sjögren syndrome, and dermatomyositis. Treatment of pulmonary hypertension in patients with collagen vascular diseases should be patterned after the protocol for IPAH detailed above.[25,44,45]

The role of immunosuppressive therapy in patients with pulmonary hypertension secondary to collagen vascular diseases is unclear. Sanchez and coworkers[42] reviewed the literature and found improvement in pulmonary hemodynamics with various immunosuppressive regimens in seven of 11 published cases. There have been no randomized, controlled trials with these agents, and this approach is not recommended as the primary treatment strategy.

Although patients with pulmonary hypertension secondary to collagen vascular disorders are sometimes excluded from con-

sideration of lung transplantation, transplants have been performed in such patients, with prolonged survival.[46]

Several disorders are associated with vasculitis involving the pulmonary vasculature; however, pulmonary hypertension associated with vasculitis is rare. The exceptions to this rule are Takayasu disease [*see 15:VIII Systemic Vasculitis Syndromes*], in which pulmonary arteritis and hypertension are common findings,[47] and rheumatoid arthritis[48] and systemic lupus erythematosus, in which pulmonary hypertension occurs much less commonly.[49]

Pulmonary Veno-occlusive Disease

Pulmonary veno-occlusive disease is a rare but distinct form of pulmonary hypertension characterized by obstruction of the small intrapulmonary veins.[50] About one third of patients are children, and there are some cases that seem to be related to HIV infection, use of chemotherapy drugs, or bone marrow transplantation.

Patients with this disorder experience increasing dyspnea, sometimes with hemoptysis. Findings on chest radiography suggest left ventricular failure; such findings include enlarged pulmonary arteries, Kerley B lines, pulmonary edema, and pleural effusions. The diagnosis should be considered when these radiographic findings are associated with no echocardiographic evidence of left ventricular dysfunction, mitral valvular disease, or obstruction to flow in the left atrium. CT scan of the chest can provide support for the diagnosis[51] and can help exclude obstruction of the pulmonary veins in the mediastinum (fibrosing mediastinitis or tumor). The diagnosis can be confirmed by open lung biopsy, which will show the combination of chronic congestion, pulmonary hypertensive changes in the pulmonary arteries, and narrowing or occlusion of the pulmonary veins by eccentric or concentric intimal fibrosis.

Therapies that are used in IPAH are inconsistently successful in veno-occlusive disease, and epoprostenol in particular has been associated with the development of pulmonary edema. Accordingly, lung transplantation should be considered once the diagnosis is established.[50,52]

Hematologic Disorders

Pulmonary hypertension is common in adults with sickle cell disease and most likely is a complication of hemolysis resulting from interference with the nitric oxide regulatory pathway [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*].[53]

Patients with chronic myeloproliferative disorders,[54] amyloidosis,[55] and the POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome[56] have been noted to have complicating pulmonary hypertension.

Pulmonary Arteriovenous Malformations

Abnormal, direct communications between branches of the pulmonary arteries and veins, producing a right-to-left shunt, are called pulmonary arteriovenous malformations (AVMs). Such lesions may be acquired (e.g., as a result of trauma or as a complication of cirrhosis) [*see 4:IX Cirrhosis of the Liver*] or congenital.[57]

Congenital pulmonary AVMs can be either single or multiple. They may be isolated to the lung or, much more commonly, can occur as part of an autosomal dominant syndrome of widespread AVMs in skin, mucous membranes, lungs, and other internal organs. The autosomal dominant syndrome is known as Osler-Weber-Rendu disease or hereditary hemorrhagic telangiectasia (HHT)[57] [*see 5:XIII Hemorrhagic Disorders*].

Diagnosis Pulmonary AVMs may produce severe symptoms or complications, but most patients are asymptomatic. The diagnosis is suggested by solitary or multiple pulmonary nodules found on routine chest radiography.[58] Dyspnea is the most common symptom, occurring at first with exercise and later at rest. Dyspnea that worsens in the upright position and improves on reclining (platypnea) has been seen in these patients. It may be caused by worsening of the right-to-left shunt in the lung bases with the patient in the upright position, producing hypoxemia (orthodeoxia). Hemoptysis, usually mild and related to bronchial mucosal telangiectasia, is the second most common symptom. Neurologic complaints are also seen.[58,59] Headache, tinnitus, seizures, symptoms that mimic transient ischemic attack, and completed stroke may relate to complicating polycythemia, paradoxical embolus, or brain abscess. Patients with HHT may have bleeding from AVMs outside the lungs, which is often sufficient to produce anemia. Physical findings include mucous membrane telangiectasia in the patients with HHT, cyanosis, digital clubbing, and intrapulmonary bruits that increase with inspiration. Patients with pulmonary AVMs have hypoxemia, with the degree of hypoxemia being proportional to the magnitude of the shunt. As a consequence, chronic respiratory alkalosis and polycythemia may occur. Pulmonary function tests are normal except for a decreased diffusing capacity.

The diagnosis is most often suggested by the finding on chest radiograph of a well-defined solitary pulmonary nodule or multiple nodules with a feeding artery, draining vein, or both. Echocardiography with contrast can also suggest the diagnosis.[58] Spiral CT with contrast will confirm the vascular nature of lesions and may detect others that were not obvious from standard radiography. The definitive diagnostic procedure, however, is pulmonary angiography, which allows demonstration of all significant lesions; this is important in planning therapy.[59,60]

Treatment The natural history of pulmonary AVMs is poorly understood. In asymptomatic patients, the treatment decisions must be made with the recognition of the risk of hemoptysis, paradoxical embolization, and brain abscess.

The treatment options include thoracotomy with selective resection or percutaneous embolization. In patients with solitary or unilateral lesions, resection can be performed with minimal morbidity and mortality.[61] The only consideration is the possibility of the development or persistence of pulmonary hypertension after the low-resistance AVMs are removed in patients whose pulmonary vasculature has become remodeled in response to the high flow through the AVMs, or who have the ALK-1 genetic mutation associated with HHT and pulmonary hypertension.[62] In such patients, percutaneous balloon obstruction of the AVMs allows preoperative measurement of pulmonary hemodynamics.

The techniques and safety of percutaneous embolization have been improved. With the use of detachable balloons and metal coils, single or multiple AVMs can be treated.[61] The main risk is systemic embolization of the obstructing material. This technique is rapidly replacing surgery as the treatment of choice.

Pulmonary Arterial Aneurysms

Aneurysms of the pulmonary arteries are very rare.[63] They are seen as congenital anomalies, often along with abnormalities of the other great vessels and heart; as part of connective tissue disorders (e.g., Marfan syndrome); as a consequence of trauma (pseudoaneurysms caused by Swan-Ganz catheters may be confused for pulmonary aneurysms), infection (syphilis, tuberculo-

sis, pyogenic bacteria, or fungi), or immunologic disorders (Behçet disease[64] or Hughes-Stovin syndrome); and in association with pulmonary diseases such as pulmonary hypertension or bronchiectasis.

In many cases, pulmonary arterial aneurysms are asymptomatic. However, cough, dyspnea, and particularly hemoptysis can be seen. Rupture of the aneurysm into an airway can be associated with sudden, massive, and usually fatal hemoptysis. Dissection of the pulmonary artery can also occur. The diagnosis can be made from a contrast-enhanced CT scan or by pulmonary angiography.

Aneurysms of the main and proximal right and left pulmonary arteries can be surgically repaired.[65] Aneurysms in smaller pulmonary arteries can be removed by surgical resection of the involved area of lung.

OTHER CAUSES OF PULMONARY HYPERTENSION

Residence at high altitude may be associated with the development of pulmonary hypertension.[66] This response is maladaptive and occurs in only a small portion of the population living at high altitude.[67] In these patients, moving to a lower altitude best reduces pulmonary arterial pressure. Patients with obstructive sleep apnea without other forms of lung disease often have complicating pulmonary hypertension.[68] Development of pulmonary hypertension is associated with greater body mass index and degree of daytime hypoxemia, small airway closure during tidal breathing, and heightened pulmonary pressor responses to hypoxia and increased pulmonary blood flow.[69,70] Treatment of sleep apnea is associated with improvement in pulmonary hemodynamics[70] [*see 14:VI Ventilatory Control during Wakefulness and Sleep*]. Because these patients are often sedentary, obese, and have risk factors for left-sided heart disease, the clinical evaluation should assess for recurrent pulmonary thromboembolic disease and left ventricular dysfunction (systolic and/or diastolic) as underlying causes for the pulmonary hypertension.

Compression or stenosis of the pulmonary arteries or veins in the mediastinum by tumor or fibrosing mediastinitis [*see 14:IX Disorders of the Pleura, Hila, and Mediastinum*] or stenosis of multiple peripheral segments of the pulmonary artery can produce precapillary or postcapillary pulmonary hypertension. These disorders can usually be diagnosed by spiral CT or pulmonary angiography.

A rare cause of pulmonary hypertension is pulmonary capillary hemangiomatosis, a disorder that clinically mimics or can be a component of pulmonary veno-occlusive disease.[1,71] The lung biopsy specimens of these patients have patchy regions of severe congestion that contain capillary-sized blood vessels that appear to invade the walls of the pulmonary veins and, to a lesser degree, the pulmonary arteries. A CT scan can assist in differentiating this disorder from IPAH.[72] The only effective treatment is lung transplantation.

The author has received grants for clinical research and served as an advisor or consultant to Actelion, Pfizer, Inc., Cotherix, Inc., Myogen, Inc., and Schering-Plough Corp.

Sildenafil has not been approved by the FDA for uses described in this chapter.

I INTRODUCTION TO THE RHEUMATIC DISEASES

SHAUN RUDDY, M.D., F.A.C.P.

In 2002, arthritis and chronic joint disease affected one in three adults in the United States, or 70 million persons. Arthritis and musculoskeletal disorders are the leading causes of disability in persons 18 to 65 years of age and are common causes of disability related to employment. Risk factors for these disorders include lower education level, sedentary lifestyle, high body-mass index, and female sex. Age is a major risk factor: the prevalence of these disorders increases with age, with more than 60% of those age 65 and older being affected[1] [*see Figure 1*]. By 2030, when the percentage of the population that is 65 and older will have risen to 20%, the number of people in this age group with arthritis will nearly double, from 21.4 million to 41.1 million.[2]

One in seven patients who visit a physician's office has a complaint regarding the musculoskeletal system.[3] Although many of these patients have benign, self-limited conditions that respond to simple remedies, some patients have serious, complex problems for which timely intervention may be crucial for a successful outcome.

Approach to Diagnosis

Diagnosis of the rheumatic diseases primarily relies on the history and physical examination.[4,5] Expensive laboratory and imaging studies are usually of little use; most have low sensitivity and specificity, and their findings are seldom definitively diagnostic. For example, the serum level of uric acid, a substance intimately involved in the pathogenesis of gout, is of little use in diagnosing gouty arthritis. Uric acid levels are normal in 20% of patients with gout (i.e., false negative results), and most persons with elevated levels will never have gouty arthritis (false positive results) [*see 15:IX Crystal-Induced Joint Disease*]. Wide-ranging and expensive investigations often lead to the wrong conclusions. The dearth of useful laboratory aids to diagnose rheumatic disease makes the clinical skills of the physician very important and the diagnosis of such disease an exciting undertaking.

History

A careful and detailed history is the most important part of the evaluation of a patient with arthritis. It focuses the subsequent physical examination and laboratory studies. Relevant factors in the history include the patient's age, sex, and race. In addition, the physician should elicit the location of the pain, which includes both the distribution of affected joints and the point of origin of the pain (i.e., whether it arises from a joint or surrounding structures) [*see Table 1*]. Symmetrical involvement of the small joints of the hands and feet but not the distal interphalangeal joints suggests rheumatoid arthritis. In contrast, distal interphalangeal involvement often occurs in psoriatic arthritis. Bony overgrowth with distal interphalangeal involvement suggests osteoarthritis. Asymmetrical involvement of the large joints accompanied by back pain in a young man is characteristic of spondyloarthropathy. The sudden onset of severe pain in the great toe is a feature of gout (podagra).

Knowing the nature of the pain helps the physician determine whether the disease is inflammatory or noninflammatory [*see Table 1*]. The date of onset and the temporal course of the pain should also be elicited [*see Figure 2*]. The new involvement of joints that had not previously been affected in a patient with joint involvement is common in rheumatoid arthritis and systemic lupus erythematosus (SLE). Migratory polyarthritis, in which one affected joint becomes asymptomatic as another becomes painful, occurs in gonococcal arthritis, Reiter syndrome, and acute rheumatic fever. Intermittent arthritis, in which asymptomatic intervals are punctuated by acute flares, is common in crystal-induced arthritis.

RHEUMATOLOGIC EMERGENCIES

Although rheumatologic emergencies seldom occur, failure to recognize any of a few important symptoms or signs [*see Table 2*] may result in permanent disability or death; thus, the initial contact with the patient requires being alert for these conditions.[5] If a rheumatologic emergency is suspected, prompt initiation of appropriate diagnostic testing and treatment is essential.

After emergencies have been excluded, the approach to diagnosis need not be rushed. Although patients often come to the office with the preconceived notion that they have arthritis and expect quick diagnostic confirmation and treatment, they often must be observed for some time before the diagnosis can be made. Considerable patience and tact may be required in communicating this need to the patient. He or she should be in-

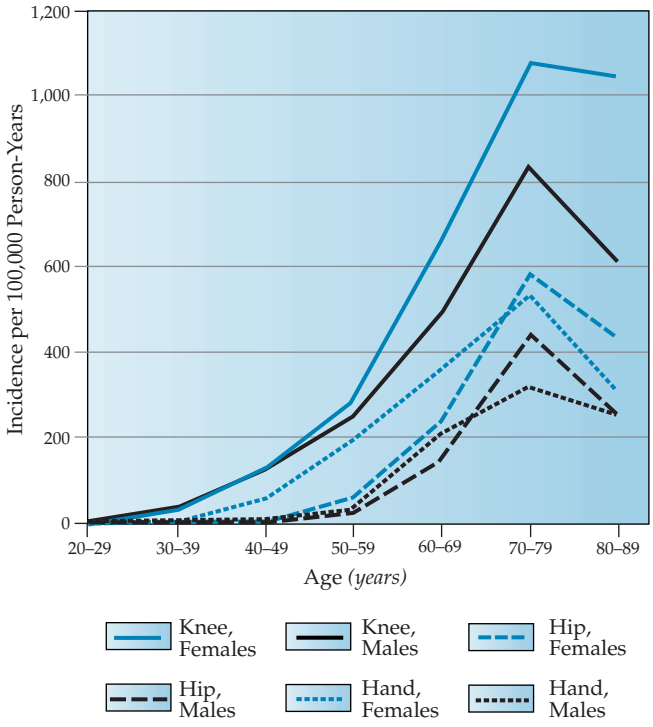

Figure 1 **Incidence of osteoarthritis of the hand, hip, and knee, in members of the Fallon Community Health Plan, 1991–1992, by age and sex.[20]**

Table 1 Common Rheumatic Diseases

	Intra-articular	*Extra-articular*
Inflammatory	Rheumatoid arthritis Systemic lupus erythematosus Septic arthritis Gout Pseudogout Spondyloarthropathy	Tendinitis Bursitis Polymyositis Vasculitis
Noninflammatory	Osteoarthritis	Fibromyalgia

formed that an uncertain diagnosis at presentation is usually a good prognostic sign; the prognosis for patients with clear-cut, easily diagnosed disease is often poor. Temporizing with an indefinite diagnosis—for example, knee pain of uncertain etiology—is better than prematurely classifying a patient's musculoskeletal complaints into a particular diagnostic category. In at least 10% of patients, a diagnosis cannot be made with certainty.

LOCATION OF PAIN

Patients are often not precise in identifying the location of musculoskeletal pain; it helps to ask them to put their hands on the place that hurts. A patient who complains of pain in the hip may point to one of three areas: the inguinal ligament and anterior thigh, suggesting involvement of the true hip joint; the lateral hip girdle, characteristic of trochanteric bursitis; or the buttock, consistent with sacroiliac joint disease or radiation of back pain along the sciatic nerve. During the physical examination, detailed attention to the location of pain helps identify the structures affected. If a specific structure cannot be identified, the pain may be referred from elsewhere. Pain described as diffuse or poorly localized may suggest a serious systemic disease, such as polymyositis, but more commonly is a manifestation of fibromyalgia or a related pain syndrome.

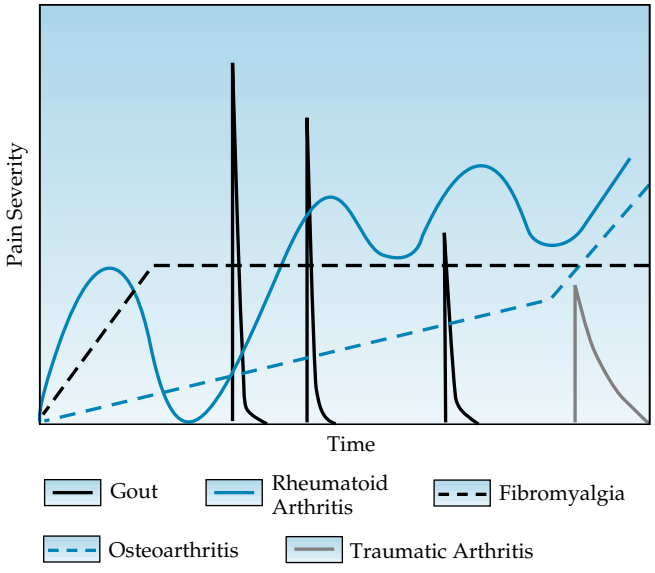

Figure 2 **Variations in the temporal course and severity of pain in the rheumatic diseases. The pain of rheumatoid arthritis may vary in intensity over time. The pain of osteoarthritis tends to be slowly progressive until late in the course of disease, when it may become very severe. The pain of fibromyalgia remains constant. Gout has an intermittent course of high-intensity pain flares. Traumatic arthritis improves more slowly than gout.[4]**

CHARACTER OF PAIN

Pain that arises from joints and that is dull, alleviated by rest, and worsened by weight bearing or movement of the joint suggests joint damage such as that which occurs in osteoarthritis. Pain that is more intense, accompanied by swelling, and present when the patient is at rest or pain that awakens the patient at night suggests an inflammatory process such as rheumatoid arthritis. Inflammation also causes stiffness after prolonged immobility—the so-called gelling phenomenon, which may last longer than 30 minutes. Patients who have inflammatory joint pain caused by rheumatoid arthritis or SLE typically have significant morning stiffness that lasts as long as several hours and that improves as the day goes on—or at least until they are overwhelmed by the deep fatigue that also accompanies these diseases. The duration of morning stiffness is a rough measure of the activity of the inflammatory disease. Patients who have the noninflammatory joint pain that characterizes osteoarthritis, tendinitis, or bursitis describe focal morning pain that lasts for a few minutes; they are most uncomfortable at the end of the day, after prolonged activity. Shooting, burning, or so-called pins-and-needles discomfort is usually neurogenic.

Symptoms of giving way or locking in a weight-bearing joint generally suggest a mechanical process, such as a cartilage or ligament tear or a loose body within the joint. Locking may also occur when soft tissue inflammation impairs mobility, as when triggering of a finger is caused by a nodule in a flexor tendon as a result of tenosynovitis.

WEAKNESS

A complaint of weakness may reflect one of several disease processes. In patients with focal loss of muscle power in a specific region, indicated by complaints such as, "I can't raise my arm," the obvious possibilities include a neurologic lesion; local

Table 2 Symptoms and Signs of Rheumatologic Emergencies[5]

Symptom or Sign	*Condition*
History of significant trauma	Fracture, compartmental syndrome, rhabdomyolysis
Systemic symptoms (fever, weight loss)	Infection (septic arthritis, osteomyelitis, endocarditis, necrotizing fasciitis)
Weakness	
Focal	Radiculopathy, entrapment neuropathy, compartmental syndrome, motor neuron disease, mononeuritis multiplex
Global or progressive	Spinal cord compression, myelopathy, transverse myelitis, myositis, response to toxin
Neurogenic pain (burning, numbness, paresthesias)	Radiculopathy, entrapment neuropathy
Point tenderness	Fracture
Red, hot, swollen joint	Septic arthritis, gout, pseudogout
Asymmetrical painful, swollen leg	Deep vein thrombosis
Diffuse shoulder and hip pain, headache in elderly patient	Temporal arteritis
Bowel or bladder dysfunction	Cauda equina syndrome

muscle atrophy; failure of a musculoskeletal unit, such as a ruptured tendon or torn muscle; or weakness secondary to joint pain. A patient who says, "I feel weak all over," should be asked to distinguish true muscle weakness (i.e., loss of power or endurance) from a more generalized sense of asthenia, malaise, or fatigue. The patient with true muscle weakness has difficulty starting or maintaining an activity that requires muscle strength, such as arising from a chair, getting out of bed, or walking up stairs. Physical examination usually confirms the muscular nature of such problems, with the proximal musculature being most affected in myopathies and the distal muscles involved in neuropathies. If the examination shows no objective weakness or other neurologic abnormalities, such as loss of deep tendon reflexes, the patient's report of weakness probably corresponds to asthenia, fatigue, and loss of sense of well-being. If this occurs together with other constitutional symptoms, such as anorexia, weight loss, and low-grade fever, it may indicate an active systemic rheumatic disease such as rheumatoid arthritis or SLE. If the asthenia and fatigue are not accompanied by objective constitutional symptoms, fibromyalgia is more likely.

FUNCTIONAL IMPAIRMENT AND PSYCHOSOCIAL FACTORS

After pain, loss of function is of the greatest concern to patients, making the functional assessment an important part of the history. Exploring this area often affords the physician insights into the way the patient views the disease and what the patient expects. Simple questions asked by the physician may include the following: How has your disease affected you? What can you not do now that you could do before? What can you not do that you would like to do? Patients with significant functional impairment should be asked more-detailed questions about routine activities of daily living. Explicit questions about sexual function may uncover problems that the patient might otherwise hesitate to describe. The sexual history also identifies risk factors for sexually transmitted joint diseases, such as gonococcal arthritis, Reiter syndrome, and HIV-associated arthropathy. A vocational history may identify specific tasks that exacerbate the disease and that need modification; it may also indicate whether the patient is likely to be exposed to ticks carrying Lyme disease. The history of use of devices such as a cane or crutches and information as to when the patient began using them is helpful in assessing the temporal course of the disease. Claims for workers' compensation or disability or other pending litigation should also be noted.

FAMILY HISTORY

Many rheumatic diseases have strong familial predispositions. Ankylosing spondylitis is the best known, but other autoimmune diseases, such as rheumatoid arthritis and SLE, also have a genetic basis, as do gout and, to a lesser extent, pseudogout.

REVIEW OF SYSTEMS

Once a specific disease is suspected, the patient should be questioned about the presence of other systemic features of the disease. A partial list of clues to systemic disease that can be gleaned from the review of systems is shown [*see Table 3*].

Table 3 Diagnostic Clues from the Review of Systems

Feature	*Condition*
Facial rash, photosensitivity	Systemic lupus erythematosus
Hair loss	Systemic lupus erythematosus
Uveitis	Spondyloarthropathy, sarcoidosis, Behçet syndrome
Conjunctivitis	Reactive arthritis
Dry eyes and/or mouth	Sjögren syndrome
Oral ulcers	Systemic lupus erythematosus
Nasal discharge, ulcers	Wegener granulomatosis
Diabetes	Diabetic stiff-hand syndrome, Dupuytren contractures, reflex sympathetic dystrophy, carpal tunnel syndrome
Thyroid problems	Osteoporosis, myopathy
Pleurisy	Systemic lupus erythematosus
Hemoptysis	Systemic lupus erythematosus, Wegener granulomatosis
Abdominal pain, bowel dysfunction	Crohn disease, fibromyalgia (with irritable bowel syndrome)
Urethral burning or discharge	Reactive arthritis, septic arthritis
Kidney stones	Gout
Numbness or paresthesias	Carpal tunnel syndrome, vasculitis
Vaginal burning or discharge	Behçet syndrome, septic arthritis

Physical Examination

GENERAL EXAMINATION

By the time the history is finished, the clinician should have formulated some diagnostic hypotheses that can be used to guide the physical exam. If a patient's complaints are localized and the history elicits no suggestion of a more generalized process, the examination may be limited to the region involved. When systemic symptoms are present, a complete and detailed examination is required. Asymmetrical joint disease and inflammatory back pain raise the possibility of psoriatic arthritis and spondylitis, in which case the physician should very carefully inspect the skin for a patch of psoriasis of which the patient may be unaware. In the sexually active patient with asymmetrical involvement of large joints and a history of conjunctivitis, detailed examination of the genitalia for the lesions of Reiter syndrome should be performed. The patient with complaints of sinus trouble, arthritis, and hemoptysis should undergo thorough scrutiny of the nasopharynx and sinuses for the lesions of Wegener granulomatosis. Other important findings are iritis or conjunctivitis, nodules, pericardial or pleural rubs, hepatic or splenic enlargement, lymphadenopathy, and neurologic abnormalities.

JOINT EXAMINATION

By looking at and palpating the joints, the physician can identify the precise anatomic structures that are the source of the patient's pain and decide whether the pain is caused by inflammation. A goal of the examination is to reproduce the patient's pain, either by motion of the joint or by palpation. Frank redness of the skin overlying a joint is unusual; however, increased temperature, best detected by palpation with the backs of the fingers, is not unusual and, when present, indicates inflammation.

Apparent swelling may be caused by periarticular edema, an effusion in the joint, synovial proliferation, or bony overgrowth; in all cases, it indicates organic disease. Palpation for tenderness may reveal whether the problem lies within the joint or is discretely localized to an overlying bursa or tendon sheath. The finding of fine crepitus with motion of the structure corresponds to the grinding of subchondral bone, denuded of articular cartilage, against opposing bone. Coarser (so-called creaking) crepitus is associated with the fibrinous tendinitis that occurs in scleroderma or traumatic tendinitis. When the examiner is able to move the joint through a passive range of motion that exceeds the active range of motion accomplished voluntarily by the patient, failure of a musculoskeletal unit (e.g., rupture of the rotator cuff in the shoulder) or a neurologic deficit should be suspected. Examination of the spine is the most neglected part of the musculoskeletal examination, probably because it entails moving the patient from the sitting position through the supine and prone positions and then to the standing position. Patients with findings suggestive of a lumbar radiculopathy should have detailed testing of the motor, sensory, and reflex systems in the legs. Reviews of such testing are available on the Internet, at http://www.neuropat.dote.hu/neurology.htm and at http://www.neuroexam.com. An experienced physician can perform a complete musculoskeletal examination in less than 10 minutes.

Laboratory Studies

THE ACUTE-PHASE RESPONSE

The cellular response to inflammation or tissue injury elaborates cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF), which have profound effects on the hepatic synthesis of plasma proteins.[6] Concentrations of C-reactive protein (CRP) increase as much as 100-fold within 1 or 2 days after tissue damage; parallel increases in serum amyloid A protein occur. Slower and less marked increases occur in coagulation proteins such as fibrinogen and prothrombin, most of the complement components, normal plasma protease inhibitors, and transport proteins such as ferritin and haptoglobin. Corresponding decreases occur in serum transferrin and albumin, accounting for the low serum iron and albumin levels that accompany inflammatory diseases.

The erythrocyte sedimentation rate (ESR) is the time-honored test used to detect the acute-phase response.[7] The increased rate of fall of the column of erythrocytes is caused by stacking of the cells into rouleaux, induced mainly by increases in the highly asymmetrical fibrinogen molecule; the increased levels of immunoglobulins seen in chronic inflammatory conditions also favor rouleaux formation. The ESR is influenced by many extraneous factors [*see Table 4*], the most important of which is age. The upper limit of normal for men is obtained by dividing the age in years by 2; for women, it is obtained by adding 10 to the age in years and then dividing that number by 2.

The CRP level is measured by immunoassay and is not influenced by most of the extraneous factors that affect the ESR. It also increases more rapidly than the ESR, which may take several days to increase.

The ESR and CRP tests are nonspecific: ESR and CRP levels may be elevated in a number of inflammatory conditions, such as malignancy, chronic infection, pneumonia, and acute myocardial infarction. Even increases in very low levels of CRP, as detected on a so-called ultrasensitive test, serve as a biomarker for atherosclerosis.[8] These tests are most useful in excluding significant inflammatory disease. For example, in a patient with diffuse pain and tenderness at trigger points, suggesting fibromyalgia, a normal ESR value supports this diagnosis; an ESR of 90 mm/hr dictates close scrutiny for other diseases. If the patient with these symptoms is older than 60 years, polymyalgia rheumatica and temporal arteritis are the primary possibilities. The acute-phase tests are also moderately useful in distinguishing inflammatory from noninflammatory arthritis and in monitoring the course of an inflammatory disease such as rheumatoid arthritis or polymyalgia rheumatica.

Table 4 Factors That Influence ESR[7]

Factors That Increase ESR	*Factors That Decrease ESR*
Advancing age	Congestive heart failure
Female sex	Sickle cell disease
Pregnancy	Altered erythrocyte shape (e.g., anisocytosis, spherocytosis, acanthosis, microcytosis)
Hypercholesterolemia	
B cell neoplasm (e.g., myeloma, macroglobulinemia, cryoglobulinemia)	Polycythemia
	Extreme leukocytosis
	Cachexia
Renal failure	Hypofibrinogenemia
	Cryoglobulinemia

ESR—erythrocyte sedimentation rate

IMMUNOLOGIC TESTS

As a class, immunologic tests have low specificity and only moderate sensitivity. They are also more expensive and less reproducible than most other clinical laboratory tests. They should never be used as screening tests; their greatest utility occurs when the pretest probability of disease is high. The misuse of immunologic tests frequently confounds the diagnosis. Two common examples of unnecessary rheumatology referrals are the octogenarian with arthritis of the knees or shoulders who tests positive for rheumatoid factor (unnecessary because positivity in healthy persons increases with age, and osteoarthritis of these joints is common in octogenarians) and the young woman with fatigue; diffuse pains; and a positive, usually low-titer, antinuclear antibody test (unnecessary because low titers of antinuclear antibody are found in as many as 32% of young women[9]; the patient probably has depression or fibromyalgia). The use of so-called arthritis panels, in which many serologic tests are bundled together, increases the likelihood of an abnormal result in a patient without rheumatic disease and should be avoided. Highly specific (and expensive) tests, such as those for antineutrophil cytoplasmic antibody, Lyme disease serology, HLA-B27, antiphospholipid antibody, and antibodies against individual nuclear constituents, should be performed only when the pretest probability of a particular disease is high. In one study of patients with swelling of at least one joint, the rheumatoid factor test had a sensitivity of 65% and a specificity of 87% for the diagnosis of rheumatoid arthritis.[10] At disease onset, a positive test result for rheumatoid factor is predictive of increased severity, as assessed by radiographic evidence of erosions.[11] Antibodies to cyclic citrullinated peptides (anti-CCP) formed by posttranslational modification of arginine residues in proteins such as fillagrin are found in the serum of many patients with rheumatoid arthritis. The 70% sensitivity and 98% specificity of the anti-CCP assays make them very useful in the diagnosis of rheumatoid arthritis, especially during the early

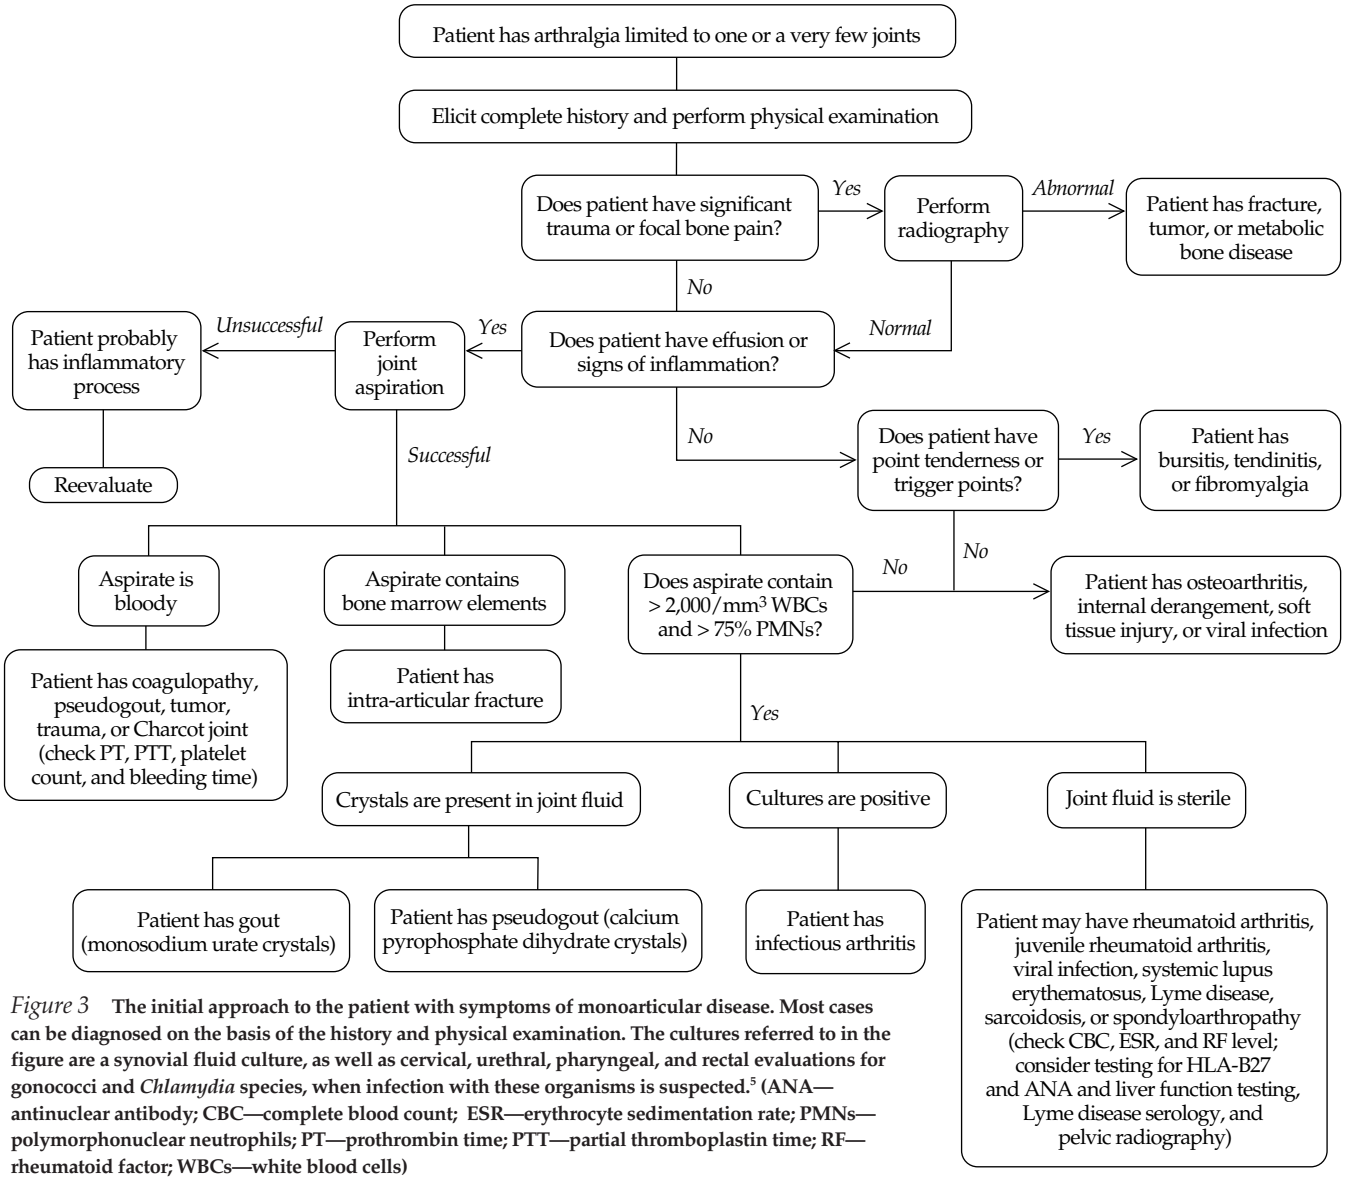

Figure 3 **The initial approach to the patient with symptoms of monoarticular disease. Most cases can be diagnosed on the basis of the history and physical examination. The cultures referred to in the figure are a synovial fluid culture, as well as cervical, urethral, pharyngeal, and rectal evaluations for gonococci and *Chlamydia* species, when infection with these organisms is suspected.[5] (ANA—antinuclear antibody; CBC—complete blood count; ESR—erythrocyte sedimentation rate; PMNs—polymorphonuclear neutrophils; PT—prothrombin time; PTT—partial thromboplastin time; RF—rheumatoid factor; WBCs—white blood cells)**

phases of the disease, when the anti-CCP assay may become positive before the rheumatoid factor test.[12]

SYNOVIAL FLUID ANALYSIS

Examination of synovial fluid is perhaps the most important diagnostic test in rheumatology. It gives the physician one of the few opportunities available for the precise diagnosis of rheumatic disease and permits immediate initiation of specific and effective therapy. In addition, aspiration of synovial fluid is a low-risk procedure: the frequency of iatrogenic infection is less than one in 10,000. Joint aspiration should be performed with aseptic technique as part of the evaluation of every case of acute monoarthritis.

Analysis of the synovial fluid includes a white blood cell count and differential, appropriate cultures and stains for microorganisms, and polarized-light microscopy. The white blood cell count in the synovial fluid is useful in distinguishing inflammatory from noninflammatory arthritis: levels greater than 2,000 cells/mm^3 are consistent with inflammation. Patients with crystal-induced arthritis usually have counts in excess of 30,000 cells/mm^3. The reliability of the examination of fluid for crystals by polarized-light microscopy depends very much on the laboratory doing the test. The finding of monosodium urate or calcium pyrophosphate dihydrate crystals on polarized-light microscopy is pathognomonic for gout and pseudogout, respectively. The absence of crystals does not exclude these diagnoses, nor does their presence exclude the possibility of coexistent infection. Gram stain and culture may be diagnostic of infection. If patients with established arthritis have fever and an apparent flare, joint infection should be excluded by joint aspiration because septic arthritis occurs more frequently in such patients.

IMAGING

The findings on radiography are unlikely to be abnormal in most patients with acute arthritis, mechanical back pain, tendinitis, or bursitis; radiography should not be used in these cases. In patients with acute back pain of less than 6 weeks' duration, imaging is not indicated unless there is a high suspicion of systemic disease or progressive neurologic deficit[13] [*see 15:XII Back Pain and Common Musculoskeletal Problems*]. For patients

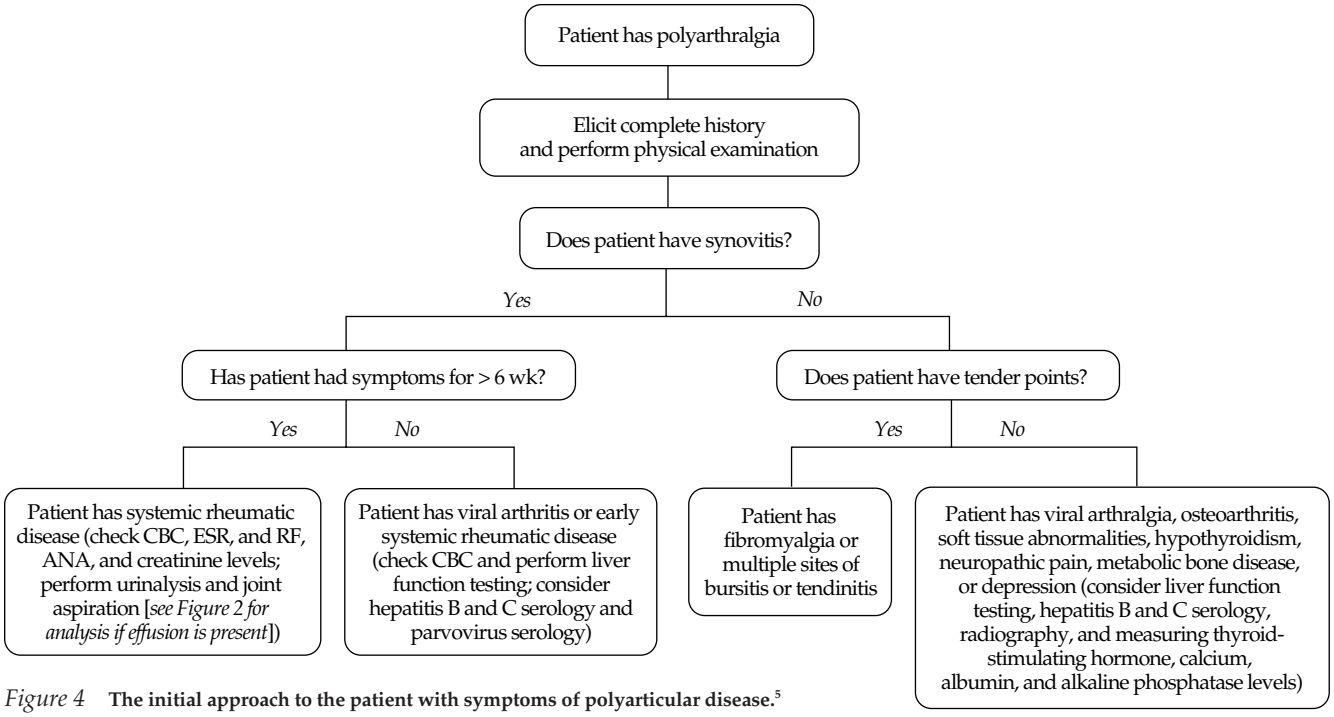

Figure 4 **The initial approach to the patient with symptoms of polyarticular disease.**[5]

with established arthritis, such as rheumatoid arthritis, it takes longer than 6 months for radiographic abnormalities such as joint space narrowing and marginal erosions to appear. In patients with osteoarthritis, radiography may be useful in assessing the extent of joint damage, but the correlation between its findings and patients' symptoms is surprisingly poor.

Plain radiography is most useful in patients with significant trauma that suggests the possibility of fracture, in those who experience a sudden loss of function (e.g., an inability to bear weight), in those with symptoms that do not improve despite appropriate treatment, and in those with a suspected infection or neoplastic disease. Computed radiography and digital imaging improve the quality of plain radiographs, make long-distance transmission easy, and eliminate the problem of the lost radiograph. When it is likely that a fracture is present, special views may be required; repeat imaging 7 to 10 days later may detect callus formation at a previously unrecognized fracture site. In patients with chronic disease, repeat radiography is useful in assessing the progress of disease or the necessity of surgical intervention.

Although computed tomography, magnetic resonance imaging, and radionuclide bone scanning are powerful techniques for obtaining information about bones and joints, they should be used only when their results will be used to make important diagnostic or therapeutic decisions. As is true for plain radiography, myelography, and even autopsy, MRI of the spine often reveals abnormalities in people who do not have back pain. In one study, only 36% of patients free of back pain had normal findings on MRI of the lumbar spine.[14] Bone scans are useful in detecting osteomyelitis, stress fractures, and metastases to bone.

Clinical Presentation and Initial Approach

MONOARTICULAR DISEASE

Patients with symptoms that involve one or, at most, a few joints may have posttraumatic syndromes, bursitis, tendinitis, septic arthritis, crystal-induced inflammation (gout or pseudogout), or an atypical presentation of a systemic arthritis such as rheumatoid arthritis [*see Figure 3*]. Arthralgia, in which pain arises from structures surrounding the joint, must be distinguished from arthritis, in which there is evidence of frank involvement of the joint itself. Monoarticular arthritis should be considered to have an infectious etiology until proved otherwise. Prompt aspiration and examination of synovial fluid are usually indicated.

POLYARTICULAR DISEASE

In contrast to monoarticular disease, which often requires an aggressive and invasive diagnostic approach, arthritis involving numerous joints usually requires a more gradual and expectant strategy. The one exception is septic arthritis, which may have a polyarticular onset in up to 20% of patients. In other diseases, there is less urgency in arriving at the diagnosis, and observation for 6 weeks or more may be required. During this period, it is unwise to alarm the patient unnecessarily by musing about the possibility that he or she has a particular systemic rheumatic disease; a wait-and-see attitude is more appropriate. Eventually, most patients with polyarthralgia will prove not to have a systemic rheumatic disease but to have a more benign condition [*see Figure 4*].

DIFFUSE ACHES AND PAINS

Most patients with diffuse aches and pains have a benign, self-limited illness of unknown cause that improves after 1 or 2 weeks of observation. The history often identifies antecedent viral infection or exertional stress as a precipitating factor. Another substantial number of patients prove to have fibromyalgia, which is suggested by an inability to precisely locate the anatomic origins of the pain on physical examination and by the finding of tender trigger points [*see 15:XIII Fibromyalgia*]. A hemogram and measurements of the ESR or CRP, thyroid-stimulating hormone, creatine kinase (if weakness is an issue), calcium, and phosphate levels are usually sufficient to exclude other diseases [*see Table 5*].

Benign postviral syndromes
Postexertional syndromes
Fibromyalgia
Polymyalgia rheumatica
Temporal arteritis
Hypothyroidism
Metabolic bone disease
Hypophosphatemia
Atypical onset of systemic rheumatic disease (e.g., rheumatoid arthritis, systemic lupus erythematosus)

Prognosis

Patients who present with complaints of joint pain often express the opinion, "Nothing can be done for my arthritis—I'll just have to learn to live with it." Correcting this misconception is one of the most important things the physician can do during the initial contact. Most kinds of arthritis can be managed quite effectively, and the patient must understand that treatment greatly improves the condition of most patients with arthritis. Even for the most severe diseases, such as rheumatoid arthritis, very effective treatments have been available for 20 years and have brought distinct improvements in long-term outcome.[15,16] New treatments with biologic agents that block the inflammatory cytokines TNF-α and IL-1 are very effective, have a rapid onset of action, and prevent radiographic progression of the disease.[17-19] Educating the patient about the effectiveness of treatment is the first step toward a successful outcome.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

II RHEUMATOID ARTHRITIS

GARY S. FIRESTEIN, M.D.

Rheumatoid arthritis (RA) is the most common chronic inflammatory arthritis and affects about 1% of adults; it is two to three times more prevalent in women than in men. RA may begin as early as infancy, but onset usually occurs in the fifth or sixth decade. There are no specific laboratory tests for RA; diagnosis depends on a constellation of signs and symptoms that can be supported by serology and radiographs. Involvement of the small joints of the hands and feet is often the key to the diagnosis. Specific clinical criteria have evolved [*see Table 1*], but in practice, diagnosis is established by careful observation of the pattern of disease activity over time.

Immunogenetics

Genetic makeup plays a critical role in susceptibility to RA. Identical twins show 30% to 50% concordance for the disease; first-degree relatives of patients with RA have about a twofold to threefold increased incidence. Study of the major histocompatibility complex (MHC) has identified a shared epitope on the β chains of certain HLA-DR haplotypes in RA patients. This susceptibility epitope is associated with the third hypervariable region of DR β chains, which contains amino acids 70 through 74 (glutamine-leucine-arginine-alanine-alanine, also known as QKRAA) found in *DRB1*0401*, *DRB1*0404*, and other immunologically distinct alleles.[1] This sequence is common to most RA patients, although the disease develops in only a small fraction of those with the epitope.

Susceptibility to RA is likely polygenic; for instance, certain immunoglobulin genotypes and, perhaps, genetic differences in the galactosylation of immunoglobulin may be predisposing factors. Further studies have identified associations with microsatellite alleles of cytokines. Tumor necrosis factor (TNF) alleles are in linkage disequilibrium with the *DR β* gene and may be independent risk factors for RA.[2] In addition, a polymorphism of the interleukin-1α (IL-1α) gene is associated with juvenile RA.[3] Studies of IL-10 promoter polymorphisms have been variable,

Table 1 American Rheumatism Association Criteria for the Classification of Rheumatoid Arthritis[96]

Criteria

Morning stiffness: morning stiffness in and around the joints lasting at least 1 hr before maximal improvement

Arthritis of three or more joint areas: at least three joint areas have simultaneously had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician; the 14 possible joint areas (right and left) are proximal interphalangeal (PIP), metacarpophalangeal (MCP), wrist, elbow, knee, ankle, and metatarsophalangeal (MTP) joints

Arthritis of hand joints: at least one joint area swollen as above in wrist, MCP, or PIP joint

Symmetrical arthritis: simultaneous involvement of the same joint areas (as in arthritis of three or more joint areas, above) on both sides of the body (bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry)

Rheumatoid nodules: subcutaneous nodules over bony prominences or extensor surfaces or in juxta-articular regions that are observed by a physician

Serum rheumatoid factor: demonstration of abnormal amounts of serum rheumatoid factor by any method that has been positive in fewer than 5% of normal control subjects

Radiographic changes: radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist x-rays, which must include erosions or unequivocal bony decalcification localized to or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

Exclusions

The presence of any of the following excludes the diagnosis of rheumatoid arthritis:

Typical rash of systemic lupus erythematosus (SLE)

High concentration of lupus erythematosus cells (four or more in two smears); because of the frequent finding of LE cells in patients with clinically typical rheumatoid arthritis, however, it is suggested that such patients be listed separately

Histologic evidence of polyarteritis nodosa with segmented necrosis of arteries associated with nodular leukocytic infiltration extending perivascularly, including many eosinophils

Persistent muscle swelling of dermatomyositis or weakness of neck, trunk, and pharyngeal muscles

Definite scleroderma (not limited to the fingers)

A clinical picture characteristic of rheumatic fever with migratory joint involvement and evidence of endocarditis, especially if accompanied by subcutaneous nodules, erythema marginatum, or chorea (an elevated antistreptolysin titer will not rule out the diagnosis of rheumatoid arthritis)

A clinical picture characteristic of gouty arthritis with acute attacks of swelling, redness, and pain in one or more joints, especially if responsive to colchicine

Tophi

A clinical picture characteristic of acute infectious arthritis of bacterial or viral origin with an acute focus of infection or a close association with a disease of known infectious origin; chills; fever; acute joint involvement, usually initially migratory (especially if organisms are present in the joint fluid or there is a response to antibiotic therapy)

Tubercle bacilli in joints or histologic evidence of joint tuberculosis

A clinical picture characteristic of reactive arthritis with urethritis and conjunctivitis associated with acute joint involvement, usually initially migratory

A clinical picture characteristic of the shoulder-hand syndrome with unilateral involvement of shoulder and hand and diffuse swelling of the hand, followed by atrophy and contractures

A clinical picture characteristic of hypertrophic osteoarthropathy with clubbing of fingers or hypertrophic periostitis, or both, along the shafts of the long bones, especially if an intrapulmonary lesion is present

A clinical picture characteristic of neuroarthropathy with condensation and destruction of bones of involved joints and associated neurologic findings

Homogentisic acid in the urine grossly detectable by alkalinization

Histologic evidence of sarcoid or a positive Kveim test

Multiple myeloma evidenced by marked increase in plasma cells in the bone marrow or by Bence Jones protein in the urine

Characteristic skin lesions of erythema nodosum

Leukemia or lymphoma with characteristic cells in peripheral blood, bone marrow, or tissues

A clinical picture characteristic of ankylosing spondylitis, psoriasis, ulcerative colitis, or regional enteritis

Note: for classification purposes, a patient is said to have rheumatoid arthritis if he or she has satisfied at least four of the above seven criteria. The first four must be present for at least 6 wk. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is *not* to be made.

although on balance, there does not appear to be an association between a specific polymorphism and susceptibility to RA.

Etiology

It is unlikely that a single etiologic factor accounts for all cases of adult RA. A pathogenic organism is often assumed to be responsible, but despite some suggestive data, no conclusive evidence implicates bacteria or mycoplasmas. Viruslike particles have been isolated from synovial effusions in RA,[4] and some RA patients exhibit evidence of a recent parvovirus B19 infection.[5] The potential role of parvovirus B19 is controversial. Whereas some studies have not shown any correlation between RA and serologic evidence of previous infection or presence of *B19* genes in synovial tissue, one study demonstrated parvovirus B19 proteins by immunohistochemistry and potentially infectious virus particles in RA synovium.[6] Some data suggest that B19 can infect cultured synovial fibroblasts and increase invasion into cartilage matrix.[7]

Other viruses that have been isolated from synovial fluid include rubella and Epstein-Barr virus (EBV). Sera from most RA patients contain greater amounts of antibodies to various EBV-derived antigens than normal sera. Suppression of EBV infection by lymphocytes from RA patients is impaired, possibly because T cells mount an insufficient response with low levels of interferon gamma. Although EBV infection is probably not the initial event in RA, it may contribute to persistent immunologic stimulation by acting as a polyclonal activator of B cells, thereby augmenting the production of autoantibodies.

Lymphocytes from some RA patients respond to a region of EBV glycoprotein gp110 that contains the same QKRAA sequence as the susceptibility epitope on DR β chains.[8] Thus, molecular mimicry may lead to autoimmunity in certain EBV-infected individuals. Other xenoproteins, most notably *Escherichia coli* DNA J protein, also contain QKRAA and may contribute to a response against self-MHC.[9] Although many patients undergo an autoimmune response to type II collagen, this response is nonspecific and may be of secondary etiologic significance.

Retroviruses could also serve as infectious causes of RA-like diseases. Synovial human T cell lymphotropic virus type I (HTLV-I) infection is associated with chronic arthritis, and in vitro transduction of synoviocytes with the HTLV-I *tax* gene leads to increased growth.[10] Retrovirus-like particles have been observed in some synovial samples, and expression of zinc-finger proteins associated with retroviral infections offers some support.[11]

Some RA patients show evidence of autoimmunity long before the appearance of clinical arthritis. For instance, rheumatoid factors and other autoantibodies (e.g., anticyclic citrullinated peptides) can be detected in the blood of patients many years before the onset of disease.[12] Although autoimmunity occurs in patients with RA, it may not be responsible for the initiation of the disease. An alternative hypothesis ascribes the initiation of disease to the activation of innate immunity in the synovium of susceptible persons.[13] This process, which involves primitive pattern-recognition receptors on macrophages, dendritic cells, mast cells, and neutrophils, leads to nonspecific articular inflammation. A local immune response then occurs as the synovium permits the influx of lymphocytes, which, in the appropriate cytokine milieu, recognize a variety of xenoantigens and autoantigens. In this scenario, no single etiologic agent is required. Instead, nonspecific inflammation in a patient with a particular gene set can lead to local responses directed at many articular antigens.

Pathogenesis

SYNOVIAL HISTOPATHOLOGY AND INVASION

The synovial tissue in RA becomes markedly hyperplastic, with redundant folds, frondlike villi, and edema. In the earliest stages, blood vessel proliferation and endothelial damage are prominent. Hyperplasia of the synovial intimal lining (the region in direct contact with synovial fluid) can occur, although the sublining inflammatory infiltrate can be mild. As the chronic phase begins, intimal lining hyperplasia becomes more prominent, increasing up to fivefold from the normal thickness of one or two cell layers [*see Figure 1*]. Synovial lining hyperplasia is caused, in part, by local proliferation of the fibroblast-like type B synoviocytes and migration of new macrophage-like type A synoviocytes from bone marrow and blood into the joint. The rate of cell death also determines tissue cellularity. Many cells of the intimal lining contain damaged DNA that normally leads to apoptosis (programmed cell death), but relatively few cells complete this process.[14] RA synovial cells possibly have defective apoptosis that contributes to hyperplasia.

In chronic RA, inflammatory cells (including T cells, B cells, macrophages, and plasma cells) accumulate in the sublining region. Lymphocytes can organize into discrete aggregates, although diffuse mononuclear cell infiltration or relatively acellular fibrous tissue can also be present. The majority of T cells are $CD4^+$ memory cells with small nuclei and scant cytoplasm. Although the cells are functionally quiescent, many express surface antigens that suggest previous activation. An increased number of blood vessels remains a prominent finding in the chronic phase. Capillary morphometry studies suggest that the capillary network is more disorganized than normal, and the tissue bulk outstrips the proliferation of blood vessels.

Rheumatoid synovitis is usually accompanied by increased synovial effusions. The white blood cell (WBC) count in synovial fluid in active RA is about 10,000/mm^3 (about 70% neutrophils). In contrast to the synovium, there are more $CD8^+$ T cells than $CD4^+$ T cells in synovial effusions. Total WBC counts sometimes

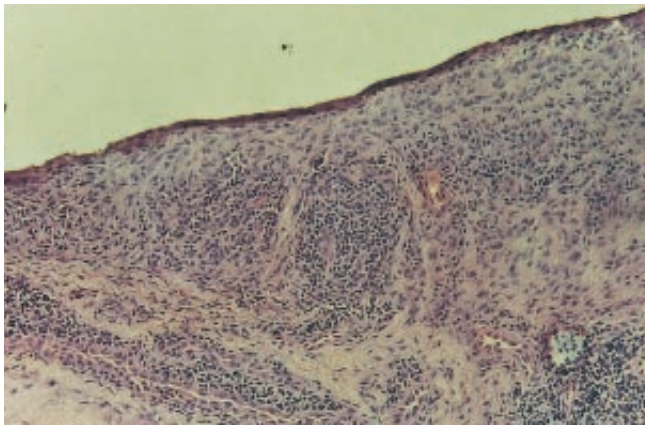

Figure 1 **Section of a proliferative synovium from a patient with classic rheumatoid arthritis reveals synovial lining hyperplasia and a sublining lymphocyte infiltration and aggregation.**

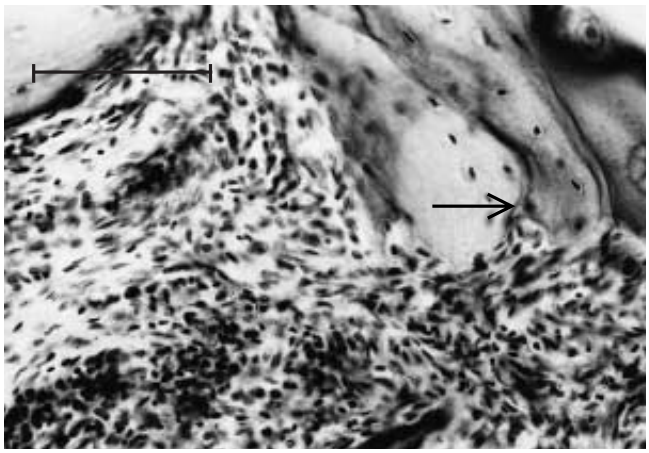

Figure 2 **At the junction between a proliferative inflamed rheumatoid synovium and the bone, scalloped regions of erosion can be seen (arrow). Section is stained with hematoxylin and eosin (bar scale = 100 μm).**

exceed 50,000/mm^3 and include 90% to 95% polymorphonuclear leukocytes. The polymorphonuclear leukocytes are drawn into the joint fluid along a gradient formed by chemotactic substances that include leukotriene B4, platelet-activating factor, the C5a fragment of complement, and chemokines such as IL-8. Lymphocytes, macrophages, and shed lining cells are also seen in synovial fluid. Surprisingly, very few neutrophils are present in RA synovium, even though they are abundant in the effusions.

Pannus, the invasive region of synovium that erodes into cartilage and bone [*see Figure 2*], contains macrophages and primitive mesenchymal cells but very few lymphocytes. It is not clear whether these mesenchymal cells are related to type B synoviocytes, but morphologic and functional studies suggest that pannus-derived fibroblasts (pannocytes) have distinctive characteristics (e.g., very high expression of vascular cell adhesion molecule–1).[15] Mesenchymal stem cells have also been described in RA synovial tissue; these cells express distinct surface proteins (e.g., bone morphogenic protein receptors and endoglin) and can migrate into the synovium directly through pores in the bone or through the circulating blood.[16]

Damage to bone and cartilage by synovial tissue and pannus is mediated by several families of enzymes, including serine proteases and cathepsins. The most damaging enzymes are the metalloproteinases (e.g., collagenase, stromelysin, and gelatinase) and cathepsins (especially cathepsin K), which can degrade the major structural proteins in the joint. Cytokines such as IL-1 and TNF-α are potent inducers of metalloproteinase gene expression. Although protease inhibitors, like tissue inhibitors of metalloproteinases, are expressed by the rheumatoid synovial lining, the balance between proteases and inhibitors appears to favor the former in RA.[17] Chondrocytes in the cartilage, synoviocytes in pannus, and osteoclasts in the bone are the primary sources of proteases. The receptor activator of nuclear factor κB (RANK) and the RANK ligand (RANKL) together play a critical role in local osteoclast activation and bone destruction; the RANKL/RANK system is counterbalanced by the natural inhibitor osteoprotegerin (OPG). In animal models of arthritis, administration of OPG markedly decreases bone destruction, even though inflammation is unaffected.[18]

Destruction of extracellular matrix by rheumatoid synovium mesenchymal cells may occur either as a result of a normal response to the inflammatory cytokine milieu or as a result of abnormal synoviocyte function.[19] Evidence of partial transformation of RA synoviocytes, including adhesion-independent growth and loss of contact inhibition in vitro, suggests that immunosuppression may slow but not necessarily halt joint destruction. Cultured RA synoviocytes that have been coimplanted with cartilage explants into mice with severe combined immunodeficiency disease invade the cartilage matrix, whereas osteoarthritis synoviocytes and normal dermal fibroblasts do not.[20] Somatic mutations in the genes encoding key regulatory proteins, such as the *p53* tumor-suppressor gene, may contribute to the transformed phenotype of synoviocytes.[21] Such mutations are likely caused by the high local concentration of oxidants in the rheumatoid joint. Hence, the invasive component of rheumatoid synovitis potentially functions as an autonomous cytokine-independent tissue that erodes into cartilage.

CELLULAR IMMUNITY

Attempts to identify an etiologic agent by determining the proliferative response of synovial T cells to specific antigens have been relatively unrewarding. Articular T cells are often less responsive than peripheral blood cells. For instance, the proliferation of lymphocytes in synovial fluid in response to mitogens or recall antigens (e.g., tetanus toxoid) is significantly lower than the proliferation of blood T cells. Production of cytokines (e.g., interferon gamma and IL-2) by synovial fluid T cells in vitro is also low after stimulation by nonspecific mitogens. The mechanism of defective T cell responses in RA appears to be related to abnormal intracellular redox balance, which interferes with transduction of the T cell receptor signal.[22] Mycobacterial antigens and the 60 kd heat shock protein appear to be exceptions in that lymphocyte proliferation in response to these antigens is greater in cells from rheumatoid effusions than in blood cells. However, this response is not specific to RA and is even more prominent in reactive arthritis.

Immune dysregulation has been observed in peripheral blood T cells in patients with RA, especially with EBV infection. The deficient T cell response can be correlated with disease activity, but it also occurs in patients with other forms of arthritis. A more specific defect is observed in the autologous mixed lymphocyte reaction, in which T cells proliferate and produce cytokines in response to MHC class II antigens expressed on autologous antigen-presenting cells. Autoimmune responses directed toward joint-specific antigens can contribute to synovitis. In addition to type II collagen, which is localized to hyaline cartilage, other articular antigens have been implicated. For instance, T cell immunity directed against heat shock proteins, cartilage protein gp39, cartilage link protein, and proteoglycans have been variably implicated in RA. Many of these antigens can induce arthritis in mice or rats when the animals are immunized with the antigen in combination with complete Freund adjuvant. An unusual T cell phenotype ($CD4^+$, $CD28^-$) has been noted in the synovial tissue of patients with RA that might possess functions of both innate and adaptive immunity.[23]

HUMORAL IMMUNITY

Rheumatoid Factors and Other Autoantibodies

Rheumatoid factors are immunoglobulins with antibody specificity for the Fc region of IgG. The tests usually employed in clinical diagnosis (latex fixation, sensitized sheep red blood cell agglutination, nephelometry, and enzyme-linked immunosor-

bent assay) detect only IgM rheumatoid factors. The tests are positive in up to 90% of patients with classic RA, depending on the method used. Although patients with classic RA may have negative test results, a high-titer positive result indicates a poor prognosis—an unremitting course and a greater degree of joint damage.

Rheumatoid factor is not a specific finding for RA. Significant titers are found in patients with related diseases (e.g., systemic lupus erythematosus [SLE], progressive systemic sclerosis, and dermatomyositis) and in patients with nonrheumatic chronic inflammatory disorders and infections. Healthy elderly persons, particularly women, often have positive test results. Rheumatoid factor may be a feature of the early immune response to many proteins, facilitating antigen clearance by macrophages.

IgM rheumatoid factor is most commonly detected; IgG and, less frequently, IgA rheumatoid factors are also sometimes found. The presence of IgG rheumatoid factor is associated with a higher rate of systemic complications (e.g., necrotizing vasculitis).[24] Rheumatoid factors in RA may result from somatic mutation in response to an antigen-driven immune response.[25] Rheumatoid factors can be synthesized by B cells and plasma cells that infiltrate the synovium in RA patients, including some seronegative patients.

Another autoantibody system has been described that could have considerable clinical utility. Antibodies directed against keratin or to the filament-aggregating protein filaggrin were defined in patients with RA. Their specificity is determined by their ability to bind to a modified arginine residue known as citrulline. Many proteins are citrullinated in synovial tissue, and citrullination occurs in animal models of arthritis.[26] The enzyme responsible for altering this amino acid is peptidylarginine deiminase (PAD); and certain isoforms of PAD, such as PAD4, are overexpressed in inflamed joint tissues. Certain haplotypes of the enzyme PAD4 appear to confer an increased risk of developing RA. Although citrullinated peptides are commonly produced at sites of inflammation, antibodies directed against PAD epitopes appear to be specific for RA. B cells that produce these IgG and IgM anticitrulline antibodies are present in rheumatoid synovial tissue. Anticitrulline antibodies (often assayed using cyclic citrullinated peptide [CCP]) are as prevalent as rheumatoid factor and may be more specific for RA. High titers of anti-CCP antibodies also correlate with more aggressive and destructive disease.

Other autoantibodies also have a role in RA, including antibodies directed at joint-specific antigens such as gp39, RA33, and p205.[27] Antibodies to glucose-6-phosphate isomerase (GPI), a ubiquitous antigen, can cause arthritis in mice and have also been detected in patients with RA and other inflammatory arthropathies.[28] Anti-GPI antibodies appear to localize in the joints and activate complement, perhaps because GPI can adhere to articular cartilage. The relative contribution of autoantibodies to RA as either a primary or a secondary phenomenon is still uncertain. Anti-GPI antibodies are present in only a small percentage of RA patients; they are also detected in the blood of patients with other forms of inflammatory arthritis.

Complement Activation

Interaction of rheumatoid factors with normal IgG activates complement and thereby starts a chain of events that includes production of anaphylatoxins and chemotactic factors. Polymorphonuclear leukocytes then engulf the rheumatoid factor–IgG-complement complexes and release lysosomal enzymes and other products. Complexes of IgG rheumatoid factor with IgG and complement components are readily detected in the synovium, synovial fluid, and extra-articular lesions. Although the synovium is a rich source of complement production, the levels in rheumatoid synovial fluid are low because of local consumption. Deposits of immunoglobulin and complement have been identified in avascular cartilage and other collagenous tissues of rheumatoid joints and may play a role in the formation of the destructive lesion of RA. These deposits, which are highly specific for RA, may be an attractant for the invasive pannus.

Cytokines

Early studies suggested an unrestricted abundance of cytokines in the rheumatoid joint. However, later experiments demonstrated a relative paucity of many T cell–derived cytokines, including IL-2, IL-4, and TNF-β.[29] One exception is IL-17, which can regulate cartilage metabolism and may be produced by $CD4^+$ T cells in the joint.[30] T cells can also potentially contribute to macrophage and synoviocyte activation by inducing metalloproteinase gene expression via direct cell-cell contact.

T helper cells can be divided into subsets that mediate distinct functions of the immune system. T helper type 1 (Th1) cells produce interferon gamma and IL-2 but not IL-4, IL-5, or IL-10; T helper type 2 (Th2) cells produce the opposite cytokine profile. Th1 overactivity predominates in most animal models of autoimmunity, whereas Th2 cytokines mediate disease suppression.[31] The small amounts of T cell cytokines that can be detected in RA are biased toward the Th1 phenotype, including IL-17. In contrast, Th2 cytokines (especially IL-4) are virtually absent from the joint. Some IL-10 is present but is derived mainly from macrophages, and the amount is not sufficient to suppress Th1 cytokine production.[32] The relative lack of suppressive Th2 cytokines may contribute to the pathogenesis of rheumatoid synovitis. Levels of other suppressive cytokines, such as the natural IL-1 receptor antagonist (IL-1ra), are also low in RA joint tissues.[33]

Macrophage- and fibroblast-derived cytokines (e.g., IL-1, IL-6, TNF-α, and granulocyte-macrophage colony-stimulating factor [GM-CSF]) are abundantly expressed in the rheumatoid joint.[34] Although many of these cytokines are involved in the pathogenesis of RA, TNF-α and IL-1 are major pathogenic factors: both can induce synoviocyte proliferation, collagenase production, and prostaglandin release; overexpression of either TNF-α or IL-1 can induce arthritis in animal models. IL-15 is produced by macrophages but shares many activities of the T cell–derived cytokine IL-2. It increases the ability of T cells to induce TNF-α production by macrophages through an antigen-independent mechanism that involves cell-cell contact.[35] IL-18 is also present in the RA joint and can bias T cell responses toward Th1 or directly activate macrophages to produce proinflammatory mediators.[36] Cytokine networks can potentially establish paracrine or autocrine networks that can perpetuate arthritis long after the etiologic agent has been cleared. Recent studies suggest that anti-cytokine therapy (including therapy with IL-1, TNF-α, and IL-6) is effective in severe RA and demonstrates the importance of fibroblast and macrophage products in chronic synovitis.

Diagnosis

CLINICAL FEATURES AND DISEASE COURSE

The onset of RA in adults may be either acute or insidious. In the latter case, systemic manifestations may precede overt symp-

toms of arthritis by months. In some patients, external events (e.g., major infections, surgical procedures, trauma, or childbirth) precede the clinical onset. How these events relate to pathogenesis is unknown. Small joints of the hands and feet are usually involved at the outset, although large joints (e.g., knees and ankles) are sometimes affected first. In about 10% of cases, monoarthritis of a large joint can presage progression to polyarticular RA.

An insidious onset followed by progression to polyarticular involvement is the most common course. Most patients experience some degree of joint stiffness, especially in the morning after awakening, which may accompany or precede joint swelling or pain. These symptoms are hallmarks of disease activity and help distinguish RA from noninflammatory diseases such as osteoarthritis. However, joint stiffness and swelling are not specific for RA and can occur with other types of inflammatory arthritis. RA patients frequently complain of morning stiffness that lasts more than 30 minutes (often up to several hours).

Examination of the joints reveals varying degrees of swelling, warmth over the involved joint, tenderness to palpation, and limitation of active and passive range of motion. Swelling may be caused by thickening, edema, and increased vascularity of the synovium; by synovial effusions; or by combinations of these factors. In small joints, such as metacarpophalangeal joints, effusions may be difficult to detect: the presence of synovial thickening causes loss of the anatomic landmarks and can obscure the peaks and valleys formed by the joints. In large joints, especially the knees, effusions are usually easy to demonstrate. Unlike acute inflammatory arthritides (e.g., gout or septic arthritis), RA tends not to cause marked erythema, and swelling usually does not extend far beyond the articulation. In elderly patients, the most prominent manifestation may be diffuse swelling of the hands accompanied by aching and marked stiffness in the absence of erythema. This can be difficult to distinguish from polymyalgia rheumatica, especially in patients lacking rheumatoid factor.

Classically, RA is symmetrical. When RA is progressive and unremitting, nearly every peripheral joint may eventually be affected, although the thoracic, lumbar, and sacral spine are usually spared. This clinical presentation is observed in perhaps 10% of patients. In about 75%, the disease waxes and wanes over a period of years. In the remaining patients, complete remissions may be achieved with no evidence of inflammation. Remissions may be only partial, with mild clinical disease persisting despite clear improvement. When the course is progressive, the periods of remission may become shorter, and less impressive decreases in symptoms and findings may occur.

A relatively favorable course with long remissions tends to be associated with age less than 40 years, acute onset restricted to a few large joints, disease duration less than 1 year, and negative test results for rheumatoid factor. Conversely, an unfavorable prognosis is often associated with insidious onset, constitutional symptoms (e.g., weight loss, low-grade fever, and profound fatigue), rapid appearance of rheumatoid nodules, and high titers of rheumatoid factor. Homozygosity for the QKRAA sequence in the HLA-DR locus is also associated with more severe disease with extra-articular manifestations. The duration and intensity of inflammation correlates with long-term disability, and there is a significant relationship between persistent elevations in the level of C-reactive protein and poor outcome. The appearance of bone erosions early in the course of disease also portends a worse prognosis.

Pregnancy often relieves the symptoms of RA in the second or third trimester through a poorly clarified mechanism. One possible explanation is that the placenta produces large amounts of the suppressive cytokine IL-10. The risk of developing RA appears to be lower in women who have been pregnant. The effect of oral contraceptives on disease susceptibility is controversial; the effect, if any, is probably small.[37] In long-term studies, multiple pregnancies or the use of oral contraceptives did not significantly alter the course of RA.[38]

Mortality is higher in RA patients than in the normal population. For the most part, RA patients die of the same causes as the general public, albeit earlier. In severe RA, mortality can approach that of severe congestive heart failure or Hodgkin disease, thereby justifying aggressive early management. Cardiovascular disease accounts for about 40% to 45% of deaths in RA patients; cancer, about 15%; and infection, about 10%. The inflammatory response, especially when associated with an increase in C-reactive protein and the use of proatherogenic treatments such as corticosteroids, correlates with an increased incidence of coronary artery disease.[39] The incidence of lymphoproliferative diseases is increased in patients with RA; non-Hodgkin lymphoma, leukemia, multiple myeloma, and Hodgkin disease account for most excess malignancies.

Specific Joint Disease

Hands and wrists Involvement of the hands and wrists is the most characteristic finding. Swelling and tenderness are usually noted first at the metacarpophalangeal and proximal interphalangeal joints [*see Figure 3*]. Fusiform swelling at the proximal interphalangeal joints is typical. Distal interphalangeal joints are usually spared. Grip strength is decreased because of pain and mechanical derangement. Flexor tenosynovitis is common; progressive flexion limitation prevents the making of a fist.

Depending on the site and severity of the rheumatoid lesions, varying degrees of ulnar deviation and subluxation at the metacarpophalangeal joints result. These deformities are, in large part, caused by inflammation and radial deviation at the wrist. As the wrist abnormalities progress, the extensor tendons apply torque across the metacarpophalangeal joints and tend to pull the digits into the classic ulnar deviation position. Other changes in the phalanges include (1) hyperextension at the prox-

Figure 3 **The hand and wrist are common sites of synovitis in rheumatoid arthritis. Marked swelling in the wrist and metacarpophalangeal joints is caused by synovial proliferation. Modest ulnar deviation of the fingers is also present.**

Figure 4 **Rheumatoid nodules commonly form near the extensor surface of the elbow. They can be fixed to the underlying periosteum or can be freely mobile.**

imal interphalangeal joint and flexion at the distal interphalangeal joint (so-called swan-neck deformity) and (2) flexion at the proximal interphalangeal joint and extension at the distal interphalangeal joint (boutonnière deformity). Several deformities also affect the thumb and interfere with grasp and pinch. In extreme instances, the fingers are markedly deformed and flail as a result of destruction of cartilage and bone.

In early RA, relatively painless swelling of the dorsum of the wrist may be noted. Most often, the wrist is painful and is the source of functional limitations (e.g., inability to remove the lid from a jar). At the volar aspect, median nerve compression caused by synovial expansion can produce carpal tunnel syndrome. On the dorsal surface, synovial proliferation may erode and rupture the extensor tendons of the fingers, rendering the patient unable to extend the fingers actively at the metacarpophalangeal joints. Decreased dorsiflexion and plantar flexion of the wrist caused by fusion of carpal bones is common in severe disease. Volar subluxation and radial deviation are also common deformities; the ulnar styloid is often one of the first sites of bone erosion.

Elbows and shoulders Synovitis of the elbow joint and inflammation and nodules in the olecranon bursa are frequent in established RA [*see Figure 4*]. Mild flexion contractures occur early; late in the disease, more severe flexion contractures cause functional disability, especially when associated with decreased shoulder abduction and rotation. Pain with decreased range of motion is commonly caused by synovitis of the glenohumeral joint; occasionally, large anterior effusions are evident. Shoulder pain commonly causes difficulty sleeping at night and functional disability. In chronic RA, the joint space becomes contracted, and rupture of the rotator cuff is very common. On physical examination, true glenohumeral joint arthritis can usually be distinguished from acromioclavicular pain, rotator cuff tendinitis, and subdeltoid bursitis.

Hips The hip is affected later than most other joints. In osteoarthritis, the femoral head tends to migrate superiorly in the acetabulum, but in RA, symmetrical destruction of cartilage leads to axial migration. End-stage rheumatoid disease with typical cartilage loss produces acetabular protrusion of the femoral head [*see Figure 5*].

Knees Knee arthritis is common and is occasionally a primary manifestation in early RA. Swelling and thickening of the synovium and effusions are usually simple to detect; arthrocentesis readily provides synovial fluid for analysis. Occasionally, large effusions expand into the suprapatellar pouch. Atrophy of muscles around the knee, especially the quadriceps, and resultant weakness can be detected early. Persistent synovitis eventually limits walking because of cartilage destruction, ligament laxity, joint instability, and contractures.

Baker cysts of the popliteal space are lined with synovial membrane and usually communicate with the cavity of the knee joint. The high pressure generated during knee flexion may be propagated posteriorly and cause rupture or dissection of these cysts. Calf swelling, pain, and erythema result, mimicking thrombophlebitis. Rupture of cysts is not specific to RA, occurring in other forms of inflammatory synovitis as well. Diagnosis of popliteal cysts can be confirmed by ultrasonography or arthrography. Generally, treatment of the cyst is directed toward the underlying knee synovitis. Corticosteroid injections are usually directed into the knee rather than into the cyst.

Ankles and feet Inflammation of the ankle joints and of the small joints of the feet is common. Pain on flexion and extension is a result of tibiotalar arthritis, whereas pain on inversion and eversion is caused by subtalar disease. The metatarsophalangeal joints are sites of early synovitis, which causes pain in the ball of

a

b

Figure 5 **(*a*) A pelvic roentgenogram of a patient with classic seropositive rheumatoid arthritis was taken early in the course of the disease. (*b*) Another roentgenogram taken 4 years later demonstrates marked acetabular protrusion and resorption of the femoral heads, both of which are characteristic of the disease.**

the foot on weight bearing [*see Figure 6*]. Later in the disease, there is subluxation with protrusion of the metatarsal heads, hallux valgus, and collapse of the arch.

Cervical spine Joints of the thoracic, lumbar, and sacral spine are relatively unaffected in adult RA, but cervical spine disease is frequent and may result in severe pain or neurologic complications.[40] The lesion that has received the most attention is atlantoaxial subluxation and consequent separation at the atlantoodontoid articulation [*see Figure 7*]. This deformity is best seen on lateral roentgenograms obtained with the neck flexed, so that the separation of the anterior margin of the odontoid process from the posterior margin of the anterior arch of the atlas can exceed 3 mm. When the separation is severe, the odontoid process may protrude into the foramen magnum and exert pressure on the spinal cord, causing paresthesia or even muscle weakness in the arms and hands. Often, the odontoid process itself is eroded, which minimizes pressure complications but produces instability. Prophylactic surgery to correct subluxation is usually not recommended because of the high morbidity and mortality associated with the procedure. Surgical fixation is indicated in the presence of neurologic signs and symptoms related to spinal cord compression. If the patient requires other surgical procedures, the anesthesiologist should be alerted to the presence of atlantoaxial subluxation to minimize complications of intubation.

Other cervical spine lesions are also seen, including subluxation at multiple levels, erosions at end plates or apophyseal joints, or fusion at these joints. Management of cervical spine pain in the absence of significant subluxation can be frustrating. Traction can be gently applied, but one must always be cognizant of instability. Soft collars can provide some temporary relief, but if used excessively, they can exacerbate the problem by weakening the cervical muscles.

Figure 6 **Erosions (arrows) are visible in the metatarsal heads and in some of the phalanges in this roentgenogram of the foot of a patient with classic seropositive rheumatoid arthritis.**

Figure 7 **The anterior edge of the odontoid process (O) is abnormally separated from the posterior margin of the arch of the atlas (A) in this lateral roentgenogram of the cervical spine of a patient with rheumatoid arthritis. Subluxations of the lower cervical vertebral bodies (arrows) are also visible.**

Other joints Synovitis of the temporomandibular joints may produce pain on chewing and limit jaw motion. If the joint is sufficiently destroyed, posterior subluxation of the jaw may cause a receding chin. Sternoclavicular arthritis is uncommon but occurs in patients with widespread arthritis. In acute cricoarytenoid arthritis, hoarseness and pain on swallowing may accompany tenderness over the larynx.

Extra-articular Manifestations

RA is a systemic disease, even though it characteristically affects structures in and around the joints. Its systemic manifestations include mild fever, anorexia, weight loss, fatigue, and muscular weakness. Specific organ involvement usually occurs in the context of severe RA, with high titers of rheumatoid factor and nodule formation.

Rheumatoid nodules Rheumatoid nodules are the most common extra-articular manifestation, occurring in about 15% of patients. Almost all patients in whom nodules develop are seropositive for rheumatoid factor and have erosive disease [*see Figure 8*]. Nodules are usually subcutaneous and often are found in areas exposed to pressure—for example, over the extensor surfaces of the forearm, the olecranon bursa, the knuckles, the ischial regions, the Achilles tendon, and the bridge of the nose (if glasses are worn). They also occur in viscera. Rheumatoid nodules are firm and are either freely movable or attached to connective tissue (e.g., periosteum or tendons). They range from a few millimeters to more than 2 cm in diameter and often occur in clusters. Nodules typically have a rubbery or gritty feel and can

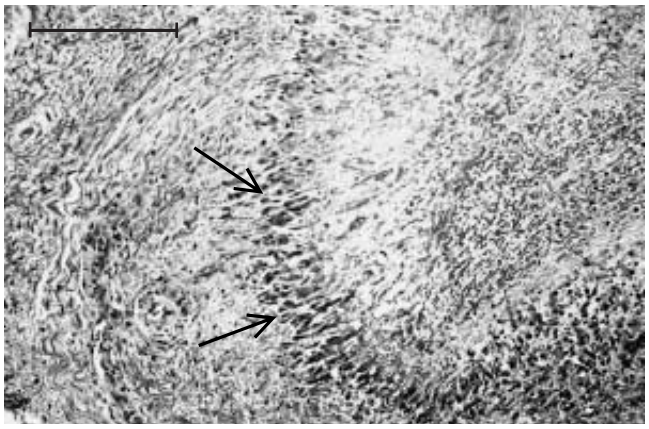

Figure 8 **A typical rheumatoid nodule contains an area of fibrinoid necrosis (center) surrounded by palisading histiocytes (arrows). At the periphery are round cells (predominantly lymphocytes). Stain is hematoxylin and eosin (bar scale = 300 μm).**

be indistinguishable from gouty tophi on physical examination. The lesion contains a center of fibrinoid necrosis (a mixture of fibrin and other proteins, such as degraded collagen) surrounded by a zone of histiocytes, which tend to be arranged radially. Lymphocytes and plasma cells form an outer layer. The pathogenesis of nodules is likely similar to that of synovitis, with early vascular involvement and local cytokine production.

There is no specific therapy for nodules other than treatment of the underlying arthritis. Surgical removal is often ineffective because nodules can return; it is generally reserved for severe functional impairment or obvious cosmetic problems. The appearance of fresh crops of nodules can indicate active disease. In some cases, exuberant nodule production (rheumatoid nodulosis) is a complication of methotrexate therapy. Rheumatoid nodules are not specific to RA, occurring in other connective tissue diseases (e.g., SLE) or in isolation (e.g., granuloma annulare).

Eyes The sicca syndrome, which is part of Sjögren syndrome, is the most frequent ocular manifestation of RA. Symptoms include sensations of grittiness, accumulation of dried mucoid material (especially in the morning immediately after waking up), and decreased tear production. The relative paucity of tears is demonstrated by decreased wetting of a filter paper strip in a Schirmer test. The dryness is not limited to the eyes and involves other exocrine glands, including those in the nose, the mouth, the rectum, and the vagina. Marked enlargement of lacrimal and salivary glands can occur in severe cases, although this is more common in primary Sjögren syndrome than in RA.

The genetic basis of RA with dry eyes is different from that of primary Sjögren syndrome, which is associated with HLA-DR3 antigen rather than HLA-DR4 antigen.[41] In patients who have the primary syndrome without joint inflammation, there is a greater frequency of recurrent parotitis, Raynaud phenomenon, purpura, lymphadenopathy, myositis, and renal involvement. In all patients with sicca syndrome, lacrimal and salivary glands are characterized histologically by lymphocyte infiltration and distortion of ductal structures. Patients with Sjögren syndrome often have high titers of anti-Ro antibody (also called anti–SS-A). Biopsy of minor salivary glands in the lip can help establish the diagnosis.

Scleritis is painful and may lead to perforation of the sclera and blindness. Episcleritis is common and can often be managed with topical corticosteroids. Matrix loss around the limbus and corneal melting may also lead to perforation. Uveitis and iritis occur no more often in adults with RA than in control populations.

Lungs The most common form of lung involvement in RA is pleurisy with effusions.[42] Evidence of pleuritis is often found at postmortem examination, but symptomatic pleurisy occurs in fewer than 10% of patients. Clinical features include gradual onset and variable degrees of pain and dyspnea. The effusions generally have protein concentrations greater than 3 to 4 g/dl, as well as glucose concentrations lower than 30 mg/dl; the latter finding has been ascribed to a primary defect in glucose transport. The leukocyte count is rarely higher than 5,000/mm^3 and is dominated by lymphocytes. The lactate dehydrogenase level is often markedly elevated; occasionally, the lipid content is also high. Complement levels are usually low, and rheumatoid factors are present. Pleural biopsy usually reveals nonspecific fibrosis or granulomas. The pleural effusions usually resolve spontaneously within months. Occasionally, repeated aspirations are required to relieve dyspnea; if effusions are troublesome, instillations of glucocorticoids are useful.

Rheumatoid nodules occur in the pulmonary parenchyma and on the pleural surface. They range in size from just detectable to several centimeters in diameter. They may be single or multiple, and at times, they cavitate. Such nodules can be difficult to distinguish radiologically from tuberculous or malignant lesions and often require further evaluation, including biopsy.

Progressive, symptomatic interstitial pulmonary fibrosis that produces coughing and dyspnea in conjunction with radiographic changes of a diffuse reticular pattern (i.e., honeycomb lung) is usually associated with high titers of rheumatoid factor. The lesion is histologically indistinguishable from idiopathic pulmonary fibrosis. Chest radiographs show pleural thickening, nodules, diffuse or patchy infiltrates, and a restrictive ventilatory defect that is characterized by a decreased CO diffusion rate. These abnormalities are often associated with cigarette smoking, other extra-articular manifestations, and active disease. Bronchiolitis obliterans, an unusual form of airway obstruction that usually has a viral or toxic etiology, may also develop.

Heart Cardiac involvement in RA is common but rarely symptomatic. Echocardiographic evidence of pericardial effusion or thickening has been found in about one third of patients studied.[43] Autopsy findings include rheumatoid nodules, healed or active pericarditis, myocarditis, endocarditis, and valvular fibrosis.

Symptomatic pericarditis is most frequent in patients with severe seropositive disease. Overt manifestations include chest pain, friction rub, and associated pleural effusions. The pericardial effusions resemble the pleural effusions in RA. Cardiac tamponade is rare, as is constrictive pericarditis.

Rheumatoid nodules and inflammation in the valves and the conduction system may cause conduction disturbances, including complete heart block. Aortic regurgitation secondary to aortitis and dilation of the aortic root may lead to congestive heart failure.

Blood Mild anemia of chronic disease is characteristic of active RA, although the hemoglobin level is usually greater than 10 mg/dl. Nonsteroidal anti-inflammatory drugs (NSAIDs) often cause GI blood loss, leading to iron deficiency. Although its lev-

els are not reduced in RA, administration of erythropoietin alleviates anemia.[44]

The constellation of RA with splenomegaly and leukopenia is known as Felty syndrome.[45] The mean serum leukocyte count in such patients is usually 1,500 to 2,000/mm^3, and the mean granulocyte count is 500 to 1,000/mm^3. Severe thrombocytopenia is uncommon. Infections, particularly of the skin, the perianal region, and the lungs, are frequent and are usually caused by common organisms. Other findings in Felty syndrome include hepatomegaly, lymphadenopathy, and chronic cutaneous ulcerations.

The neutropenia is the result of excessive vascular margination of leukocytes, increased peripheral destruction of leukocytes caused by IgG and IgM antigranulocyte antibodies,[46] and the inhibitory effects of T cells on granulopoiesis. Some cases of Felty syndrome are associated with oligoclonal or monoclonal expansion of large granular lymphocytes in the blood and represent a form of chronic leukemia.[47] Splenectomy usually produces an increase in the leukocyte count, but this increase is sustained in only 30% of patients. Lithium chloride may alleviate the neutropenia, as may treatment of active arthritis with disease-modifying drugs such as methotrexate.[48] Treatment with recombinant colony-stimulating factors, such as granulocyte colony-stimulating factor (G-CSF), can increase peripheral granulocyte counts in patients with Felty syndrome. The drug must be given for extended periods because discontinuance leads to relapse.

Neuromuscular involvement Weakness of muscles adjacent to joints with active synovitis is common. The most common neuropathy is median nerve compression caused by synovitis of the wrist. Entrapment of the ulnar nerve at the elbow or branches of the sural nerve in the tarsal tunnel also occurs.

Mononeuritis multiplex is seen in patients who have severe disease with necrotizing vasculitis and, frequently, deposits of immune complexes in the walls of the blood vessels supplying the involved nerves.[49] In milder cases, only segmental demyelination without vascular abnormalities may be found. Aseptic meningitis resulting from a hypersensitivity reaction to NSAIDs has been documented.[50]

Blood vessels Vasculitis in small synovial vessels is a hallmark of early RA, but more widespread vascular inflammation of medium-sized muscular arteries also occurs in older men with advanced disease, rheumatoid nodules, and high titers of rheumatoid factor. The involvement of larger vessels is distinct from small vessel disease; such involvement includes leukocytoclastic vasculitis or nail-fold infarcts. The course and prognosis of systemic rheumatoid vasculitis are similar to those of polyarteritis nodosa. Clinically, patients with rheumatoid vasculitis demonstrate polyneuropathy (mononeuritis multiplex), skin ulcerations, purpura, and cutaneous infarctions (sometimes progressing to gangrene). Manifestations of visceral ischemia, including bowel perforations, myocardial infarctions, and cerebral infarctions, are also common. Treatment usually requires high-dose corticosteroids or cyclophosphamides, or both, and still may not be effective. This feared complication has become quite rare, perhaps because of improved therapy for the underlying disease.

Other systems Apart from gastric and duodenal lesions caused by NSAIDs, GI complications are rare in RA. Rheumatoid nodules may involve the pharynx and esophagus. Mild elevations of liver enzymes are common and are usually drug related. Other hepatic abnormalities, particularly elevations in serum alkaline phosphatase and 5′-nucleotidase levels, occur in Sjögren syndrome. These hepatobiliary lesions are ascribed to immune responses to cross-reacting salivary and biliary antigens. Hepatitis C infection is also associated with the development of the sicca syndrome.[51] RA rarely causes specific renal lesions; NSAIDs and amyloid are more often responsible.

IMAGING FEATURES

Because early joint pathology in RA is confined to the synovium, standard radiographs are often not useful. Periarticular osteopenia of the metacarpophalangeal joints and proximal interphalangeal joints in the hand can be evident within months of onset. Joint space narrowing, caused by the loss of articular cartilage, indicates irreversible damage to such cartilage; RA must be active for at least 6 months for such damage to occur. Arthroscopic visualization of articular cartilage (e.g., in the knee) identifies damage to cartilage considerably earlier, but such findings have no value in the management of RA. Subchondral sclerosis is a feature of osteoarthritis but not of RA. Prominent periostitis with new bone formation is much more common in psoriatic arthritis or reactive arthritis syndrome.

Radiographically visualized bone erosions are best seen at the margins of the joint, where the synovium is reflected near the attachment of the capsule. The bone in this region (the so-called "bare area") is not protected by a layer of cartilage and is directly attacked by the invading synovium and osteoclasts. The erosions associated with RA may be difficult to distinguish from those of gout: the latter tend to have sharper borders and overhanging edges of bone, whereas the former are usually small and irregularly shaped. Cystlike radiolucencies may be seen in larger joints. Entire portions of bone adjacent to the joints, such as the metacarpal ends and the ulnar styloid process, may be resorbed. Cartilage destruction caused by RA tends to be evenly distributed within a joint. For instance, both the medial and the lateral compartments of the knee joint are narrowed in RA, whereas the medial compartment is more often affected in osteoarthritis. Progression of erosions takes time in RA; it is rarely necessary to repeat radiographs more often than every 12 months. Damage that is radiographically evident often occurs during the first 2 to 5 years and can progress inexorably in the absence of treatment.

MRI can distinguish synovial pannus from cartilage and synovial fluid and thus can detect pannus as it invades joint structures. The use of intravenous contrast materials, such as gadolinium, permits accurate assessment of synovial invasion and volume. MRI has replaced arthrography for the investigation of large joints, such as the knees.[52] The use of MRI to monitor response to therapy is still experimental because of a lack of uniform standards for judging damage. Although most erosions persist or progress, up to one quarter of them heal spontaneously.[53] Because of the lack of standardization, plain radiographs remain the gold standard for following disease progression.

LABORATORY EVALUATION

A mild normochromic, normocytic anemia and an elevated platelet count are usually present in patients with RA. The leukocyte count is generally normal, although neutropenia occurs in association with splenomegaly in Felty syndrome. The erythrocyte sedimentation rate (ESR) and the C-reactive protein level are usually elevated in active RA and are useful in monitoring disease activity and response to therapy. Results of serum

chemistry studies are normal, although the use of either NSAIDs or methotrexate can lead to elevations in liver enzyme levels. Urinalysis is generally normal.

About 80% to 85% of patients with RA are seropositive for rheumatoid factor. If seropositivity develops, it usually does so before the end of the first year of disease. From 1% to 5% of healthy persons test positive for rheumatoid factor, with the higher percentage noted in the elderly. Many chronic inflammatory conditions besides RA are associated with positive rheumatoid factor test results, although the titers are usually lower. Compared with rheumatoid factor, testing for antibodies to CCP appears to be more specific for RA (85% to 90%) but may be less sensitive (50% to 60%). Testing for anti-CCP antibodies could be useful as a diagnostic test in selected cases.

Other serologic tests commonly used to diagnose rheumatic diseases are of limited value in RA. Antinuclear antibodies (ANA) are often present in low titer. If anti-DNA antibodies are detected, they are almost always directed against single-stranded DNA rather than native double-stranded DNA. Antibodies to the antigens associated with Sjögren syndrome (SS-A and SS-B) may be positive. Serum complement levels are normal in uncomplicated RA; hypocomplementemia suggests systemic rheumatoid vasculitis. Serologic tests for viruses may help identify patients with postrubella arthritis or parvovirus B19 infection. Hepatitis B and C serologies can also provide useful information, because these infections can cause a self-limited symmetrical polyarthritis that mimics RA.

Analysis of synovial fluid provides supportive data but is rarely diagnostic. Synovial fluid in RA usually appears straw colored and mildly turbid. Bits of fibrin and, occasionally, small fronds of synovium may be aspirated. Leukocyte counts range from 2,000 to 20,000/mm^3. On differential counts, most of the cells (50% to 80%) are neutrophils; the remainder are lymphocytes (mainly T cells) and monocytes. The synovial fluid glucose level is usually normal, which distinguishes RA from acute infection. Synovial fluid complement levels are usually low in inflamed rheumatoid joints despite abundant production of complement proteins by synovium. Tests for rheumatoid factor, antinuclear antibodies, total protein, or lactate dehydrogenase in synovial fluid are not clinically useful. Synovial biopsies, either blind or arthroscopically directed, can be used in clinical trials to assess response to therapy. However, their utility for differential diagnosis or in predicting response to therapy remains limited.

Differential Diagnosis

The onset and course of RA can be highly variable, and the lack of a specific biologic marker makes diagnosis difficult. Prolonged observation and the integration of clinical and laboratory data that meet established criteria are often required.

Diagnostic criteria have been formulated by the American College of Rheumatology [*see Table 1*]. Conditions mimicking RA should be ruled out, if possible. Patients with other rheumatic diseases often have a symmetrical polyarticular arthritis resembling RA. The presence of high-titer ANA and anti–double-stranded DNA, a low serum complement level, and major organ system involvement (especially nephritis) are clues to the diagnosis of SLE. Careful physical examination often helps the clinician distinguish other rheumatic diseases. Elderly persons with polymyalgia rheumatica can present with peripheral synovitis, although prominent proximal muscle stiffness and a very high ESR (often higher than 80 to 100 mm/hr) are useful differential findings. Viral arthritis mediated by immune complex deposi-

Table 2 Comparison of Various Antirheumatic Treatments

Drug	*Response Rate; Onset of Action*	*Magnitude of Efficacy (0 to ++++)*	*Major Toxicities*	*Dosage*
Adalumimab	50%–70%; 2–4 wk	+++	Injection-site reactions, infections	40 mg S.C. every 2 wk
Anakinra	30%; 1–3 mo	+ to ++	Injection site reactions, infection	100 mg/day S.C.
Azathioprine	30%–50%; 2–3 mo	++	Hematologic, immunosuppression, cholestasis	100–150 mg/day
Cyclosporine	30%; 2–3 mo	++	Renal (irreversible), hypertension, hypertrichosis, immunosuppression	2.5–5.0 mg/kg/day
Etanercept	50%–70%; 2–4 wk	+++	Injection-site reaction, ?immune surveillance	25 mg S.C. twice a week
Gold	30%; 3–6 mo	++	Skin rash, hematologic, renal	5.0 mg/wk I.M. × 6 mo
Hydroxychloroquine	30%–50%; 2–6 mo	++	Retinopathy, myopathy, hyperpigmentation	200 mg b.i.d.
Infliximab	50%–70%; 2–4 wk	+++	Increased infection	3 mg/kg I.V. q. 8 wk
Leflunomide	50%; 2–3 mo	++	Liver, teratogen, gastrointestinal, skin rash	100 mg/day × 3, then 20 mg/day
Methotrexate	> 70%; 6–8 wk	+++	Liver (fibrosis, elevated enzymes), hematologic, oral ulcers	7.5–15 mg/wk
NSAIDs	> 75%; < 2 wk	+	Gastric erosion, renal	Varied
Prednisone	> 90%; < 1 wk	+++	Skin atrophy, cataracts, osteoporosis, avascular necrosis	5.0–7.5 mg/day
Sulfasalazine	> 30%; 2–3 mo	++	Dyspepsia, hemolysis in glucose-6-phosphate dehydrogenase deficiency	1 g b.i.d. or t.i.d.

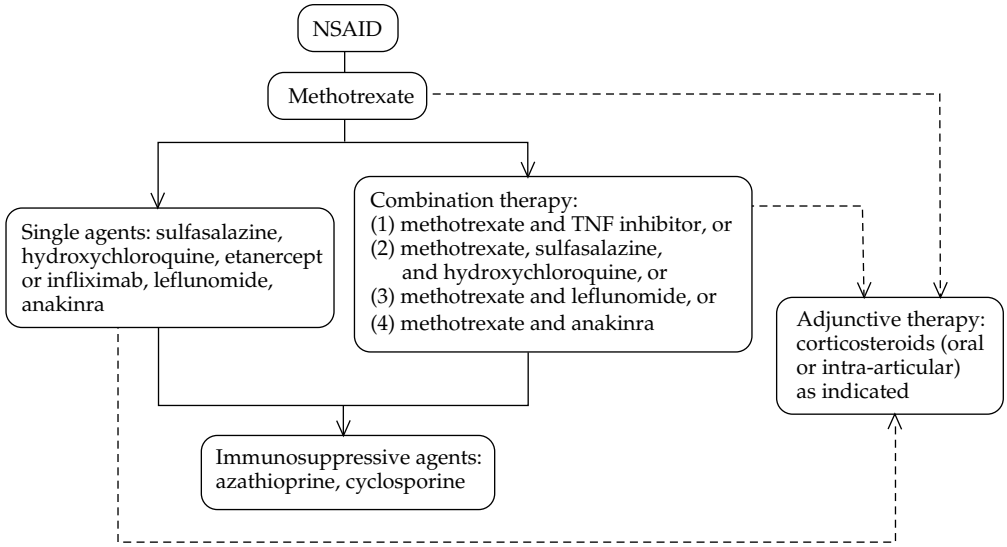

Figure 9 **Proposed algorithm for pharmacologic management of rheumatoid arthritis. The solid lines indicate the standard management options, and the broken lines indicate stages at which adjunctive therapy may be introduced. Most patients require rapid advancement from nonsteroidal anti-inflammatory drugs to a second-line agent, most often methotrexate.**

tion, as in hepatitis B or rubella, often has the same distribution as RA but is transient.

Metabolic disorders such as gout and calcium pyrophosphate deposition arthropathies can mimic RA. Radiographs may indicate characteristic gouty erosions or chondrocalcinosis. The finding of crystals in synovial fluid distinguishes these disorders from RA. Septic arthritis is also relatively easy to identify through clinical examination and evaluation of synovial fluid.

Seronegative spondyloarthropathies can present a diagnostic challenge when they exhibit peripheral polyarticular disease. They can generally be distinguished by the lack of symmetry, the distribution of affected joints (usually, lower extremities are affected more than upper, and large joints more than small), the absence of rheumatoid factor, the presence of proliferative bone changes on radiographs, and characteristic skin lesions. However, in some cases, psoriatic arthritis has a clinical picture almost identical to that of RA.

Morning stiffness and involvement of the wrist and metacarpophalangeal joints are uncommon in osteoarthritis, which typically affects the weight-bearing joints and the distal interphalangeal joints. Patients with osteoarthritis usually are seronegative for rheumatoid factor and lack marginal erosions. Synovial effusions are noninflammatory, with a WBC lower than 2,000/mm^3 and a predominance of mononuclear cells.

Rheumatoid joints are more susceptible to bacterial infection than normal joints, and superimposed sepsis may not be readily apparent. The usual signs (e.g., localized erythema, increased pain, and limitation of motion) may be difficult to distinguish from the underlying rheumatoid synovitis or may be suppressed by antirheumatic therapy. Multiple joints may be infected simultaneously; the diagnosis requires arthrocentesis and culture [*see 7:XV Septic Arthritis*].

Management

Optimal management requires an awareness of the variable course of the disorder. Statistical predictions about outcome can be made from clinical features and laboratory abnormalities, but remissions and exacerbations are common, and the risks associated with drugs and surgery must be viewed in the light of this uncertainty. The patient should be aware of the risks both of taking a drug and of not taking it. Active synovitis that persists for a year or more after the onset of RA results in irreversible cartilage damage, joint destruction, and increased mortality. Thus, every effort should be made to suppress the synovitis by pharmacologic methods during the early months.

No specific climate or diet alters the course of RA. Alternative therapies, including cartilage extracts, rarely have more than a placebo effect. However, the power of placebo effects should not be underestimated; most arthritis and pain studies demonstrate a "therapeutic" response in 20% to 30% of patients who receive placebo. Glucosamine and chondroitin sulfate have been studied in osteoarthritis, but few data support their use in RA.

In addition to conveying to the patient an understanding of the disease, management involves efforts to relieve pain and discomfort, preserve strength and joint function, prevent deformities, and attend to systemic complications. Surgical intervention is important not only for replacing destroyed joints but also, at times, for restoring function or preventing further damage.

DRUG THERAPY

Drugs are used for analgesia, to control inflammation, and to alter the natural history of disease. Only empirical data support the use of some currently available agents; the mechanism of action of these agents is unknown. In formal studies of individual drug therapies, systematic measurements are taken of the number of inflamed joints, the extent of swelling, and the range of joint motion. Laboratory measurements (e.g., ESR and hematocrit value) and assessments of subjective features (e.g., pain and morning stiffness) are also made. The information is then assessed globally. Some objective and subjective improvement is usually observed with any agent; placebo effects may be striking [*see Table 2*].

General Recommendations

The appropriate management of RA is rapidly evolving; previous treatment algorithms based on a gradual escalation of treatment (i.e., the traditional pyramid approach) have been replaced by more aggressive treatment approaches.[54] The change has been fomented by a variety of factors, including the follow-

ing: (1) active RA significantly decreases the life span of affected individuals; (2) active inflammation is associated with increased morbidity and mortality; (3) more effective therapy is available; and (4) the advent of combination therapy and new drugs has had a clear effect on the natural history of disease. No single algorithm can capture the complexity of RA management today because of the extensive pharmacopoeia, although broad guidelines can be given [*see Figure 9*].

Most patients require rapid advancement from NSAIDs to a second-line agent, most often methotrexate. Because symptoms of RA will not be adequately controlled in 70% of patients by methotrexate alone, the clinician is usually faced with the choice of either "add-on" therapy or testing a series of single agents (e.g., sulfasalazine, antimalarials, leflunomide, a TNF inhibitor, or gold). In the United States, most rheumatologists prefer to increase the methotrexate dosage rapidly to 20 to 25 mg/wk and then add another agent within 2 to 3 months if necessary. Morning stiffness lasting longer than 30 minutes, continued pain, or evidence of active synovitis on physical examination is an indication for advancing therapy even if the patient has experienced significant improvement on methotrexate. Typically, one would add either a TNF inhibitor, leflunomide, or sulfasalazine (with or without hydroxychloroquine). Care must be exercised, especially with combinations of methotrexate and leflunomide, because of hepatotoxicity.

Few data demonstrate the superiority of one combination of drugs over another, although there is an increasing bias toward use of TNF inhibitors early in management.[55] Prednisone is generally reserved for patients requiring adjunctive "bridge" therapy to improve their ability to perform activities of daily living; the prednisone therapy is maintained until a single-drug or combination therapy permits its use to be tapered or discontinued. The most recent addition to the armamentarium, the IL-1 inhibitor anakinra, is modestly effective; it is usually reserved for patients who do not respond to combinations of methotrexate and TNF inhibitors.[56]

Alternative algorithms have also been proposed for the management of RA. Some data suggest that early management with triple therapy (e.g., sulfasalazine, hydroxychloroquine, and methotrexate) is very effective.[57] Other options include early high-dose corticosteroid treatment, with the dose tapered over several months, in combination with methotrexate and sulfasalazine given in stable doses. In such protocols, patients tend to improve quite rapidly because of the steroid. This form of early aggressive treatment appears to have a persistent effect and is associated with less radiographically evident joint damage, even after corticosteroids or one of the other agents has been discontinued.[58] However, it is very difficult to assess the efficacy of second-line drugs if prednisone is added early in the course of treatment.

Although the number of cases of treatment-resistant disease is decreasing, a fraction are recalcitrant to all of the aforementioned drugs. Immunosuppressive agents such as azathioprine or cyclosporine can be used, although the therapeutic ratio is narrow. Experimental approaches can also be considered with appropriate oversight from institutional review boards.

Nonsteroidal Anti-inflammatory Drugs

The use of aspirin for RA has decreased substantially because of the availability of newer NSAIDs. Nonacetylated salicylate compounds, such as choline salicylate and choline magnesium trisalicylate, produce less gastric irritation than aspirin but are more expensive and exert less anti-inflammatory effect.

Other NSAIDs are probably no more effective than aspirin but may have certain advantages (e.g., fewer GI effects, better pharmacokinetics, and, usually, fewer pills to be taken daily, which may enhance compliance). The prostaglandin analogue misoprostol, proton pump inhibitors, and, to a lesser extent, H_2 receptor blockers can suppress the GI toxicity of NSAIDs[59] and should be considered for patients who take a nonselective cyclooxygenase inhibitor but have a history of duodenal ulcer or gastritis.[60] *Helicobacter pylori* infection, use of salicylates, and use of NSAIDs are likely independent risk factors for peptic ulceration.[61]

Pharmacokinetics aside, there are a few pharmacologic differences between the various NSAIDs. Sulindac may have less renal toxicity than other NSAIDs, but the clinical relevance is not certain. Most currently available NSAIDs nonselectively block both the constitutively expressed cyclooxygenase COX-1 and the inducible cyclooxygenase COX-2, although the relative selectivity for COX-2 can be favorable with some compounds (e.g., meloxicam and diclofenac). Selective COX-2 inhibitors (e.g., celecoxib and valdecoxib) are also effective anti-inflammatory and analgesic agents.[62] They have fewer GI side effects than nonselective COX inhibitors. In addition, they do not block platelet function and may be used in some situations in which traditional NSAIDs may be contraindicated. Both selective and nonselective agents, however, can alter renal blood flow and glomerular filtration rate. Celecoxib is administered in a dosage of 100 to 200 mg orally once or twice daily, whereas valdecoxib is usually given in a once-daily oral dosage of 10 mg. The association of cardiovascular events with prolonged use of the COX-2 inhibitor rofecoxib (Vioxx) prompted the withdrawal of the drug from the global market in 2004.[63,64] There is scant evidence to assess the long-term risk of other COX-2 inhibitors. When prescribing COX-2 inhibitors, clinicians should weigh the potential cardiovascular risks against anticipated benefits and consider issues such as dose and comorbid conditions.

Advancement from NSAIDs to second-line agents is recommended if (1) symptoms have not improved sufficiently after a short trial of NSAIDs, (2) the patient has aggressive seropositive disease, or (3) there is radiographic evidence of erosions or joint destruction. The trend today is for more aggressive treatment, and the majority of patients require additional pharmacotherapy.

Methotrexate

Methotrexate is one of the most effective second-line drugs. Methotrexate not only alleviates the signs and symptoms of RA but also decreases the ESR and raises the hematocrit value.[65] It probably also slows the rate of bone erosion in RA, perhaps by decreasing expression of destructive enzymes such as collagenase in synovium.[66]

Methotrexate is usually given in weekly oral doses, beginning at 7.5 mg and, if necessary, increasing to 15 mg over 2 to 3 months. Response to therapy is usually relatively rapid, with improvement occurring in 6 to 8 weeks. If no response is observed, the dose can be increased to 20 to 25 mg/wk [*see Figure 9*]. Further increases up to 45 mg/wk administered parenterally had minimal additional benefit.[67] Over 70% of patients have a response to methotrexate, and half remain on the drug for at least 5 years. Efficacy remains excellent even after years of use.[68] Complete remissions are uncommon, although patients' sense of well-being is often dramatically improved. Inflammation usually reappears within weeks after discontinuance. Monitoring of hematologic and liver parameters every 4 to 8 weeks is required. The primary action of methotrexate is anti-inflammatory at the

doses used in RA, although immunosuppression resulting in *Pneumocystis* pneumonia has been reported. Improved survival as a result of a reduction in cardiovascular mortality has been reported in patients treated with methotrexate.[69]

Risk factors for toxicity include alcoholism, diabetes, obesity, advanced age, and renal disease. The major concern is hepatic fibrosis, although marrow toxicity and sterility are also important side effects. Methotrexate is a potent teratogen and should not be used in women of childbearing age unless they are using a reliable form of contraception. Idiosyncratic interstitial lung disease can develop even at low doses. Other adverse reactions to methotrexate include nausea, stomatitis, leukopenia, diarrhea, and elevations of serum aminotransferase levels. Some of these toxicities (especially oral ulcers) can be minimized by prophylactic administration of folic acid, 1 mg/day.[70] Hepatotoxicity leading to clinically significant fibrosis or cirrhosis is exceedingly uncommon; accordingly, most centers have abandoned routine monitoring with liver biopsies.[71] A biopsy should be performed if a patient develops persistent abnormalities in blood tests for liver enzymes that do not promptly resolve with discontinuance. Other medications that interfere with folate metabolism (e.g., trimethoprim) should be used with caution in patients taking methotrexate.

Leflunomide

Leflunomide is an effective antirheumatic agent that blocks the pyrimidine synthesis required for stimulated lymphocytes to proliferate. In vitro, it inhibits mitogen-stimulated proliferation of both B cells and T cells. Randomized, controlled trials have demonstrated that leflunomide is approximately as effective as methotrexate in the treatment of active RA.[72] In addition to being clinically effective, leflunomide slows radiographic progression of RA.[73]

Because the half-life of leflunomide is 2 weeks, loading doses are necessary to achieve therapeutic blood levels promptly. A loading dose of 100 mg/day for 3 days is sometimes given, followed by daily dosing with 20 mg/day. Leflunomide can be used in combination with methotrexate, although in this setting the initial dose of leflunomide is usually 10 mg/day; patients must be followed very carefully for hepatotoxicity.[74]

Adverse effects include diarrhea, liver toxicity, rash, oral ulcers, and reversible hair loss.[75] Periodic monitoring of liver enzymes is required. In animal studies, leflunomide has been associated with birth defects; thus, this agent should not be used by pregnant women or women of childbearing age who are not using a reliable form of contraception.

Antimalarial Drugs and Sulfasalazine as Single and Combination Agents

The antimalarial drug hydroxychloroquine is useful as early second-line therapy for RA.[76] Its response rate is lower than that of methotrexate, and less improvement is seen; however, its relative safety makes it an ideal choice for patients with mild early disease or as an additive agent in combination therapy. Adverse reactions to antimalarials occur, particularly retinopathy that may lead to an irreversible decrease in vision; this reaction is rare and can be minimized with regular ophthalmologic examinations.

Sulfasalazine is also useful.[77] It is effective in at least 30% of patients at a dosage of 2 to 3 g/day in divided doses. Only moderate side effects have been reported, especially GI upset. Sulfasalazine is well tolerated; over 30% of patients continue to take it for at least 5 years.[78]

A significant percentage of RA patients do not experience satisfactory symptomatic relief with a single disease-modifying antirheumatic drug. This lack of response has led clinical investigators to study combination regimens,[79] but most of the studies performed have been poorly controlled. A prospective study examining azathioprine and methotrexate alone and in combination demonstrated safety but no additive benefits.[80] A 2-year study showed that a combination of methotrexate, sulfasalazine, and hydroxychloroquine is more effective than any of the agents alone.[81]

Gold Salts

Injectable gold salts decrease inflammation and increase the likelihood of remission. Gold was once the primary second-line agent, but its relatively modest efficacy and high side-effect profile, coupled with the increased use of methotrexate and anticytokine therapy, have led to a dramatic decrease in its use.

Treatment usually consists of intramuscular administration of a compound such as gold sodium thiomalate in a test dose of 10 mg, followed by a single 25 mg dose 1 week later and then by 50 mg once weekly for 20 weeks. If the response is satisfactory at this point, the compound can be given every other week for another several months and monthly thereafter for an indefinite period. The response rate to gold is about 30%, although toxicity and lack of efficacy result in discontinuance in almost 90% of patients within 5 years.

Major adverse side effects involve hematologic, renal, and dermatologic reactions. Oral gold preparations appear to be less toxic than injectable ones but are less effective.

Anticytokine Therapy

TNF inhibitors Interference with the function of TNF-α, either by soluble receptor blockade or by giving monoclonal antibody, is effective in treating RA.[82] By itself, the soluble 75 kd TNF receptor has a very short biologic half-life. Recombinant technology was used to engineer the fusion of the receptor to the Fc portion of the immunoglobulin molecule (etanercept), greatly prolonging the half-life and making twice-weekly subcutaneous injections feasible. The fusion protein is entirely human in origin, and antibody formation against it is minimal.

Etanercept has been approved for use in the United States (25 mg S.C. twice a week) and has been shown to be beneficial in patients who have only a partial response to methotrexate used either in combination therapy or as monotherapy.[83] A single injection of 50 mg/wk appears to have similar efficacy. The fusion protein is also effective in children with RA.

Two monoclonal antibodies have been approved for use in RA: the human-mouse chimeric monoclonal antibody infliximab and the human monoclonal antibody adalumimab. There are subtle differences in the pharmacology of etanercept and the monoclonal antibodies. Etanercept binds both TNF-α and TNF-β, whereas the monoclonal antibodies have a greater affinity for the TNF-α ligand and bind only to TNF-α. However, the clinical impact of this difference is not clear, and the response rates are similar.

Infliximab is used in combination with methotrexate for treatment of RA; this appears to permit long-term use of infliximab with less formation of neutralizing antibodies.[84] Infliximab is administered by intravenous infusion; the recommended dose is 3 to 10 mg/kg every 8 weeks. As with etanercept and all TNF inhibitors, the drug must be used with care in the presence of infections.

Adalimumab has demonstrated efficacy similar to that of infliximab and etanercept in RA. It is generally administered at a dose of 40 mg S.C. every 2 weeks. In perhaps 10% of patients, the frequency of administration must be increased to once a week.

The clinical response to TNF inhibitors can be dramatic, and an improved sense of well-being can occur within days. Typically, patients who respond to TNF inhibitors will notice decreased pain and stiffness after a few weeks of therapy. About two thirds of patients have at least 20% improvement in the number of swollen and tender joints, and half of these patients will have more than 50% improvement. Concomitant with decreased symptoms, serum and synovial cytokine levels decrease, and peripheral blood markers of inflammation (i.e., ESR and the C-reactive protein level) decline. Although the clinical effect occurs sooner with the TNF inhibitors than with methotrexate, a significant benefit over methotrexate has not been demonstrated after 3 months of therapy.[83]

In addition to providing symptomatic improvement, TNF inhibitors prevent or slow bone and cartilage destruction in RA. Perhaps most intriguing is the observation that radiographic progression is prevented even in patients who do not experience clinical improvement after treatment with infliximab. This observation could have important implications for the widespread clinical use of these agents if long-term studies confirm these findings. For now, however, these agents are generally used only after an adequate trial of methotrexate.

Because TNF is important in host defense and possibly in tumor surveillance, impairment of these functions in treated patients could increase the risk of infection and even cancer. The most common adverse reaction to etanercept is local inflammation at the injection site, although serious bacterial and mycobacterial infections have also been observed with TNF inhibitors.[85] Hence, these agents should be used with caution in patients with active infections. Before therapy with an anti-TNF agent is initiated, a skin test should be performed and a chest x-ray obtained to rule out tuberculosis; prophylactic treatment with isoniazid should be initiated if indicated. More intriguing is the induction of antinuclear and anti-DNA antibodies and, in a few cases, frank SLE in some RA patients treated with anti–TNF-α therapy. Long-term studies of larger numbers of patients are required to assess these problems, although very few serious side effects have been noted in patients treated for over 5 years with etanercept. However, demyelinating syndromes and aplastic anemia have been noted in a small number of patients receiving TNF inhibitors. These agents appear to exacerbate multiple sclerosis; this finding is possibly related to the protective role TNF-α may play in the central nervous system.[86]

Although no overall increase in malignancies has been observed, some concerns have been raised regarding an increased risk of lymphoma in patients receiving TNF inhibitors. However, this question is confounded by the fact that the prevalence of lymphoma is higher in patients with RA, compared with that in normal individuals, and it is unclear whether the use of TNF inhibitors further increases the risk of lymphoma. Another important consideration is whether the improved control of disease activity provided by TNF inhibitors diminishes mortality in RA overall, even if their use may be associated with a slight risk of certain malignancies.

IL-1 inhibitor The natural inhibitor to IL-1, IL-1ra (anakinra), demonstrates modest anti-inflammatory activity in RA.[87] Anakinra also appears to have disease-modifying activity, evidenced by a decrease in radiographic progression. Anakinra is administered subcutaneously at a dose of 100 mg by daily injection, either alone or in combination with methotrexate.[88] The most common side effect is injection-site reaction, although an increased incidence of infections has also been reported. Use of anakinra in combination with TNF inhibitors may markedly increase infectious complications; therefore, such combinations should be avoided until further studies clarify the risks and benefits. Anakinra has been approved for use in the United States.

Other anticytokine therapies Antibodies to the IL-6 receptor also may be effective in RA. Similarly, anti–B cell therapy with rituximab and blockade of T cell costimulation with CTLA4-Ig looked promising in phase II clinical trials. A preliminary study using IL-10 to treat RA did not show significant alterations in synovial histology, synovial cytokine production, or clinical disease activity.[89] Many other approaches are also under investigation, including the use of anti–IL-12 antibodies, IL-18 binding proteins, and inhibitors of specialized chemoattractant cytokines called chemokines.

Glucocorticoids

Glucocorticoids are some of the most potent anti-inflammatory agents available. When used systemically, they decrease joint swelling, pain, and morning stiffness and improve ability to function. Unfortunately, the dosages necessary to maintain such improvement are usually high enough to be associated with long-term side effects (e.g., osteoporosis, osteonecrosis, increased susceptibility to infection, cataracts, myopathy, and poor wound healing). Alternate-day therapy usually cannot be used to reduce these side effects, because RA patients are usually symptomatic on the off days. The conventional wisdom is that glucocorticoids neither alter the course of the disease nor affect the ultimate degree of damage to joints or other structures; however, some evidence indicates that low-dose prednisolone given early in RA can slow the rate of radiographic progression.[90] Although there is considerable difference of opinion regarding the most appropriate use of steroids in RA, they are typically employed as "bridge" therapy for severe disease while awaiting a therapeutic response from other second-line agents. Systemic glucocorticoids, however, even in these low dosages, are associated with accelerated bone loss. Supplemental calcium (1,000 to 1,500 mg daily) and vitamin D (400 to 800 I.U. daily) can be given to postmenopausal women who require daily prednisone therapy, even in low doses.[91] Dual-energy x-ray absorptiometry (DEXA) scans should be used to monitor bone mineral density, and bisphosphonates should be used to treat or prevent osteoporosis in susceptible patients.

Intra-articular glucocorticoids are also useful in limited flares. Administration of such agents requires careful aseptic technique. The procedure involves injection of a local anesthetic agent (e.g., lidocaine) and an insoluble glucocorticoid preparation (e.g., triamcinolone hexacetonide, 20 to 40 mg) into a large joint; smaller amounts (5 to 10 mg) may be injected into small joints, bursae, and tendon sheaths. These local injections usually result in relief of pain and inflammation within days and do not often produce serious side effects. The risk of infection is probably about one in 10,000 procedures. The beneficial effects may last for weeks or months (on average, about 3 to 6 months), but repeated injections may result in increased cartilage destruction, osteonecrosis, and tendon rupture. Thus, intra-articular glucocorticoids are only occasionally useful in relieving inflammation in one or two joints that are particularly symptomatic.

Immunosuppressive Agents

Alkylating agents, particularly cyclophosphamide, and antimetabolites such as azathioprine have been used in patients with severe progressive disease who have not responded to the measures already described. These drugs decrease inflammation and possibly reduce the frequency of new joint erosions. Cyclophosphamide is also effective in controlling rheumatoid vasculitis in some patients. Hematologic toxicity and GI toxicity can be severe; hemorrhagic cystitis is a disturbing complication of oral cyclophosphamide therapy. Azathioprine is safer but has only modest efficacy. The additional potential hazard of inducing neoplasias and chromosomal abnormalities also restricts the usefulness of these agents.

Cyclosporine is a more focused immunosuppressive drug than azathioprine or cyclophosphamide because it targets T cells; it has been used extensively in allograft rejection. Hypertension and decreased creatinine clearance are common side effects, generally related to the cumulative dose. In RA, cyclosporine at a dosage of 2.5 to 5.0 mg/kg/day is an alternative to cyclophosphamide or azathioprine in patients who need immunosuppressive therapy, provided patients are closely monitored for renal toxicity.[92] Despite its potent immunosuppressive effects, a minority of patients have a meaningful clinical response to cyclosporine.

Other Chemotherapeutic Agents

In some studies, minocycline appeared to provide benefit for RA patients.[93] Its mechanism of action is unclear and may be related to the ability of tetracycline analogues to inhibit metalloproteinases. Current research into therapies for RA includes trials of recombinant products and humanized monoclonal antibodies. Some of these preparations showed promising results in early open studies, only to fail in controlled trials. This is especially true of antibodies directed against T cell markers (e.g., CD4).[94] Other novel therapies have had mixed success. Attempts to induce tolerance by oral administration of type II collagen or cartilage protein gp39 have not provided significant benefit. A diet supplemented with fish oils, which contain omega-3 fatty acids, reduces synthesis of inflammatory arachidonate metabolites and may be a useful adjuvant therapy for selected patients.[95]

PHYSICAL THERAPY

Hospitalization is occasionally helpful in the management of patients with RA, although this approach in an era of managed care and cost constraints is not feasible. Removing the patient from a stressful home environment and instituting a program of rest combined with physical therapy are of great value. Splinting inflamed joints may decrease synovitis.

Physical therapy has a role in the management of RA, although data supporting its ability to change outcome are lacking. Passive range-of-motion exercises help prevent contractures. Isometric exercises build up muscle strength without subjecting inflamed joints to excessive wear, and isotonic exercises further increase muscle strength and help preserve function. Most physical measures, such as whirlpools, heated wax, ultrasonography, and diathermy, make patients feel better during the procedure and perhaps for a short time afterward but offer no significant long-term functional, anti-inflammatory, or disease-modifying benefit; consequently, many patients eventually become disillusioned with them. It is important for patients to maintain an active life, and guidance from physical therapists for range-of-motion exercises and aerobic training is useful. Swimming or other water exercises are especially useful aerobic stresses that minimize the load on the lower extremities.

SURGERY

Indications for surgical intervention include intractable pain and impaired function. Eroded cartilage, ruptured ligaments, and progressive destruction of bone can lead to severe functional derangement that is amenable only to surgical correction. Besides helping restore function to weight-bearing joints, surgery may also restore function in severely deformed hands. In a joint such as the wrist, dorsal synovectomy may prevent extensor tendon ruptures. Although proliferative synovitis often recurs after synovectomy, it may take 1 or 2 years to return and may be less intense than it was initially. Surgery is also useful for removing frayed menisci and other loose bodies that interfere with joint function. In the hands and wrists, operations on periarticular structures (e.g., repair of capsules and replacement of tendons) may restore appearance and function; release of carpal tunnel compression usually relieves pressure on the median nerve. Arthroscopic surgery to remove cartilaginous fragments and to perform a partial synovectomy may be useful when a large, accessible joint (e.g., the knee) is involved with proliferative synovitis.

If gross deformity and joint destruction have occurred, more definitive procedures may be required. In some joints, such as the wrist and ankle, function may be improved by stabilizing the joint through fusion, albeit at the cost of loss of motion. For destroyed joints, total replacement may be necessary. Hip prostheses provide a stable, pain-free joint with a good range of motion in more than 90% of patients. Metal-to-plastic prostheses are also useful in reconstruction of knee, elbow, and shoulder joints. Joint replacement procedures involve a relatively high risk of thromboembolism, but serious infections are rare. Loosening of the components has been observed within several years in as many as 20% of patients.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III SERONEGATIVE SPONDYLOARTHRITIS

Frank C. Arnett, m.d., f.a.c.p.

Definition

The term spondyloarthritis encompasses a family of clinically, epidemiologically, and genetically related inflammatory diseases that primarily affect spinal and peripheral joints. Once considered a variant of rheumatoid arthritis, spondyloarthritis has been shown to differ in such fundamental clinical and pathogenetic ways from rheumatoid disease that the two are now considered distinctly separate entities [*see Table 1*]. The term seronegative refers to the uniform absence of serum IgM autoantibodies to IgG (rheumatoid factor) in patients with spondyloarthritis. Other distinguishing characteristics are the following:

1. The sacroiliac joints are affected (sacroiliitis); ascending spinal inflammation and bony fusion (spondylitis) often develop after sacroiliitis.
2. Peripheral joints are affected, typically in an oligoarticular and asymmetrical pattern.
3. There is inflammation of sites of ligamentous insertions into bone (entheses), referred to as enthesitis or enthesopathy, as well as inflammation of joint synovium. Inflammation occurs both along the spine and near peripheral joints.
4. There may be inflammation of extra-articular sites, including the eye, the aortic valve, the gastrointestinal tract, the genitourinary system, and the skin.
5. Disease onset typically occurs in young adulthood.
6. There is a strong familial tendency and a striking genetic association with the histocompatibility antigen HLA-B27.
7. Certain bacteria play important pathogenetic roles.

Classification

Spondyloarthritis includes the prototypical spinal arthritis, ankylosing spondylitis; reactive arthritis (formerly known as Reiter syndrome); psoriatic arthritis; enteropathic arthritis (accompanying ulcerative colitis and Crohn disease); juvenile spondyloarthritis (or juvenile ankylosing spondylitis); and such rare disorders as acne-associated arthritis, or SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) syndrome, and Whipple disease. The various forms of spondyloarthritis can usually be distinguished from one another by the pattern of joint involvement and associated extra-articular features [*see Table 2*]. However, some patients have overlapping clinical manifestations that defy categorization; these patients are usually designated as having undifferentiated spondyloarthritis. Because of such patients, the European Spondyloarthropathy Study Group (ESSG) proposed classification criteria for spondyloarthritis that may be useful in clinical diagnosis and epidemiologic studies.[1]

Epidemiology

Estimations of prevalence rates for spondyloarthritis using the ESSG criteria are few.[1-3] Among Germans in Berlin, the prevalence of spondyloarthritis has been reported to be 1.9%; in Inuits in Alaska and Siberia, rates of 2% to 3.4% have been reported. Spondyloarthritis appears to be rare in African and Japanese populations. These differences among ethnic groups are explainable in large part by differences in the frequency of HLA-B27.[1]

Pathogenesis

The various forms of spondyloarthritis appear to be complex disorders resulting from the interplay of several genetic and environmental factors, only a few of which have been identified.

genetic factors

Heredity plays a major role in predisposition.[4,5] Family studies have shown that 15% to 20% of patients with ankylosing spondylitis have one or more first-degree relatives with the same disease. In the families of some patients with ankylosing spondylitis, there are relatives with other types of spondyloarthritis or other associated disorders, such as uveitis, psoriasis, and inflammatory bowel disease. Concordance for ankylosing spondylitis in monozygotic twins approaches 63% to 75%, compared with 13% to 23% in dizygotic twins. Genetic modeling in twins and families indicates that ankylosing spondylitis is associated with a multiplicative, polygenic pattern of inheritance, with 97% of the susceptibility to the disease attributed to genetics. These studies suggest that the environmental factors that contribute to development of the disease are probably ubiquitous.

The HLA-B27 allele encoded by the class I HLA-B locus within the major histocompatibility complex (MHC) is the one genetic factor identified thus far that is strongly associated with spondyloarthritis. This allele is present in 90% of patients with ankylosing spondylitis and confers a relative risk for the disease of over 100, but it is found less often in patients with other forms of spondyloarthritis [*see Table 2*].[5] HLA-B27 shows linkage to ankylosing spondylitis in families and appears to contribute 30% to 50% of the genetic risk; in most cases, it appears essential for disease expression.[4] Other HLA alleles, including HLA-B60, HLA-DR1, and HLA-DR8, also appear to increase the risk of ankylosing spondylitis. In addition, different HLA alleles predispose to psoriasis and psoriatic arthritis, including HLA-B13, HLA-B17, HLA-Cw6, HLA-B38, and HLA-B39.[6] The HLA region shows genetic linkage to inflammatory bowel diseases, but specific HLA alleles show only weak associations.[7] Ongoing human genome searches have revealed additional non-HLA loci linked to ankylosing spondylitis,[4,5] some of which also may be common to Crohn disease[8,9] and psoriasis.[5,10]

Laboratory evidence strongly suggests that the *HLA-B27* gene itself, rather than a linked locus, directly participates in the pathogenesis of ankylosing spondylitis and reactive arthritis. Transgenic rats expressing the human *HLA-B27* and β_2-microglobulin genes spontaneously develop colitis, peripheral and spinal arthritis, enthesitis, skin and nail lesions resembling psoriasis, and genitourinary inflammation.[11] Littermates raised in a germ-free environment do not develop most of these manifestations, however. That finding emphasizes the importance of both the *HLA-B27* gene and gut bacteria, possibly *Bacteroides* species, in pathogenesis and suggests that antibiotics (e.g., sulfasalazine) may be useful in the treatment of reactive arthritis and ankylosing spondylitis in humans. The mechanism by which HLA-B27 promotes disease is unknown, but the following are the prevailing hypotheses[12]: (1) in its function as an MHC class I molecule,

HLA-B27 presents a so-called arthritogenic self-peptide or bacterial peptide to cytotoxic $CD8^+$ T cells, which causes an autoimmune attack on various self-structures; (2) HLA-B27 contains stretches of amino acid sequences that also occur in bacterial proteins, and as a result of this molecular mimicry, a cytotoxic or humoral immune response to these bacterial sequences also involves HLA-B27; (3) HLA-B27, either intracellularly or extracellularly, promotes bacterial persistence or dissemination to joints and other structures; and (4) HLA-B27 is unique among HLA class I molecules in forming so-called homodimers, which may cause misfolding of the protein, resulting in an inflammatory response.[5,13,14]

ENVIRONMENTAL FACTORS

Reactive arthritis provides the strongest evidence of bacterial pathogenesis in spondyloarthritis. Enteric infections by *Shigella flexneri, Salmonella* (many species), *Yersinia enterocolitica, Y. pseudotuberculosis*, and *Campylobacter jejuni* have all been implicated as triggers of the disease in various epidemics and in sporadic cases, especially in HLA-B27–positive persons.[15,16] Similarly, sexually acquired infections with *Chlamydia trachomatis*[15,16] and perhaps *Ureaplasma urealyticum* may cause reactive arthritis.[17] Pulmonary infection with *Chlamydophila pneumoniae* (formerly known as *Chlamydia pneumoniae*) has also been implicated.[18] Patients with chronic reactive arthritis have been found to have IgA antibodies to the initiating microbe, suggesting a persistent mucosal infection.[19] Moreover, synovial fluid T cells were found to proliferate when challenged with the bacterium that triggered the arthritis.[12] There is no evidence, however, that these microorganisms cause ankylosing spondylitis. Normal gut flora seem more likely to be implicated in ankylosing spondylitis, as suggested by studies of the HLA-B27 transgenic rat[11] and by a high frequency of asymptomatic foci of gut inflammation in patients with ankylosing spondylitis or reactive arthritis.[20]

Pathology

Chronic inflammation with infiltrating mononuclear cells (macrophages, T cells, and B cells) occurs in both peripheral and axial joint structures of patients with spondyloarthritis.[12,21,22] $CD4^+$ helper T cells and $CD8^+$ suppressor-cytotoxic T cells appear to be equally represented. A high concentration of the inflammatory cytokine tumor necrosis factor–α (TNF-α) has been found in the dense cellular infiltrates in synovial portions of sacroiliac joints.[21] When cytokines from the joints and blood of patients with spondyloarthritis were compared with those of patients with rheumatoid arthritis, the cytokines from patients with spondyloarthritis showed a higher ratio of immunosuppressive cytokines, such as interleukin-4 (IL-4) and IL-10, to inflammatory cytokines, such as TNF-α and interferon gamma. This leads to a blunted T helper type 1 (Th1) response in patients with spondyloarthritis.[22] Inherent levels of cytokines, such as TNF-α and IL-10, are determined by genetic polymorphisms in their respective genes.[22] In ankylosing spondylitis, the observed tendency for ligamentous ossification, enthesopathy, and widespread new bone formation is associated with the finding of transforming growth

Table 1 Comparison between Spondyloarthritis and Rheumatoid Arthritis

	Spondyloarthropathies	*Rheumatoid Arthritis*
Distribution	Racial (more prevalent in whites)	Worldwide
Prevalence	0.2%–1.9%	1%–2%
Etiology	Genetic and bacterial	Genetic and unknown
Positive family history	Frequent	Rare
Sex distribution	More frequently diagnosed in males	More common in females
Age at onset	Peak incidence at 20–30 yr	All ages affected; peak incidence 30–50 yr
Joint involvement	Oligoarthritis; asymmetrical; large joints; lower limbs more than upper limbs	Polyarthritis; symmetrical; small and large joints; upper and lower limbs
Sacroiliac involvement	Yes	No
Spinal involvement	Ascending; all segments with fusion	Cervical only; erosions and instability
Subcutaneous nodules	No	Yes
Aortic regurgitation	Yes	No
Ocular involvement	Uveitis, conjunctivitis	Sicca syndrome; scleritis; scleromalacia perforans
Lung involvement	Upper lobe pulmonary fibrosis	Pleural effusions; lower lobe pulmonary fibrosis; nodules; Caplan syndrome
Rheumatoid factor and/or anti-CCP	No	Yes
HLA-B27	Yes	No (normal frequency)
HLA-DR4	25% (normal frequency)	60%–70%
Pathology	Synovitis and enthesopathy	Synovitis
Radiographic findings	Asymmetrical erosive arthritis and periostitis; new bone formation and ankylosis; sacroiliitis, spondylitis	Symmetrical erosive arthritis with bony destruction

anti-CCP—antibodies to cyclic citrullinated peptides

Table 2 Features of Seronegative Spondyloarthritis

	Ankylosing Spondylitis	*Reactive Arthritis (Reiter Syndrome)*	*Psoriatic Arthritis*	*Enteropathic Arthritis*
Sex distribution	Male > female	Male > female	Female > male	Female = male
Age at onset (years)	≥ 20	≥ 20	Any age	Any age
Mode of onset	Gradual	Sudden	Gradual	Peripheral sudden Spinal gradual
Peripheral joints	Often lower limbs Asymmetrical	Usually lower limbs Asymmetrical	Upper > lower limbs Asymmetrical	Lower > upper limbs Symmetrical
Enthesopathy	+	+	+	– Peripheral + Spinal
Heel pain	Occasional	Frequent	Occasional	Infrequent
Spinal involvement	+++ (always)	+ (20%)	+ (20%)	+ (10%)
Symmetry (sacroiliitis and syndesmophytes)	+	+/–	+/–	+
Familial aggregation	++	+	++	++
HLA-B27 positive	90%	63%–75%	20% (50% with sacroiliitis)	10% (50% with sacroiliitis)
Risk for B27-positive person	2% (20% when a relative)	20% (when infected)	?	?
Urethritis	–	+	–	–
Skin involvement	–	+	+++	+
Nail involvement	–	+	+++	–
Mucous membrane involvement	–	++	–	+
Cardiac involvement	+	+	Rare	Rare
Self-limiting	–	+	–	++ Peripheral – Spinal

factor–β (TGF-β) near these sites. TGF-β is a reparative cytokine that stimulates connective tissue matrix formation.

Reactive arthritis was once considered a sterile joint disease triggered in some unknown manner by a distant infection, but more recent studies of synovial fluids and tissues affected by reactive arthritis have consistently revealed the presence of intracellular bacterial antigens from each of the known offending microorganisms.[14,23,24] Moreover, with electron microscopy and polymerase chain reaction, living but dormant *C. trachomatis* has been detected in synovial macrophages and fibroblasts even after many years of disease.[23] It is still unclear whether the enteric pathogens causing reactive arthritis are viable.[14,24] Spinal joint tissue from patients with ankylosing spondylitis is difficult to obtain. Limited studies of sacroiliac joint biopsies have not revealed bacterial antigens.[25]

Ankylosing Spondylitis

EPIDEMIOLOGY

The prevalence of ankylosing spondylitis parallels the frequency of HLA-B27 in different ethnic populations.[1,26] HLA-B27 occurs in 7% to 9% of the white population, and the disease has a prevalence of approximately 0.2% to 0.9%.[2,3,26] One study from Norway, where the frequency of HLA-B27 is twice that seen in the white populations of the United States and the United Kingdom, found that ankylosing spondylitis occurred in 1.9% to 2.2% of men and 0.3% to 0.6% of women.[3] The disease is distinctly rare in African and Japanese populations, in which HLA-B27 is found in low frequency; however, ankylosing spondylitis is common in certain Native-American groups, such as the Haida and Pima, in which the frequency of HLA-B27 is high.[26]

In randomly chosen cohorts of whites possessing HLA-B27, ankylosing spondylitis developed in approximately 2% to 6%.[3] In HLA-B27–positive relatives of patients with ankylosing spondylitis, however, the risk of disease is 20% to 30%. Similar estimates are not available for other ethnic groups, but rates may differ because multiple molecular subtypes of HLA-B27 have been discovered, each with different distributions among various ethnic groups.[5,25-27] HLA-B*2705, followed in frequency by HLA-B*2702, is predominantly found in whites; HLA-B*2704 is found in Chinese; and HLA-B*2703 is found in Africans. Most HLA-B27 subtypes appear to predispose to ankylosing spondylitis, with the possible exceptions of HLA-B*2706, found in Indonesians and Thais, and HLA-B*2709, found in Sardinians.

Ankylosing spondylitis was once considered to be almost exclusively a disease of males, but recent studies suggest a more uniform distribution by sex (the ratio of males to females is 3:1).[1] In females, the disease may be diagnosed less frequently and later in the course of disease because physicians still consider it primarily a disorder of males. Some studies suggest that females have milder disease, with less progressive spinal involvement and more peripheral arthritis. Other studies suggest that the overall pattern of disease is similar in males and females.

Onset typically occurs between 16 and 30 years of age, peaking at around 24 years; ankylosing spondylitis seldom begins in patients older than 40 years. Childhood onset before 16 years

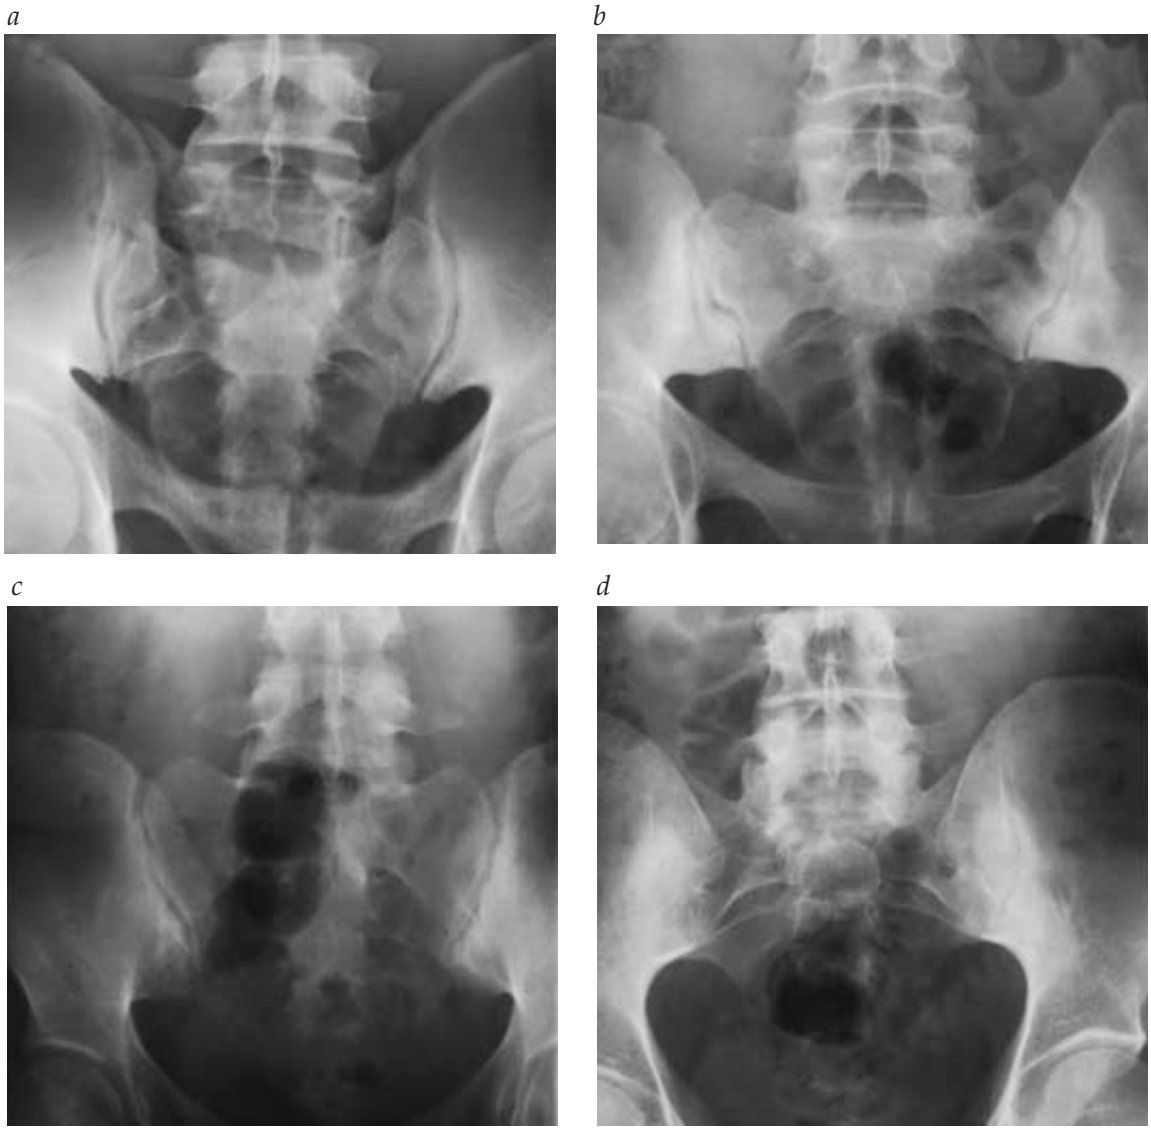

Figure 1 **(*a*) Radiograph of normal sacroiliac joints showing clearly defined joint margins and no sclerosis (grade 0). (*b*) Sclerosis on both margins of each sacroiliac joint but no joint erosions (grade II). (*c*) Sclerosis and erosions of both sacroiliac joints (grade III). (*d*) Complete bony fusion of both sacroiliac joints (grade IV).**

of age occurs in approximately 10% to 20% of cases in the United States and Europe but is more common (54%) in developing countries, suggesting earlier exposure to the environmental triggers.[28]

DIAGNOSIS

The modified New York criteria[1] are currently used to diagnose ankylosing spondylitis. A patient should have one or more of the following clinical criteria:

1. Low back pain of at least 3 months' duration that is alleviated by exercise and is not relieved by rest.
2. Restricted lumbar spinal motion.
3. Decreased chest expansion relative to normal values for age and sex.

In addition, the patient must have definitive radiographic evidence of sacroiliitis (i.e., bilateral sacroiliitis of grade II to IV or unilateral sacroiliitis of grade III or IV) [*see Figure 1*].

A simpler approach in diagnosis is to accept symptomatic sacroiliitis as an adequate definition. Sacroiliitis, as defined radiographically, should be definitive (i.e., grade III or IV changes should be evident) and should be present bilaterally [*see Figure 1*]. In addition, the patient should have no other diseases that could cause sacroiliitis (i.e., reactive arthritis, psoriasis, or inflammatory bowel disease).

Clinical Presentation

Low back pain and stiffness are the usual presenting symptoms of ankylosing spondylitis. Because back pain is such a common complaint in the general population and its causes are myriad, certain characteristics that specifically suggest inflammatory back pain have been formulated:

1. Onset in a person younger than 40 years.
2. Insidious rather than abrupt onset.
3. Persistence of back symptoms for 3 months or longer.
4. Worsening of back pain or stiffness with inactivity.
5. Subsiding of back pain or stiffness with exercise.

Some patients describe buttock pain that often alternates from one side to the other and sometimes radiates down the posterior leg, which is indicative of sacroiliac joint disease. Other patients present with a peripheral arthritis, typically monoarticular or oligoarticular, that affects joints of the lower extremity, often the knee. Careful questioning about subtle musculoskeletal symptoms in such patients is often fruitful. Fatigue can be a major symptom in patients with ankylosing spondylitis and has been found to correlate with level of disease activity, functional ability, global well-being, and mental health status.[29] Elicitation of a history of uveitis or the presence of spondyloarthritic features in family members also strongly suggests the disease. Radiologic evidence of sacroiliitis in any of these clinical presentations, however, is essential in confirming a diagnosis of ankylosing spondylitis [*see* Radiographic Features, *below*]. In patients whose sacroiliac radiographs are normal, the presence of HLA-B27 is highly suggestive but not definitive evidence of the disease. Follow-up studies of patients in whom the diagnosis was strongly suspected on the basis of the clinical picture and HLA-B27 positivity showed that sacroiliac joint abnormalities eventually appear on plain x-rays, but the evolution may occur over as many as 10 years. MRI of the sacroiliac joints is a very sensitive method for detecting early sacroiliitis, as well as inflammation elsewhere in the spine.

Patients with juvenile-onset ankylosing spondylitis typically present with peripheral oligoarthritis, often with enthesopathy and infrequently with spinal symptoms.[28] Such patients may be misdiagnosed as having juvenile rheumatoid arthritis [*see* Juvenile Spondyloarthritis, *below*]. Spinal involvement usually appears later, in young adulthood.

Physical Examination

Examination of the back may be relatively normal early in the course of the disease. Sacroiliac joints are usually painful when palpated or stressed. When the disease advances into the lumbar spine, the normal lordotic curvature may be lost, and paravertebral muscle spasm is prominent. Forward bending, or flexion, may be restricted, as measured by the Schober test. In this measurement, two points are drawn with the patient standing erect, one at the L5–S1 region and the other 10 cm above this region. With normal flexion, the distance between these two points increases by 4 to 6 cm, but when the lumbar spine becomes fused, there may be little or no increase in distance between the two points. Lateral lumbar bending and extension are also typically restricted.

Thoracic spine involvement causes an exaggerated dorsal kyphosis; in patients with costovertebral joint fusion, chest expansion (as measured circumferentially at the fourth intercostal space from full expiration to inspiration) is reduced to 2.5 cm or less. When the disease ascends into the neck and causes fusion, cervical lordosis is lost and a fixed flexion deformity may occur. Spinal fusion often results in the patient's being severely stooped forward with neck immobile and flexed; the patient has difficulty looking straight ahead.

Peripheral arthritis, especially of the hips, shoulders, and knees, occurs in approximately 30% of patients with ankylosing spondylitis and further increases disability. Peripheral enthesopathic features may include Achilles tendinitis, plantar fasciitis, or costochondritis.[30]

Laboratory Findings

The HLA-B27 histocompatibility antigen is present in more than 90% of ankylosing spondylitis patients. HLA-B27 testing of individual patients, however, is indicated only in atypical cases, when the clinical suspicion is high but the most definitive finding—radiographic evidence of sacroiliitis—is not present. In HLA-B27–positive patients and HLA-B27–negative patients, the patterns and severity of arthritis are similar. HLA-B27–negative patients differ from HLA-B27–positive patients in that in HLA-B27–negative patients, disease onset occurs at an older age, there is no family history of spondylitis, and uveitis or cardiac complications occur infrequently.[1,26] HLA-B27 is found less commonly (50%) in patients with ankylosing spondylitis who are of African ancestry.

Elevation of the erythrocyte sedimentation rate (ESR) occurs in many patients, but it may be normal despite severe disease. C-reactive protein (CRP) levels may be elevated. Serum IgA levels are often elevated.[19] Some patients have a mild normocytic normochromic anemia because of chronic inflammation; in these patients, the platelet count may be high.

Radiographic Features

Bilateral sacroiliitis is the most specific finding that supports a diagnosis of ankylosing spondylitis, and meticulous interpretation of the radiographs is imperative. A grading system that assesses each sacroiliac joint for juxta-articular bony sclerosis, blurring or erosion of joint margins, and bony fusion has been formulated and tested [*see Figure 1*]. Grade 0 findings are normal. Grade I findings are suspicious but not definitive. Grade II findings show sclerosis on both sides of a joint; such findings are even more suspicious when they occur bilaterally, but they should be interpreted with great caution. Findings of grades III and IV are definitive. Another radiographically defined entity, osteitis condensans ilii, may be misinterpreted as sacroiliitis, and vice versa. Patients with osteitis condensans ilii have sclerosis on the iliac side of both sacroiliac joints; the condition occurs in women who have borne children. Although quantitative radionuclide scans, computed tomography, and MRI have been suggested as superior diagnostic methods, well-performed plain radiographs of the sacroiliac joints (Ferguson view or oblique view) are usually adequate.

An early spinal change seen on radiographs is squaring of the normally concave anterior side of vertebral bodies [*see Figure 2*]. This phenomenon is caused by inflammation and bony erosion at the site of insertion (enthesitis) of the outer fibers of the annulus fibrosus. Later changes are ossification of ligaments, which are seen on radiographs as syndesmophytes that bridge adjacent vertebral bodies [*see Figure 3*], producing the classic bamboo-spine appearance [*see Figure 4*]. Zygapophyseal joints become fused into solid bone. Finally, diffuse osteoporosis may occur, making the spine susceptible to fracture. Bony fusion across joint spaces of affected peripheral joints in ankylosing spondylitis may be the most distinctive change seen on radiographs.

Similar spinal changes are seen in primary ankylosing spondylitis and in the spondylitis associated with inflammatory bowel disease. In spondylitis associated with reactive arthritis and psoriatic arthritis, the sacroiliitis and syndesmophytes tend to be asymmetrical.[31] Another disease that may mimic ankylosing spondylitis is diffuse idiopathic skeletal hyperostosis (DISH).[32] DISH occurs in middle-aged and older persons, especially men; it is characterized by large, flowing syndesmophytes that restrict spinal motion; sacroiliitis is not found, however, and there is no association with HLA-B27.

Figure 2 **Loss of the normal anterior concavity of vertebral bodies, resulting in so-called squaring in early ankylosing spondylitis.**

Extra-articular Manifestations

A number of extraskeletal features may complicate the course of ankylosing spondylitis and contribute to morbidity and mortality.

Ocular involvement Acute anterior uveitis, usually occurring episodically and affecting one eye at a time, occurs in 25% of patients. Acute pain, redness, and photophobia are the usual symptoms. Prompt referral to an ophthalmologist for treatment is essential. Uveitis does not correlate with arthritis activity or severity and shows a strong association with HLA-B27, even in patients without spondyloarthritis.[33]

Cardiovascular disease A fibrosing cardiovascular lesion occurs in 2% to 10% of patients with ankylosing spondylitis. The lesion causes the aortic valve and proximal root to thicken, and it often extends into the conducting system, causing aortic regurgitation, atrioventricular block, or both. The lesion probably occurs with a similar frequency in patients with reactive arthritis.[34] In rare instances, mitral regurgitation may also occur. One study emphasized a high prevalence of underlying spondyloarthritis, often undiagnosed, in men requiring cardiac pacemakers for bradyarrhythmias.[34] In addition, this study revealed the strong association of the clinical combination of lone aortic regurgitation and heart block with HLA-B27, with or without apparent arthritis. Fulminant cardiac disease typically appears only after the patient has had spondyloarthritis for many years, but such disease has been described even in very early spondyloarthritis. Echocardiography may detect cardiac abnormalities in some patients without clinical signs.[35] No treatment is known to prevent progression of spondylitic heart disease; most patients require permanent cardiac pacemakers, aortic valve replacement, or both.

Pulmonary disease Despite restriction of chest wall motion by joint fusion, respiratory function is preserved in most patients with ankylosing spondylitis, owing to good diaphragmatic function. Severe kyphotic deformity, however, may compromise breathing. Approximately 1% of patients with ankylosing spondylitis, usually those with severe disease, also have fibrosis in the upper lung fields that mimics tuberculosis.[36] Cavitation may occur and may be complicated by *Aspergillus* infection. Cough, dyspnea, and even hemoptysis are typical symptoms. Currently available treatment is unsatisfactory.

Renal disease Kidney function is usually normal. The appearance of proteinuria, with or without a nephrotic syndrome, usually indicates complicating amyloidosis or IgA nephropathy. Secondary amyloidosis occurs in approximately 4% of patients and can be diagnosed with abdominal fat-pad or rectal biopsy.[37]

IgA nephropathy is being increasingly recognized. It correlates with high serum IgA levels. Renal function may become impaired, but episodes are usually self-limited.[19]

Neurologic disease Spinal fracture is a major cause of morbidity and mortality in patients with ankylosing spondylitis; cord compression occurs even with seemingly minor trauma.[1] A rigid and osteoporotic cervical spine is most susceptible to fracture, usually at the C6 or C7 level. A high degree of suspicion for fracture is always warranted in patients with localized spinal pain, even when plain x-rays fail to reveal an acute abnormality;

Figure 3 **Progression of ankylosing spondylitis is demonstrated by ossification of the anterior fibers of the annulus fibrosus (syndesmophytes).**

Figure 4 **Patients with severe ankylosing spondylitis may develop the classic bamboo spine, as shown in this radiograph.**

additional imaging with CT is often necessary.

A cauda equina syndrome occurs in rare instances, usually because of arachnoiditis around sacral nerves that leads to progressive leg weakness, paresthesias, and sphincter dysfunction.[38]

Retroperitoneal fibrosis Fibrosis in the retroperitoneum may be another extra-articular feature of ankylosing spondylitis.[39]

TREATMENT AND PROGNOSIS

Early diagnosis and treatment of ankylosing spondylitis appear to improve functional outcome, but it is not clear whether any drug modifies the disease pathology. Objectives of treatment are pain relief, reduction of inflammation, and maintenance of good posture and spinal function.[40] Patient education is very important. Excellent sources for patient education are available at www.spondylitis.org and www.arthritis.org.

Nonsteroidal anti-inflammatory drugs (NSAIDs) relieve inflammatory symptoms of pain and stiffness and allow patients to engage in an appropriate exercise program. In clinical practice, certain NSAIDs appear to be more often effective than others as treatment for spondyloarthritis [*see Table 3*]. However, the efficacy of individual agents varies greatly from patient to patient; for that reason, some patients may need to try several NSAIDs before finding one that provides relief. There is no strong evidence that any NSAIDs alter disease progression.

There are now incontrovertible data that selective cyclooxygenase-2 (COX-2) inhibitors, and possibly other NSAIDs, increase a person's risk for cardiovascular disease. Therefore, careful assessment of other risk factors and of the potential benefit compared with risk is essential in all patients. Gastrointestinal intolerance of any of the NSAIDs may present as nausea, gastric discomfort, diarrhea, or, more seriously, gut hemorrhage or perforation. Concomitant use of a gastroprotective agent, such as misoprostol or a proton pump inhibitor, may significantly reduce GI toxicity in patients treated with NSAIDs. All of these drugs may decrease renal tubular capacity to secrete potassium and can cause an abrupt reduction in renal function when used in patients with renal disease or with renal hypoperfusion resulting from ineffective circulatory volume. Because patients with ankylosing spondylitis will probably take NSAIDs for many years, physicians must diligently monitor for renal and GI tract damage.

In a 6-month randomized, controlled clinical trial, the bisphosphonate pamidronate, given monthly by intravenous infusion, was shown to be effective in improving symptoms and function in patients with ankylosing spondylitis whose disease was refractory to treatment with NSAIDs.[41]

Low-dose corticosteroids (e.g., prednisone, 5 to 10 mg daily) may be necessary to quell inflammation in some patients with highly active disease, but these agents should be used sparingly because they promote osteoporosis and do not improve spinal disease. Injection of repository corticosteroids into affected peripheral joints also may be useful. Injection into the sacroiliac joint, guided by either CT or MRI, may offer relief.

Sulfasalazine, 2 to 3 g daily in two divided doses, has been shown in several placebo-controlled trials to be an effective long-term treatment of ankylosing spondylitis, as well as of other types of spondyloarthritis. Sulfasalazine is very effective for peripheral joint symptoms but not especially effective for axial joint symptoms.[1,40] The drug moiety responsible for the efficacy of sulfasalazine has been proved to be sulfapyridine rather than salicylate; however, it is not clear whether the efficacy results from antimicrobial or other properties of the drug.[42] Because sulfasalazine has been shown to lower acute-phase reactants, such as the ESR and the CRP level, it may modify disease progression; however, this desirable effect has yet to be proved.

Other long-acting agents used to treat rheumatoid arthritis, including gold salts, penicillamine, and hydroxychloroquine, are not effective in ankylosing spondylitis.[40] Methotrexate therapy, which is highly effective for rheumatoid arthritis, is clearly effective in psoriatic arthritis but not in other forms of spondyloarthritis.[6] Administration of radiation therapy to the spine was once used successfully but is no longer recommended because of the risk of subsequent malignancy.

The TNF antagonists etanercept and infliximab have been approved for the treatment of ankylosing spondylitis, as well as psoriatic arthritis. An increasing number of controlled and open-label studies of the use of these agents in each of the forms of spondyloarthritis have shown dramatic and rapid improvement in symptoms; significantly reduced inflammatory changes in the spine and peripheral joints, as evidenced on MRI; and lowered acute-phase reactants such as ESR and CRP. Long-term efficacy and modification of disease progression and outcome have yet to be determined.[5,43-45] Treatment with TNF-α antagonists also has been shown to halt progression of secondary amyloidosis.[46] Because of the high cost of these agents and still-unanswered questions about their long-term safety, guidelines have been developed by international consensus to facilitate the judicious use of TNF antagonists.[5] Many patients with mild disease may never require TNF antagonists.

All patients with ankylosing spondylitis should be informed of potential spinal deformities and how to prevent them. Good posture should be emphasized. A firm mattress and minimal pillow support are recommended. An exercise program of spinal extension and peripheral joint range-of-motion exercises, along

Table 3 Treatment for Spondyloarthritis

Drug	*Dose*	*Efficacy Rating*	*Comments*
Indomethacin*	50 mg t.i.d. or 75 mg SR, q. 12 hr	Effective for symptoms	Side effects: headaches, changes in mentation, peptic ulcers, GI toxicity, intolerance, renal insufficiency
Tolmetin*	600 mg t.i.d.	Effective for symptoms	Side effects: peptic ulcers, GI toxicity, renal insufficiency
Piroxicam*	20 mg q.d.	Effective for symptoms	Side effects: peptic ulcers, GI toxicity, renal insufficiency
Diclofenac*	75 mg b.i.d.	Effective for symptoms	Side effects: peptic ulcers, GI toxicity, renal insufficiency
Sulfasalazine†	1–3 g daily in two divided doses	Long-term efficacy; lowers acute-phase reactants	Side effects: headache, GI intolerance
Methotrexate†	7.5–20 mg weekly	Effective for skin and arthritis in psoriatic arthritis; effectiveness in other diseases unproved	Side effects: GI intolerance, hepatotoxicity, marrow suppression, pulmonary disease
Doxycycline†	100 mg bi.d.	Effective in preventing relapse and in long-term treatment of reactive arthritis only	Side effects: GI intolerance, photosensitivity
Infliximab†	5 mg/kg I.V. every 6–8 wk after loading	Highly effective and immediate response; improved inflammation in joints by MRI; long-term effects unknown	Side effects: allergic reactions; increased susceptibility to infection, especially tuberculosis
Etanercept†	25 mg subcutaneous injections twice a week	Same as infliximab	Injection-site reactions, increased risk of infections

*Concomitant treatment with a proton pump inhibitor or misoprostol recommended for gastric protection.

with hydrotherapy, should be prescribed. Swimming is a very effective means of achieving exercise goals.[1,5]

Some patients who experience hip involvement—a major cause of disability—greatly benefit from total hip replacement. Wedge osteotomy for severe spinal kyphosis is available only at a few medical centers. Treatment of spinal fractures is controversial. Pregnancy does not appear to be significantly affected by ankylosing spondylitis.

The prognosis for individual patients is often difficult to ascertain.[47] Worse outcomes have been associated primarily with hip joint involvement and, to a lesser extent, early age at onset. The course of the disease in its first 10 years appears to predict its future course and the functional outcome. Despite long-standing and severe disease, ankylosing spondylitis often does not affect a patient's ability to work. Mortality from the disease is infrequent but may result from cardiac or neurologic complications or amyloidosis.

Reactive Arthritis

Reactive arthritis was originally defined as the triad of nongonococcal urethritis, conjunctivitis, and arthritis. It is now recognized that most patients present with arthritis alone and have no clinical evidence of urethritis or conjunctivitis.[15,16,23,24] The concept of reactive arthritis arose from observations that the disease followed certain enteric infections (such cases are termed epidemic or postenteric) and sexually acquired infections (such cases are termed endemic or postvenereal) [*see* Pathogenesis, Environmental Factors, *above*]. Despite this association with previous infection, affected sites were seemingly sterile when cultured for bacteria. It has been found that bacterial antigens, if not viable microorganisms, are present in the joints of affected patients[15,16,26] [*see* Pathology, *above*]. Like ankylosing spondylitis, reactive arthritis may be complicated by sacroiliitis, spondylitis, uveitis, and cardiac lesions. It is also strongly associated with HLA-B27 [*see Table 2*].

EPIDEMIOLOGY

Reactive arthritis probably has a worldwide distribution, but most epidemiologic and clinical studies have come from Europe and the United States.[15-17] The prevalence of the disease is difficult to ascertain because it changes over time, depending on sexual behavior and the prevalence of enteric pathogens in different populations.[48] It was estimated that from 1950 to 1980 in Rochester, Minnesota, the incidence of reactive arthritis in men younger than 50 years was 0.035%; however, 10- to 20-fold higher rates were reported in homosexual men and in certain Native Americans in whom the frequency of HLA-B27 was high (30% to 40%) and who had endemic exposure to enteric or venereal pathogens.[15]

Reactive arthritis, probably the postvenereal form, is the most common cause of inflammatory arthritis in young men. The disease is recognized in women far less frequently; the reasons for this are unclear, because the ratio of affected men to affected women after epidemics of gastroenteritis is typically 1:1 and, overall, the incidence of reactive arthritis approaches 1% to 2% of persons infected with any of the triggering pathogens.[15,16,26] The incidence appears to have fallen significantly since the HIV epidemic and the adoption of safer sexual practices.[48]

HLA-B27 is found in 63% to 75% of patients with both forms of reactive arthritis and confers a relative risk of approximately 37. Of persons with HLA-B27 who are infected with one of the causative bacteria, reactive arthritis develops in approximately 20%.

DIAGNOSIS

Clinical Presentation

Reactive arthritis typically develops 10 to 30 days after an

episode of gastroenteritis or sexual exposure to a venereal pathogen; however, many patients deny any such antecedent events.[15] Episodes of urethritis or conjunctivitis may have been mild and transient or not perceived at all. Thus, recognition of the pattern of musculoskeletal involvement, as well as several other mucocutaneous manifestations, is important in establishing the correct diagnosis.

The arthritis usually is oligoarticular and asymmetrical and predominantly affects lower-extremity joints, most often the knees, ankles, and feet. Diffuse, painful swelling of entire digits (sausaging or dactylitis) occurs frequently. Pain in the heels from Achilles tendinitis or plantar fasciitis, or both, reflects the most common sites of enthesitis; however, enthesopathic pain at other sites is also frequent.[30] Low back pain is a complaint of 60% of patients, and 20% ultimately experience radiographically detectable sacroiliitis. An ascending spondylitis ensues in approximately 10% to 12% of patients.

One or more of the mucocutaneous features can be found on examination in more than 50% of patients, usually early in the disease. Keratoderma blennorrhagica is a papulosquamous skin rash that usually begins on the soles or palms as painless and nonpruritic excrescences resembling mollusk shells [*see Figure 5*]. With time, these lesions evolve into scaling plaques that may coalesce into a more generalized exfoliative dermatitis. Keratoderma blennorrhagica is clinically and histopathologically the same as the disorder pustular psoriasis [*see 2:III Psoriasis*]. A similar scaling rash on the glans penis in circumcised men is termed circinate balanitis. Moist, shallow ulcers characterize balanitis in uncircumcised men, who may be unaware of the lesions unless the foreskin is retracted [*see Figure 6*]. Similar painless oral ulcers may be found on the tongue or palate. Nails may become hyperkeratotic, thickened, and deformed, but the characteristic nail pitting of psoriasis is usually absent [*see Figure 6*]. It is important to search for all of these lesions; they are frequently asymptomatic but are definitive and can establish a diagnosis.

Figure 5 **Typical keratoderma blennorrhagica rash of reactive arthritis on the sole of the foot.**

Figure 6 **Superficial penile ulceration of circinate balanitis in an uncircumcised patient with reactive arthritis. Also note dystrophic fingernail.**

Some patients experience low-grade or high fever at disease onset; malaise—or even prostration—and significant weight loss may ensue. Acute anterior uveitis occurs in approximately 20% of patients with reactive arthritis. Cardiac bradyarrhythmia, aortic regurgitation, or both may also occur during the acute disease phase or may appear later in patients whose illness follows a chronic course.[34] Patients with reactive arthritis who are HLA-B27 positive are more likely to experience sacroiliitis and spondylitis, as well as uveitis, cardiac lesions, or both, and to experience a prolonged disease course.

Reactive arthritis has been frequently described in patients with HIV infection; the joint and skin disease may be more severe than usual in such persons.[15,16,26] This association is now believed to result from sexually acquired enteric and venereal pathogens common to both diseases.

Laboratory Evaluation

Tests of patients with reactive arthritis usually show a modest leukocytosis, thrombocytosis, and anemia, along with elevation of the ESR, reflecting systemic inflammation. Examination of the synovial fluid reveals inflammatory changes of poor mucin clot and leukocytosis; but in contrast to septic arthritis, the glucose level is not low, and bacterial cultures are negative. Polymerase chain reaction (PCR) analysis of synovial fluid or tissue biopsies has been used successfully to detect specific bacterial DNA or RNA in research laboratories; PCR kits should become clinically available soon.[49] Cultures or molecular probes for *C. trachomatis* should be obtained in patients with venereal exposure, genitourinary symptoms, or both.[50] At the same time, tests for concomitant gonorrhea, syphilis, and HIV infection should be performed. In patients with preceding GI symptoms, stool cultures for the triggering organisms are usually negative by the time joint symptoms appear. Serologic tests for *Salmonella* and other enteric pathogens are usually unreliable but may be useful in some cases.[51]

Radiographic Features

X-rays are of no diagnostic value early in the disease; however, MRI may show inflammatory changes of enthesitis and arthritis. After several months of persistent joint symptoms, enthesopathic symptoms, or both, radiographs may show the distinctive changes of periostitis and bony ankylosis. Patients with chronic heel pain may show a fluffy periosteal reaction or spur formation at the Achilles or plantar tendon insertions.[30] Similar radiographic changes may be seen along metatarsal or phalangeal bones of the feet; bony fusion across joints may be visible. Sacroiliitis, when present, is more often unilateral than bilateral, and large asymmetrical syndesmophytes may be seen in the lumbar spine.[31]

TREATMENT AND PROGNOSIS

Reactive arthritis runs a self-limited course in most patients, lasting 4 to 12 months, although annoying residual musculoskeletal symptoms may persist for years.[51] From 15% to 30% of patients suffer permanent disability.[40] Relapses are not uncommon; it is unclear whether they result from repeat infection or other endogenous mechanisms. The same NSAIDs used to treat ankylosing spondylitis [*see* Ankylosing Spondylitis, Treatment and Prognosis, *above*] [*see Table 3*] are usually effective in quieting inflammatory joint symptoms. Some patients with highly active disease, however, may require short courses of low-dose systemic corticosteroids or repository corticosteroid injections into joints.

Early treatment of genitourinary infections with appropriate antibiotics (e.g., tetracycline or erythromycin) has been shown to reduce the likelihood of subsequent reactive arthritis; however, even early antibiotic use in patients with gastroenteritis does not appear to prevent reactive arthritis.[15,40] A blinded, placebo-controlled trial of the use of tetracycline for the treatment of reactive arthritis demonstrated that the duration of disease was shortened only in patients who had *Chlamydia*-induced disease.[40] Ciprofloxacin has not been shown to shorten the course of chronic reactive arthritis.[40] Controlled studies have shown that sulfasalazine, in dosages similar to those used in the treatment of ankylosing spondylitis, is effective in all forms of spondyloarthritis.[40] Whether any of these antibiotic approaches change the natural history of the disease remains to be proved. Patients with spondyloarthritis that persists despite treatment with NSAIDs and antibiotics may benefit from the use of anti-TNF agents. An increasing number of studies are documenting immediate and dramatic benefit from the use of TNF-α antagonists (e.g., infliximab and etanercept) in such patients.[43] Physical therapy is important in maintaining joint motion and preventing disability.

Psoriatic Arthritis

EPIDEMIOLOGY

The prevalence of cutaneous psoriasis is estimated to be 2% in most white populations; it appears to be lower in populations who are of African or Asian ancestry.[52] An inflammatory arthropathy attributable to psoriasis appears in 5% to 7% of patients with the skin disease, especially in those whose nails are affected.[6] Psoriasis is highly familial, and there is strong evidence that it is a complex genetic disease associated with several HLA alleles and other non–HLA-linked loci[5,53] [*see* Pathogenesis, *above*]. Genomic studies now strongly suggest major but yet unidentified loci for psoriasis susceptibility near HLA-C in the MHC region and on chromosome 17.[5,10] HLA-B27 is only weakly associated with psoriasis and peripheral psoriatic arthritis, but it occurs in 50% of persons who have psoriatic spondylitis. Potential environmental triggers are streptococcal infection and physical trauma. Psoriatic arthritis is slightly more common in females than in males. Psoriasis frequently first appears in childhood; psoriatic arthritis typically appears in early or middle adulthood, although there are many exceptions. The arthritis may appear before the psoriasis in as many as 40% of children and 15% of adults. Although the incidence of psoriasis and psoriatic arthritis in HIV-positive persons is similar to that in uninfected persons, severe exacerbations of both skin disease and joint disease have been observed in patients with HIV infection, especially as the number of $CD4^+$ T cells declines.

DIAGNOSIS

Clinical Presentation

In general, there is little relation between joint and skin severity. In fact, psoriatic skin lesions may be found only after careful scrutiny of the scalp, the umbilicus, or the gluteal region, and nail pitting or other changes may be the only clues supporting a diagnosis of psoriatic arthritis. Several clinical patterns of joint involvement, often overlapping, have been described:

1. Asymmetrical oligoarthritis of both small and large joints is the most common form of psoriatic arthritis. Involvement of distal interphalangeal joints and sausage-shaped toes or fingers are highly suggestive signs. A disparity is often noted between clinical appearance and subjective symptoms; overtly involved joints may be largely asymptomatic, unlike the concordance usually found in rheumatoid arthritis.
2. Symmetrical polyarthritis may resemble rheumatoid arthritis, although tests for rheumatoid factor and antibodies to cyclic citrullinated peptides (anti-CCP) should be negative. Anti-CCP is a newly discovered autoantibody marker for rheumatoid arthritis that is 65% sensitive and 96% specific. Uncertainty about classification is reasonable because psoriasis and rheumatoid arthritis are both relatively common diseases and are expected to occur together by chance.
3. Arthritis mutilans is the most destructive form of psoriatic arthritis; it occurs in approximately 5% of patients with psoriatic arthritis. Striking bone resorption and telescoping of fingers (opera-glass hand) are characteristic. Affected patients often have concomitant spinal involvement.
4. Psoriatic spondylitis occurs in approximately 20% of patients with psoriatic arthritis, often with unilateral sacroiliitis and large asymmetrical syndesmophytes, similar to the pattern seen in patients with reactive arthritis.
5. Dominant or exclusively distal interphalangeal joint involvement with psoriatic nail changes may occur.

Laboratory Findings

An elevated ESR or CRP level, anemia, and hyperuricemia may be found. Rheumatoid factor, anti-CCP, and antinuclear antibody tests are negative. Synovial fluid shows nonspecific inflammatory changes.

Radiographic Features

A characteristic change is whittling of the distal ends of phalanges, giving the joints a so-called pencil-in-cup appearance, which is radiographically distinctive for psoriatic arthritis. Periostitis—which results in whiskering around joints—bony erosions, and joint fusion in the absence of osteopenia also are common and diagnostically useful findings.

TREATMENT AND PROGNOSIS

NSAIDs similar to those used for ankylosing spondylitis [*see* Ankylosing Spondylitis, Treatment and Prognosis, *above*] [*see Table 3*] are the mainstay of arthritis therapy in most patients but have no effect on the skin disease, which may require separate dermatologic approaches [*see 2:III Psoriasis*]. Sulfasalazine, methotrexate, or cyclosporine may be beneficial for both skin and joint disease in NSAID-resistant or severe, progressive disease.[6] Well-controlled studies have demonstrated that TNF-α antagonists (etanercept and infliximab) are highly effective for symptoms and probably modify outcomes for both the arthritis and the skin disease.[43] Gold, penicillamine, and hydroxychloroquine are not useful agents.

Psoriatic arthritis usually runs a more benign course than rheumatoid arthritis does, although clearly there are many patients with severe disease. Many patients with psoriatic arthritis maintain reasonable function, often despite extensive deformities.

Enteropathic Arthritis

Two major clinical patterns of arthritis associated with inflammatory bowel diseases are peripheral arthritis and spondylitis.

PERIPHERAL ARTHRITIS

Approximately 20% of patients with Crohn disease or ulcerative colitis experience an acute peripheral arthritis.[20] Symmetrical swelling of the knees, ankles, or wrists is the most common articular pattern; large effusions may occur. The pathogenesis of the arthritis is unknown, but the disease occurs during periods of active inflammation of the gut and may be the first sign of a bowel flare-up. HLA-B27 is not increased in frequency among inflammatory bowel disease patients with peripheral arthritis, as compared with the normal population. Extraskeletal and extraintestinal manifestations may occur simultaneously and include fever, acute anterior uveitis, painful oral ulcers, erythema nodosum (in Crohn disease), and pyoderma gangrenosum (in ulcerative colitis). Treatment of the arthritis should be aimed at controlling the inflammatory bowel disease. The arthritis seldom results in deformities.

SPONDYLITIS

Sacroiliitis develops in about 10% of patients with inflammatory bowel disease. Clinically, the spondylitis may progress to total spinal ankylosis; radiographically, it is indistinguishable from ankylosing spondylitis.[20,31] There is no correlation of the spondylitis with activity of the bowel disease. HLA-B27 is found in approximately 50% of such patients. Therapy is largely the same as for ankylosing spondylitis [*see* Ankylosing Spondylitis, Treatment and Prognosis, *above*]. Despite the bowel disease, NSAIDs are usually well tolerated.

UNDIFFERENTIATED SPONDYLOARTHRITIS

Inevitably, the presentations of many patients do not conform to the typical presentations described above, and the symptoms and signs defy specific disease classification.[1,54] Examples are a patient with unilateral sacroiliitis, a sausage digit, and uveitis; a patient with typical reactive arthritis who experiences psoriatic arthritis; and a patient with typical ankylosing spondylitis who years later experiences Crohn disease. Such patients are often designated as having undifferentiated spondyloarthritis. The ESSG criteria[1] now make the classification of patients with spondyloarthritis more definitive. There remains, however, a large number of patients with formes frustes that do not fulfill the new criteria but probably fall within the spectrum of spondyloarthritis. Such entities, which are strongly associated with HLA-B27, are chronic inflammatory back and chest pain syndromes (in which radiographs are normal), chronic dactylitis, chronic plantar fasciitis or Achilles tendinitis, pustular psoriasis (keratoderma blennorrhagica), circinate balanitis, acute anterior uveitis, and spondylitic heart disease without evidence of arthritis. In patients suspected of having a limited form of spondyloarthritis, typing for HLA-B27 may prove clinically useful in supporting such a diagnosis.[1,54]

Juvenile Spondyloarthritis

Until recently, the term juvenile rheumatoid arthritis was used, inappropriately, to describe all forms of chronic childhood arthritis. Careful clinical evaluation, autoantibody testing, and HLA typing have revealed a heterogeneous group of diseases in which only a small proportion of affected children truly have rheumatoid arthritis.

Juvenile spondyloarthritis occurs most often in boys; it typically begins in late childhood or adolescence with lower extremity oligoarthropathy and enthesopathy.[28] Spinal symptoms are rare initially but often appear years later. Bony ankylosis of the tarsal bones has been described in some of these patients. Acute anterior uveitis is not uncommon. Such patients are seronegative for rheumatoid factor, anti-CCP, and antinuclear antibodies but are positive for HLA-B27. Less often, a patient may present with chronic polyarthritis with prominent cervical spine fusion rather than lower spine involvement.

Subsets of juvenile arthritis include the following:

1. Oligoarthritis appearing in early childhood, more often in girls; it is associated with antinuclear antibodies, a high risk of chronic iridocyclitis and blindness, and HLA-DR5 (DR11), HLA-DR8, or HLA-DR6, as well as HLA-DP2, but not HLA-B27.
2. Polyarthritis appearing in early childhood, more often in girls who are seronegative for rheumatoid factor and antinuclear antibodies; it is associated with HLA-DR8 and HLA-DP3 but not HLA-B27.
3. Polyarthritis associated with rheumatoid factor, anti-CCP, and HLA-DR4 (but not HLA-B27), which probably represents true juvenile rheumatoid arthritis.
4. Still disease, characterized by high, spiking fever, evanescent rash, hepatosplenomegaly, lymphadenopathy, and polyarthritis in patients who are seronegative and HLA-B27 negative.

Miscellaneous Arthropathies

ACNE-ASSOCIATED ARTHRITIS

A rare inflammatory oligoarthritis may occur in patients with severe forms of acne, including acne conglobata, acne fulminans, hidradenitis suppurativa, and dissecting cellulitis of the scalp.[55] Such patients experience fever and inflamed joints; symptoms resemble those of septic arthritis, but the joints are sterile by culture. Sacroiliitis has been described in some patients.

SAPHO is an acronym for a syndrome that consists of synovitis, severe acne, palmoplantar pustulosis, hyperostosis, and osteitis and that may be a form of spondyloarthritis.[55-57] These arthritides may represent forms of reactive arthritis, but patients are usually HLA-B27 negative. Antibiotic therapy is usually of little or no benefit, but some patients respond to NSAIDs or low-

dose corticosteroids. Surgical excision of the affected skin, when possible, has been reported to resolve the arthritis.

WHIPPLE DISEASE

Whipple disease is a rare multisystem disorder that usually affects men (the ratio of affected men to women is 9:1). Patients may present with arthralgias or transient episodes of additive, symmetrical polyarthritis that is nondeforming. Sacroiliitis has been reported in rare instances, and the frequency of HLA-B27 may be increased in patients with Whipple disease. Patients usually have GI symptoms, including diarrhea, steatorrhea, and profound weight loss. Other clues to diagnosis are skin hyperpigmentation, serositis (pleural effusions), lymphadenopathy, uveitis, nervous system disease (ocular palsies or encephalopathy), leukocytosis, and thrombocytosis. The diagnosis traditionally has been based on small-bowel biopsies showing deposits on periodic acid–Schiff staining or electron microscopic demonstration of rodlike bacillary organisms in intestinal macrophages. The causative organism has been identified by RNA sequence analysis and cultured as a gram-positive actinomycete named *Tropheryma whippelii*.[58] Diagnosis can be made on the basis of results from PCR analysis of DNA from affected tissues or blood samples. Long-term treatment with tetracycline usually results in complete remission.

IV SYSTEMIC LUPUS ERYTHEMATOSUS

Michael D. Lockshin, m.d.

Disease Definition and Subclassification

Lupus is a chronic autoimmune illness characterized by autoantibodies directed at nuclear antigens and causing a variety of clinical and laboratory abnormalities, including rash, arthritis, leukopenia and thrombocytopenia, alopecia, fever, nephritis, and neurologic disease. Most or all of the symptoms of acute lupus are attributable to immunologic attack on the affected organs. Many complications of long-term disease are attributable both to the disease and to its treatment.[1]

The term lupus applies to several variants of the illness [*see Table 1*], of which systemic lupus erythematosus (SLE) is the most serious and most common. SLE is the prototype of a systemic autoimmune illness, involving multiple organ systems in pathogenically similar ways. Characteristically, patients with SLE progress through periods of active inflammation (flare) and periods of quiescence (remission), both of which may occur spontaneously; periods of flare and quiescence may also be induced. The reasons for the varying course are unknown. Intense sun exposure, drug reactions, and infections are circumstances that are known to induce flare; the aim of treatment is to induce remission.

SLE may occur as an overlap syndrome that shares features with other autoimmune illnesses, such as mixed or undifferentiated connective tissue disease, dermatomyositis, Sjögren syndrome, rheumatoid arthritis, and scleroderma. Organ-specific autoimmune diseases, such as thyroiditis, autoimmune hemolytic anemia, and idiopathic thrombocytopenia, frequently accompany and may be part of SLE.

Lupus may also appear as a skin disease only. Discoid lupus occurs as a destructive, scarring rash, unaccompanied by systemic symptoms or autoantibodies.[2] Subacute cutaneous lupus comprises a characteristic persistent, polycyclic rash; relatively minor visceral symptoms; and strongly positive blood tests.

Drugs such as procainamide and some anticonvulsants induce a lupuslike syndrome, which is called drug-induced lupus.[3] Uncommonly, persons (often relatives of lupus patients) have positive blood tests for lupus but are clinically well. In the absence of symptoms, such persons are not considered to have lupus.

Approximately one third of lupus patients have antiphospholipid antibody, which induces blood clots and fetal death. The presence of this antibody, in the absence of clinical lupus, is referred to as primary antiphospholipid antibody syndrome.[4]

Neonatal lupus is a syndrome consisting of rash, thrombocytopenia, and congenital heart block occurring in infants born of mothers who carry antibody to the SS-A (Ro) and SS-B (La) antigens.[5] It does not evolve into SLE.

Epidemiology and Genetics

SLE is primarily a disease of young women, but the female predominance of SLE has not been explained. Women between 15 and 45 years of age are the most commonly affected; the female-to-male ratio in this age group is between 6:1 and 9:1. African Americans are four times as likely to develop lupus as are whites.[6] The disease incidence in Asians, Hispanics, and Native Americans falls between that of blacks and whites [*see Figure 1*]. No cogent explanation offered to date suggests why African Americans are more frequently affected; racial differences in SLE incidence persist when socioeconomic differences have been controlled. SLE severity in men is similar to that in women. Overall survival is lower in African Americans.[7]

The familial aspects of lupus are striking: approximately 10% of persons with lupus have family members with lupus or other autoimmune disease. Susceptibility to lupus is higher in persons with specific genetic deficiencies [*see* Other Genetic Susceptibilities, *below*].

Pathophysiology and Pathogenesis

AUTOANTIBODIES

Circulating antibodies to a broad list of autoantigens characterize SLE. Antinuclear antibodies, usually defined by immunofluorescence, are present in almost all lupus patients; tests for antinuclear antibody constitute a screening test (sensitive, but not specific) for the illness. Autoantibodies to nuclear constituents—primarily to double-stranded (native) DNA but also to single-stranded (denatured) DNA, histones, ribonuclear proteins, and other nuclear antigens, such as the Smith (Sm) antigen—confirm the diagnosis and are likely pathogenic. For example, these autoantibodies cause glomerulonephritis by inciting inflammation when deposited as complement-fixing immune complexes on glomerular basement membranes (GBMs) or by binding directly to the GBM.[8] Both animal models and clinical observations suggest that autoantibodies in the presence of complement mediate lupus-associated glomerulonephritis, hemolysis, and thrombocytopenia. Antibodies to phospholipid-binding proteins (beta$_2$-glycoprotein I, prothrombin, and others) mediate thrombosis and fetal loss. Lupus rash and arthritis are less clearly linked to autoantibodies, but immune reactants and inflammation are demonstrable in relevant biopsy specimens, primarily at the GBM.[9] Among lupus manifestations, neurologic lupus is least clearly caused by anti-DNA or other autoantibody; however, anti–ribosomal P antibody may define mood disorders in neurologic lupus.[10] A hypothesis that antibody to a glutamate receptor has diagnostic and pathogenic importance in SLE-associated cognitive dysfunction has proved to be untrue.[11]

ABNORMAL INNATE AND ADAPTIVE IMMUNITY

Genetic defects of immune complex processing are unusually frequent in lupus patients, suggesting that SLE arises because of incomplete or improper disposal of exogenous material.[12] Such defects include abnormalities in complement (deficiencies of C1q, C2, or C4), Fc receptor, apoptotic pathways, and phagocytic cells.[13] Defective clearance of immune complexes may result in their persistence in large quantities,[14] and autoantibodies may be a protective mechanism to neutralize them. Other theories of pathogenesis argue that genetic predispositions that promote T helper type 2 cell (Th2) responses or cytokine dysregulation are the underlying defects leading to the development of SLE.

In animal models, several immune defects that may cause SLE have been identified. These include abnormalities in genes affecting overall immunoreactivity (apoptosis [*Fas*, *Fas* ligand,

Bcl-2]), B cell activation (*FcγRIIB, SHP-1, CD22, CD19, PD-1, Lyn, Blys-1*), T cell activation (*TGF-β, TGF- βR, PD-1*), cell proliferation (*p21, Fli-1*), and cytokines (*IFN-γ, IL-4, IL-10, TNF-α*); and genes affecting autoantigen clearance (*C1q, C4, SAP, DNAse-1*).[15,16] Gene array data strongly indicate that interferon genes are markedly upregulated in patients with active SLE. Whether this is causative or a result of disease is not known.[17]

OTHER GENETIC SUSCEPTIBILITIES

Twin and family studies of SLE make it abundantly clear that the illness is highly heritable. HLA types DR3 and DR4 predominate in SLE patients.[18] Specific susceptibility loci on chromosomes 1, 4, and 7, among others, have been identified.[19] Persons with genetic deficiencies of complement appear to be more susceptible to the development of lupus.[20] Specific FcIII gamma receptor alleles increase the severity of lupus nephritis, particularly in whites.[21] The genetics of lupus are extremely complex, however, and no single genetic trait is unequivocally linked to susceptibility to the illness. Several national registries are currently attempting to definitively describe the genetics of lupus.

INFECTIONS

Although an infectious trigger of SLE has long been suspected, no single infection has been found. Universal exposure of children with SLE to Epstein-Barr virus has been noted (at an age when 50% exposure is the norm), suggesting a possible link of this virus to disease.[22] Autoantibodies can be identified in serum specimens up to a decade before the earliest symptoms of SLE. Autoantibodies first appear as one specific antibody, then generalize just before clinical onset. Whether this progression reflects response to infection or autoimmunity is unknown.[23]

ESTROGEN

Some investigators attribute the female predominance of SLE and its occurrence in childbearing years to the upregulating effect of estrogen on the immune system, a phenomenon demonstrable largely in vitro. However, this argument applies to autoimmunity in general, not specifically to lupus, and it fails to explain why other autoimmune diseases have much less striking female-to-male ratios. Furthermore, postmenopausal estrogen replacement and oral contraceptive use do not significantly alter SLE incidence or severity, nor does pregnancy; minor differences in incidence or susceptibility have on occasion been reported.[24-26] Alternative explanations for a high female-to-male ratio include an estrogen-sensitive threshold mechanism[27] or sex differences of exposure to exogenous agents (although none has been convincingly suggested.[28] Reports of patients with Klinefelter syndrome and SLE have prompted investigators to consider the possible involvement of male hypogonadism in the pathogenesis of lupus; patients with Klinefelter syndrome may be unusually susceptible to lupus.

COMPLICATIONS OF CHRONIC ILLNESS

Most current information on SLE pathogenesis focuses on upregulation or downregulation of components of the immune response, genetic controls of immunity, and potential etiologic agents. However, the long-term damage of chronic disease, from tissue injury or treatment, is as important to patients as acute inflammatory disease. Some elements of damage are clearly attributable to therapy: osteoporosis, osteonecrosis, cataracts, and tendon ruptures are all associated with long-term corticosteroid therapy. Other elements of damage result directly from the inflammatory and immunologic aspects of the illness, which lead to tissue necrosis and scarring: progressive renal failure, destruc-

tive joint disease, and brain infarcts. Many of these complications are more severe in patients of minority races or lower socioeconomic classes.[29] Still other elements of chronicity bear an uncertain relationship to disease and treatment: accelerated atherosclerosis,[30] valvular heart disease, cognitive dysfunction, and psychosocial dysfunction.

Diagnosis

The American College of Rheumatology (ACR) has defined criteria for the classification of SLE [*see Table 2*].[31] Although the ACR criteria are useful for ensuring uniformity of patients reported in medical journals, the criteria are often mistakenly used as diagnostic criteria. For individual patients, the criteria have high false negative and false positive rates.[32] For instance, a patient with biopsy-proven lupus nephritis, positive antinuclear antibody, and anti-Sm antibody as the only manifestations of disease does not fulfill ACR criteria, whereas a patient with rheumatoid arthritis who has a positive antinuclear antibody, low positive anti-DNA antibody, and leukopenia (e.g., from Felty syndrome) does fulfill ACR criteria. As a rule, characteristic disease of one organ system (kidney, joints, skin) plus a high-titer anti-dsDNA or Sm antibody suffices to make the clinical diagnosis.

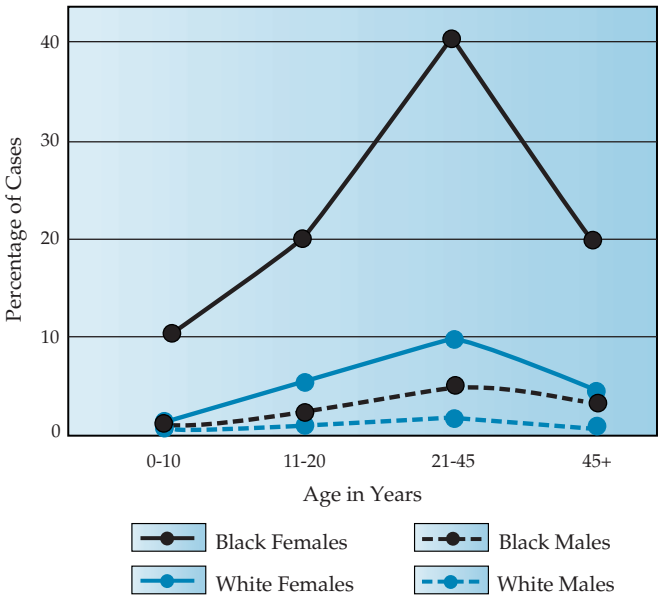

Figure 1 **Age, sex, and race distribution of the incidence of SLE.[6]**

In clinical practice, diagnosis of SLE is based on a combination of autoantibody assays, clinical manifestations, and laboratory studies of affected organ systems. The clinical manifestations of lupus are protean. Patients with lupus activity or damage may be asymptomatic or may present with findings that reflect the specific organ systems involved [*see Table 3*].

Symptoms and signs accumulate over time in patients with SLE [*see Table 4*].[33] At any given time, especially at the onset of illness, most often only a few manifestations are present. Arthritis, malaise, cytopenias, and rashes are the most prominent early findings. Nephritis (with renal failure), arthritis, osteoporosis and osteonecrosis (corticosteroid complications), neurologic disease, accelerated atherosclerosis, and cardiac valvular disease dominate the late course. With disease activity and with its treatment, the risk of opportunistic infection is high. For conceptual purposes, it is easiest to consider disease activity and manifestations separately for each affected organ system.

SYSTEMIC SIGNS AND SYMPTOMS

Malaise, arthralgia, myalgias, fever (usually low grade), and weight loss are common manifestations of active SLE. Some patients will have high temperatures (> 40° C [104° F]). Even with very high fever, shaking chills are unusual; when present, they suggest infection. Like the organ-specific manifestations of lupus, the systemic symptoms vary considerably during the day and

Table 2 American College of Rheumatology Criteria for the Classification of SLE*

Malar rash
Discoid rash
Photosensitivity
Oral ulcers
Arthritis
Serositis (pleuritis or pericarditis)
Renal disorder (proteinuria > 0.5 g/day or cellular casts)

Immunologic disorder (anti-DNA, anti-Sm, or antiphospholipid antibodies [anticardiolipin, lupus anticoagulant, or biologic false positive test for syphilis])
Antinuclear antibody

Note: these are not diagnostic criteria.
*Four criteria are required to include a patient in an SLE cohort of a research study.

over weeks. In approximately one third of lupus patients, sun exposure, usually intense, will induce systemic flare. Sun exposure that is mild or of short duration does not harm most patients.

SKIN AND MUCOSAL INVOLVEMENT

Up to half of lupus patients manifest some degree of alopecia. Typically, this takes the form of broken frontal hairs and diffuse thinning, which recovers when health is regained. Severe alopecia may occur. Discoid rashes cause focal patches of hair loss.

Most patients develop a rash at some point during their illness. The well-known butterfly rash, on both cheeks and across the bridge of the nose [*see Figure 2*], occurs in only a minority of patients, but most rashes involve the face in some manner. Commonly the tip of the chin, the upper lip, the eyebrows, and the hairline are also involved. The rash may consist of erythema only or may be papular and scaly or deeply pigmented (discoid rash). Discoid rashes, which may scar, are hyperpigmented at the circumference and often depigmented centrally [*see Figure 3*]. Patients with discoid rashes may have either discoid lupus or SLE. Other types of rashes occur only in SLE.

Diagnostic inflammatory rashes are somewhat raised, scaly, and relatively uniform in appearance across the lesion; they may ulcerate; and they have sharp borders. Less diagnostic rashes occur on the extensor surfaces of the upper arms, the blush area of the neck and shoulders, and the extensor surfaces of the elbows and fingers. These are usually erythematous macular rashes. The erythematous rashes evolve over days to weeks and often leave hyperpigmentation as they recede; they may appear more prominent with fever or pregnancy. Vasculitic rashes (usually small, ulcerating papules) occur on the extensor tips of the elbows; painful, erythematous vascular lesions occur at the distal fingers and palms (lupus pernio). A polycyclic, persistent rash, primarily on the trunk, and specifically associated with anti–SS-A antibody, is known as subacute cutaneous lupus [*see Figure 4*]. A painful subcutaneous lesion that is deeply indurated and tender and may ulcerate is called lupus profundus.

Some patients have only erythema in distributions typical of lupus rashes. Unlike the other rashes, erythematous rashes are not by themselves diagnostic of lupus, but they add to the overall diagnostic information. Lupus rashes are often confused with rosacea (although rosacea is more oily and more papular), polymorphous light eruptions, and allergic reactions.

Chronic nasal ulcers and recurring painless mouth ulcers [*see Figure 5*] (particularly on the hard palate, but also on the gums and buccal mucosa) are characteristic of more severe disease. Mucosal ulcers are irritating rather than severely painful. Periungual telangiectasias and small, ulcerating, vasculitic ulcers on the elbows also occur in more severe disease. A particular type of palmar and digital pulp erythema, known as lupus pernio, is a form of vasculitis. In rare cases, subcutaneous inflammation leads to lupus profundus, consisting of local fat necrosis and painful nodules.

LYMPH NODE INVOLVEMENT

Lymphadenopathy is common in active disease. It is modest in extent and generalized (often noted on computed tomography scans of the abdomen or chest). It resolves rapidly in patients started on corticosteroid therapy for other manifestations of SLE.

CARDIOPULMONARY INVOLVEMENT

SLE is associated with a range of cardiopulmonary disorders [*see Table 5*]. These usually cause symptoms or abnormal physical findings; it is unnecessary to test asymptomatic patients for cardiovascular disease.

Pleuropericarditis is frequently symptomatic but is not usually life-threatening. It causes pain on breathing, as well as elevation of the diaphragm that is evident on physical examination or x-ray. Atelectasis at the bases of the lungs is audible as fine crackling rales or is visible on x-ray as horizontal lines (plate atelectasis). Pulmonary function tests may reflect reduced diffusion capacity, reduced lung volumes, and reduced lung elasticity.

Pleural effusions also occur, but they are not usually large. On thoracentesis, LE cells (polymorphonuclear leukocytes with ingested nuclear debris appearing as a homogeneous round inclusion) may be found on a Wright stain of the fluid buffy coat.

A minority of patients develop respiratory insufficiency from pulmonary fibrosis. A rare manifestation is so-called lupus lung.

a

b

Figure 2 **Most lupus rashes involve the face (a). The butterfly rash of lupus, on both cheeks and across the bridge of the nose (b), occurs in only a minority of patients.**

Figure 3 **Discoid lupus rashes are hyperpigmented at the circumference and often depigmented centrally.**

This consists of inflammatory lung disease or pulmonary hemorrhage, either of which is life threatening.[34] Pulmonary hypertension is uncommon but serious when it occurs, which is most often in patients with intense Raynaud phenomenon, recurrent pulmonary emboli, or pulmonary fibrosis.

Transthoracic echocardiography demonstrates valvular heart disease in up to 30% of patients with long-standing SLE; with transesophageal echocardiography, the frequency is much higher.[35] Libman-Sacks lesions occur primarily on the mitral valve but also occur on the aortic valve and, rarely, on the pulmonic or tricuspid valves. Symptomatic valve disease may be more common in patients with antiphospholipid antibody. Pericardial effusions or thickening occurs during active disease, but otherwise, they are uncommon. Small pericardial effusions, which may be symptomatic or asymptomatic, occur often in patients with active SLE. Life-threatening large effusions are uncommon.

Accelerated atherosclerosis is a risk of long-standing lupus,[36,37] leading to myocardial infarction and other vascular occlusive manifestations before the age of 40. Myocardial infarction may also be caused by coronary vasculitis, but this is less common. It is important to consider atherosclerosis, together with vasculitis and thrombosis (from antiphospholipid antibody), in patients with long-standing lupus who present with complaints of vascular insufficiency.

Diffuse nonischemic myocarditis may also occur. Newborns suffering the neonatal SLE syndrome may have complete congenital heart block and may die of congestive heart failure.

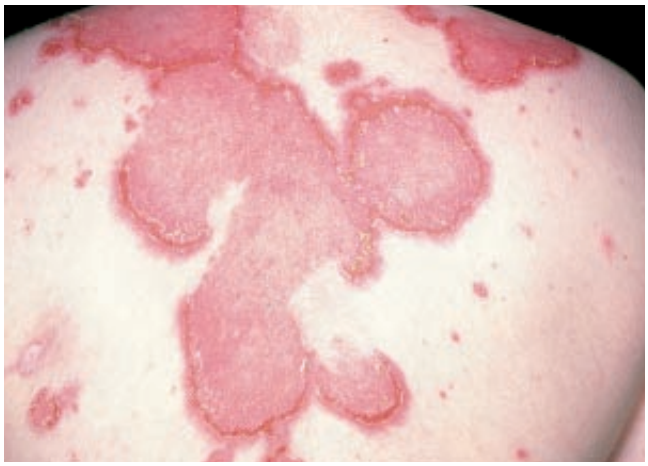

Figure 4 **The rash of subacute cutaneous lupus is polycyclic and persistent.**

MUSCULOSKELETAL INVOLVEMENT

The arthritis of SLE is typically painful, transient, and symmetrical, involving the wrists, small joints of the hands, elbows, knees, and ankles. Swelling and redness are modest. Less often, SLE arthritis will present as asymmetrical oligoarthritis or intensely inflamed, sustained polyarthritis resembling that of rheumatoid arthritis. Although deformity may occur as a result of ligamentous laxity (reversible subluxations, Jaccoud arthropathy),[38] rheumatoid-like joint destruction is uncommon.

Inflammatory myositis occurs primarily in patients with overlap features with scleroderma or dermatomyositis. It presents as proximal myopathy; serum levels of muscle enzymes are modestly elevated; and results of electromyography, magnetic resonance imaging, and muscle biopsy, if done, are similar to those seen in dermatomyositis. However, abnormal enzyme levels associated with proximal muscle tenderness or weakness are sufficient for diagnosis in a patient with established SLE.

Lupus does not involve bone directly. However, bone involvement can occur secondary to organ system failure (e.g., renal failure), severe illness (e.g., osteoporosis from inactivity or catabolic state), or treatment (e.g., corticosteroid-induced osteoporosis or avascular necrosis).

Osteoporosis presents as atraumatic fractures of vertebrae or long bones. Its occurrence is a severe threat to SLE patients, even premenopausal women, because of the frequent use of corticosteroids for treatment and because of inactivity attendant upon polyarthritis and systemic illness.

Avascular necrosis (osteonecrosis) most often occurs in patients who have had a severe flare treated with high-intensity corticosteroid therapy, but this complication can develop in patients who have never received corticosteroid treatment. Marked cushingoid features during steroid treatment and Raynaud phenomenon may be predictors of its occurrence.[39] The femoral head is the most commonly involved site, but shoulders, ankles, wrists, metacarpals, and shafts of long bones are also vulnerable.[40] Typically, affected areas become painful at the initial occurrence of infarction and again years later when the necrotic bone collapses. The most typical presentation of osteonecrosis is sudden hip pain 2 or 3 years after a major flare of lupus. Some patients receiving infusions of high-dose intravenous methylprednisolone complain of intense pain at preexisting osteonecrotic sites during and shortly after the infusion. Reducing the corticosteroid dose at the time of occurrence of pain has no effect on the course of the complication.

GASTROINTESTINAL AND HEPATIC INVOLVEMENT

Esophageal dysfunction is rare in SLE; it occurs primarily in patients with severe Raynaud phenomenon or in patients with scleroderma overlap disease. Gastroduodenal ulcer may occur as a result of treatment but is not directly linked to SLE. Ischemia of the small and large intestines may result from systemic vasculitis; it presents as abdominal angina, pneumatosis intestinalis, infarction or perforation, or pseudo-obstruction. Intestinal ischemia is a rare complication, occurring only in the most severely ill patients.[41]

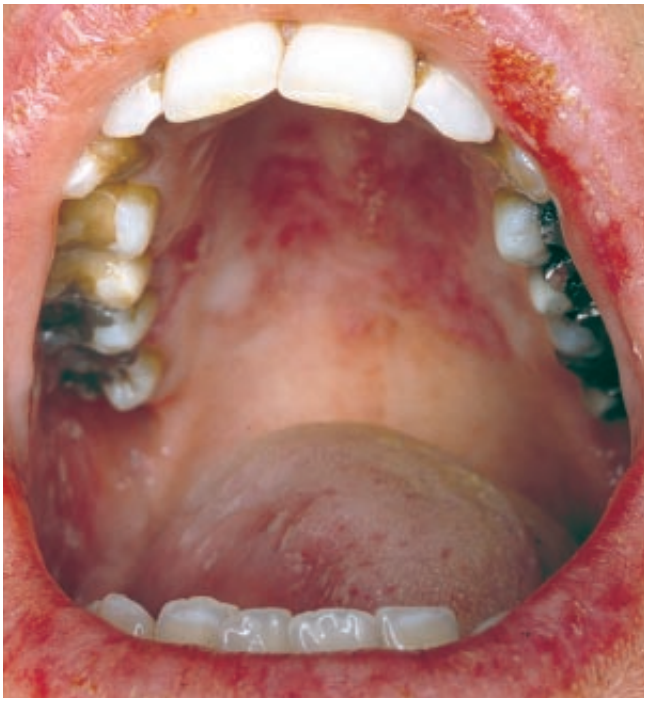

Figure 5 **Painless mouth ulcers, most often found on the hard palate but also found on the gums and buccal mucosa, are characteristic of more severe lupus.**

Diverticulitis often develops in patients with long-standing SLE, especially after prolonged treatment with corticosteroids. The symptoms of diverticulitis are easily masked by corticosteroid therapy. Consequently, diverticular perforation or abscess is frequently misdiagnosed, especially in young SLE patients.

Chemical hepatitis may follow use of nonsteroidal anti-inflammatory drugs (NSAIDs) (lupus patients appear to be unusually susceptible to this side effect) or other drugs, such as azathioprine.[42] Occasionally, patients suffer concomitant autoimmune hepatitis or primary biliary cirrhosis. In the absence of other causes, abnormalities of liver enzyme levels because of SLE are uncommon.

HEMATOLOGIC INVOLVEMENT

Leukopenia is such a regular feature of SLE that its absence, in untreated disease, should raise suspicion that the diagnosis is incorrect or that infection or tissue necrosis is present. Usually, lymphocyte counts show greater reductions than do granulocyte counts: a leukocyte count of about 3.5/mm^3, with 10% lymphocytes, is usual. Leukopenia of this degree seldom places patients at serious risk of infection. There is usually no need to administer granulocyte-macrophage colony-stimulating factor (GM-CSF); there are anecdotal reports that administration of this agent may induce lupus flare.

Thrombocytopenia in SLE is usually low grade, with platelet counts greater than 50,000/mm^3. Severe thrombocytopenia may occur, however; idiopathic thrombocytopenic purpura (ITP) may be an initial presentation of SLE.

SLE may result in anemia of chronic disease and anemia from autoimmune hemolysis. The anemia of chronic disease in SLE patients responds to administration of recombinant erythropoietin.

NEUROLOGIC INVOLVEMENT

Neurologic signs and symptoms represent one of the most serious and least understood aspects of SLE. The primary neurologic manifestations of SLE consist of generalized and focal (usually vascular) brain disease, myelopathy, peripheral neuropathy, mononeuritis multiplex, and cognitive dysfunction. Secondary neurologic events can also occur; these include seizures from hypertension or hemorrhage, delirium from drugs or uremia, brain or spinal cord abscess, and stroke from atheroma or embolus. Attribution of a specific neurologic symptom to active lupus (which is treatable with immunosuppression), as opposed to a complication of lupus or its treatment (which is treatable by ameliorating the offending problem) requires deep investigation and good clinical judgment. Confusion about diagnostic criteria for neurologic lupus led the ACR to publish nomenclature and case-definition criteria for these syndromes.[43]

General Brain Disease

Patients with SLE frequently complain of progressive cognitive dysfunction, such as confusion, forgetfulness, and so-called foggy thinking.[44,45] Retrospective and cross-sectional studies document a high frequency of poor performance on tests of cognitive function, particularly in the executive, short-term memory, and verbal-processing spheres.[46,47] It is not known whether this deficit results from immunologic attack on the brain (by antineuronal or other autoantibodies) or diffuse vascular disease. Cognitive dysfunction may respond to corticosteroid therapy. It seldom progresses to advanced dementia.

Headaches are common in SLE. A special form of migraine called lupus headache has been described, but whether it exists as a definable entity remains a matter of debate.

Focal Brain Disease

Seizures, strokes, cranial neuropathies (including blindness), and cerebellar dysfunction may occur in SLE. These events are assumed to result from vascular occlusion, but they may occur in patients with no known thrombotic diathesis, embolization, atherosclerosis, or vasculitis. Stroke is one of the most common presentations of the antiphospholipid antibody syndrome. Seizures are most common in severely active, febrile, multisystem dis-

ease. In this circumstance, they generally do not persist after the disease is brought under control.[48]

Myelopathy

Transverse myelitis occurs in two patterns: (1) abrupt onset, with progression in hours from the first symptom, often heralded by a burning, dysesthetic pain in the legs; and (2) slower progression, in a stuttering fashion, worsening over days. Unless treated immediately and aggressively, both forms may progress to advanced paraparesis or paraplegia. Although few direct data exist to support these hypotheses, it is likely that the first form represents vascular occlusion with spinal cord ischemia and the second form represents inflammatory disease. It is mandatory to exclude a space-occupying mass in all such patients.

A slowly progressive and intermittent myelopathy, very much resembling multiple sclerosis (so-called MS-like or lupoid sclerosis), develops in some lupus patients. There is no definitive way to exclude concomitant MS in these patients except by the association of the myelopathy with SLE and by its failure to progress in the way MS usually does. In this form of lupus myelopathy, cerebrospinal fluid examinations may reveal oligoclonal bands, but MRI studies are atypical for MS.

Peripheral Neuropathy

Stocking-and-glove neuropathy is a slowly progressive lesion that tends to occur in patients with continuing, active disease. Its pathogenesis is unclear; it may result from direct immune attack on peripheral nerves or from vasculitic occlusion of the vasa nervora. Abrupt loss of motor and sensory function, such as sudden occurrence of footdrop or wristdrop, is diagnosed as mononeuritis multiplex. This is a very serious manifestation indicating vasculitis of the vasa nervora; it implies systemic vasculitis, as well.

RENAL INVOLVEMENT

Approximately half of lupus patients develop lupus nephritis, and approximately 10% overall will progress to dialysis or transplantation. Lupus nephritis presents as proteinuria (or an otherwise abnormal urinalysis), hypertension, or a rising serum creatinine level, all of variable degree. In its early stages, lupus nephritis is painless and asymptomatic. In more advanced stages, edema, anemia, symptomatic hypertension, and symptomatic uremia occur. Patients with inflammatory forms of nephritis are usually hypocomplementemic; most have high levels of anti-DNA or anti-Sm antibody. Signs or symptoms of disease active in other organ systems need not accompany lupus nephritis.

The World Health Organization (WHO) pathologic classification of lupus nephritis has been revised. The revised criteria differ from previous classifications by taking into account normal biopsies, scarring, and tubulointerstitial changes; in addition, they incorporate information from immunofluorescence and electron microscopy studies [*see Table 6*].[49] This classification includes indices of disease activity and chronicity, which delineate acute necrosis, inflammatory infiltrate, crescent formation, scarring, and tubular atrophy to provide further prognostic information.[9] Electron microscopy demonstrates immune complex deposits in subepithelial spaces in membranous lupus nephritis and in subendothelial spaces in proliferative lupus nephritis, as well as in mesangial locations. Characteristic tubuloreticular structures, thought to be RNA degradation products, also appear. Immunofluorescence studies demonstrate IgG, IgM, and C3 deposits in the same distributions. Vascular inflammation or endothelial proliferation is also seen.

Although lupus nephritis may present as anuria, acute hypertension, or fluid retention, most often it is first noted by an abnormal urinalysis. If left untreated, lupus nephritis progresses to renal insufficiency over months to years. Biopsy is necessary primarily when the result will change treatment. Urinalysis and blood chemistry results correlate only roughly with biopsy findings [*see Table 7*].

SPECIAL PRESENTATIONS

Neonatal Lupus Syndrome

Approximately 25% of infants born to mothers with anti–SS-

Table 6 International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 Classification of Lupus Nephritis

Class	*Name*	*Description*	*Clinical Presentation*
I	Minimal mesangial	Normal light microscopy, mesangial immune deposits by immunofluorescence	Normal urinalysis, normal function
II	Mesangial proliferative	Infiltrating cells and proliferation of mesangium	Mild proteinuria, celluria, normal function
III A III A/C III C	Focal active Focal active and chronic Focal chronic	Infiltrating cells and immune complex deposits in portions of the glomerulus and in < 50% of glomeruli (active) or scarring (chronic)	Variable proteinuria, celluria, normal function
IV A IV G IV-S A/C IV-G A/C IV-S C IV-G C	Diffuse and active (A), global (G), segmental (S), chronic (C)	Infiltrating cells and moderate immune complex deposits in entire glomeruli and in ≥ 50% of glomeruli with segmental or global lesions, with or without scarring	Variable proteinuria, celluria; often severe, decreasing function
V	Membranous	Global or segmental subendothelial immune deposits by light, immunofluorescence, or electron microscopy, with or without mesangial lesions	Marked proteinuria, slowly decreasing function
VI	Advanced sclerotic	≥ 90% of glomeruli globally sclerosed without residual activity	Variable proteinuria, decreased function

Table 7 Likely Renal Biopsy Findings According to Urinalysis and Serum Creatinine Results

Urinalysis		*Creatinine Level*	*Most Likely Pathology*
Protein	*Cells*		
None	None	Normal	Normal or mesangial
Little	WBCs	Normal	Mesangial, focal proliferative
Moderate	WBCs, RBCs	Normal	Mesangial, focal or diffuse proliferative
Moderate	WBCs, RBCs, casts	Normal or elevated	Focal or diffuse proliferative
Severe	WBCs, RBCs, casts	Normal or elevated	Diffuse proliferative, membranoproliferative
Severe	Few	Normal or elevated	Membranous
Moderate	WBCs	Normal or elevated	Interstitial (tubular) disease (in patients with acidosis or electrolyte abnormalities)

A or anti–SS-B antibody will develop a photosensitive rash or thrombocytopenia, both of which are transient. A very small number of these infants will develop complete congenital heart block in utero. Both the cardiac and the skin manifestations constitute the neonatal lupus syndrome. Either can be present independently. The syndrome appears to result from transplacental passage of maternal antibody, and it subsides when the antibody disappears. However, the heart block persists and may be lethal. The antibody likely targets transiently expressed antigens in the fetal conducting system; signals for apoptosis and fibrosis are upregulated.[50]

Antiphospholipid Antibody Syndrome

Between one third and one half of lupus patients have anticardiolipin antibody, lupus anticoagulant, or both. When either of these antibodies is present in high titer, patients are susceptible to recurrent thromboembolic disease, thrombocytopenia, livedo reticularis, and cardiac valvular disease. Women are susceptible to recurrent pregnancy loss. These symptoms, combined with positive blood tests, constitute the antiphospholipid syndrome (APS).[51] In the absence of lupus, the disorder is termed primary APS (PAPS); and when lupus or another rheumatic disease is present, the syndrome is designated secondary APS (SAPS). Current research suggests that the true antigen for the syndrome is the phospholipid binding protein, beta$_2$-glycoprotein I, rather than negatively charged phospholipids themselves. In some patients, antibody to an alternative phospholipid binding protein, such as prothrombin, induces the same syndrome. It is not known what induces clotting events in individual patients, but evidence of endothelial activation or injury, such as circulating endothelial cells, appears to be associated with thromboembolic episodes. The sites of thrombosis are not inflammatory and are best treated by anticoagulation rather than by immunosuppression. However, studies of pregnancy loss in animal models indicate that complement activation is a critical component of fetal injury, suggesting anew the possible involvement of the innate immune system in the development of APS.

LABORATORY TESTS

Tests of a variety of body fluids may be abnormal in patients with SLE [*see Table* 8]. Not all tests are abnormal in all patients. If lupus is suspected, an antinuclear antibody test, a complete blood count, and a urinalysis should be performed; if the results of these tests are all normal, SLE is excluded. However, because lupuslike illnesses are also usually suspected, it is often efficient also to obtain at first visit the following tests: erythrocyte sedimentation rate (ESR) or C-reactive protein level; assays for antibodies against dsDNA, Sm, RNP, SS-A, and SS-B; partial thromboplastin time (or other screening test for lupus anticoagulant) and cardiolipin antibodies; and a chemistry profile that includes liver function tests and serum creatinine level.

The antinuclear antibody (ANA) assay is a screening test for lupus. The ANA assay is almost always positive in high titer (> 1:80) in untreated patients with active disease, but a positive result does not by itself confirm a diagnosis of lupus. Only the anti-dsDNA antibody and anti-Sm antibodies, when present in high titer, are diagnostic of lupus. Anti-dsDNA antibody and complement levels are rough guides to disease activity, but many patients remain well for long periods of time with severely abnormal tests. Hypocomplementemia reflects proliferative lupus nephritis but not other aspects of SLE, including membranous lupus nephritis. The ESR remains elevated in many otherwise well SLE patients, as does the C-reactive protein level.

Brain Imaging Studies

Evaluation of neurologic involvement in SLE is complex. MRI scans, usually with contrast, are indicated for any clinical suspicion of central nervous system disease, such as seizures, cognitive dysfunction, new severe headache, chorea, or stroke symptoms. CT scans are far less definitive, except in stroke. Cerebral angiography or magnetic resonance angiography (MRA) is rarely helpful.

CT and MRI scans of the brain frequently demonstrate atrophy and infarcts (the latter including hyperintense areas in the white matter). These lesions correlate poorly with neurologic disease other than stroke syndromes.[13] Findings on fluorodeoxyglucose positron emission tomography (PET), magnetic resonance spectrography (MRS), and single-photon emission computed tomography (SPECT) are frequently abnormal even in asymptomatic patients and correlate poorly with all but the most severe neuropsychiatric disease.[52] Interpretation of abnormal findings in asymptomatic patients is uncertain.[53,54]

Vascular Evaluation

Vascular evaluation is indicated when there is clinical suspicion of medium-size vascular occlusion. Ultrasound, Doppler studies, angiography, and MRA can demonstrate thromboembolic disease from antiphospholipid antibody or atherosclerosis. The small vessel vasculitis that occurs in SLE is usually beyond the resolution of these technologies.

Table 8 Commonly Abnormal Tests on Body Fluids in SLE

Test	*Abnormality*	*Interpretation*
CBC	Normochromic anemia, leukopenia (WBC ~3,000, thrombocytopenia)	Active SLE
ESR and CRP	Elevated	Active SLE
Urinalysis	Proteinuria, hematuria, leukocyturia, cylindruria	Active lupus nephritis
Coombs and reticulocyte count	Positive, high	Hemolytic anemia
APTT, dRVVT	High	If confirmed with mixing test, lupus anticoagulant
Antinuclear antibody	Strongly positive	Positive in almost all patients during active disease; not specific for lupus
Anti-dsDNA antibody	Strongly positive	Positive in two thirds to three quarters of patients during active disease; diagnostic of lupus
Anti-Sm antibody	Positive	Positive in one quarter to one third of patients; diagnostic of lupus
Anti–SS-A, anti–SS-B, and anti-RNP antibodies	Positive	Positive in one third of patients; nonspecific
Anticardiolipin antibody	Positive	Antiphospholipid antibody syndrome
Complement C3, C4, and CH50	Low	Lupus nephritis likely; also hemolytic anemia and cryoglobulinemia
Cryoglobulin	Present	Active SLE
BUN and serum creatinine	Elevated	Severe lupus nephritis, drug toxicity
Liver function tests	Elevated	Drug toxicity (rarely, active SLE)
CSF protein and cells	Elevated	Present in a minority of patients with CNS SLE
Synovial fluid	WBC 5,000–10,000, normal glucose level	Lupus arthritis
Pleural fluid, pericardial fluid	WBC 5,000–10,000, normal glucose level, low complement, LE cells present	Lupus serositis

APTT—activated partial thromboplastin time BUN—blood urea nitrogen CBC—complete blood count CNS—central nervous system CRP—C-reactive protein CSF—cerebrospinal fluid dRVVT—dilute Russell viper venom time ESR—erythrocyte sedimentation rate WBC—white blood cells

Renal Evaluation

All lupus patients should have urinalyses performed, preferably at each clinic visit, because renal disease may appear de novo at any time. All patients with any abnormality on urinalysis or with an abnormal blood urea nitrogen (BUN) or serum creatinine level should have monitoring of 24-hour urine protein and creatinine clearance no less often than every 6 months. It is important to consider the results of renal testing in context: a serum creatinine level of 1.2 mg/dl may be within the laboratory range of normal, but in a 110 lb young woman, a level that high is very likely abnormal. Falling creatinine clearance always demands evaluation, even when the patient is clinically well.

Kidney biopsy The primary indication to perform a kidney biopsy is to help the physician make a treatment decision. Although abnormal biopsy results may be found in asymptomatic patients with normal urinalyses, it is not clear whether treatment of such patients improves outcome. The well patient with normal urinalysis results and normal renal function generally does not need a kidney biopsy, even if the anti-DNA antibody level is high and the complement level is low. The very ill patient with multisystem disease, including abnormal urinalysis results and abnormal renal function, likely will be treated aggressively anyway and does not need a kidney biopsy. The patient with mild systemic disease, mild urinary abnormalities, or both generally should undergo biopsy, because the decision for conservative or aggressive treatment may depend on the result. Occasionally, a biopsy is done to document end-stage, untreatable disease and thereby permit withdrawal of therapy. However, renal ultrasonography can usually provide the same information.

Cardiac Evaluation

Cardiac monitoring with echocardiography or stress tests is unnecessary on a routine basis. Because of the high frequency of accelerated atherosclerosis, however, any occurrence of dyspnea, dyspepsia, or shoulder or arm pain merits consideration of ischemic cardiac disease.

Differential Diagnosis

The differential diagnosis of lupus involves two linked questions: does the patient have a rheumatic disease, and if so, which one?

NONRHEUMATIC ILLNESSES THAT MIMIC SLE

The syndrome of fever, cytopenia, rash, and adenopathy suggests many infections, including HIV, cytomegalovirus, mononucleosis, and bacterial endocarditis. Acute polyarthritis, rash,

and cytopenias can result from many viral infections, such as hepatitis, parvovirus, and rubella. These syndromes resolve spontaneously within several weeks. This syndrome also suggests hematologic malignancies, primarily the lymphomas, leukemias, and myelodysplastic syndromes. Although the presence of antinuclear antibody is common in many of these illnesses, the presence of anti-DNA or anti-Sm antibodies is not; also uncommon are the specific rashes of lupus, nephritis, and vascular manifestations such as periungual telangiectasia and vasculitic papules. Photosensitivity and frontal alopecia are also characteristics of lupus that do not occur in these other illnesses.

Non-SLE causes of nephritis include poststreptococcal glomerulonephritis, Goodpasture disease, genetic nephropathies, and toxemia. The rash of rosacea is commonly mistaken for that of lupus. ITP or autoimmune hemolytic anemia may occur as isolated illnesses or as part of the multisystemic involvement of lupus. In these circumstances, full clinical and serologic evaluation for lupus will place the findings in proper context.

RHEUMATIC ILLNESSES THAT RESEMBLE SLE

Lupus may resemble a variety of other rheumatic diseases [*see Table 1*]. These include rheumatoid arthritis and Sjögren syndrome [*see 15:II Rheumatoid Arthritis*], as well as scleroderma [*see 15:V Scleroderma and Related Diseases*]. The polyarthritic presentation of lupus is very similar to that of rheumatoid arthritis, Lyme disease, and other rheumatic illnesses. Early scleroderma often presents with bilateral hand edema that is mistaken for polyarthritis.

Dermatomyositis [*see 15:VI Idiopathic Inflammatory Myopathies*] peaks in three age groups: 5 to 10 years of age, late teens and early 20s, and older than 45 years. The rash of dermatomyositis is similar to that of lupus, but they tend to involve the eyes differently: in dermatomyositis, telangiectasia causes the so-called heliotrope appearance of the eyelids; lupus rashes involve the eyebrows, but the malar rash stops abruptly at the orbits. Also, the rash in dermatomyositis commonly spares the ear canals, whereas the ear canals are commonly involved in lupus. Periungual telangiectasia is more dramatic in dermatomyositis than in lupus; it also occurs in scleroderma. Rash over the small joints of the hands suggests dermatomyositis; rash between the joints suggests lupus.

Compared with SLE, rheumatoid arthritis occurs in older persons (40 to 60 years of age) and has less of a female predominance (2:1 to 3:1). Although morning stiffness, fatigue, and weight loss are common in patients with rheumatoid arthritis, specific visceral multisystem disease is not. Leukocytosis rather than leukopenia is characteristic of rheumatoid arthritis. Renal disease is very rare, and when it does occur, it is attributable to tubular disease or amyloidosis rather than to glomerulonephritis. High fever does not occur in rheumatoid arthritis. From 10% to 20% of patients with rheumatoid arthritis have antinuclear antibodies; a small percentage have low-titer anti-DNA antibodies, and a minority have anti–SS-A and anti–SS-B antibodies. Complement levels are usually elevated. Rheumatoid factor is present in 80% of patients with rheumatoid arthritis, compared with its presence in 25% of lupus patients.

OVERLAP DISEASE

Some patients have symptoms suggestive of lupus (most commonly, arthritis, pleuritic pain, and cytopenia) but lack the specific diagnostic criteria for lupus (e.g., butterfly rash, glomerulonephritis, and high-titer anti-DNA or anti-Sm antibody). Other patients have lupuslike symptoms together with findings suggestive of rheumatoid arthritis, dermatomyositis, or scleroderma. Patients with no definable serology and a nondescript clinical picture are defined as having undifferentiated connective tissue disease (UCTD). Still other patients have inflammatory myositis, Raynaud phenomenon, and sclerodactyly together with very high titer antibodies to the ribonucleoprotein antigen (U1 RNP) and no anti-DNA or anti-Sm antibody. This set of findings is defined as mixed connective tissue disease (MCTD).

The differentiation of SLE from UCTD, MCTD, and Sjögren syndrome depends on the extent and pattern of different organ involvement (glomerulonephritis is rare in all these disorders except lupus) and on the accompanying serologic abnormalities. High-titer anti-DNA antibody or anti-Sm antibody generally indicates lupus; high-titer anti-RNP antibody with no other positive antibodies indicates MCTD; and anti–SS-A and anti–SS-B antibodies are consistent with Sjögren syndrome but occur in lupus and rheumatoid arthritis, as well. Occasionally, patients have characteristic rheumatoid destructive arthritis, subcutaneous nodules, and high-titer rheumatoid factor and anti-DNA antibody. These patients, as well as those with other overlap features, should be treated as if they have both diseases.

The prognosis in patients with UCTD tends to be more benign than that in patients with SLE. Patients with MCTD do not develop glomerulonephritis, but the long-term prognosis for patients with this disorder is worsened by the eventual development of pulmonary hypertension.

Treatment

ACUTE DISEASE

Management recommendations for the acute symptoms of lupus depend on the severity and organ systems involved. Non–life-threatening manifestations, such as minor arthritis, arthralgia, malaise, myalgias, serositis, and low-grade fever can often be controlled with full doses of NSAIDs. There is no specific preference among the NSAIDs, but lupus patients are unusually susceptible to hepatic and renal toxicities, which must be monitored. Also, in rare cases, lupus patients have developed abrupt high fever and meningitis after taking ibuprofen and similar drugs. Patients who do not respond to NSAIDs usually do respond to low doses (5 to 10 mg/day) of prednisone. As a rule, patients with inflammatory rashes, as well as patients anticipated to be on treatment for months or longer, should receive antimalarial therapy with hydroxychloroquine, 200 mg twice daily. Over a course of 3 months or more, hydroxychloroquine reduces arthralgia, myalgia, rash, fatigue, malaise, and similar symptoms.[55] Patients expected to take corticosteroids for more than a few weeks should strongly consider bone-protective measures (*see* Osteoporosis, *below*). Such patients should also consider the addition of a lipid-lowering agent, such as a statin, to the regimen. Facial rashes, especially erythematous lesions with edema or telangiectasia, may respond to topical therapy with corticosteroid creams.

Alopecia may recover spontaneously, but it is not otherwise easily amenable to therapy. Wigs and falls or hair extenders are useful. Skillful use of makeup can cover most pigment changes caused by discoid lupus.

Low-dose corticosteroid therapy may be appropriate for modest thrombocytopenia or anemia. Leukopenia does not usually require treatment. High-dose corticosteroid therapy (60 mg

of prednisone daily) is used for patients with severe systemic symptoms, renal disease, or other visceral disease that is potentially life threatening. Treatment should be initiated in split doses during the day, maintained for 4 to 6 weeks, and then tapered; too early reduction of dose usually results in recurrence of disease activity. If longer-term use of corticosteroids is anticipated, if vasculitis or life-threatening disease is present, or if corticosteroid toxicity is unacceptable, it is generally advisable to add immunosuppressive therapy. Immunosuppressive agents used for lupus include cyclophosphamide administered orally or intravenously, azathioprine, and mycophenolate mofetil. A standard regimen for active lupus nephritis includes a high-dose corticosteroid and intravenous cyclophosphamide. The cyclophosphamide is given at a dosage of 1 g/m^2 monthly for 6 months and then every 3 months for 2 years.

Acute cerebral symptoms (other than stroke) are usually treated with high-dose corticosteroids. Hallucinations and other psychotic symptoms respond to antipsychotic medications such as haloperidol, which is often administered in conjunction with corticosteroids. Because psychosis may also result from the use of a high-dose of a corticosteroid alone, withdrawal of corticosteroids may be necessary in some cases. The distinction between so-called steroid psychosis and lupus psychosis is quite difficult. No single set of criteria distinguishes between the two; evidence of ongoing active lupus in other organ systems is an indication to treat the patient for lupus psychosis. Acute lupus episodes are often treated with bolus doses of a corticosteroid (usually, 1,000 mg of methylprednisolone administered by rapid I.V. infusion [1 hr] once daily for 3 days). Very few formal studies support this practice, but clinical experience suggests its efficacy and relative safety. Bolus corticosteroid treatment may cause abrupt increases in blood pressure, acute vasospasm leading to stroke, cardiac infarct, or intestinal infarct. Transient oliguria and increased serum creatinine levels may also occur. To prevent these complications, bolus therapy should be monitored closely and withheld if hypertension is not controlled. Access to renal replacement therapy must be available in the event that the patient experiences diminished renal function.

Many new therapies are being investigated. These are largely biologic therapies and include the use of drugs directed against receptors of immune-activating cells or recognition cells and the use of modulators of immune response, such as CD154, CTLA-4, and anti-C5b. Removal of antibody by passing patient plasma over an absorptive column is also being studied. Tumor necrosis factor–α (TNF-α) inhibition, which was once thought to be dangerous for SLE patients, is under reconsideration. Attempts at hormone manipulation, as with dehydroepiandrosterone (DHEA), have had only modest success.

No single test informs the physician whether treatment for acute SLE is successful or not. Instead, it is necessary to monitor the entire clinical picture, including symptoms and results of physical examination, routine laboratory tests, and immune function studies.

INDICES OF DISEASE SEVERITY

Flare

Increase of inflammation in any SLE-affected organ system is known as flare. In a subpopulation of SLE patients, flare is a continuous, not a dichotomous, variable. In a given patient, it may occur in different organ systems at different rates and intensities; for instance, rash may become severe while nephritis remains stable. As a result, several different schemas for measuring flare exist. They differ in giving different weights to individual measures of disease activity (for instance, does new nephritis count more or less than new rash?) and whether serologic measures (antinuclear antibody titer, anti-DNA antibody, complement) do or do not count in the determination. The available indices—SLE Disease Activity Index (SLEDAI), Systemic Lupus Activity Measure (SLAM), and British Isles Lupus Assessment Group (BILAG)[56]—generally agree in identifying flare in populations of patients but often disagree in specifics. There is poor consensus about distinguishing between day-to-day variation of disease activity and a definite flare. Several components of the indices (e.g., quantitation of rash or of arthritis) are sufficiently subjective that investigators in clinical trials must undergo standardization training before they can validate their scores on individual patients.

Flare in pregnancy Proteinuria, thrombocytopenia, and other pregnancy events that occur in the absence of lupus invalidate most scoring systems for pregnant patients. A specific instrument, the SLE Pregnancy Disease Activity Index (SLEPDAI), has been devised for use in pregnant patients.[57]

Damage

Recurring inflammation and vascular occlusion induce irreversible scarring and such permanent deficits as stroke, cataract, skin thinning, osteoporosis, osteonecrosis, and renal failure. It is common practice, therefore, to score SLE patients according to their activity (flare) indices and their damage indices. The most widely used damage index is the Systemic Lupus International Collaborating Clinics (SLICC).[58]

SLE DURING PREGNANCY

Pregnancy in patients with SLE, once thought to be contraindicated, is now a routine event. The complications of pregnancy in these patients are related to three major issues: abnormal renal function, the presence of antiphospholipid antibody, and the presence of anti–SS-A and anti–SS-B antibody. It remains debatable whether lupus is exacerbated by pregnancy, but consensus now exists that pregnant SLE patients do not need prophylactic increases of corticosteroid therapy; rather, they should be treated in the same manner as patients who are not pregnant, except that drugs with fetal toxicity should not be given.

Renal disease, particularly renal insufficiency, strongly predisposes to toxemia of pregnancy. Hypertension, reduced creatinine clearance, and active SLE all threaten the viability of the fetus. Conversely, women who enter pregnancy with no renal disease and no hypertension usually do well. Recurrent pregnancy loss, particularly in the second trimester, is one of the prime clinical manifestations of the antiphospholipid antibody syndrome; for antiphospholipid antibody–positive patients, the peripartum period is one of high risk for thromboembolic disease. Women who have antibody to the SS-A or SS-B antigen are at risk of delivering children with the neonatal lupus syndrome.

CHRONIC DISEASE AND COMPLICATIONS

The major treatment issue for long-term lupus patients is the prevention or management of damage to the arteries, kidneys, bones, and brain rather than the control of immune response and inflammation. The physician must anticipate chronic effects of both the disease and its therapy.

During treatment with high-dose corticosteroids, with or without immunosuppressive agents, avoidance of infections is a

primary concern. Herpes zoster, tuberculosis, and a variety of bacterial infections are the primary threats. *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection is seen relatively infrequently; most rheumatologists do not routinely suggest prophylaxis against this organism. Complications of long-term corticosteroid therapy include osteoporosis (see below) and cataracts, cutaneous striae, cutaneous hemorrhage, diabetes, and oral and vaginal candidiasis. In patients with long-standing disease, these complications produce as much morbidity as the disease itself.

Antiphospholipid Antibody Syndrome

Treatment of antiphospholipid antibody syndrome is anticoagulation to an international normalized ratio (INR) of 2.0 to 3.0. Warfarin and low-dose aspirin are used to prevent thrombotic manifestations of the syndrome; heparin or low-molecular-weight heparin is used in pregnant patients.[59] Recent data suggest that the addition of statin drugs, to downregulate endothelial activation, may also be of benefit.[60]

Atherosclerosis

Early-onset, severe atherosclerosis is a common problem in patients with long-standing SLE. Atherosclerosis most commonly presents as coronary and cerebral artery occlusion; peripheral vascular occlusion also occurs. The cause is unknown, but chronic inflammation, corticosteroid therapy, uncontrolled hypertension, diabetes, smoking, and other factors have been implicated. Most specialists in this area recommend early and vigorous treatment of known risk factors in all lupus patients. The atherosclerosis of lupus is managed in the same manner as atherosclerosis in other situations, except that vascular interventions in patients with antiphospholipid antibody syndrome are hazardous.

Osteonecrosis

Although the mechanism of osteonecrosis is not clearly known, many authorities believe that a steroid-induced increase in the volume of lipocytes increases pressure in the bone marrow, cutting off blood flow to the vulnerable areas. Consequently, if osteonecrosis is recognized before the joint has collapsed (usually by bone scan or MRI), trephining the bone to reduce intraosseous pressure (so-called core decompression) has been recommended. However, the validity of this theory and the efficacy of the treatment remain unproved. Usually, joint replacement is eventually required.[61]

Osteoporosis

Osteoporosis follows long-term corticosteroid therapy with sufficient frequency that all patients receiving such therapy should receive prophylaxis for this complication. High-dose oral calcium (i.e., 1,500 mg daily), vitamin D, a bisphosphonate drug, and parathyroid hormone are the primary preventive measures; estrogen replacement may be considered in postmenopausal women who do not have antiphospholipid antibody. Weight-bearing exercise should be encouraged. Other prophylactic measures, including calcitonin and parathyroid hormone, may be appropriate. Because lupus patients are photosensitive, increased sun exposure to prevent osteoporosis is unwise. Bisphosphonates should not be used in women anticipating pregnancy.

Cardiac Disease

Inflammatory cardiomyopathy responds to corticosteroids; ischemic cardiomyopathy does not. Valvular insufficiencies and thromboemboli are late complications of lupus cardiac disease. Bacterial endocarditis rarely complicates this abnormality. Valvulitis generally does not respond to treatment, although it has been reported that acute valvulitis will respond to corticosteroid therapy.[62] Small numbers of patients require valve replacement, usually of the aortic or mitral valve. The mechanism of valvulopathy in SLE is unknown, as are methods of prevention.

PALLIATIVE CARE

A common mistake in the treatment of SLE is to assume that a given complaint reflects ongoing inflammatory disease, rather than irreversible damage, and that it can be controlled with anti-inflammatory and immunosuppressive therapy rather than with palliation. Examples of such symptoms include seizures, dementia, and other neurologic syndromes associated with brain infarcts; cutaneous ulcers caused by long-standing vascular insufficiency; embolic phenomena from atherosclerosis; respiratory insufficiency from pulmonary fibrosis or pulmonary hypertension; arthritis from osteonecrosis, erosive rheumatoid-like arthritis, or tendinosis; and progressive renal insufficiency from arteriolonephrosclerosis, interstitial fibrosis, or glomerulosclerosis.

Dementia

Chronic neurologic disease, often in the form of dementia, is a long-term sequela of SLE. Some causes are stroke (atherosclerotic, hypertensive, or thrombotic associated with antiphospholipid antibody), autoantibody attack on specific brain targets, small vessel occlusive disease, and drugs. Occasionally, patients are severely disabled. No effective prophylaxis is known.

Renal Failure

Patients with renal disease often need angiotensin-converting enzyme inhibitors for proteinuria, antihypertensives for hypertension, erythropoietin for anemia, and diuretics for edema. Renal failure in lupus occurs in three modes. In the first, acute inflammatory nephritis is characterized by distinctly abnormal urinalyses and clinically and serologically evident disease activity. Patients with this type of renal picture have rapidly rising serum creatinine levels and enter renal failure early after diagnosis. If treated aggressively, with high-dose corticosteroids and immunosuppressive drugs, renal failure will be reversible in approximately one third of these patients.[63] In the second mode of renal failure, which occurs only occasionally, patients will have renal failure from drug toxicity—usually NSAIDs—or acute tubular necrosis. Other manifestations of SLE are modified in uremia: rash is less prominent; and fever, cachexia, mucosal ulcers, and cytopenias are more prominent.

In the third mode, which is the most common, lupus patients enter renal failure slowly after many years of disease. Characteristically, at the time renal failure first appears, the patient has little systemic illness and has had months to years of modest renal insufficiency (with creatinine clearance at 10 to 30 ml/min and serum creatinine below 3.5 mg/dl), slowly rising serum creatinine levels, relatively noninflammatory urinary sediments, and progressive anemia. Then, over a few months, the patient develops hypertension and fluid retention with or without cardiac failure. Abdominal pain is frequently present. Ultrasound shows small, fibrotic kidneys or thin, scarred renal cortices. Renal failure is only transiently reversible in such patients. Aggressive immunosuppressive therapy is not helpful at this stage; on the contrary, it may hasten renal deterioration and will complicate initiation of dialysis.

Less commonly, renal failure is caused by antiphospholipid antibody-associated thrombotic microangiopathy. In these cases, the presentation comprises modest proteinuria with bland urine sediment and slowly rising serum creatinine levels, often with moderate hypertension. Lupus vasculitis involving the kidneys tends to be abrupt in onset, with severely abnormal urinalyses, severe hypertension, and rapidly progressive renal failure. This complication is treated with high-dose corticosteroids and immunosuppression. However, full recovery is uncommon.

Lupus patients, particularly those who enter renal failure slowly, tolerate dialysis and renal transplantation well. However, preexisting cardiac, cerebral, and osteoarticular damage may be limiting factors. Patients who enter renal failure acutely often have other active systemic disease, with seizures and cytopenias being the most common. The common belief that lupus becomes inactive in renal failure is likely not true. Rather, in the majority of patients who enter dialysis, the lupus was already inactive systemically and remains so; probably, the renal failure results not from continuing disease but from progressive scarring. In the minority of patients who enter renal failure during an acute systemic flare, usually early in the course of the illness, active systemic disease tends to continue, and it represents a relative contraindication to renal transplantation. Patients on dialysis who have active SLE usually have high anti-DNA antibody levels and low complement levels. They respond to corticosteroid therapy, usually at lower doses than patients who are not on dialysis.

Prognosis

Prognosis in SLE has four elements: immediate prognosis for life, immediate prognosis for individual organ systems, and long-term prognosis for organ systems and for life.

During the early phases of lupus, complete reversal of almost all manifestations (i.e., rash, arthritis, fever, cytopenias, and nephritis) with aggressive therapy is expected. Exceptions include the scarring discoid rash, brain or spinal cord infarcts, and severe nephritis or nephrosis. In rare cases (< 5%), patients have such severe disease that despite treatment, they rapidly progress to death within 2 years. Because most newly diagnosed patients respond to therapy, 5-year survival is 80% to 90%, 10-year survival is 70% to 90%, and 20-year survival is nearly 70%.[6] Determinants of survival are age, renal disease, and race, with African Americans having lower overall survival than whites.[64]

One organ system (e.g., kidneys or platelets) may fail to respond completely to treatment but not directly threaten the patient's life. Such patients may be monitored without intervention. A patient may develop chronic renal insufficiency (e.g., serum creatinine, 3.0 mg/dl) or have persistent thrombocytopenia (platelet count, 30,000/mm^3) and be considered to be in remission and in no need of treatment.

Long-term prognosis is a function of organ damage from either SLE or its treatment. Pulmonary fibrosis and pulmonary hypertension respond poorly to therapy, although new protocols, such as bosentan or infusion of prostacyclin, may be useful for pulmonary hypertension. Patients with cardiopulmonary failure who have no other system disease limitations are candidates for heart and lung transplantation. Lupus patients with renal failure are candidates for dialysis and for renal transplantation.

V SCLERODERMA AND RELATED DISEASES

George Moxley, m.d.

Scleroderma

definition and classification

Scleroderma, or systemic sclerosis, is a rare, slowly progressive rheumatic disease characterized by deposition of fibrous connective tissue in the skin and other tissues. It is accompanied by vascular lesions, especially in the skin, lungs, and kidneys. No cure is known.

Scleroderma may be either systemic or localized, with the systemic illness being either diffuse or limited. The limited form of systemic scleroderma, or CREST syndrome (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasias), involves internal organs less often than diffuse scleroderma. Except when pulmonary hypertension is present, patients with the limited form have a better prognosis than those with the diffuse form [*see Table 1*]. Systemic scleroderma can be fatal.

Localized scleroderma is confined to the skin, subcutaneous tissue, and muscle and is not accompanied by the Raynaud phenomenon, acrosclerosis, or visceral involvement. There are two forms of localized scleroderma: morphea, which presents as variable-sized plaques of skin induration, and linear, which presents as bands of skin induration on the face or a single extremity. Linear scleroderma may be associated with muscle atrophy and involvement of the underlying bone. It usually afflicts children or young adults and may lead to significant growth impairment of the involved part. In the morphea version, the lesions may persist for months or years, after which improvement may occur [*see Table 1*]. Although there is a possibility of disfigurement, localized scleroderma is not a severe illness, and patients with the disease generally have a normal life span.

epidemiology

The Raynaud phenomenon is associated with scleroderma [*see* Diagnosis, Clinical Manifestations, *below*]. Primary Raynaud phenomenon (Raynaud phenomenon without underlying illness) is quite common, with up to 30% of young women having episodes. A meta-analysis showed that the transition rate to a defined inflammatory rheumatic disease (e.g., scleroderma or lupus) is 3.2 per 100 patient-years of observation; the eventual development of an inflammatory rheumatic disease occurred in 12.6% of individuals. The best predictor of development of inflammatory disease is an abnormal nailfold capillary pattern, which has a predictive value of 47%; a positive antinuclear antibody test has a predictive value of 30%.[1] Racial, genetic, and environmental factors have been proposed as influences of scleroderma risk and disease pattern.[2]

The overall global incidence of scleroderma is approximately 17 to 19 per one million population per year, with higher rates for women than for men. African Americans experience diffuse scleroderma more often than other ethnic groups; whites are more often diagnosed with the CREST variant.[3] The prevalence in the United States is approximately 24 per 100,000 population[3]—fourfold to ninefold the prevalence in other countries. Mortality factors include diffuse disease, older age at onset, and internal organ involvement, particularly pulmonary and renal involvement. Some investigators have suggested that scleroderma is associated with various environmental exposures.[4] For example, workers exposed to polyvinylchloride may experience the Raynaud phenomenon and scleroderma-like skin thickening.[5] However, no substance has yet been convincingly linked with scleroderma.[5] Silicone breast implants have not been found to be associated with scleroderma.[6]

etiology

The etiology of scleroderma is largely unknown. The disease shows familial aggregation consistent with a genetic component, and family history is the strongest risk factor.[3] In the United States, about 1.6% of relatives are affected, an over 60-fold higher prevalence than in the general population (0.026%).[3] One etiologic factor may be a fibrillin defect. Fibrillin is a macromolecule that is a component of elastic fibers, and it is defective in Marfan syndrome. In an animal model (the tight-skin mouse, *tsk1*), a scleroderma-like condition is caused by an insertion into the fibrillin gene that apparently encodes a latent binding region for the transforming growth factor–β (TGF-β) cytokine. One proposed explanation is that the abnormal fibrillin binds an increased number of fibroblast growth factors that influence nearby fibroblasts. The current knowledge extends to Japanese and Oklahoma Choctaw scleroderma patients, who likely have a scleroderma-related genetic defect (e.g., secreted protein acidic and rich in cystein [SPARC]) in the fibrillin chromosomal region either in or near the gene.[7] However, other genes (e.g., *IL-1A, TGF-β,* and *IL-4*) or environmental exposures may also be involved.

pathophysiology and pathogenesis

The common pathologic features of tissues with scleroderma involvement are progressive fibrosis, vascular abnormalities, and inflammation. Fibrosis involves an accumulation of excessive collagen and other extracellular matrix constituents, such as glycosaminoglycans and fibronectin. The vascular abnormalities are intimal hyperplasia with collagen deposition and adventitial fibrosis, capillary dropout, dilatation, tortuosity, and fibrotic atherosclerosis. The inflammatory changes may include cellular infiltration. These pathologic characteristics are believed to be the result of three or more interacting components: autoimmunity, an endothelial abnormality, and a skin fibroblast lesion. An alternative explanation is that these characteristics are the result of a disease process akin to graft versus host disease (GVHD).

Table 1 Classification of Scleroderma

Form	*Syndrome*
Scleroderma (systemic sclerosis)	Diffuse skin involvement Limited skin involvement (CREST syndrome) Overlapping features of mixed connective tissue disease
Localized scleroderma	Morphea: single or multiple plaques or generalized lesions Linear scleroderma

CREST—calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasias

Immune Cell and Cytokine Abnormalities

Activated thymus-derived lymphocytes predominate among the cells that infiltrate involved tissues; activated inflammatory cells are also present. Such immune and inflammatory cells release a plethora of cytokines and soluble mediators. Of particular note are cytokines influencing fibroblast function: interleukin-1 (IL-1), IL-4, IL-6, IL-8, RANTES (regulated upon activation, normal T cell expressed and secreted), tumor necrosis factor (TNF), and TGF-β. TNF and interferon gamma are antifibrotic,[8] but the action of TGF-β results in a pattern of tissue damage similar to the pattern seen in scleroderma. TGF-β stimulates fibroblasts and vascular smooth muscle cells to make collagen, and it stimulates endothelial cells to make endothelin-1, which, in turn, causes vasoconstriction and collagen production. B cells are also activated in patients with scleroderma, and some autoantibodies are relatively specific for scleroderma. Whether such humoral responses result in scleroderma tissue damage is under investigation.

Fibroblast Abnormalities

As with lymphocytes and macrophages showing activation in scleroderma, fibroblasts are also metabolically activated. Such activated cells overproduce collagen, other extracellular matrix molecules, and cellular adhesion molecules.[9] The reasons why collagen gene expression is increased and sustained have not been fully explained. One possible explanation is that the presence of cytokines such as IL-4 and TGF-β strongly foster collagen production.[8] TGF-β acts in large part through specific receptors that lead to activation of Smads, a family of second messenger/transcription factor proteins.[10] Some genetic studies have supported the proposition that scleroderma is associated with TGF-β markers.[11]

Vascular Abnormalities

Vessels in involved tissues show disrupted pattern and function, characterized by altered endothelial permeability, adhesion of platelets and leukocytes to endothelium, and the presence of inflammatory cells. One current pathogenetic theory is that endothelial homeostasis is disrupted, leading to increased endothelin-1 production, reduced prostacyclin release, and enhanced coagulation.[12] Endothelial cells express increased numbers of adhesion molecules necessary for inflammatory cell adhesion and extravasation. Capillaries become obliterated but are not replaced; involved tissues may become ischemic and then reperfused. The Raynaud phenomenon [*see* Diagnosis, Clinical Manifestations, *below*] is a hallmark vascular lesion that likely represents an exaggerated response of a stiff vessel wall to a typical environmental exposure. Microscopic analysis of the nailfolds of patients with scleroderma and Raynaud phenomenon reveals capillary disappearance and dilatation. In scleroderma, small arteries develop concentric intimal fibrosis and thus become narrow; this narrowing in turn greatly increases the vascular reactivity to alpha$_2$-adrenergic agents.

Chimerism and Microchimerism

Chimerism denotes a state in which a person has cells derived from two or more other people. Male DNA consistent with microchimerism has been found more frequently and in higher concentrations in the circulation of women with scleroderma who have had a previous male delivery than in women without scleroderma who have also had a male delivery. In addition, microchimerism has been found in tissues of mothers with scleroderma but not in the tissues of healthy mothers.[13] However, cause and effect are not yet established,[14] and parous women are reported to have a reduced scleroderma risk (odds ratio, 0.3).[15]

Figure 1 **Severe involvement of the hands in a patient with long-standing scleroderma includes flexion contractures of the fingers related to fibrosis of the skin and of subcutaneous tissues. Increased pigmentation has occurred, and melanin loss (vitiligo) is evident in some areas. The distal aspects of the terminal phalanges in some fingers have undergone resorption or shortening. This process, termed autoamputation, usually occurs without ulceration of the terminal digit; the mechanism is unknown.**

DIAGNOSIS

Clinical Manifestations

Skin The first signs of scleroderma in the skin are swelling and thickening of the fingers and hands, with or without involvement of the face; later in the illness, other areas of skin may become thickened. Involvement of the trunk and arms proximal to the elbows is associated with visceral involvement and a poorer prognosis. The skin continues to thicken during the first 2 to 3 years after the onset of disease; the thickening then ceases and may recede, giving the impression that the skin is softening. In subsequent years, skin atrophy occurs, with con-

Figure 2 **Telangiectasias appear on the hands, face, and tongue in a patient with the CREST (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasias) variant of scleroderma. Thumbs are bandaged because of chronic ulcerations associated with the Raynaud phenomenon.**

Figure 3 **In scleroderma, extensive calcinosis (hydroxyapatite crystal deposition) may be found in connective tissues and around joints. If extensive, calcinosis is usually associated with at least partial loss of joint motion.**

comitant loss of hair, sebaceous glands, and sweat glands, as well as a loss of pliability. In addition, the skin becomes hidebound—tightly drawn and bound to underlying structures.

Skin involvement is often most prominent in the hands and fingers (sclerodactyly); frequently, the face is also affected. A tightening of facial skin results in decreased skin lines, a pursed appearance, and a diminution in the oral aperture. The skin tightness may limit mobility, especially in the fingers. Flexion contractures may also develop in the fingers [*see Figure 1*]. Several other skin abnormalities may accompany these changes. Telangiectasias occur frequently and may be numerous [*see Figure 2*]. They are often most prominent on the face, hands, and oral mucosa. Calcinosis—the deposition of hydroxyapatite crystals in subcutaneous areas—may be limited or widespread and is usually located around joint capsules [*see Figure 3*]. Skin ulceration over calcific deposits may lead to drainage of a white material with a consistency resembling toothpaste. A diffuse increase in melanotic pigmentation may extend over the entire skin surface; areas of hypopigmentation are also commonly seen.

The Raynaud phenomenon is an episodic manifestation of numbness or pain accompanied by a two- or three-phase color change in the digits; these changes are triggered by cold temperatures or emotional stress and are relieved by warming the involved part. In severe cases, however, the relation to ambient temperature is sometimes less obvious. The episode typically begins with pallor, followed by cyanosis and, finally, by redness caused by reactive hyperemia [*see Figure 4*]. Prolonged ischemia may lead to painful digits, ulceration, and even gangrene. Almost all patients (95%) with diffuse or limited scleroderma experience the Raynaud phenomenon. The Raynaud phenomenon is also seen in patients with other disorders, including other autoimmune diseases such as systemic lupus erythematosus (SLE), polymyositis, and several forms of vasculitis; in patients who are receiving certain drugs, such as bleomycin, ergot derivatives, beta blockers, and methysergide; and after occupational exposure to vinyl chloride, cold temperatures, and vibrating tools.

In scleroderma, the Raynaud phenomenon is a manifestation of vasculopathy involving small arteries and capillaries; it occurs not only in the extremities but also in some involved viscera, such as the lungs and kidneys. Patients with scleroderma and the Raynaud phenomenon have characteristic capillary changes on nailfold microscopy. Nailfold microscopy consists of observation of the capillary structure of the periungual tissues with a handheld magnifying lens, such as that used in a standard ophthalmoscope. Patients with underlying scleroderma may exhibit loss of some capillaries and dilatation of capillaries in other nailfold areas. Such changes often occur in asso-

Figure 4 **Vascular pathology usually manifests itself as the Raynaud phenomenon in patients with scleroderma. The cyanotic phase of the Raynaud phenomenon often involves the distal two thirds of the second and third fingers of both hands.**

Table 2 Antinuclear Antibodies in Scleroderma

Immunofluorescent Pattern of Antinuclear Antibody Staining	*Antigens*	*Clinical Pattern*	*Approximate Frequency (%)*	*Specificity*
Nucleolar	Nuclear ribonucleoproteins (nRNPs)	Diffuse or limited scleroderma	50	Moderate
	RNA polymerases I, II, and III	Diffuse scleroderma	23	High
	Nuclear proteins PM-1 (PM-Scl) and Ku	Scleroderma-polymyositis overlap	< 5	High, for scleroderma and polymyositis
Centromeric (large speckles)*	Centromere proteins (CENP-A, CENP-B, and CENP-C)	Usually in limited scleroderma (CREST syndrome)	50 (of patients with CREST syndrome)	High
Diffuse (fine speckles)	Topoisomerase I (Scl-70)	Diffuse scleroderma	20–33	High
Homogeneous	Histones (mainly H1 and H3)	Localized scleroderma	50	Moderate

*Requires a human epithelial carcinoma cell line (HEp-2).

ciation with internal organ involvement and may be used to predict the development of diffuse scleroderma when visceral involvement is not clinically apparent.

Proposed criteria for early diagnosis of scleroderma include either objective observation or measurement of cold-induced vasospasm, plus either abnormal nailfold microscopy, presence of antibodies directed toward characteristic autoantigens [*see Table 2*],[16] or patient reports of Raynaud phenomenon and the presence of nailfold microscopic changes and autoantibodies.

Musculoskeletal system A mild, usually symmetrical, inflammatory arthritis can occur in scleroderma. Juxta-articular bone erosions occur frequently, especially in the distal interphalangeal joints, but the degree of destruction is usually less than that seen in rheumatoid arthritis. Flexion contractures of the fingers often develop and are most likely related to fibrosis

Figure 5 **Over an 8-year period, radiographs taken of the hand of a patient with scleroderma demonstrate a progressive, terminal resorption of the digits. The earlier film (left) shows a loss of the spherical terminal portion of the distal phalanx of the thumb and a small, dense calcific deposit at the terminal aspect of the thumb. After an 8-year period, dramatic changes can be seen (right). An almost complete loss of the terminal phalanx of the thumb and a partial loss of the distal phalanges of the remaining fingers are observed. In addition, the entire distal phalanx of the third finger is lost along with part of the middle phalanx. Loss of the middle phalanx is less common than loss of the distal phalanges. A generalized osteopenia is present in the later stage, which is probably related to osteoporosis of disuse, and a calcific deposit has formed in the ulnar aspect of the wrist. The apparent narrowing of interphalangeal joint spaces may be associated with flexion contractures of the fingers, which are caused by the fibrous thickening of the connective tissues of the hand.**

of the tendons and joint capsules. Crepitus and friction rubs, detected by palpation or auscultation over tendons and bursas, are characteristic findings related to fibrotic changes of underlying tissues. Another skeletal complication is acral osteolysis, which is the resorption of the terminal phalanges and surrounding soft tissue with consequent shortening of the digits [*see Figure 5*]. It may occur without infection or ulceration. Patients with scleroderma may have one or more of a variety of muscle disorders,[17] such as fatigue without objective evidence of muscle damage, a simple myopathy, or clear-cut inflammatory myositis.

GI tract Almost every part of the GI tract may be involved in scleroderma.[18] Sjögren syndrome, which causes dry eyes and dry mouth, occurs in about one third of patients with scleroderma. Esophageal hypomotility, which is demonstrated by cinefluoroscopic examination and manometric studies, occurs in more than 90% of patients with scleroderma, many of whom are asymptomatic [*see Figure 6*]. The absence of normal peristaltic waves in the lower two thirds of the esophagus may cause dysphagia; incompetence of the gastroesophageal sphincter leads to reflux esophagitis and sometimes may result in esophageal stricture. Barrett esophagus, esophageal carcinoma, and candidal esophagitis may ensue. Similarly, hypomotility of the stomach, small intestine, colon, and anorectal area may occur, possibly causing gastroparesis, pseudo-obstruction, colonic impaction, or impaired anorectal function. Telangiectasias may be present in the gastric mucosa and the mucosa of the small intestine and colon. Gas may dissect into the intestinal wall (pneumatosis intestinalis) and leak into the peritoneal cavity, simulating a perforated viscus. Characteristic wide-mouthed diverticula of the colon may develop; these are pathognomonic of scleroderma. The early lesions of the GI tract may be caused by autonomic nerve dysfunction; autonomic nerve dysfunction may in time lead to smooth muscle atrophy and irreversible muscle fibrosis of the gut. Primary biliary cirrhosis and drug-induced hepatitis may also be associated with scleroderma.

Figure 6 **Hypomotility of the esophagus in scleroderma, which is demonstrated by the lack of peristaltic waves in the barium column, is frequently an asymptomatic finding, but it may be associated with dysphagia and incompetence of the gastric sphincter, which results in reflux esophagitis.**

Lungs Pulmonary involvement represents an important cause of scleroderma-related morbidity and mortality[19]; lung disease is the most frequent cause of scleroderma-related death. Although scleroderma-related findings may range from associated malignancy and silicosis to calcinosis and hemorrhage, the most common findings are pulmonary vascular disease and interstitial inflammation and fibrosis. Isolated pulmonary hypertension is typically found in the CREST syndrome (prevalence is 50% to 65% in the limited cutaneous subset and up to 35% in the diffuse subset)[20]; interstitial pulmonary fibrosis may be found in both limited and diffuse scleroderma (at postmortem examination, the frequency is about 75%).

Isolated pulmonary hypertension usually results in cough, dyspnea, and syncope; it has a severe prognostic outlook (5-year survival < 10%). Pulmonary hypertension is defined by a resting mean pulmonary arterial pressure greater than 25 mm Hg or an exercise-induced mean pulmonary arterial pressure greater than 30 mm Hg; in addition, pulmonary hypertension is often associated with abnormal diffusing capacity for carbon monoxide. In persons with limited cutaneous involvement, decreasing diffusing capacity of the lung for carbon monoxide (D_{LCO}) is an excellent predictor of subsequent pulmonary hypertension; one study of 106 patients reported that at baseline, patients who subsequently developed pulmonary hypertension had a mean pulmonary arterial pressure only slightly higher than patients who did not, but the D_{LCO} in patients with pulmonary hypertension declined from a mean of 80% to a mean of 35%. The early clinical features associated with subsequent pulmonary hypertension included more severe Raynaud phenomenon and digital tip ulcers, as well as positivity for serum autoantibodies directed toward nucleoli.[21]

Interstitial fibrosis is typically accompanied by dyspnea and cough, and the 5-year survival is about 45%. Although chest roentgenograms may show linear and reticular abnormalities, high-resolution CT scanning is favored for the detection of early disease; on CT scans, alveolitis appears as patchy areas with a ground-glass appearance. Interstitial fibrosis appears to result from inflammatory alveolitis: the release of various cytokines and chemokines in the course of the inflammatory process results in fibroblast activation and extracellular matrix remodeling. Association between severe esophageal involvement and interstitial fibrosis suggests that gastroesophageal reflux may contribute to fibrotic changes.[22]

Heart Patients with clinically evident scleroderma-related heart disease have a poor prognosis.[23] The myocardium is

involved in approximately 20% to 25% of clinical cases of systemic scleroderma. Scleroderma-associated myocardial disease is typically characterized by patchy areas of myocardial fibrosis replacing normal muscle; this may cause hypertrophy and diminished cardiac output, particularly with exercise. Diastolic dysfunction[24] and atherosclerotic coronary artery disease are common. Myocardial infarctions may develop in patients with scleroderma who have normal findings on coronary artery catheterization. Myocarditis may also occur in patients with scleroderma-associated inflammatory myositis. The patchy myocardial fibrosis and conduction system involvement may result in various arrhythmias and sudden death. Pericardial disease is common at autopsy, but clinically evident pericardial manifestations occur in only 5% to 16% of cases. Such pericardial disease may cause acute pericarditis, arrhythmias, pericardial effusions, or sudden death. In limited cutaneous scleroderma, apart from a similar frequency of cardiac arrhythmias and conduction defects, heart involvement is generally less frequent and less severe than in diffuse scleroderma.

Kidneys Chronic mild proteinuria and mild hypertension are common effects of scleroderma but typically do not result in significant renal dysfunction. The most significant disease process associated with scleroderma is renal crisis,[25] which consists of the rapid development of malignant hypertension, hyperreninemia, microangiopathic hemolytic anemia, and oliguric renal failure. Renal crisis typically occurs in the scleroderma subset characterized by rapidly progressive diffuse skin disease. Renal crisis was formerly the most common cause of death in patients with scleroderma, but aggressive treatment with angiotensin-converting enzyme (ACE) inhibitors early in the course of disease has greatly improved outcome.

Other organ systems Although scleroderma rarely involves the central nervous system, peripheral neuropathy may occur. The most frequent form is unilateral or bilateral trigeminal neuropathy of one or more of the three trigeminal branches; this neuropathy presents as progressive numbness and pain. Widespread autonomic nervous system dysfunction underlies the propensity for the Raynaud phenomenon and intestinal involvement. Hematopoietic consequences of scleroderma are uncommon.

Laboratory Findings

More than 85% of patients with scleroderma have positive test results for antinuclear antibodies[26] [*see Table 2*]. Antibodies to certain nuclear antigens are specific for scleroderma,[27] and each type of antibody is associated with a particular clinical pattern of disease. Antibodies to Scl-70 and to RNA polymerases (usually RNA polymerase III) are seen in patients with systemic scleroderma. In a meta-analysis, anti–Scl-70 antibodies had a positive predictive value of 70% for diffuse cutaneous scleroderma.[28] Anticentromere antibodies are associated with limited scleroderma (the CREST syndrome); the meta-analysis indicated a positive predictive value of 88% for limited cutaneous scleroderma.[28] Antibodies to nuclear ribonucleoprotein (nRNP) are associated with diffuse and limited scleroderma. Antibodies to PM-1 and Ku are infrequent. The presence of these antibodies is usually associated with overlapping clinical features of polymyositis and scleroderma. About 50% of patients with localized scleroderma have antibodies to histones [*see Table 2*].

MANAGEMENT

Management of scleroderma is often a severe challenge,[29] but it includes several potentially lifesaving interventions. Close attention to detecting renal and pulmonary involvement will typically improve eventual outcomes.

Renal Crisis

Renal crisis is a serious scleroderma-related manifestation that is manageable with appropriate therapy. Onset typically is within the first 2 years of the disease course and is more common in diffuse scleroderma than in the limited form of the disease[30]; renal crisis occurs in about 15% of patients with diffuse scleroderma. A clinician should instruct patients with early diffuse scleroderma about daily blood pressure monitoring and initiate antihypertensive therapy if the patient's blood pressure exceeds 130/80 mm Hg. Renal crisis is recognized by diminished renal function with new-onset hypertension (even of modest degree), microscopic hematuria, and proteinuria. Treatment of this medical emergency with ACE inhibitors and other potent antihypertensive drugs appears to arrest the deterioration in renal function. Even in patients who initially require dialysis, ACE inhibitors may restore renal function enough to make dialysis unnecessary.[31] However, this therapy has been shown to be more beneficial when initiated before serum creatinine levels have exceeded 3 mg/dl. In some patients, renal failure progresses despite good control of blood pressure, necessitating dialysis and possibly renal transplantation. Despite reduced frequency with ACE inhibitor therapy and availability of dialysis, renal crisis is associated with poor survival rates.[32]

Pulmonary Involvement

A clinician should be able to detect pulmonary involvement through yearly or twice-yearly pulmonary arterial pressure estimates (from echocardiograms) and measurements of forced vital capacity, carbon monoxide diffusing capacity, and exercise arterial blood gas levels. Patients with pulmonary function abnormalities may then be evaluated with bronchoalveolar lavage, where available, and high-resolution CT to detect the extent of lower respiratory inflammation. Progression is more likely to occur in patients with more extensive lung disease and patients who are positive for anti-Scl-70 antibodies. In diffuse scleroderma, meticulous assessment is warranted, particularly in the first 5 years after onset.[33] In patients with early fibrosing alveolitis, progression of pulmonary fibrosis may be halted by long-term therapy with cyclophosphamide and low-dose prednisone (< 10 mg/day), but this measure is not yet supported by a randomized, controlled trial.[19,33] Cyclophosphamide therapy is a powerful immunosuppressive medication; its use is sometimes associated with adverse events such as bacterial infections, herpes zoster, varicella-zoster virus infection, interstitial cystitis, and malignancies such as bladder transitional cell carcinoma. Often, intravenous cyclophosphamide is effective and somewhat less toxic than oral regimens.[33]

Pulmonary hypertension may be a particularly serious manifestation of scleroderma. In patients with suspected pulmonary arterial hypertension, on the basis of physiologic findings and serial echocardiographic examinations, a right heart catheter measurement of pulmonary arterial pressure should be obtained. Individuals with pulmonary arterial hypertension should receive influenza and pneumococcal immunizations and be counseled regarding cigarette smoking and other im-

portant exposures. When hypoxemia is present, supplemental oxygen is appropriate.

If serious pulmonary hypertension occurs, the patient should be referred to a specialist for this condition. Referral is important because current therapy is rapidly evolving, the medications used are not part of the usual formulary, and the specialist's experience will lead to reduced risk of complication and toxicity. Internet resources may prove useful in identifying local specialists and support programs available to scleroderma patients [*see Sidebar* Internet Resources for Information on Scleroderma].

The therapeutic measures employed for pulmonary arterial hypertension include the use of calcium channel blockers, anticoagulation, prostaglandin medications, phosphodiesterase V inhibitors such as sildenafil, and endothelin receptor antagonists such as bosentan. In a small fraction of patients, high-dose calcium channel blockers will reduce pulmonary arterial pressure and vascular resistance without causing serious adverse effects such as hypotension[34]; in this subset of patients, it is necessary to administer a diuretic to reduce risk of right-sided heart failure. Warfarin therapy (achieving an international normalized ratio of 2.0 to 2.5) increases survival.[34]

Various prostaglandins are helpful for therapy of pulmonary artery hypertension. The currently available prostaglandins include continuous intravenous epoprostanol (2 ng/kg/min) and continuous subcutaneous treprostinil (1.25 ng/kg/min); other oral and inhaled prostaglandins are under study. Epoprostanol has been shown to prolong life and decrease symptoms and improve hemodynamics[35-37]; however, it is exacting in terms of discomfort and disability. Subcutaneous treprostinil therapy is more convenient and improves symptoms and exercise capacity but is sometimes associated with infusion-site pain.[38] Oral sildenafil appears to improve gas exchange[39] and may act synergistically when administered with an inhaled prostaglandin (e.g., iloprost).[40] The most dramatic therapeutic development has been bosentan, an orally administered endothelin-1 antagonist (125 mg twice daily). Bosentan therapy leads to improved exercise capacity, decreased symptoms, and improved hemodynamic effects, but hepatotoxicity is a concern.[41] However, the most beneficial therapies for severe pulmonary arterial hypertension are costly (annual cost of bosentan, $36,000; epoprostanol, $72,000; and treprostinil, $93,000).

Internet Resources for Information on Scleroderma*

National Institute of Arthritis and Musculoskeletal and Skin Diseases Information Clearinghouse
http://www.niams.nih.gov
This clearinghouse provides information about various forms of arthritis and rheumatic diseases, distributes patient and professional education materials, and refers people to other sources of information.

American College of Rheumatology
http://www.rheumatology.org
This association provides referrals to doctors and health professionals who work on arthritis, rheumatic diseases, and related conditions. The association also provides educational materials and guidelines.

Scleroderma Foundation
http://www.scleroderma.org
The foundation publishes information on scleroderma and offers patient education seminars, support groups, physician referrals, and information hotlines.

Scleroderma Research Foundation
http://www.srfcure.org
The foundation's goal is to find a cure for scleroderma by funding and facilitating the most promising, highest-quality research and by placing the disease and its need for a cure in the public eye. The foundation distributes patient handbooks and a twice-yearly, research-related newsletter.

Arthritis Foundation
http://www.arthritis.org
The foundation is a voluntary organization devoted to supporting research on arthritis and other rheumatic diseases, including scleroderma. It also provides up-to-date information on treatments, nutrition, alternative therapies, and self-management strategies. Chapters nationwide offer exercise programs, classes, support groups, physician referral services, and free literature.

*Descriptions of Web sites are derived from www.niams.nih.gov.

Cutaneous Involvement

Most patients with the Raynaud phenomenon may be managed with such measures as avoidance of cold exposure. Instructions to wear warm clothing, gloves, and a hat when exposed to a cold environment may be sufficient. Cigarette smokers have a fourfold risk of digital vascular complications in surgical debridement, amputation, or intravenous vasodilator therapy[42]; smoking cessation is thus a key instruction. In addition, patients should avoid vasoconstrictive agents (e.g., decongestants, caffeine, amphetamines, beta blockers, and ergot alkaloids). For persons with attacks of the Raynaud phenomenon so frequent or so severe as to interfere with daily activities or to put them at risk for skin necrosis, pharmacologic therapy may be employed. Low-dose aspirin (81 mg daily) is recommended.[30] The calcium channel blocking agents promote vasodilatation and generally reduce the frequency and severity of Raynaud phenomenon.[43] Although nifedipine in daily doses of 30 to 60 mg has been effective for most patients, approximately one third do not respond, and some patients experience adverse effects. In double-blind, placebo-controlled trials, other calcium channel blockers have also shown efficacy for the Raynaud phenomenon; these agents include amlodipine, 5 to 10 mg daily, and felodipine, 5 to 10 mg daily. Ischemic digital ulcerations may be difficult to treat and may progress to gangrene of the fingertips. Sympathectomy should be reserved for severe ischemic crises.

GI Tract Involvement

Because gastroesophageal reflux is nearly universal in scleroderma, clinicians typically will instruct scleroderma patients to elevate the head of the bed and will administer proton pump inhibitors. Esophageal motility may be enhanced by use of metoclopramide. Esophageal dilatation may be required if strictures are present. Patients with diminished gastric emptying may be instructed regarding the frequent taking of small meals and may be given prokinetic medications such as metoclopramide. Small bowel motility may present as pain, distention, and vomiting; most episodes can be managed by increasing dietary fiber and avoiding medications that affect motility (e.g., opiates). Octreotide is used for severe small bowel dysmotility. For small bowel bacterial overgrowth with malabsorption, empirical antibiotic therapy with ciprofloxacin, metronidazole, doxycycline, or erythromycin is recommended.

Potential Disease-Modifying Therapies

Potential disease-modifying therapies for scleroderma have also been studied. Penicillamine is no longer recommended because of associated toxicity and minimal efficacy,[44] and methotrexate therapy is of uncertain benefit.[45,46] Stem cell transplants are associated with a higher procedure-related mortality but typically lead to decreased skin manifestations and stabilization of lung function.[47,48] A truly effective disease-modifying therapy is not yet available.

CLINICAL COURSE

In the CREST syndrome, skin involvement is relatively limited, usually affecting only the hands and face; the prognosis for patients with this syndrome is generally favorable unless viscera are involved. However, even the limited CREST variant tends to be unremitting and slowly progressive. Many patients experience an indolent course with little change over several years, although the progression may be more rapid. Diffuse scleroderma is highly variable in its course and manifestations; therefore, its rate of progression is difficult to predict. With the exception of some of the sclerodermatous changes in mixed connective tissue disease, diffuse scleroderma rarely remits completely. Involvement of the viscera, such as the heart, lungs, or, particularly, the kidneys, indicates a poor prognosis. Two other features of scleroderma also indicate a poor outcome: (1) active inflammation, as manifested by an elevated erythrocyte sedimentation rate, and (2) evidence of cardiopulmonary disease, renal disease, or both within 1 year after diagnosis.[49] The life-threatening complications of scleroderma—severe skin involvement, pulmonary fibrosis, and renal crisis—usually occur within the first 2 to 5 years after the onset of disease. After this interval, the disease tends to run an indolent course. The 5-year survival for patients with diffuse scleroderma is approximately 50%**,** but pediatric patients with the disease have a much better prognosis.[50]

Eosinophilic Fasciitis

Eosinophilic fasciitis can superficially resemble scleroderma. It is characterized by pain, swelling, and tenderness of the extremities, after which induration of the skin and subcutaneous tissues occurs. Joint motion may be limited, but the Raynaud phenomenon, sclerodactyly, and other manifestations of scleroderma are not seen. Laboratory test abnormalities include peripheral blood eosinophilia, which may be marked; elevation of the erythrocyte sedimentation rate; and hyperglobulinemia. Antinuclear antibody and rheumatoid factor test results are negative. Biopsy specimens of involved areas have shown inflammation and thickening of the fascia deep to the subcutaneous tissues. The skin appears normal, but the underlying deep fascia is infiltrated with lymphocytes, plasma cells, histiocytes, and sometimes eosinophils. Eosinophilic fasciitis seems to be either self-limited or responsive to low doses of glucocorticoids. Its etiology remains unknown, but several cases have been reported after strenuous muscle exertion.

Eosinophilia-Myalgia Syndrome

In 1989, a previously unrecognized syndrome associated with ingestion of contaminated L-tryptophan appeared.[51] The eosinophilia-myalgia syndrome is characterized by peripheral eosinophilia, severe and incapacitating myalgias, and fatigue of several weeks' duration. Dyspnea and cough may also be present. Skin involvement consists of variable rashes, edema, and scleroderma-like changes, usually without the visceral manifestations of scleroderma. Interstitial pulmonary infiltrates, hypoxia, pulmonary hypertension, and hypersensitivity pneumonitis may occur. Polyneuropathy has been described in a pattern of mononeuritis multiplex. Neurocognitive disorders, such as memory disturbances and difficulty in concentration, have been reported. Most patients continue to manifest symptoms from 2 to 4 years after onset but have no new signs of inflammation.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VI IDIOPATHIC INFLAMMATORY MYOPATHIES

Nancy J. Olsen, m.d.
Beth L. Brogan, m.d.

Idiopathic inflammatory myopathies, which include polymyositis and dermatomyositis, primarily affect skeletal muscle. The common features of these diseases are weakness of and inflammatory changes in skeletal muscle. In general, the idiopathic inflammatory myopathies are serious disorders that respond variably to therapy. Polymyositis and dermatomyositis may be linked with other rheumatic diseases, notably scleroderma, and with malignancies. Prognosis varies according to the specific syndrome that is expressed.

Classification

Classification of these heterogeneous muscle disorders into subtypes is useful for determining diagnostic and therapeutic approaches.[1,2] Categories are defined on the basis of clinical and histologic features rather than on laboratory or radiologic tests [*see Table 1*].

dermatomyositis

Patients with dermatomyositis usually show symmetrical proximal muscle weakness in all extremities, accompanied by a characteristic skin rash. Neck and back muscles may also be weak. Areas of skin most commonly affected by the rash include extensor surfaces of the hands and knees. Subtypes of dermatomyositis include the juvenile form [*see* Juvenile Myositis, *below*]. Another recognized subtype is amyopathic dermatomyositis.[3-5] Patients with this disorder have the characteristic rash but do not have demonstrable muscle abnormalities. One study of such patients has shown that sensitive magnetic resonance imaging techniques can reveal changes after exercise that indicate a metabolic abnormality.[6]

polymyositis

Patients with polymyositis have symmetrical proximal muscle weakness similar to that experienced in dermatomyositis, but the rash is absent. Onset of polymyositis may be more difficult to determine, in part because no rash is available as an indicator of possible inflammation. Muscle weakness and atrophy may be more profound than that usually seen in patients with dermatomyositis. However, no formal studies of long-term outcome have been carried out that prove this assertion.

juvenile myositis

Children ranging in age from younger than 5 years through the teen years may be affected by juvenile myositis. Most children have a skin rash, and vasculitis and soft tissue calcifications are much more common in children than in adults.[7] Although residual dermatologic changes, muscle fibrosis, and calcification may occur, the long-term outlook is generally favorable.[8]

myositis with malignancy

Most, but not all, cases of malignancy-associated myositis are accompanied by the typical rash of dermatomyositis. A recent study showed that patients with dermatomyositis had a relative risk of malignancy of 6.2. For patients with polymyositis or inclusion body myositis, the risk was lower but still significant.[9-11] The incidence of underlying malignancy increases with age[12] and decreases with increasing time from diagnosis.[9] Onset of the myositis may precede or follow discovery of the malignancy. Adults with dermatomyositis should be screened for occult malignancies in the first 2 years after onset of disease.

myositis with other rheumatic diseases

Inflammatory myositis may occur with another established rheumatic disease, most commonly scleroderma. Other conditions that can occur with myositis include rheumatoid arthritis, systemic lupus erythematosus (SLE), and Sjögren syndrome. Recent reports have linked scleromyxedema to dermatomyositis[13] and have linked inclusion body myositis to subacute cutaneous lupus.[14,15] Many patients with these overlap conditions have a relatively mild form of muscle inflammation that responds well to treatment. However, a small subset of patients, especially those with coexistent scleroderma, may have a severe and very debilitating muscle weakness that is resistant to therapy.[16]

inclusion body myositis

The pattern and severity of muscle weakness in inclusion body myositis (IBM) differs from the pattern of severity seen in the other idiopathic inflammatory myopathies. In addition to the presence of proximal weakness, distal muscles may be involved; and in some cases, muscle abnormalities are asymmetrical. Unlike most of the other muscle disorders discussed in this subsection, IBM afflicts more men than women, with approximately two thirds of affected persons being men. Response to treatment is generally poor.

Epidemiology

prevalence and incidence

The estimated prevalence of idiopathic inflammatory myopathies is approximately one case per 100,000 individuals.

Table 1 Classification of Myositis Syndromes

Clinicopathologic Category	*Characteristics*
Dermatomyositis	Proximal weakness, skin rash; amyopathic variant with rash only
Polymyositis	Proximal weakness without rash
Juvenile myositis	Myositis in childhood, usually with a rash
Myositis with malignancy	Myositis with associated underlying neoplastic disease
Myositis with another connective tissue disease	Coexistent syndrome, usually scleroderma, rheumatoid arthritis, or systemic lupus erythematosus
Inclusion body myositis	Severe weakness with characteristic inclusions on muscle biopsy

This prevalence makes these disorders about 1,000 times less common than rheumatoid arthritis. The rarer syndromes, such as IBM, may constitute 20% or less of all cases. In one study, the annual incidence of idiopathic inflammatory myopathies was 5.5 cases per million population.[17] Incidence rates, however, may be increasing, possibly because of improved methods of detection.

ETHNIC, RACIAL, AND GENDER GROUP DIFFERENCES

No ethnic clustering of the idiopathic inflammatory myopathies has been reported. It has been suggested that incidence rates in North America are increasing faster in African Americans than in whites.[17] In adults, polymyositis is more common than dermatomyositis, whereas in children and young adults, dermatomyositis is the predominant form. It has been suggested that incidence rates are higher in regions that have greater amounts of sun exposure.[18] Polymyositis and dermatomyositis show a female-to-male ratio of approximately 2:1. Risk of underlying malignancy increases significantly after 40 years of age.[12] Malignancies in children are rare but have been reported. The diagnosis of inclusion body myositis is rarely made in persons younger than 50 years.

Etiology and Pathogenesis

The etiology of inflammatory muscle disease remains unknown. The most widely accepted hypotheses suggest multiple factors. One possible scenario is that an initial insult—for example, a virus or another infectious agent or an environmental toxin—leads to muscle damage in a genetically susceptible host. This process in turn triggers an immune response, subsequently causing chronic muscle inflammation.[19]

INFECTIOUS AGENTS

A role for viruses in the etiology of idiopathic inflammatory myopathies has been suggested by seasonal and geographic clustering of new cases. Furthermore, infection with HIV or hepatitis C virus has been associated with the development of myopathy.[20] Most studies looking for evidence of viral genomic material in muscle tissue have failed to find such evidence.[21] Immunoreactivity for hepatitis C in involved muscle tissues has been reported in a single case.[20] Viruses may mediate tissue damage, which may in turn lead to immunologic responses that target or damage muscle tissues.[22] The relative rarity of the myositis syndromes would suggest that if a common infectious agent were involved, coexistent factors would also be required. These factors could include host-specific genetic loci that control the immune response or other noninfectious factors such as drugs or environmental toxins.[18]

NONINFECTIOUS FACTORS

Lipid-lowering agents such as clofibrate and the statin group of drugs have been associated with elevated levels of serum muscle enzymes and with muscle weakness in a small number of patients. However, most patients are asymptomatic. The list of drugs reported to be associated with development of myopathy is very long. For this reason, concomitant medications should be examined closely in any patient with unexplained muscle weakness.[23] Both HIV infection and drugs used in its treatment, such as zidovudine (AZT), have been implicated in the development of myopathy. It is possible that as yet undefined environmental toxins play a role.

GENETIC FACTORS

Familial clustering of inflammatory myositis syndromes occurs, but the great majority of cases are sporadic. Sporadic cases have been linked to HLA-DRB1*0301, whereas familial cases have shown increased prevalence of HLA-DQA1 (DQA1*0501). A form of hereditary IBM has been described in several ethnic groups. Chromosomal links with this disorder have been identified, but candidate genes are as yet undefined.[24] Many of the reported studies of genetic links in inflammatory myopathies have grouped several types of syndromes together. It is probable that future studies that perform separate analyses of the various distinct clinical syndromes will show stronger associations with genetic markers.

AUTOIMMUNE FACTORS

The presence of cellular infiltrates in muscle tissues is a defining feature of inflammatory muscle diseases [*see Figure 1*]. Light microscopic examination of these infiltrates reveals different patterns of infiltration. In tissues from patients with dermatomyositis, the lymphocytes are generally located around blood vessels and at the periphery of the muscle bundles. Invasion of muscle fibers by mononuclear cells is rarely observed, and there is a relative paucity of necrotic muscle fibers. Complement-mediated capillary damage is also more commonly observed in biopsy samples from dermatomyositis patients, especially those patients with an underlying malignancy. Some studies suggest that dermatomyositis patients with capillary damage who do not have a malignancy have a more acute syndrome that responds better to immunosuppressive treatment. In polymyositis, muscle fibers may be invaded by the mononuclear infiltrates, and focal areas of muscle destruction are seen. Tissues from patients with IBM usually show some degree of inflammation accompanied by intracellular rimmed vacuoles.[25]

Two groups have identified chimeric cells of maternal origin in the peripheral blood and inflammatory lesions of children with myositis. These findings support the hypothesis that

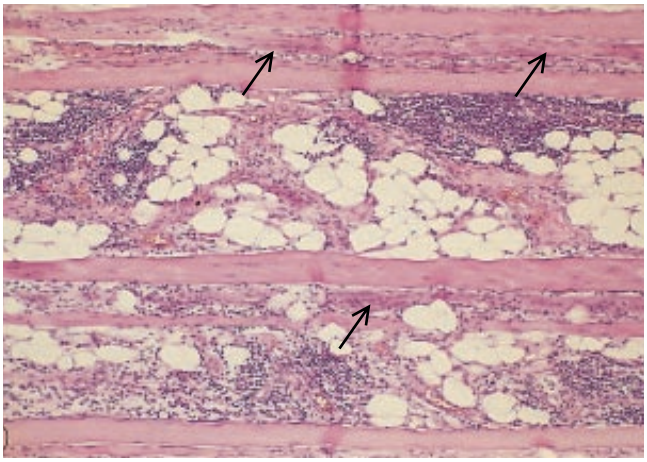

Figure 1 **Extensive pathologic changes can be seen in involved muscle in myositis. These changes include a decrease in the number of striated muscle fibers and a loss of cross-striations in the remaining fibers. Some fibers demonstrate increased numbers of rounded nuclei and basophilic staining (arrows), which suggests attempted regeneration. There is also intense infiltration of the muscle by mononuclear inflammatory cells, predominantly lymphocytes and plasma cells.**

childhood myositis is a manifestation of a graft-versus-host reaction.[26,27]

Differences between polymyositis and dermatomyositis are revealed by immunophenotyping of the cellular infiltrates.[28] Mononuclear cell infiltrates in polymyositis and probably in IBM tissues are predominantly of the $CD8^+$ cytotoxic T cell phenotype. The $CD8^+$ T cells in polymyositis show evidence of clonal expansion, which is most likely driven by muscle-specific antigens.[29] Activated $CD8^+$ T cells probably mediate cytotoxic, immune-mediated, and antigen-specific muscle cell destruction. In dermatomyositis, T cells, predominantly of the $CD4^+$ helper-inducer phenotype, are present along with B cells; restricted clonality is not seen.[29] These differences in histology support the hypothesis that polymyositis and dermatomyositis are distinct disorders with different etiologies.

Diagnosis

Major diagnostic criteria that were proposed by Bohan and Peter in 1975[1,2] remain useful for defining most of the myositis syndromes. However, IBM, which was not recognized at the time these criteria were written, differs somewhat from polymyositis and dermatomyositis. Although sophisticated diagnostic tests, including autoantibody profiles and imaging techniques, are now available, findings obtained through a careful history and physical examination remain indispensable for both making the initial diagnosis and evaluating responses to treatment.

CLINICAL FEATURES

Muscle Weakness

In polymyositis and dermatomyositis, the weakness is predominantly proximal. Distal strength is usually preserved. In IBM, the weakness may be asymmetrical, and diminished distal strength is commonly seen. Muscle strength can be tested in the office or at the bedside and estimated on a semiquantitative scale from 1 to 5. Devices for quantitative assessment of muscle strength, some of which can be used at the bedside, are also available.

Characteristic Skin Rash

The rash of dermatomyositis is a deep-red erythematous eruption, with or without mild scaling and atrophy. It occurs on the face, neck, upper chest, and extensor surfaces of joints such as elbows and those of the hands. Periorbital edema may appear, as may heliotrope erythema, which is characterized by a violet or lilac color, especially of the eyelids. Occasionally, the rash is more widespread or takes different forms [*see Figure 2*]. Erythema and telangiectasia also occur in periungual areas. In adults, vasculitis is usually confined to the skin and takes the form of urticaria, subcutaneous nodules, periungual infarcts, or digital ulcerations. Cutaneous vasculitis has been associated with underlying malignant disease.

Pulmonary Involvement

Pulmonary involvement occurs in nearly 50% of patients who have myositis, with pneumonia being the most common pulmonary abnormality. Aspiration pneumonia, which is often recurrent, is prevalent in patients who have pharyngeal muscle weakness. Ineffective coughing caused by ventilatory muscle weakness also occurs but is far less common than swallowing

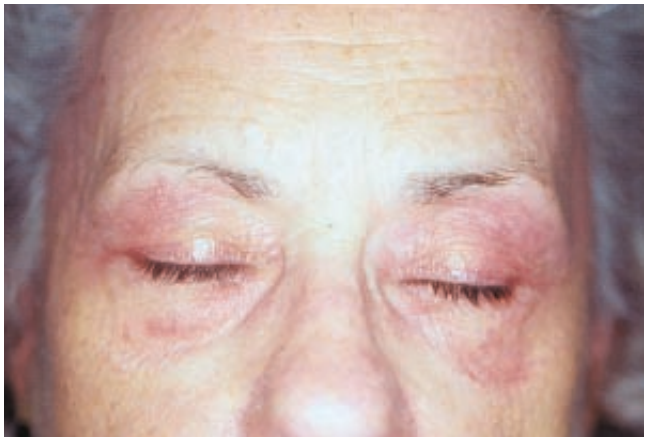

Figure 2 **Skin eruption in a patient with dermatomyositis consists of a deep-red, erythematous, papular rash over the nasal and forehead areas and a lilac-colored, or heliotrope, erythema of the upper eyelid and orbital area.**

problems. In general, the patient with recurrent aspiration pneumonia has a poor prognosis; it indicates marked dysfunction of many muscle groups. Bacterial pneumonia caused by aspiration is a major cause of death in elderly patients.[12] Opportunistic infections may occur in patients undergoing immunosuppressive drug therapy. In addition, some of these drugs, most notably methotrexate, can be associated with the development of pneumonitis, which is usually reversible but is potentially fatal.

Interstitial lung disease (ILD) occurs in up to 30% of myositis patients and in approximately 60% of patients who have antibodies directed against aminoacyl-transfer RNA (tRNA) synthetases. The advent and application of newer, sensitive diagnostic techniques such as high-resolution computed tomography may lead to an increase in the detection of pulmonary abnormalities. The most common presentation is with progressive shortness of breath, which may be accompanied by a nonproductive cough. On physical examination, basilar crepitant rales are usually detected. Progression may be slow, and symptoms may occur in patients with established disease; or onset may be rapid and may occur at the same time as the muscle weakness.[30] Hypoxemia and respiratory alkalosis may be present. In some patients, these abnormalities are detected only after exercise. High-resolution CT scanning is useful for detection of interstitial fibrosis that might not be appreciated on routine chest radiography. Pulmonary function tests may reveal reduced lung volume and diminished diffusion capacity. One of three forms of histology of ILD is usually found: interstitial pneumonia, diffuse alveolar damage, or bronchiolitis obliterans with or without organizing pneumonia. ILD occurs with or without skin involvement. There is no correlation between the development of ILD and the severity of muscle involvement, and ILD may precede or follow the onset of muscle weakness. ILD is associated with a high mortality. Treatment with cyclophosphamide or azathioprine has been reported to be beneficial in some patients.[30] A small number of patients with acute pneumonitis may respond to corticosteroid treatment alone.

Cardiac Abnormalities

Clinically significant involvement of heart muscle is unusual and is probably associated with a poor prognosis. Cardiac abnormalities may take many forms, ranging from rhythm or

conduction disturbances to myocardial inflammation or fibrosis. Cardiac muscle abnormalities may be detected by radionuclide scanning studies. However, many histologic and electrical abnormalities are not clinically significant.[31] Therefore, evaluation beyond routine diagnostic studies is rarely indicated.

Calcinosis

Soft tissue calcification is seen most commonly in children. Deposits may be deep along fascial planes or in superficial dermal areas, sometimes with ulceration through the skin. Treatments have been based on largely anecdotal reports; no systematic studies have been carried out.[32] Agents that have been found to be of use in some cases include probenecid, diltiazem, and warfarin. Some patients show spontaneous regression of calcinosis without specific treatment.

Vascular Abnormalities

Raynaud phenomenon is most commonly observed in patients whose myositis is associated with another rheumatic disease (e.g., scleroderma). Clinically significant vasculitis is unusual in adults, although dermatomyositis patients may show vascular changes on histologic examination.

LABORATORY TESTS

Muscle Biopsy

Histologic confirmation of muscle inflammation is required in many, but not all, cases of inflammatory muscle disease. Patients with the characteristic skin rash of dermatomyositis and with elevated serum muscle enzyme levels may be treated without a muscle biopsy, because these two indicators can be used to follow the course of disease. In the absence of a skin rash or elevations in muscle enzyme levels, diagnosis is more difficult; in most patients, a biopsy is needed to confirm the presence of muscle inflammation. Two types of biopsy approaches are used: open surgical and closed needle. The closed-needle approach offers the advantages of decreased morbidity and of lower cost because an operating room is not required. Tissue samples obtained with the closed-needle approach can provide sufficient diagnostic information for interpretation by the muscle pathologist. However, the quality of the specimen obtained is dependent on the skill and experience of the operator. In the absence of such a resource or in special cases in which it is desirable to obtain extra tissue, the open surgical approach is preferable. Imaging studies such as MRI or CT can be used to determine the optimal site for biopsy.

All biopsy specimens require immediate handling by an experienced surgical team working closely with the pathology laboratory to ensure optimal results. Light microscopic analysis is sufficiently informative for most purposes. Because the treatment of polymyositis and that of dermatomyositis are the same, immunophenotyping of cellular infiltrates to distinguish between these two disorders is not indicated for routine diagnostic specimens. Electron microscopy may be required to demonstrate the inclusion bodies that define IBM. Examination of the biopsy specimen by a specialist in neuromuscular pathology may be helpful, because many pathologists do not see these diseases on a regular basis.

Muscle Enzymes

Most patients with inflammatory myopathy have increased muscle enzyme levels at some point during the course of active myositis.[33] The presence of intracellular muscle enzymes in the serum most likely reflects damage to muscle cell membranes. The most commonly used muscle enzyme measurement is the creatine kinase (CK) level. The CK level may rise to many times normal. The MB isozyme of CK may be elevated because of the presence of this isoform in regenerating skeletal muscle. Measurement of CK may be confounded by the presence of naturally occurring inhibitors of this enzyme. Furthermore, racial and gender variations exist for normal levels of CK, with black males generally showing the highest values.[34] Aldolase is another muscle enzyme that may be measured in the serum and may have less variability. However, aldolase is present in tissues other than muscle, and therefore, it is not specific for muscle damage. MRI studies have shown that active muscle inflammation may exist in patients with persistently normal CK serum levels.[35] Reasons for this discordance are not known, but the findings suggest that treatment strategies should be focused on the clinical status of the patient rather than on the muscle enzyme levels.[36]

Autoantibodies

Autoantibodies to nuclear and cytoplasmic antigens are found in as many as 90% of patients with an inflammatory myopathy. These antibodies are often useful in differentiating inflammatory myopathies from diseases that are not autoimmune disorders. Some of these autoantibodies are nonspecific and are seen in several autoimmune disorders. Other autoantibodies are relatively specific for the inflammatory myositis syndromes in general or for specific diagnostic categories. About 25% of patients with inflammatory myositis test positive for antinuclear antibody; in patients with overlapping rheumatic disease syndromes, the percentage is higher. The antinuclear antibody test is generally not helpful in establishing a diagnosis of myositis or one of its subsets. Autoantibodies that are in large part directed against cytoplasmic ribonucleoproteins have been designated as myositis-specific autoantibodies (MSA). Approximately 30% of patients with myositis have one or more of these autoantibodies. They are thus relatively specific but not sensitive to the presence of myositis, and as such, these autoantibodies cannot be used to screen for the presence of disease.

Three groups of patients can be defined by the MSA specificities. These subgroups differ in clinical presentation and prognosis.[37] The first group is defined by the presence of antibodies directed against aminoacyl-tRNA synthetases. The presentation in the first group is generally characterized by an acute onset of muscle disease, with a high incidence of associated interstitial lung disease. Patients in this group may also have arthritis and a hyperkeratotic rash on the hands, known as mechanic's hands. A majority of patients in this group test positive for HLA-DR3. Responses to treatment are variable, and mortality is significant. The second group includes patients with antibodies to the signal recognition particle (SRP). This protein complex facilitates translocation of newly synthesized polypeptides across the endoplasmic reticulum. Patients with anti-SRP have an abrupt onset of muscle weakness and may have associated involvement of cardiac muscle. The majority of patients in this group are African-American women. Responses to treatment are not good, and the prognosis is poor. In one series, the 5-year mortality for anti-SRP patients was 75%. A third group is identified by antibodies to Mi-2, which is a nuclear protein with unknown function. The majority of these patients have the dermatomyositis clinical syndrome with the so-

called shawl-sign pattern of rash on the trunk and with cuticular overgrowth. Responses to treatment are generally good, and mortality is lower than that in the other groups. Most of these clinical associations, which were originally described in North American patients, have been confirmed in a large group of European patients.[38] Preliminary reports suggest that antibodies to a novel 155 kd protein may also be useful in identifying patients with amyopathic dermatomyositis.[39]

Electromyography

In most patients, electromyography reveals low-amplitude, polyphasic motor unit potentials, indicating a lack of synchronous contracture in muscle fibers within motor units. This finding correlates with the usually inhomogeneous distribution of muscle degeneration shown by histopathologic examination. Fibrillations and insertional irritability are evidence of membrane abnormalities. These findings are characteristic of, but not specific for, myositis.

IMAGING AND SPECTROSCOPY TECHNIQUES

Conventional radiographs have little value in evaluating skeletal muscle. However, other techniques, including ultrasonography, CT, and MRI, can enhance diagnostic approaches to many myopathies.[40] Of these modalities, MRI has been the most useful in the evaluation and longitudinal management of inflammatory muscle syndromes. However, it may not be the method of choice in all circumstances, and in some of these cases, the alternative modalities of ultrasonography and CT can provide helpful information. Advantages of these three techniques are that they are noninvasive and offer the possibility of examining a volume of muscle larger than that which can be obtained by biopsy. In patients for whom biopsy may be a difficult or traumatic experience, such as young children, imaging may provide sufficient information to proceed with treatment.

Magnetic Resonance Imaging

MRI is a very accurate method for muscle imaging that has been very useful in the diagnosis and management of patients with inflammatory muscle diseases of many kinds. Full assessment requires both T_1- and T_2-weighted images. The T_1 image is most useful for outlining muscle anatomy because it detects changes in muscle mass caused by atrophy or fat infiltration. Inflammation is readily detected on the T_2-weighted image, where the abnormal areas appear as brightness against the usually dark background of normal muscle [*see Figure 3*]. Studies using MRI have clearly demonstrated the patchy nature of the muscle inflammation, perhaps explaining why some patients with significant weakness have normal biopsy results. In dermatomyositis, inflammation in the thigh muscles is seen in predominantly anterior muscle compartments, and muscle mass is generally preserved. In patients with polymyositis and inclusion body myositis, extensive fat infiltration and muscle atrophy, which can include all muscle groups, are more likely to be seen. Longitudinal MRI studies can be used to document the effectiveness of immunosuppressive therapy. Patients may be studied in the usual body coil, which allows for visualization of both legs.[41] Other studies have utilized a knee coil positioned over the anterior quadriceps, which provides a greater level of detail.[35] As in all MRI studies, patients must be very carefully questioned for the presence of any indwelling metals before being placed in the magnet.

Ultrasonography

Ultrasonography is a readily available and relatively inexpensive technique that has been used to examine a wide variety of muscle disorders.[42,43] Inflammation within muscle tissues appears on ultrasonography as areas of decreased echogenicity. In addition, blood-flow changes can be measured with related techniques such as color Doppler imaging. Ultrasonography may be useful in guiding the choice of site for needle or open muscle biopsy.

Computed Tomography

CT is not useful for the detection of inflammatory muscle changes. However, areas of atrophy or fat infiltration cause decreased muscle density, which is easily detected by CT. Soft tissue calcifications such as those seen in juvenile dermatomyositis are best visualized with CT. Sometimes, these calcifications are in deep areas that cannot be readily appreciated on physical examination.

a *b*

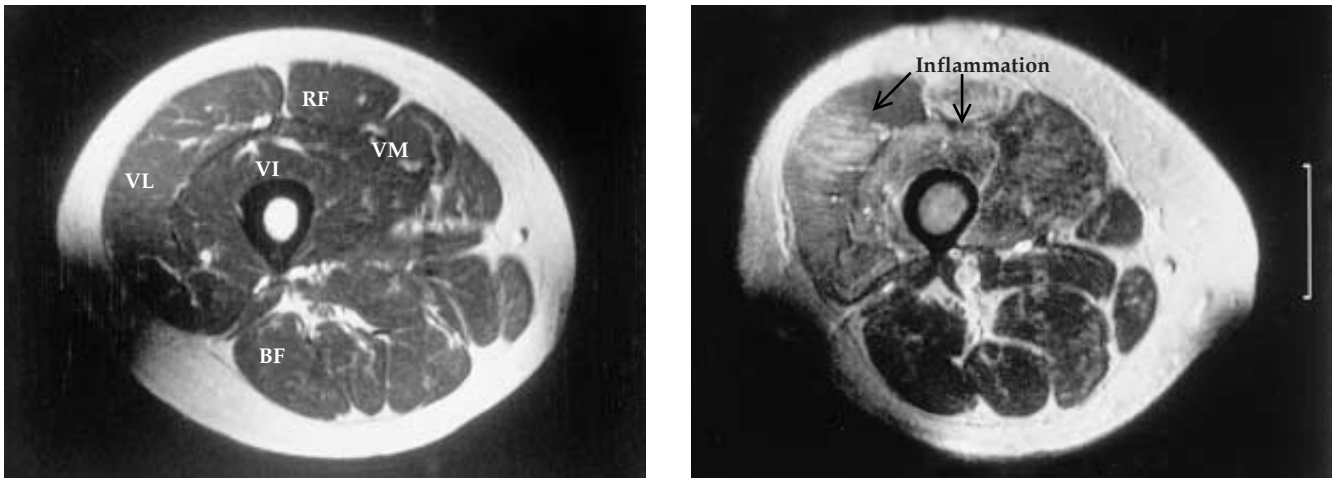

Figure 3 **Magnetic resonance images of thigh muscles in a patient with dermatomyositis. The T_1-weighted image (*a*) shows uniform density in all muscle groups, identified as VL, vastus lateralis; VI, vastus intermedius; VM, vastus medialis; RF, rectus femoris; and BF, biceps femoris. The T_2-weighted image (*b*) illustrates inflammation in muscles of the quadriceps group, shown as areas of brightness or increased signal intensity.[35]**

Magnetic Resonance Spectroscopy

Spectroscopy is primarily a research tool. However, studies have shown the utility of this noninvasive approach for evaluating muscle function, and applications in the clinic may become available in the near future.[35,44] In patients with dermatomyositis, loss of high-energy phosphate compounds needed for efficient muscle contraction has been documented with P-31 magnetic resonance spectroscopy.[44] Longitudinal studies have documented that correction of these metabolic abnormalities may lag behind improvement in muscle inflammation.

EVALUATION FOR UNDERLYING MALIGNANCY

Patients with dermatomyositis and polymyositis are at increased risk for an underlying malignancy. The magnitude of this risk is difficult to determine and varies greatly between reports. One study in a population-based cohort estimated the relative risk of cancer as 1.8 in males and 1.7 in females.[45] A more recent study from Scotland has indicated that the relative risk may be as high as 7.7 in patients with dermatomyositis, with a greater risk in females than in males.[46] In general, the risk is greater in patients with dermatomyositis than in patients with polymyositis and in all patients who are older than 40 years. There is general agreement that routine screening for malignancies should include chest radiography, mammography (in women), examination of stool for occult blood, complete gynecologic examination, and assessment for prostate-specific antigen (in men). Abnormalities seen on these screening tests may suggest the need for additional studies such as endoscopy, colonoscopy, and tissue biopsy. The most difficult malignancies to detect are those arising in the ovary. Uterine transvaginal ultrasonography or CT of the pelvis should be done in women older than 40 years, but some occult ovarian malignancies escape detection even with these tests. Some investigators advocate lower gastrointestinal studies to detect colon cancer in patients older than 65 years.[12] Other, more extensive screening tests for occult malignancies are generally not recommended.

Differential Diagnosis

Diagnosis of dermatomyositis is aided by the presence of the characteristic rash. However, because the rash has features of SLE, this diagnosis may be confused with SLE, especially when the antinuclear antibody test is positive. Patients with polymyositis may be difficult to distinguish from patients with other myopathic disorders [*see Table 2*]. These other disorders include metabolic myopathies, endocrine dysfunction, drug-induced disorders, infections, and miscellaneous syndromes such as sarcoidosis. Some types of dystrophies should also be considered in patients who have muscle weakness and elevated muscle enzyme levels. Myalgia syndromes, such as polymyalgia rheumatica, in which stiffness is a predominant complaint, may confuse the diagnosis in some patients. Fibromyalgia, which is associated with a primary symptom of fatigue rather than muscle weakness, is characterized by the presence of discrete tender points that are not usually present in myositis patients.

Table 2 Differential Diagnosis of Inflammatory Myositis

Cause	*Effect*
Metabolic myopathies	Myophosphorylase deficiency (McArdle disease) Myoadenylate deaminase deficiency Carnitine palmitoyltransferase deficiency Glycogen storage disease Periodic paralysis Hypokalemia, hypomagnesemia
Endocrine disorders	Cushing syndrome Thyroid dysfunction
Drug-induced disorders	Ethanol toxicity Penicillamine toxicity Lipid-lowering drug (statin) toxicity Zidovudine toxicity
Infections	Viral: HIV, coxsackievirus, adenovirus, influenza virus, echovirus
Other rheumatic disorders	Systemic lupus erythematosus (rash) Polymyalgia rheumatica
Miscellaneous disorders	Sarcoidosis, eosinophilia

Treatment

Guidelines for treatment of the idiopathic inflammatory myopathies are not well established for several reasons. The diseases are uncommon, making it difficult to accumulate sufficient numbers of patients to carry out randomized, controlled trials. In addition, some forms of these diseases have a slow, prolonged course, requiring long periods of observation. Finally, there is as yet no uniformly accepted classification scheme for these disorders; thus, comparisons of therapies administered to different groups of patients at different times and places may not be valid. As examples, in the past, polymyositis and dermatomyositis have been included in the same category, and IBM may not have been recognized. It is now clear that different forms of these diseases vary in prognosis and in response to therapy.

DRUG THERAPY

A table showing drugs for the treatment of inflammatory muscle diseases is provided [*see Table 3*].

Glucocorticoids

Corticosteroids are the mainstay of initial therapy. Most patients with documented muscle inflammation should be started on these drugs at relatively high levels (1 mg/kg/day), given in divided doses. A standard approach has been to maintain this dosage for up to 3 months or until clinical improvement occurs. After this initial period of high-dose therapy, the dose can be consolidated into a single morning dose and then tapered, with the total daily dose being reduced by 20% to 25% each month and a maintenance dose of 5 to 10 mg daily being achieved in about 6 to 8 months. The addition of second-line drugs to the prednisone regimen is now recommended within 3 months after initiation of treatment. Older patients with comorbid conditions such as diabetes and osteoporosis are especially at risk from side effects of steroids. Side effects may include a cushingoid appearance, compression fractures, avascular necrosis, cataracts, and infections. One study has suggested that the side effects of corticosteroid therapy contribute significantly to the morbidity of polymyositis and dermatomyositis.[47] For these reasons, any patient with severe muscle weakness,

Table 3 Drugs for the Treatment of Inflammatory Muscle Diseases

Drug	*Dose*	*Efficacy Rating*	*Comments*
Prednisone	5–60 mg/day	Highly effective for initial treatment	Side effect: cushingoid syndrome Avoid prolonged use at high doses; taper to 10 mg/day or less
Methotrexate	15–25 mg/wk	Effective, steroid-sparing	Side effects: liver abnormalities, pneumonitis Supplement with folate
Azathioprine	100–150 mg/day	Effective, steroid-sparing	Side effect: bone marrow suppression Can be combined with methotrexate
Hydroxychloroquine	200 mg b.i.d.	Effective for skin manifestations	Side effect: retinal toxicity Can be combined with other agents
Cyclophosphamide	100–150 mg daily or as intravenous pulses every 6 wk	Possibly effective for lung involvement	Side effects: bone marrow suppression, hemorrhagic cystitis
Cyclosporine	3 mg/kg/day	Use after other immunosuppressants	Side effects: hypertension, renal dysfunction
Intravenous immunoglobulin	1 g/kg/day, 2 consecutive days monthly	Use in patients in whom other regimens have failed	High cost and limited supply

limited functional status, or underlying conditions that make steroids a high risk (e.g., diabetes mellitus or osteoporosis) should be started on second-line immunosuppressive drugs at the outset.

Methotrexate and Azathioprine

The most commonly used second-line agents for the treatment of inflammatory myopathy are methotrexate and azathioprine. Methotrexate may be given orally or subcutaneously at an initial dosage of 7.5 to 10 mg weekly and then increased gradually to 25 mg weekly. As the dosage of methotrexate is increased, the dosage of prednisone is usually tapered. In general, methotrexate is well tolerated by patients with inflammatory myopathy, but there have been reports of toxicities similar to those seen in patients with rheumatoid arthritis who have taken methotrexate. Regular monitoring of liver function is necessary. Measurement of enzymes other than aminotransferases is required to prevent interference by the ongoing muscle inflammation. γ-Glutamyltranspeptidase is a liver-specific alternative. Methotrexate may be useful in the treatment of interstitial lung disease associated with myositis, but because this drug may in rare cases cause pulmonary toxicity, it is relatively contraindicated in patients with significant lung problems.

Azathioprine has been shown to be effective in patients with myositis in a prospective, controlled, double-blind trial, but treatment for at least 6 months may be required for improvement to occur. Azathioprine therapy should be initiated at a dosage of 50 to 100 mg/day, and the dosage should be increased gradually to a maximum of 150 to 200 mg/day. Side effects include bone marrow suppression and development of infections and, possibly, malignancies. Azathioprine and methotrexate have similar efficacy in these disorders, and the choice of which to use may depend on tolerability or comorbid conditions. Patients with myositis in whom therapy with glucocorticoids and either methotrexate or azathioprine has failed may respond to a combination of methotrexate and azathioprine.[48,49]

Other Immunosuppressive Agents

Cyclophosphamide has been given both as intravenous pulse therapy and by daily oral administration. Some data suggest that it may be useful in adults with the antisynthetase syndrome and in children with vasculitis-related complications of dermatomyositis. Cyclophosphamide may be useful in the treatment of the complication of interstitial lung disease.[30] Other drugs that may be of value in patients in whom other therapies have failed include cyclosporine, FK506 (tacrolimus), chlorambucil, and mycophenolate mofetil.[50-52] The adenine analogue fludarabine has also shown some benefit in one study of refractory patients.[53]

Intravenous Immune Globulin

Intravenous immune globulin appears to benefit some patients with either polymyositis or dermatomyositis. A controlled trial of immune globulin in dermatomyositis patients demonstrated efficacy when given at a dosage of 1 g/kg/day for 2 days, repeated monthly for 3 months.[54] The combination of intravenous immune globulin and cyclosporine may be of value.[55] One controlled study suggested that intravenous immune globulin may be of benefit in IBM,[56] but studies by another group failed to show clinical improvements.[57] Treatment with intravenous immune globulin is limited by the restricted supply and very high cost and should be reserved for severe cases not responding to other therapies.

SKIN PROTECTION

The rash of dermatomyositis is usually photosensitive. Therefore, attention to protection from the sun is very important, and patients should be advised to avoid sun exposure as much as possible. Sunscreen preparations, sun-protective clothing, and tinting of windows are often effective. Some dermatologists recommend use of β-carotene, 25 to 30 mg, taken twice daily initially and then increasing to no more than five times a day. Antimalarials may be of benefit, and one report suggests the use of topical tacrolimus.[58]

PHYSICAL THERAPY

Physical therapy plays an important role in the rehabilitation of patients with myositis. During the phase of active inflammatory disease, passive range-of-motion exercises are necessary to prevent contractures. Once the inflammatory compo-

nent of the disease is controlled, active resistive exercises are useful in regaining muscle strength.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VIII SYSTEMIC VASCULITIS SYNDROMES

Brian F. Mandell, m.d., ph.d.

The diagnosis of a primary vasculitic syndrome is dependent on documentation of vasculitis and the exclusion of diseases that can cause secondary vasculitis. The diagnosis of a specific primary vasculitic disorder depends on the pattern of organ involvement, the histopathology, and the size of affected blood vessels.

The major determinants of prognosis and therapy include the type of vasculitis, the severity and extent of critical organ involvement, the rate of disease progression, and the etiology, if identifiable. The inflammatory process is often associated with nonspecific symptoms and laboratory abnormalities (e.g., elevated erythrocyte sedimentation rate, anemia, and fevers) that do not distinguish vasculitic diseases from other inflammatory, infectious, or neoplastic diseases. The toxic nature of the therapies for systemic vasculitis dictates the need for an accurate diagnosis.

Approach to the Patient with Suspected Vasculitis

EVALUATION

The physician should not be reluctant to pursue invasive testing in the diagnostic evaluation of patients with a multisystem illness, but biopsy of clinically uninvolved tissue and the use of less specific tests should be eschewed. An approach directed toward "ruling in" a specific form of vasculitis and ruling out reasonable specific alternatives should be pursued.

The first step in the diagnosis of vasculitis is to perform a detailed patient history and physical examination to document specific organ involvement. Special attention should be paid to the skin, eyes, ears, upper airway, joints, urinalysis, lymph nodes, peripheral nerves, and large vessels. A few laboratory tests [*see Table 1*] should be selectively included in the initial evaluation. Specialized studies, including serologies, should be obtained only after a differential diagnosis is formulated. If the urine dipstick test indicates blood, leukocytes, or protein, the

Table 1 Selected Laboratory Tests for Patients with Multisystem Disease and Possible Vasculitis

Test	*Comments*
Platelet count	Thrombocytosis may parallel the acute-phase response Thrombocytopenia is not expected in primary vasculitic syndromes; consider SLE, marrow infiltration, hairy-cell leukemia, TTP, DIC, hypersplenism, APLS, HIV, scleroderma renal crisis, and heparin-induced thrombocytopenia
White blood cell count	Leukopenia is not expected in primary vasculitis; consider SLE, leukemia, hypersplenism, sepsis, myelodysplasia, and HIV Eosinophilia is common in Churg-Strauss syndrome; it may occur in WG, rheumatoid arthritis, or normotensive scleroderma renal crisis
Erythrocyte sedimentation rate	Relatively low ESR is seen in DIC, liver failure, and hyperviscosity; ESR is frequently normal in HSP, may be low in Takayasu arteritis, and is normal in ≤ 20% of giant cell arteritis
Transaminases	ALT or AST is elevated in liver disease, myositis, rhabdomyolysis, hemolysis, or myocardial necrosis
Anti–glomerular basement membrane	Useful for evaluation of alveolar hemorrhage, with or without glomerulonephritis; also useful for evaluation of normocomplementemic glomerulonephritis
Antinuclear antibody	Order when there is clinical suspicion of SLE, not as a general screening test for sick patients; negative test makes SLE very unlikely
Antineutrophil cytoplasmic antibody	Order when there is clinical suspicion of WG or MPA; order specific anti-PR3 and antimyeloperoxidase
Drug screen	Order for unexplained CNS symptoms, myocardial ischemia, vascular spasm, panic attacks with systemic features, or tachycardia; urine screen should be done
Blood cultures	Useful for any patient with febrile, multisystem, or wasting illness; pulmonary infiltrates; or focal ischemia/infarction. Cultures are easy to obtain
APLA/PTT/RVVT	Order for unexplained venous or arterial thrombosis or thrombocytopenia
Purified protein derivative (± anergy)	Use in any patient who may require steroid therapy or who has unexplained sterile pyuria or hematuria, granulomatous inflammation, chronic meningitis, or possible exposure to tuberculosis
Examination of fresh urinary sediment	Perform in all patients with an unexplained febrile or multisystem illness
Hepatitis serologies	Order for abnormal transaminases or elevated hepatic alkaline phosphatase; portal hypertension; PAN or MPA syndrome; or unexplained cryoglobulinemia, polyarthritis, or cutaneous vasculitis
Complement C3, C4	Not a screening test for vasculitis; useful in the differential diagnosis of glomerulonephritis; low in cryoglobulinemia; may be low in endocarditis; usually normal in PAN, MPA, HSP, WG; may be low in viral hepatitis–related glomerulonephritis or vasculitis
Aldolase	Aldolase has no organ specificity; it has similar organ distribution as lactic dehydrogenase

ALT—alanine aminotransferase APLA—antiphospholipid antibody APLS—antiphospholipid antibody syndrome AST—aspartate aminotransferase DIC—disseminated intravascular coagulation ESR—erythrocyte sedimentation rate HSP—Henoch-Schönlein purpura MPA—microscopic polyangiitis PAN—polyarteritis nodosa PR3—proteinase 3 PTT—partial thromboplastin time RVVT—Russell viper venom test SLE—systemic lupus erythematosus TTP—thrombotic thombocytopenic purpura WG—Wegener granulomatosis

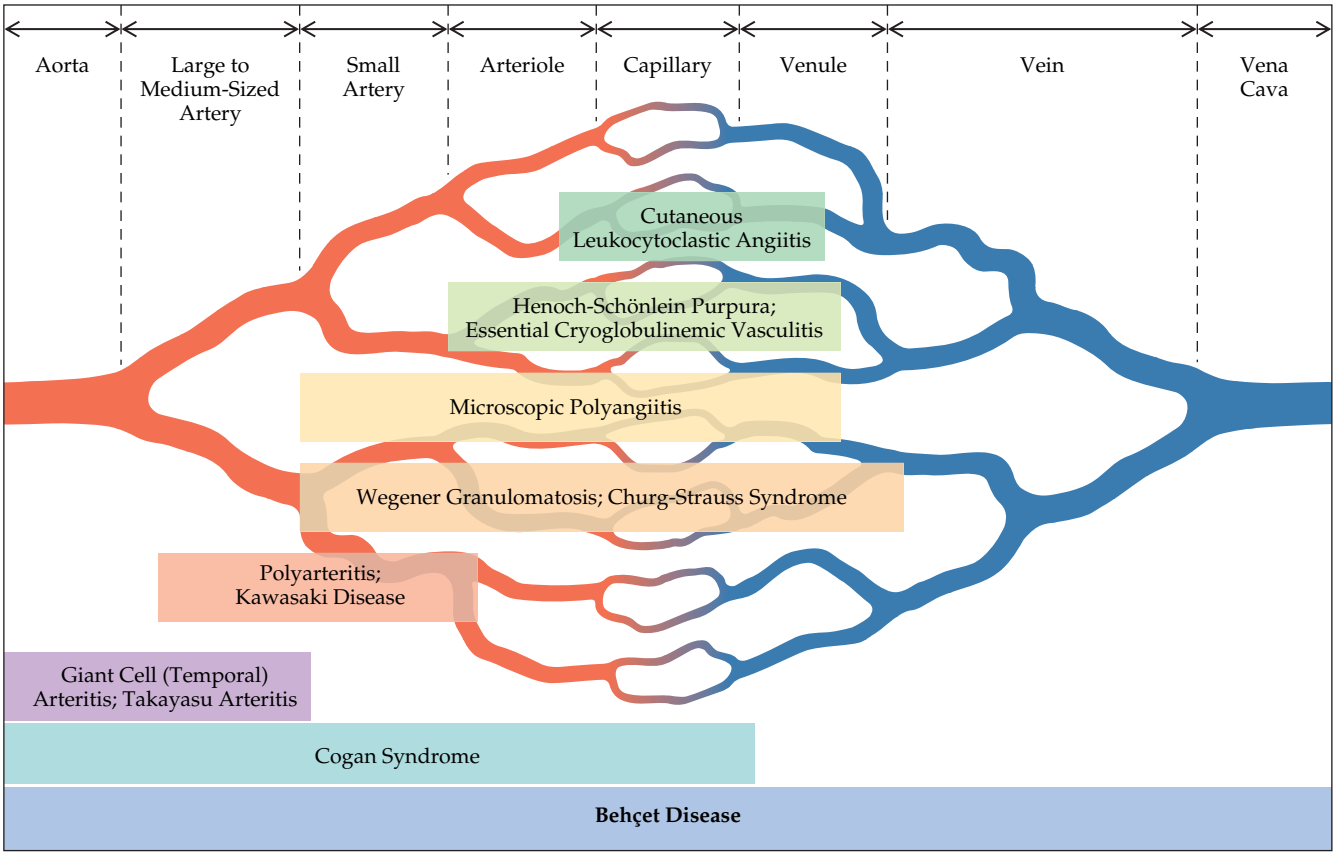

Figure 1 **Classification of the systemic vasculitis syndromes.**[1]

physician must promptly examine several fresh urine sediments. Urine that has been sitting for several hours before analysis is not as useful for identification of cellular casts, which rapidly degenerate ex vivo. The presence of red blood cell casts is highly suggestive of glomerulonephritis, but white cell casts may also be seen. Glomerulonephritis is usually asymptomatic. On the basis of the pattern of organ involvement, a differential diagnosis that includes specific types of systemic vasculitis and other disorders can then be generated.

CLASSIFICATION

Several classification schemes have been proposed for organizing the systemic vasculitic disorders into a consistent paradigm. These classifications are useful in distinguishing the clinical disorders that have distinct differences in prognosis and response to treatment.[1] No scheme is universally accepted. They all reiterate the characteristics of fulminant or classic disease, placing an emphasis on specificity of diagnosis. If a classification scheme is strictly adhered to, the newly ill patient without fully expressed disease is frequently left without a definitive diagnosis. The physician must recognize that until specific etiologies are defined, diagnostic entities remain conceptual, and overlap between diseases is not unusual. This must not be a deterrent to instituting therapy in the patient at risk for rapidly progressive organ damage. Nonetheless, classification systems provide useful constructs for communication and the design of research protocols [*see Figure 1*]. The most widely used classification schemes are based on the caliber of affected blood vessels, the pattern of organ involvement, and the presence or absence of granulomas, significant immune complex deposition, and eosinophilic infiltrates. Some authors have proposed a diagnostic role for the presence or absence of specific serum antineutrophil cytoplasmic antibodies (ANCAs), particularly antibodies to proteinase 3 and myeloperoxidase. At present, the appropriate role of these tests is to support a rationally developed clinical diagnosis, not to define one. In patients who do not fit neatly into a well-defined diagnostic category, these serologic tests should not supplant an attempt to obtain a tissue diagnosis. The presence of ANCA is not sufficient to make a diagnosis of a primary vasculitic syndrome; ANCA is not a screening test.

When the dominant symptoms and findings (i.e., neuropathy and cutaneous vasculitis) do not suggest a single specific vasculitic disorder, targeted physical examination and serologic testing may be helpful. Most valuable is biopsy confirmation of the specific disorder. The value of indiscriminate testing for antinuclear antibodies, ANCA, rheumatoid factor, and angiotensin-converting enzyme is arguable. Alternatively, infection with hepatitis B or C can be associated with a broad range of vasculitic syndromes, and these infections must be routinely excluded.[2]

OVERVIEW OF TREATMENT

The systemic vasculitides are potentially life threatening and may require potent anti-inflammatory and immunosuppressive therapy. Diagnoses should be made with as much certainty as possible. However, questions regarding alternative diagnoses or coexistent diseases may linger. Hence, even after therapy is initiated, physicians should maintain a high degree of vigilance to detect unrelated medical problems, complications of therapy,

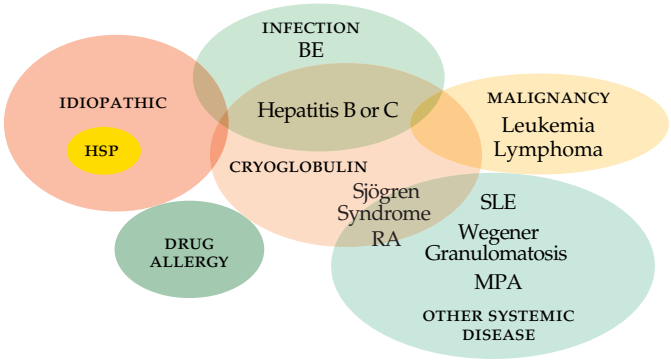

Figure 2 **A Venn diagram illustrates the relations between the causes of small vessel ("hypersensitivity") vasculitis. (BE—bacterial endocarditis; HSP—Henoch-Schönlein purpura; MPA—microscopic polyangiitis; RA—rheumatoid arthritis; SLE—systemic lupus erythematosus)**

or both. The signs and symptoms of unrecognized infection may transiently resolve with steroid therapy.[3] With the initiation of potent immunosuppressive therapy, there is a prolonged window of increased susceptibility to opportunistic infection. The greatest risks occur in patients with marked neutropenia or those receiving high doses of corticosteroids. Physicians must be particularly wary about attributing new problems to "flares" in the underlying disease without first excluding a new or recrudescent infection. Patients with varicella-zoster virus may present with fever and pain before appearance of the vesicles. *Pneumocystis carinii,* cytomegalovirus, and systemic fungal infections and reactivation of mycobacterial disease are observed more frequently in patients with systemic vasculitides than in the general population. Immunosuppression from steroids and other medications is frequently associated with mucosal candidiasis, less commonly associated with molluscum contagiosum, and rarely associated with Kaposi sarcoma.

Methotrexate, azathioprine, and cyclophosphamide may cause leukopenia and, less often, other cytopenias. In patients with decreased renal function, methotrexate must be used with caution, if at all; the dose of cyclophosphamide should be decreased and carefully monitored because the pro-drug (cyclophosphamide) is renally excreted. Bladder-emptying dysfunction is a relative contraindication to the long-term use of cyclophosphamide because increased exposure to toxic metabolites of the drug may predispose to bladder cancer or cystitis. The recent trend in the treatment of patients with certain potentially life-threatening systemic vasculitic syndromes has been to introduce therapy with a short course of corticosteroids (often with a second immunosuppressive agent), tapered from a high dose to a low dose, to induce remission and then, depending on the disease, to continue immunosuppressive therapy with an alternative regimen of corticosteroids to maintain remission. The second regimen may initially consist of cyclophosphamide, which is felt to be the most potent of these agents, but cyclophosphamide is then replaced with an agent that has a better safety profile (e.g., methotrexate or azathioprine). Therapy with that agent is then continued for many months.

Small Vessel Vasculitis

Vasculitis that affects capillaries and venules is the most common form of vasculitis and almost invariably involves the skin. It can occur at any age and affects men and women with equal frequency.

ETIOLOGY

Small vessel vasculitis can occur as an idiopathic disorder or secondary to drug allergy, bacterial endocarditis, viral infections such as those caused by hepatitis B or C, disseminated *Neisseria,* and rickettsiae; it can be part of a defined systemic autoimmune disorder such as Sjögren syndrome, systemic lupus erythematosus (SLE), or rheumatoid arthritis; or it can occur in association with hematologic, lymphoid, and solid-organ malignancies [*see Figure 2*]. Small vessel vasculitis can accompany diseases commonly associated with the involvement of larger vessels (e.g., Wegener granulomatosis [WG]).

DIAGNOSIS

Clinical Manifestations

Cutaneous involvement can occur in many of the primary or secondary vasculitic syndromes. Large, medium-sized, or small vessel occlusion can cause livedo, Raynaud phenomenon, or necrosis. Purpura is the most common manifestation of small vessel vasculitis. Small vessel vasculitis, particularly when associated with infections, is frequently associated with immune complex deposition. Vasculitis primarily involving the postcapillary venules has been termed hypersensitivity vasculitis in older literature.[4] Primary small vessel vasculitis may be limited to the skin or may be associated with visceral involvement, including alveolar hemorrhage, intestinal ischemia or hemorrhage, and glomerulonephritis.

Purpura tends to occur in recurrent crops of lesions of similar age and is more pronounced in gravity-dependent areas [*see Figure 3*]. When purpura is not primarily in gravity-dependent areas, cold agglutinin disease, cryoglobulinemia (which may be associated with an infection such as hepatitis C or with lymphoma), embolism, and infiltrative diseases should be excluded. Cutaneous vasculitis of any etiology may be associated with striking dependent edema.

In a case series of cutaneous small vessel vasculitis,[4] almost 100% of patients younger than 20 years had disease limited to the skin, whereas approximately 40% of the 172 patients older

Figure 3 **Palpable purpura of the distal extremities is the most common presentation of small vessel vasculitis.**

Table 2 Immunosuppressive Therapies for Vasculitis

Drug	*Dose*	*Efficacy Rating*	*Comments*
Prednisone	Often used at 1 mg/kg daily (split doses in severe disease) initially; tapered, with goal of discontinuance by 6 months or sooner if possible; utilize other drugs to enable this if possible	Primary therapy in all forms of life- or organ-threatening forms of vasculitis; probably most rapid-acting therapy	Ideally, check baseline PPD status; consider prophylaxis against *Pneumocystis* (when using high doses) and osteoporosis; monitor for development of glaucoma in elderly patients
Cyclophosphamide	1–3 mg/kg p.o. daily; avoid neutropenia; nadir is usually 9–14 days after initiation of therapy or change in dose; decrease dose in setting of renal insufficiency; monthly "pulse" dosing has been used (0.5–1 g/m^2), but there may be greater likelihood of relapse; give pulse dose after dialysis	Most potent nonsteroidal immunosuppressive therapy; unclear onset of action but should be given when severe disease recognized, particularly rapidly progressive glomerulonephritis	Major side effects limit long-term use of this drug: leukopenia, myeloproliferative disease, bladder damage, and malignancy; current trend is to induce remission in WG and other severe forms of vasculitis with prednisone and cyclophosphamide, with tapering of prednisone and change of cyclophosphamide to a less toxic (but likely less effective) medication (e.g., azathioprine or methotrexate)
Azathioprine	2–3 mg/kg daily p.o.	Less potent than cyclophosphamide; useful to maintain remission while trying to spare corticosteroid dosing	Not usually given as primary induction therapy; avoid leukopenia; can cause a confusing hypersensitivity reaction that includes high fever, with or without rash and eosinophilia
Methotrexate	Given once weekly (up to approximately 0.3 mg/kg/dose) along with daily folic acid (1 mg)	Less potent than cyclophosphamide; useful to maintain remission while trying to spare corticosteroid dosing; decrease dose for mild renal insufficiency; *avoid in patients with creatinine > 2.5 mg/dl*	Useful in maintaining remission; has been used as primary induction therapy with prednisone in patients with mild WG; significant frequency of relapse in WG patients maintained on this drug alone; monitor WBC, creatinine and transaminase levels (causes hepatitis and can cause cirrhosis; avoid any ethanol ingestion); can be given orally or by weekly injection; folic acid reduces "nuisance" side effects

PPD—purified protein derivative WBC—white blood cell count WG—Wegener granulomatosis

than 20 years had an associated or underlying systemic disorder. Seventeen adults had a systemic necrotizing vasculitis, four had malignancy, four had a bacterial infection causing the vasculitis, 11 had cryoglobulinemia, and 59 had Henoch-Schönlein purpura. The prevalence of infection with hepatitis C virus, likely the most common cause of mixed cryoglobulinemia,[2] was not reported in this series.

Laboratory Tests

Biopsy is most useful in excluding causes of nonvasculitic purpura such as amyloidosis, leukemia cutis, Kaposi sarcoma, T cell lymphomas, and cholesterol or myxomatous emboli. Tissue immunofluorescent staining is useful to support the diagnosis of Henoch-Schönlein purpura (specifically, IgA staining), SLE, or infection **(**the percentage of cases with positive results on immunofluorescent staining is not known**)**. The cells infiltrating and perhaps destroying the vessel wall may be neutrophils or lymphocytes, depending on the etiology. The pathology in most cases of small vessel vasculitis is leukocytoclastic angiitis (LCA). Hepatitis C infection should be excluded routinely in patients who present with unexplained purpura—an important example of the fact that even the demonstration of LCA does not indicate that a patient's illness is the result of a primary vasculitic syndrome.

CLINICAL SUBSETS

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a clinically defined small vessel vasculitic syndrome in which cutaneous features are usually striking and in which significant visceral involvement is less common. Henoch-Schönlein purpura, which occurs less frequently in adults than in children,[5] is usually associated with vascular and renal deposition of IgA-containing immune complexes. Common manifestations of Henoch-Schönlein purpura include purpura; urticaria; abdominal pain; gastrointestinal bleeding or intussusception (mostly in children); arthralgias or arthritis; and glomerulonephritis. Visceral symptoms may precede the skin lesions. Henoch-Schönlein purpura may be precipitated by medications or streptococcal or viral infections. It is usually a self-limited disorder, but the associated glomerulonephritis may, in rare instances (most often in adults), progress to renal failure. In the absence of renal dysfunction, Henoch-Schönlein purpura is often a self-limited but frequently recurrent syndrome that may require only symptomatic therapy.

Urticarial Vasculitis

Urticarial vasculitis represents a peculiar subset of small vessel vasculitis.[6] The clinical presentation is that of wheals or serpentine papules, sometimes with surrounding or geographically separate angioedema. Individual lesions are slow to resolve, often lasting for several days; the disease follows a more prolonged course than typical urticaria. There is frequently a burning, dysesthetic discomfort from the lesions. Like purpura, the lesions of urticarial vasculitis are frequently located in gravity-dependent areas and often heal with skin hyperpigmentation or an ecchymotic area. Most cases are idiopathic, although an association with an underlying systemic autoimmune disorder such as SLE, IgM paraproteinemia, or a viral infection has been described. In rare cases, urticarial vasculitis has been associated with a syndrome that includes hypocomplementemia and interstitial pulmonary disease. This syndrome is distinct from C1 esterase deficiency associated angioedema, which does not cause urticaria.

TREATMENT

Therapy for cutaneous vasculitis is first directed at eliminat-

a

b

Figure 4 **The nodular infiltrates of the lung in Wegener granulomatosis are shown less extensively in a standard radiograph (*a*) than in a computed tomographic scan (*b*).**

ing any underlying precipitant. Infectious etiologies should be sought out and treated. Potential offending drugs should be withdrawn. Association with myelodysplasia and myeloproliferative disease should be considered, especially if there are any hematologic abnormalities. If no precipitants are apparent, low-risk therapy can be attempted with nonsteroidal anti-inflammatory drugs, colchicine, pentoxifylline, dapsone, or short-term low-dose corticosteroids. Long-term corticosteroid therapy should be eschewed if at all possible. Compressive support stockings or panty hose may be useful in limiting the significant edema that often accompanies cutaneous vasculitis of the legs.

Visceral involvement with organ dysfunction may necessitate a more aggressive approach than that used in limited cutaneous vasculitis. Moderate-dose corticosteroids are generally effective. In the setting of potential complications from chronic corticosteroid use or the setting of severe visceral involvement, methotrexate, azathioprine, cyclophosphamide, or other immunosuppressive agents may occasionally be required [*see Table 2*]. When treating chronic, refractory small vessel disease that is not organ or life threatening, one must pay close attention to the risk-to-benefit ratio of selected therapies.

Wegener Granulomatosis

WG is a relatively uncommon, potentially lethal disease characterized by necrotizing granulomatous inflammation and vasculitis of small and medium-sized vessels.[7,8] Males and females of all ages can be affected.

DIAGNOSIS

Clinical Manifestations

WG is characterized by parenchymal necrosis with a variable contributory component of vasculitis. Multiple organs are often involved; there is a predilection for the upper and lower respiratory tracts, eyes, and kidneys.

Upper respiratory tract involvement Upper airway disease may be striking but is often attributed for months or even years to routine sinus disease until other manifestations of WG are recognized. Even after the diagnosis is made and immunosuppressive treatment is provided, sinus disease may be recalcitrant to therapy. This chronicity may be caused in part by superinfection of damaged tissue by *Staphylococcus aureus.* Anatomic damage can include septal perforations and saddle-nose deformities. Laryngotracheal involvement may result in subglottic stenosis, which is best treated by local corticosteroid injection therapy. Ear involvement is common, particularly otitis media, which may produce conductive hearing loss. Orbital pseudotumors may cause proptosis with intractable pain and loss of vision; these inflammatory and fibrous masses may be refractory to anti-inflammatory therapy, immunosuppressive therapy, and even radiation therapy. Conjunctivitis, uveitis, and scleritis alone or in combination commonly occur.

Lower respiratory tract involvement Lung involvement may be absent at the onset of disease or present dramatically as diffuse alveolar hemorrhage. One third of pulmonary lesions noted on imaging studies [*see Figure 4*] are asymptomatic (CT scanning is more sensitive than radiography). Nodules often undergo necrosis leading to cavity formation. Bronchospasm is not characteristic of WG. If airway obstruction is suspected, bronchoscopy should be considered to exclude endobronchial or subglottic stenoses. It is frequently necessary to rule out infectious causes of the pulmonary infiltrates, and bronchoscopy is useful in this regard. However, tissue obtained from transbronchial biopsy is usually of insufficient quantity to confirm the pathologic diagnosis of WG.

Open lung biopsy is often the optimal method for demonstrating the typical pathologic findings of WG and for excluding malignancies and atypical infections. Typical open lung biopsies[9] may contain areas of necrosis, frequently in a broad pattern; giant cells in the parenchymal tissue; and vasculitis. Not all histopathologic features may be present in the same biopsy section. Because these findings may also occur in chronic mycobacterial or fungal infections, special stains and cultures for these agents are essential.

Glomerulonephritis Glomerulonephritis is a common cause of morbidity and mortality in WG. Its presence or absence defines the generalized or limited forms of the disease.

Table 3 Clinical Features of Vasculitis

Disorder	*Common Target Organs*	*Special Pathologic Features*	*Special Laboratory Studies*	*Comments*
Microscopic polyangiitis	Nerve, glomerulus, lung (small vessels), GI tract	No giant cells, vasculitis, proliferative GN (no or rare immune deposits*)	p-ANCA (antimyeloperoxidase)	Rule out hepatitis B and C
Polyarteritis nodosa	Nerve, GI tract	Arteritis of medium muscular arteries, no giant cells, no GN	No ANCA	No small vessel involvement; rule out hepatitis B and C
Wegener granulomatosis	Upper airway, eye, lung (small vessels), glomerulus, nerve, musculoskeletal system	Giant cells, geographic necrosis, mild eosinophilia, vasculitis, proliferative GN (no or rare immune deposits)	c-ANCA (anti-PR3)	Chronic sinus or ear disease
Churg-Strauss syndrome	Nerve, lung infiltrates, heart, skin	Giant cells, eosinophilia, vasculitis, proliferative GN (no or rare immune deposits)	Eosinophilia ± ANCAs	Positive atopic history

*Presence of immune deposits suggests possible hepatitis B or C infection.
ANCA—antineutrophil cytoplasmic antibody c-ANCA—cytoplasmic ANCA GN—glomerulonephritis p-ANCA—perinuclear ANCA PR3—proteinase 3

Glomerulonephritis is often aggressive, or it may be relatively indolent. It may be clinically and pathologically indistinguishable from idiopathic rapidly progressive crescentic glomerulonephritis, and it is usually clinically silent. The evolution from subclinical to dialysis-dependent renal disease may occur over several weeks. Glomerulonephritis may be present at the outset of the disease, or it may develop only after the patient has been ill with an apparently limited form of the disease. The importance of frequent microscopic urinalyses in the initial and follow-up evaluation of patients with WG cannot be overemphasized. Especially in elderly or debilitated patients, valuable information may be obtained by occasional 24-hour urine collections, which can establish a more accurate estimate of the glomerular filtration rate (GFR) than that provided by the serum creatinine measurement. Renal biopsy may reveal focal and segmental glomerulonephritis with variable glomerular proliferative changes, crescent formation, and necrosis, in the absence of significant immune complex deposition. Although supportive of the diagnosis of WG, these findings are not diagnostic of the disease, and renal biopsy is not the preferred study to confirm the specific diagnosis of WG.

Additional clinical manifestations Musculoskeletal involvement occurs in over half of patients with WG. Symptoms may include arthralgias or arthritis; these symptoms may be migratory, additive, or of fixed distribution. Rheumatoid factor is frequently present in patients with WG, and it may cause diagnostic confusion with rheumatoid arthritis when joint symptoms are significant. The joint disease of WG only rarely produces bone erosions. Neurologic signs and symptoms occur in fewer than 50% of patients, peripheral neuropathy in fewer than 20%, and involvement of the central nervous system in fewer than 10%. Oculomotor defects may occur because of impingement by a retro-orbital mass or sinus disease. Gastrointestinal ischemia and ulcerations are infrequent but may be confused with inflammatory bowel disease, especially because the latter can be associated with ANCA (usually perinuclear ANCA, or p-ANCA). Up to 50% of WG patients exhibit cutaneous involvement with purpura, panniculitis, or ulcerations. The activity of the skin disease generally parallels systemic disease activity.

Laboratory Tests

Unexplained chronic inflammation of the respiratory tract or eye or the presence of glomerulonephritis is consistent with the diagnosis of WG. The probability of WG is increased when multiple organ involvement is present, upper airway disease is destructive, and pulmonary nodules (especially with cavities) are demonstrated by radiography. Any combination of organ involvement is possible, but most patients exhibit upper airway involvement at the time of diagnosis.

If the entire clinical picture is compatible with WG and if alternative diagnoses have been appropriately ruled out, the finding of circulating cytoplasmic ANCA (c-ANCA) with anti–proteinase 3 specificity is sufficient to make the provisional diagnosis and initiate therapy without a tissue diagnosis. Approximately 20% of patients with WG may have p-ANCA with antimyeloperoxidase specificity. If there are any atypical features or special concerns regarding the initiation of immunosuppressive therapy or if the patient does not respond appropriately to therapy, histopathologic confirmation of the diagnosis is mandatory. The presence of ANCA is not equivalent to the presence of vasculitis; ANCAs can be found in other diseases. The ANCA level is not a reliable means to follow disease activity.[10-12] Because WG generally requires therapy with a glucocorticoid plus a cytotoxic agent, it should be distinguished from other inflammatory disorders, including other vasculitic syndromes [*see Table 3*], which may be effectively treated with a less toxic regimen.

TREATMENT

Initial treatment of generalized WG virtually always requires dual-drug immunosuppressive therapy. Corticosteroids may produce symptomatic improvement in the upper airway, lungs, skin, and musculoskeletal system, but tapering usually results in a flare in the disease. Acutely serious disease, particularly renal disease that is progressing, is treated initially with corticosteroids and daily cyclophosphamide with subsequent tapering of the corticosteroids over several months. Many authors recommend that once remission is achieved, cyclophosphamide therapy should be replaced by methotrexate or azathioprine therapy for an additional 12 months of therapy [*see Table 2*]. There are some strong relative contraindications to the long-term use of cyclophosphamide, including bladder dysfunction (increased risk of drug metabolite–induced cystitis and bladder cancer) and leukopenia. In milder or limited WG, weekly doses of methotrexate (0.20 to 0.30 mg/kg, adjusted for renal function) with folic acid or leucovorin may be substituted for cyclophosphamide. Patients undergoing treatment with immunosuppressives must be continuously monitored for flares

in disease, opportunistic infections, and side effects. Flares may be more frequent in patients treated with methotrexate than in those receiving longer courses of cyclophosphamide.[12] Side effects include cytopenias and drug-induced pneumonitis. Methotrexate may cause hepatitis, marrow suppression, and, on rare occasions, cirrhosis. It should be avoided in the setting of renal insufficiency or alcohol use. Some authors have suggested using trimethoprim-sulfamethoxazole as adjunctive therapy for the treatment of WG and for prevention of bacterial infections that may promote flares of upper airway disease. This approach remains highly controversial. Administration of trimethoprim-sulfamethoxazole three times weekly is useful in protecting patients against *P. carinii* pneumonia while they are receiving intensive immunosuppressive therapy. Local nasal and sinus toilet and otolaryngoscopic evaluations are a routine part of the care of patients with upper airway disease. Prophylactic measures to prevent osteoporosis should always be considered when corticosteroids are used on a long-term basis.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS), or allergic granulomatosis angiitis, is a rare syndrome that affects small to medium-sized arteries and veins in association with bronchial asthma.

DIAGNOSIS

Clinical Manifestations

CSS displays clinical similarities to WG in terms of organ involvement and pathology, especially in patients with upper or lower airway disease or glomerulonephritis. It can follow a rapidly progressive course. CSS differs most strikingly from WG in that the former occurs in patients with a history of atopy, asthma, or allergic rhinitis, which is often ongoing. In the prevasculitic atopy phase, as well as during the systemic phase of the illness, eosinophilia is characteristic and often of striking degree (≥ 1,000 eosinophils/mm^3). When eosinophilia is present in WG, it is usually more modest (~500 eosinophils/mm^3).

Systemic features of CSS include some combination of pulmonary infiltrates, cardiomyopathy, coronary arteritis, pericarditis, polyneuropathy (symmetrical or mononeuritis multiplex), ischemic bowel disease, eosinophilic gastroenteritis, ocular inflammation, nasal perforations, glomerulonephritis, cutaneous nodules, and purpura.[13,14]

The patchy pulmonary infiltrates of CSS are often transient and may be associated with alveolar hemorrhage. Pulmonary nodules are uncommon and rarely cavitate. Pleural effusions are common and often contain abundant eosinophils. Clinical distinction from hypersensitivity pneumonitis, allergic aspergillosis, and pulmonary lymphoma is at times difficult. Several cases of CSS have been reported to have occurred after the introduction of inhibitors of 5-lipoxygenase and while patients with chronic bronchial asthma are being weaned off corticosteroids.

Cardiac disease can be severe and is a leading cause of mortality. Valvular heart disease is not as striking or as common as it is in the idiopathic hypereosinophilic syndrome. Neurologic involvement occurs in more than 60% of patients. Such involvement may be severe; it is generally attributable to arteritis. Cutaneous purpura, urticaria, polymorphous erythematous eruptions, and nodules occur. Gastrointestinal involvement resulting from ischemic vasculitis, eosinophilic gastroenteritis, or both may cause pain, cramping, and diarrhea.

Laboratory Tests

Histopathology typically exhibits extravascular granulomatous inflammation, with a prominent eosinophilic infiltrate and vasculitis. Vasculitis in a given tissue section may be granulomatous or nongranulomatous. Granulomas can be found in tissue at areas separate from the demonstrable vasculitis. Eosinophilic infiltrates are more striking than in WG. Neither abundant eosinophils, granulomas, nor giant cells are found in classic polyarteritis nodosa (PAN) or microscopic polyangiitis (MPA). The pathology of the nodules is not by itself sufficient to make a diagnosis of CSS, because similar pathology can be seen in lymphoma and sarcoidosis. Glomerulonephritis is frequently not as severe as in WG, but when present, it is usually focal and segmental and indistinguishable from other forms of so-called pauci-immune glomerulonephritis (i.e., glomerulonephritis that is without significant tissue deposition of immune complexes).

TREATMENT

CSS is generally responsive to corticosteroid therapy. Most patients are able to be withdrawn from steroids. However, bronchial asthma and sinus disease may require ongoing therapy, even if the vasculitic component of the disease has remitted. Patients with severe or refractory visceral organ involvement are empirically treated with additional agents such as cyclophosphamide, methotrexate, or azathioprine; the corticosteroids are tapered after remission is achieved [*see Table 2*].

Polyarteritis Nodosa and Microscopic Polyangiitis

CLASSIFICATION

Attempts to separate PAN and MPA, two forms of necrotizing small to medium-sized vessel arteritis, have not been universally accepted. A recent international conference proposed that the diagnosis of these disorders be based on the absence of granulomatous inflammation in both and by involvement of arterioles, capillaries, venules, and glomerular capillaries in MPA but *not* in PAN. Older studies of patients with PAN did not uniformly make this distinction. Even more important, patients with viral hepatitis B or C were not excluded from older studies. The recognition of viral hepatitis is crucially important because chronic hepatitis B or C[2,15] can elicit a secondary vasculitic syndrome indistinguishable from PAN or MPA in presentation but distinct in response to therapy.[16] MPA involves vessels ranging in size from capillaries and venules to medium-sized arteries [*see Figure 1*].[17] Clinically, MPA can mimic WG, although some authors have arbitrarily defined MPA as excluding involvement of the upper airway.

DIAGNOSIS

Clinical Manifestations

Glomerulonephritis, particularly rapidly progressive glomerulonephritis, and alveolar hemorrhage are common in MPA and absent, by definition, in classic PAN.

PAN affects the medium-sized muscular arteries and, like MPA, is associated with peripheral neuropathy and bowel ischemia.[18-20] Azotemia and hypertension in PAN may occur because of arteritis of the renal arteries but not because of glomerulonephritis. Microaneurysm formation in medium-sized visceral arteries may be striking, and they may rupture.

Constitutional symptoms such as fever, asthenia, and myalgias are common in both PAN and MPA. Elevated acute-phase reactants, thrombocytosis, leukocytosis, and the anemia of inflammatory disease are common, although they are not uniformly present.

When the clinical syndrome of PAN or MPA is suspected, bacterial infection (e.g., endocarditis) and viral infection (e.g., hepatitis B or C) must be excluded. The association with hepatitis B or C infection may not dramatically alter the presentation of the PAN or MPA syndrome, except that membranous glomerulonephritis, cryoglobulinemia, immune complex–associated glomerulonephritis, hepatic failure, and thrombocytopenia are more likely to occur with viral hepatitis–associated vasculitis.

Antiphospholipid antibody syndrome (APLS) can mimic PAN by presenting as mesenteric ischemia or renal insufficiency caused by thrombotic occlusion of mesenteric and renal vessels.[21] Features of APLS and arteritis affecting muscular arteries include livedo reticularis [*see Figure 5*]. Glomerulonephritis cryoglobulinemia, immune complex–associated glomerulonephritis, and peripheral neuropathy are not expected in APLS unless the patient also has SLE. Thrombocytopenia can occur with APLS but is not expected in PAN. Cholesterol embolization should also be considered as a cause of livedo, renal insufficiency, eosinophilia, and constitutional symptoms[22]; the clinical history of a recent vascular procedure and the performance of a biopsy will help confirm the diagnosis.

Laboratory Tests

The diagnosis of MPA and PAN should ideally be based on histopathologic demonstration of arteritis and the clinical pattern of disease. A biopsy specimen of clinically involved, nonnecrotic tissue that demonstrates the presence of arteritis of muscular arteries is the ideal supportive finding for the diagnosis of arteritis of a medium-sized vessel, but such a biopsy is not always possible. The presence of serum p-ANCA with antimyeloperoxidase specificity (in 60% of MPA patients) supports the clinical diagnosis of MPA, but p-ANCA is not specific for this disease. ANCAs are not characteristic of PAN. MPA is a form of pauci-immune glomerulonephritis; that is, the renal biopsy tissue in MPA, as in WG and CSS, does not contain extensive immune complexes on immunofluorescent staining and electron microscopy. Lung biopsy in the setting of pulmonary infiltrates or hemorrhage reveals capillaritis, a histopathologic pattern that can also be seen in WG, SLE, and anti–glomerular basement membrane disease. Biopsy is most useful in ruling out alternative pulmonary diagnoses; open lung and thoracoscopic techniques have a higher yield for demonstrating vasculitis than transbronchial biopsy. Classic PAN does not cause glomerulonephritis or pulmonary parenchymal disease.

The demonstration of arteritis in PAN may be difficult, especially in the setting of dominant constitutional symptoms and the absence of easily accessible, disease-affected tissue. Biopsy efforts should be directed toward tissue that is abnormal as demonstrated by symptoms or objective testing. Sural nerve biopsy has become a popular option when attempting to diagnose an arteritis that is affecting medium-sized muscular vessels. The sural nerve is an accessible pure sensory nerve, and its vasa nervorum contains small as well as medium-sized muscular arteries. Nerve conduction studies can identify a diseased ischemic sural nerve before the appearance of clinical symptoms.[23] Multiple reports have emphasized the low diagnostic yield from the biopsy of asymptomatic and electrically normal nerve. Even nerves exhibiting abnormal conduction have reportedly showed no diagnostic pathology 46% of the time.[24] There is notable morbidity associated with sural nerve biopsy; 13 of 60 patients experienced wound infections or delayed healing, and three patients suffered from new pain in the distribution of the sural nerve that underwent biopsy.[24] Biopsy of clinically uninvolved tissue (i.e., asymptomatic muscle) has a diagnostic yield of less than 30%.

Figure 5 **Livedo reticularis is characterized by reddish-blue mottling of the extremities caused by occlusion of the deep dermal arterioles.**

Abdominal angiography is frequently utilized in the evaluation of patients who may have medium-sized vessel arteritis when biopsy has been unrewarding or is not an option. Arteries affected by polyarteritis nodosa and other disorders of medium-sized muscular arteries may develop microaneurysms or stenoses that can be visualized by angiography. When angiography is used in an effort to diagnose systemic necrotizing vasculitis in the absence of pathologic evidence of the disease, several caveats must be noted. Angiography has limited spatial resolution; smaller vessels are not well seen. In patients with primarily smaller vessel disease, the angiogram will not likely be diagnostic. In one study, angiograms were diagnostic in only four of 30 patients with MPA, a disease that affects both small and medium-sized arteries.[17] Different investigators have reported aneurysms in 60% to 90% of patients with PAN. Aneurysms take time to develop and may not be present early in the course of the illness. In addition to being associated with aneurysms, arteritis may be associated with stenoses, which may be longer and smoother than typical atherosclerotic lesions or occlusion. To maximize the yield from the procedure, angiography should in-

clude the celiac, renal, and mesenteric vessels. Lack of clinical involvement of an organ (i.e., no intestinal ischemia) does not exclude the possibility of finding abnormal vessels on angiography. It has been suggested that the visualization of aneurysms in PAN denotes more severe disease; it is unclear whether their presence may alternatively relate to the actual duration of the untreated illness. Aneurysms may resolve with successful treatment of primary or viral hepatitis–associated disease. The presence of visceral microaneurysms is not diagnostic of PAN. They have also been anecdotally described in patients with WG and MPA, likely representing medium-sized muscular artery involvement in these diseases. Microaneurysms also occur in nonvasculitic disorders. Isolated case reports have described aneurysms in patients with atrial myxoma, bacterial endocarditis, peritoneal carcinomatosis, or severe arterial hypertension and after methamphetamine abuse. Inadequate data are available to assess the sensitivity and specificity or the predictive value of abdominal angiography in the diagnosis of necrotizing arteritis. As is the case when interpreting a biopsy result of suspected vasculitis, imaging studies must be considered in the light of the entire clinical profile. Angiography is generally avoided in the setting of progressive or significant renal insufficiency.

TREATMENT

Treatment of both PAN and MPA is empirical[25] [*see Table 2*]. Corticosteroids in high doses (1 mg/kg daily of prednisone or its equivalent) remain the initial mainstay of therapy for both disorders in the acutely ill patient. Use of corticosteroids alone may be sufficient in patients who do not have critical organ involvement, defined as renal insufficiency, gastrointestinal ischemia, cardiomyopathy, or dense peripheral neuropathy. Therapy with corticosteroids alone may fail more frequently in MPA than in PAN, given the tendency for frequent relapses in MPA.[17] Patients who require long-term corticosteroid therapy for disease control or patients who have clinical markers of severe disease are usually treated with glucocorticoids and an additional immunosuppressive agent such as cyclophosphamide. The indications for initial combination therapy have not been adequately studied.

When active hepatitis B or C infection is present, a relatively short course of steroids should be considered on the basis of disease severity and the organs at acute risk for failure, in conjunction with aggressive antiviral therapy.

Kawasaki Disease

Kawasaki disease (KD) was first described in 1967 as mucocutaneous lymph node syndrome.[26] It typically affects infants and young children, causing dominant cutaneous manifestations, fever, and coronary arteritis. It can on rare occasions affect adults.

DIAGNOSIS

The presence of characteristic clinical features has permitted the establishment of diagnostic criteria for KD [*see Table 4*]. Vasculitis may involve vessels ranging in size from venules to the aorta. Prominent inflammation is noted in the larger coronary arteries, which results in aneurysm formation in approximately 25% of untreated patients. The immediate and delayed life-threatening cardiac complications of the disease, coupled with its unique therapy (aspirin and intravenous γ-globulin), mandates prompt clinical diagnosis. Biopsy is generally not necessary, nor is it likely to yield a specific diagnosis.

High, spiking fevers may persist for 1 to 2 weeks if left untreated. Rapid defervescence is usually observed with initiation of appropriate therapy. Nonexudative conjunctivitis often appears with the fever. Aseptic (lymphocytic) meningitis is common. Oral involvement includes erythema, dryness and fissuring of the lips, nonexudative pharyngitis, and tongue erythema with very prominent papillae. Mucosal ulcerations are not characteristic of this illness. Distal limb swelling may appear days after the fever, with erythema and tenderness that are not limited to the joints. Desquamation, often in sheets, may begin days to a few weeks after the onset of fever. When desquamation occurs early in KD, it may appear concurrently with a truncal rash and eye and lip changes; it may mimic a drug reaction or Stevens-Johnson syndrome. The rash is usually diffuse and polymorphous, with urticarial, morbilliform, annular, or plaque components, but it is not vesicular. Adenopathy, which is present in 75% of patients, is most apparent in the cervical region.

The morbidity and mortality (< 3%) of KD is overwhelmingly associated with the development of inflammatory coronary artery aneurysms, most of which are asymptomatic at the time of formation. Aneurysms may be detected by echocardiography. Thrombosis can occur in the aneurysms, resulting in direct or embolic coronary artery occlusion. Coronary events may occur weeks or even many years after the febrile illness. A baseline echocardiogram should be obtained at the time of the acute illness and repeated 2 and 6 weeks later. Early recognition of the disease and treatment with intravenous immunoglobulin and aspirin have significantly decreased the frequency of aneurysm formation and thrombotic coronary events.

TREATMENT

Treatment of KD should be initiated with intravenous immunoglobulin (2 g/kg as a single dose) and aspirin (80 to 100 mg/kg/day every 6 hours) as soon as the disease is seriously suspected.[27] Aspirin is more effective than corticosteroids in preventing aneurysms. Corticosteroid therapy is usually unnecessary, and some authors feel that it is relatively contraindicated. Symptoms tend to respond within several days after the institution of aspirin and intravenous immunoglobulin. In resistant cases, however, corticosteroids are frequently added to the above therapies.

Table 4 Diagnostic Criteria for Kawasaki Disease

- Persistent fever (> 5 days)
  - *plus*
- Four of the following five conditions:
  - Nonpurulent bilateral conjunctivitis
  - Oral mucosal involvement
    - Erythematous pharynx
    - Red or fissured lips
    - Strawberry tongue
  - Soft tissue abnormalities of hands and feet
    - Edema/erythema
    - Desquamation
  - Polymorphous, nonvesicular rash
  - Cervical adenopathy

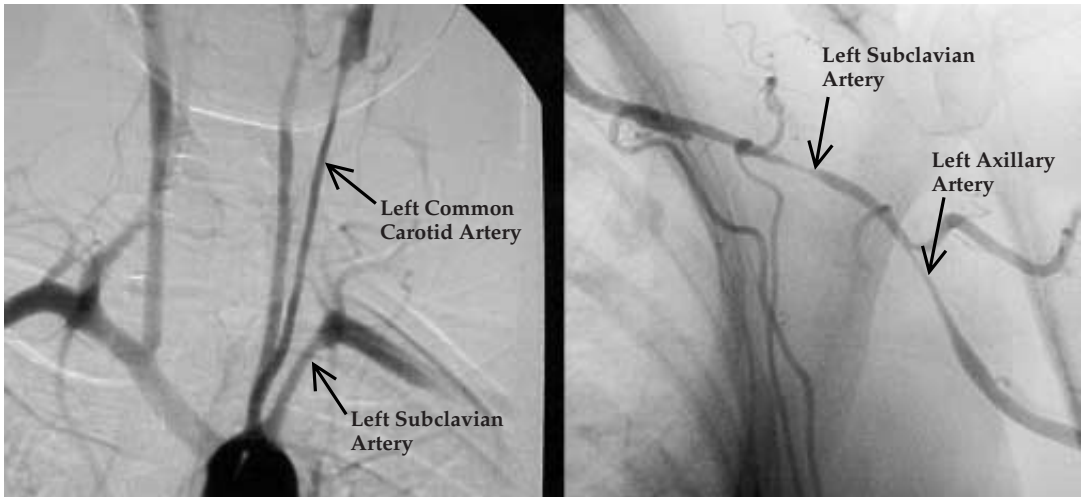

Figure 6 **Angiograms of a patient with Takayasu aortitis demonstrating long, smooth stenotic lesions of the left subclavian artery and involvement of other branches of the aortic arch vessels.**

Large Vessel Arteritis

Temporal, or giant cell, arteritis (GCA) of the elderly and Takayasu arteritis (TA) are the most common inflammatory diseases of the aorta and its major branches. Similar vascular targeting may occur in Behçet disease, Cogan syndrome, and sarcoidosis. The last two conditions are recognized by the pattern of extra-aortic organ involvement. It is uncertain whether TA and GCA are distinct disorders or are the same disorder with modified expression in different age groups.

TEMPORAL OR GIANT CELL ARTERITIS

GCA generally affects individuals older than 50 years.[28,29] In many patients, it is associated with the syndrome of polymyalgia rheumatica (PMR). PMR is characterized by proximal muscle pain, with nocturnal and early morning worsening. There may be a subjective sense of weakness, without true weakness on examination and without elevation of serum muscle enzyme levels.

GCA is variably associated with fever, scalp tenderness, headache, masticatory muscle claudication, peripheral vascular disease, inflammatory aortic aneurysms, and retinal ischemic syndromes. Oligoarticular arthritis, often in the upper extremity, and acute carpal tunnel syndrome can occur. The ischemic symptoms and signs may be clinically indistinguishable from those occurring in arteriosclerotic obliterative disease.

Examination for disparate four-extremity blood pressure readings, abdominal aneurysms, and bruits must be part of the routine follow-up visits of patients with GCA or PMR. Pathologic findings of GCA can occur in superficial temporal arteries of patients with PMR, even without any symptoms of GCA. However, routine biopsy of the superficial temporal arteries in patients with PMR, without any other symptoms of GCA, is not warranted.

Levels of acute-phase reactants are elevated in more than 80% of patients. Definitive diagnosis of GCA is generally made by biopsy of the superficial temporal artery. Pathology in GCA usually reveals chronic mononuclear cell infiltrates; destruction of the internal elastic lamina; and giant cells. The presence of giant cells is not requisite to make the diagnosis. The presence of characteristic clinical features such as new headache and jaw claudication, especially with concurrent PMR, may allow for a presumptive diagnosis in the absence of a biopsy or even when the superficial temporal artery biopsy is negative. However, because other conditions can mimic GCA, including atherosclerosis, an attempt to diagnose GCA by biopsy is warranted in most patients.[30] Corticosteroid therapy will not rapidly affect the biopsy results and should not be withheld from a patient strongly suspected of having GCA who is awaiting biopsy. Bilateral superficial temporal artery biopsy increases the diagnostic yield.

TAKAYASU ARTERITIS

Takayasu arteritis (pulseless disease) is a chronic inflammatory disease affecting the aorta and its major branches.[31] Usually diagnosed in younger, predominantly female patients of reproductive age, TA can also occur in young children and older patients of either sex. TA is more commonly associated with stenoses and aneurysms of the aorta and aortic branch vessel than is GCA.

The presenting clinical syndrome may include a prolonged flulike illness, including a polymyalgia rheumatica pattern of muscle pain. Many patients initially present with symptoms of limb, cerebral, or cardiac ischemia in the absence of any constitutional features. The characteristic features of the disease reflect the ischemia produced by the inflammatory stenoses of the aorta and its major branches. Renal ischemia can elicit high renin hypertension. Predominant sites of stenosis are the aortic arch vessels, particularly the subclavian arteries [*see Figure 6*]. Arm claudication with bruits is common. Superficial artery pain and tenderness (e.g., carotidynia) may be found on examination but are not diagnostic of TA. Severe central hypertension caused by renal artery stenosis may not be recognized because of coexistent arm artery stenosis; thus, four-extremity blood pressure readings must be evaluated initially and monitored on a frequent basis. Occasionally, stenoses exist in all major vessels of the extremities, and cuff monitoring may be an unreliable measure of central aortic pressures. Stroke is not uncommon and is often related to undetected central hypertension. It is extremely difficult to assess the activity of TA; the presence or absence of constitutional features or elevated acute-phase reactants are poor measures of disease activity. This impression is supported by vessel histopathology ob-

tained during reconstructive surgery. Over 40% of vascular specimens from patients thought to be in remission revealed active inflammation.

Diagnosis of TA is usually made by arteriographic demonstration of stenotic lesions; aneurysms are less commonly observed. The entire arch, as well as the abdominal aorta and renal vessels, should be evaluated. It is of paramount importance that central arterial pressure be routinely obtained at the time of angiography and compared with simultaneously obtained arm and leg cuff pressures. The role of sequential vascular magnetic resonance imaging in the evaluation and follow-up of these patients is currently under investigation.[32] This technique may reveal therapy-related changes in vessel wall thickness and edema as well as changes in lumen size. Pathologic documentation is difficult to obtain in TA, but the histopathology, usually obtained at the time of bypass surgery, is similar to that for GCA. Preoperative discussion with the vascular surgeon is mandatory to ensure that appropriate tissue samples are obtained if possible.

TREATMENT OF GCA AND TA

Corticosteroids are the initial treatment for both TA and GCA. GCA is generally very responsive to steroid therapy, although the most appropriate initial dose remains controversial. Initial daily doses of between 20 mg and 1 mg/kg have been advocated, with tapering over 8 to 12 months. It is generally recommended (without the support of data from controlled trials) that patients with any symptoms of ocular ischemia be initially treated with high-dose corticosteroids (at least 1 mg/kg of prednisone or its equivalent, with some authors suggesting I.V. methylprednisolone in doses of up to 1 g daily for several days). A significant proportion of patients with GCA require several years of therapy. Measurement of acute-phase reactants provides an imperfect index of disease activity and should not be the sole guide for adjustment of steroid dosing. If significant steroid side effects occur or if patients experience relapses during tapering, a second-line agent such as methotrexate is often added on an empirical basis to the corticosteroid therapy. However, the value of adjunctive steroid-sparing agents in GCA is currently unproved. A recent large prospective, randomized trial was unable to demonstrate a positive effect from methotrexate therapy.[33] Vascular reconstructive surgery, angioplasty, and stent placement are adjunctive therapeutic options in some patients. Although very preliminary experience suggests a high degree of stent failure, the frequent involvement of the subclavian vessels in TA must be taken into consideration when choosing the graft implantation site for coronary or carotid bypass procedures. High-dose corticosteroid therapy, especially in the elderly, has potentially dangerous side effects. Special attention must be paid to the prevention of opportunistic infections, osteoporosis, glaucoma, hyperglycemia, and hyperlipidemia.

The author has received grants from Abbott Laboratories and Wyeth Pharmaceuticals, and he has received grants from and served as advisor or consultant for Pfizer/Pharmacia and Centocor, Inc.

The drugs cytoxan, corticosteroids, methotrexate, pentoxifylline, colchicine, and dapsone have not been approved by the FDA for uses described in this chapter.

IX CRYSTAL-INDUCED JOINT DISEASE

Christopher Wise, m.d.

The presence of precipitated crystals in the synovium or synovial fluid can be associated with an inflammatory response that usually manifests itself as an acute arthritis associated with synovial fluid leukocytosis. The identification of monosodium urate (MSU) crystals in the synovial fluid of patients with acute gout in 1961 by McCarty and Hollander represented the initial recognition of arthritis associated with articular crystal deposition.[1] This development was followed in 1962 by the recognition of so-called pseudogout, which is associated with calcium pyrophosphate dihydrate (CPPD) crystals.[2] Since then, a great deal has been learned about these two common types of arthritis. In addition, the role of crystals in the pathogenesis of osteoarthritis and other arthropathies has been further explored. The diagnosis of crystal-induced arthritis requires the identification of crystals in synovial fluid or tissue; in most cases, this acute arthritis is self-limited.

Gout

DEFINITION AND CLASSIFICATION

Gout is defined as an arthritis associated with the presence of MSU crystals in synovial fluid or tissue. Gout is often classified as primary or secondary [*see Table 1*], and both forms are associated with hyperuricemia. Gout associated with an inborn error in metabolism or decreased renal excretion without other renal disease is referred to as primary gout, whereas gout associated with an acquired disease or the use of a drug is called secondary gout. In both primary and secondary gout, chronic hyperuricemia may be the result of overproduction of uric acid caused by increased purine intake, synthesis, or breakdown, or it may be the result of decreased renal excretion of urate.

EPIDEMIOLOGY

Gout is predominantly a disease of middle-aged men, but there is a gradually increasing prevalence in both men and women in older age groups. The annual incidence of gout in men in most studies is in the range of one to three per 1,000, but the incidence is much lower in women. In the Framingham Study, for example, the 2-year incidence of gout was 3.2 per 1,000 men versus 0.5 per 1,000 women.[3] A study of gout in Rochester, Minnesota, over the past 2 decades has suggested that the incidence of gout may be increasing.[4]

The overall prevalence of self-reported gout in the general population is 0.7% to 1.4% in men and 0.5% to 0.6% in women. However, in people older than 65 years, prevalence increases to 4.4% to 5.2% in men and 1.8% to 2.0% in women.[5] In male populations, the prevalence of gout reaches impressive levels by the fifth decade. In a study of male medical students, the prevalence of gout reached 5.8% in whites and 10.9% in African Americans surveyed for a mean of 28 years after graduation.[6] In patients who experience the onset of gout after 60 years of age, the prevalence in men and the prevalence in women are almost equal; in those who experience onset after 80 years of age, the prevalence is greater in women.[7]

The incidence and prevalence of gout are parallel to the incidence and prevalence of hyperuricemia in the general population. Serum urate levels increase by 1 to 2 mg/dl in males at the time of puberty, but females exhibit little change in urate levels until after menopause, when concentrations approach those seen in males.[8] Most patients with elevated serum uric acid levels do not have gout, but hyperuricemia is clearly associated with an increased risk of gout.[9] For example, in persons with serum urate levels greater than 10 mg/dl, the annual incidence of gout is 70 per 1,000 and the 5-year prevalence is 30%, whereas in persons with levels less than 7 mg/dl, the annual incidence is only 0.9 per 1,000 and the 5-year prevalence is 0.6%. Additional factors that correlate strongly with serum urate levels and the prevalence of gout in the general population include serum creatinine levels, body weight, height, blood pressure, and alcohol intake.

PATHOGENESIS AND ETIOLOGY

The development of gout tends to be associated with chronically increased serum levels of uric acid. However, a substantial minority of patients with acute gout have normal uric acid levels, and hyperuricemia does not always lead to the development of gout. Humans are one of the few species with an inactive uricase gene, which results in elevated levels of uric acid. It has been postulated that humans have a propensity to develop hyperuricemia because uric acid confers protection against degenerative diseases by acting as an antioxidant.[10,11] Urate at high levels and under certain conditions will precipitate into MSU crystals, and the deposition of these crystals within the synovium or synovial fluid may lead to the development of gout (see below).

Table 1 Classification of Hyperuricemia and Gout

Primary Hyperuricemia and Gout with No Associated Condition	*Secondary Hyperuricemia and Gout with Identifiable Associated Condition*
Uric acid undersecretion (80%–90%)	Uric acid undersecretion
Idiopathic	Renal insufficiency (any cause)
Urate overproduction (10%–20%)	Polycystic kidney disease
Idiopathic	Lead nephropathy
HGPRT deficiency	Drugs
PRPP synthetase overactivity	Diuretics
	Salicylates (low dose)
	Pyrazinamide
	Ethambutol
	Niacin
	Cyclosporine
	Didanosine
	Urate overproduction
	Myeloproliferative diseases
	Lymphoproliferative diseases
	Hemolytic anemias
	Polycythemia vera
	Other malignancies
	Psoriasis
	Glycogen storage disease
	Dual mechanism
	Obesity
	Ethanol consumption
	Hypoxemia and tissue hypoperfusion

HGPRT—hypoxanthine-guanine phosphoribosyltransferase
PRPP—phosphoribosylpyrophosphate

Gout has been recognized as a familial disorder since the time of Sir Alfred Garrod. About 40% of patients in most series report a family history of gout, and the hereditary component for serum uric acid levels in the general population has been estimated to be approximately 40%.[8,12] The mechanisms for this association are still not understood, but most available data suggest that serum uric acid levels are controlled by multiple genes involving both production and excretion of uric acid.

Hyperuricemia

The plasma concentration of uric acid is maintained at a relatively constant level in humans because of a balance between production and excretion. Uric acid derives from exogenous and endogenous sources: it is the end product of the metabolism of dietary purines and occurs as a result of the breakdown of purines from nucleic acids during cell turnover. A very small amount of uric acid is passively eliminated through the gastrointestinal tract. Almost all plasma uric acid is filtered at the glomerulus, and 80% is reabsorbed in the proximal tubule. Some of this plasma uric acid is subsequently secreted back into the lumen; a small amount undergoes distal reabsorption.[8,11]

Hyperuricemia can result from decreased renal excretion or increased production of uric acid. In 80% to 90% of patients with primary gout, hyperuricemia is caused by renal underexcretion of uric acid, even though renal function is otherwise normal. The defect in renal excretion of uric acid in patients with primary gout may be attributed to reduced filtration, enhanced reabsorption, or decreased secretion, but it is unclear which of these mechanisms is most important. Even patients with high levels of urate excretion (overproducers) demonstrate a relative decrease in urate clearance compared to patients with normal levels of uric acid production.[13]

Hyperuricemia may develop secondary to numerous conditions (e.g., renal insufficiency, myeloproliferative diseases, obesity, alcohol consumption, and drug intake) [*see Table 1*]. Patients with secondary gout related to renal disease are hyperuricemic because of a decreased filtered load of uric acid, although decreased tubular secretion may play a role in some patients. Patients with lead nephropathy seem to be particularly prone to the development of gout, and recent studies have suggested that subclinical exposure to environmental lead may contribute to some of the hyperuricemia and gout seen in the general population.[14,15] The hyperuricemia associated with diuretic therapy results from volume depletion, which leads to a decreased filtered load, and from enhanced tubular reabsorption.[16] A renal mechanism is the cause of most other cases of drug-associated hyperuricemia. Low-dose aspirin can cause significant changes in renal handling of urate within a week after therapy is started, particularly in elderly patients.[17] Hyperuricemia and gout may be associated with cyclosporine therapy in renal and cardiac transplantation patients, and it appears to be the result of a combined effect of cyclosporine on renal blood flow and tubular function.[18-20]

Overproduction of uric acid, caused by increased purine synthesis, is seen in about 10% to 20% of patients with primary gout. In addition, four specific heritable defects of purine synthesis have been identified: phosphoribosylpyrophosphate synthetase overactivity, glucose-6-phosphatase deficiency, fructose-1-phosphate aldolase deficiency, and hypoxanthine-guanine phosphoribosyltransferase (HGPRT) deficiency. Of these heritable defects, the best-known is HGPRT deficiency. Complete deficiency of this enzyme is associated with the Lesch-Nyhan syndrome in children, and a partial deficiency has been associated with early-onset gout and nephrolithiasis.

Most diseases that cause secondary hyperuricemia characterized by overproduction of uric acid are associated with increased nucleic acid turnover. These diseases include multiple myeloma, polycythemia, pernicious anemia, hemoglobinopathies, thalassemia, other hemolytic anemias, other myeloproliferative and lymphoproliferative disorders, and other neoplasms. In addition, some critically ill patients may experience hyperuricemia resulting from accelerated breakdown of adenosine triphosphate (ATP).

Uric Acid Precipitation and Crystal-Induced Inflammation

Uric acid dissociates almost completely to the urate anion form at a pH of 7.4. At concentrations greater than 6.5 to 7.0 mg/dl, urate precipitates in the form of MSU crystals. Local conditions in tissues responsible for crystal precipitation and deposition include lower temperature (as is found in peripheral joints), lower pH level in extracellular fluid, and reduced urate binding to plasma proteins. Other local factors that contribute to precipitation and deposition of crystals are trauma and rapid increases in local urate concentration as a result of mobilization of water from peripheral tissues (as occurs when edematous feet are elevated during sleep).

The factors responsible for the inflammatory response to crystals are not completely understood.[8,21] The phlogistic properties of crystals seem to be linked to their ability to bind immunoglobulins and other proteins, particularly complement and lipoproteins. These complexes bind to surface receptors on macrophages and mast cells, leading to activation and release of proinflammatory cytokines, chemotactic factors, and other mediators. An influx of phagocytic cells—particularly neutrophils—follows. Crystals are engulfed, and subsequent disruption of lysosomes releases arachidonate metabolites, collagenases, and oxygen radicals. Several factors have been postulated as contributing to the self-termination of attacks. These factors include digestion of crystals by myeloperoxidase, increased heat and blood flow leading to dissolution and removal of crystals from the joint, alteration of the crystal properties by the inflammatory process itself, and phagocytosis of crystals by more mature macrophages later in the attack.[22,23]

CLINICAL STAGES

Acute Gouty Arthritis

Acute gouty arthritis is usually characterized by a sudden and dramatic onset of pain and swelling, usually in a single joint. This condition occurs most often in lower extremity joints and evolves within hours to marked swelling, warmth, and tenderness. The process often extends beyond the confines of the joint and may mimic cellulitis. The pain of gout is often severe enough to make even the light pressure of bedclothes intolerable, and weight bearing is usually very difficult. Even without treatment, attacks of gout usually subside within a few days, although some attacks may last a few weeks. Early in the course of gout, affected joints usually return to normal after attacks.

The initial attack of gout is monoarticular in 85% to 90% of patients. At least half of initial attacks occur in the first metatarsophalangeal joints (a condition known as podagra), but other joints of the foot may be involved simultaneously or in subsequent attacks. Other lower extremity joints, including the ankles

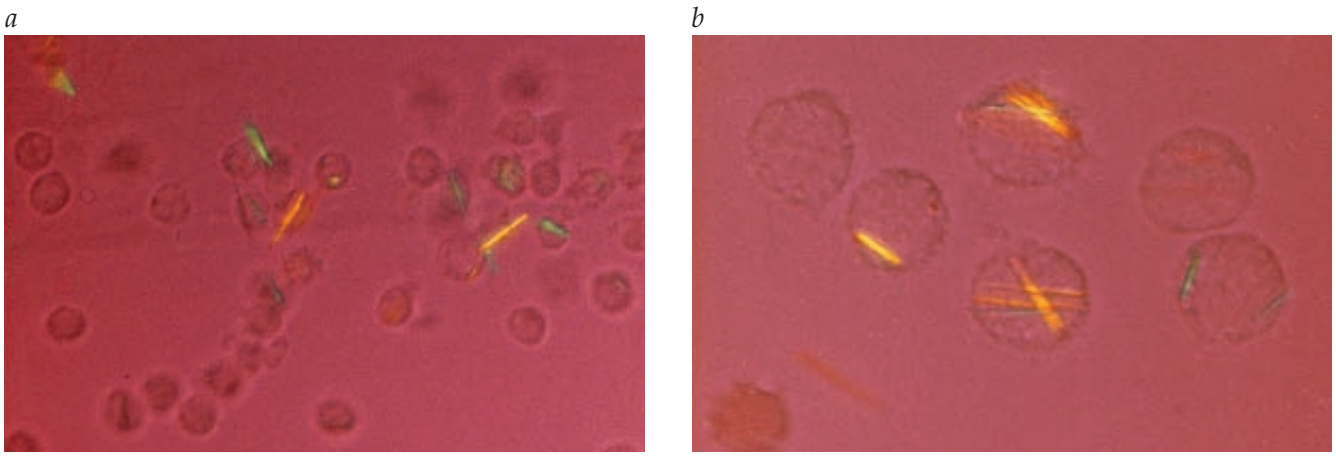

Figure 1 **Gout can be diagnosed by demonstration of negatively birefringent monosodium urate crystals in synovial fluid examined by polarized-light microscopy, either free (*a*) or within polymorphonuclear leukocytes (*b*).**

and knees, are often affected; in more advanced gout, attacks may occur in upper extremity joints, such as the elbow, wrist, and small joints of the fingers. In older women in particular, involvement of the small joints of the fingers (previously affected by osteoarthritis) is more commonly seen earlier in the course of the disease.[24,25] Acute episodes may also involve the bursae, particularly in the olecranon or prepatellar areas. Polyarticular gout occurs as the initial manifestation in about 10% to 15% of patients and may be associated with fever.[26]

Almost all synovial fluid aspirated early in an acute attack contains typical needlelike crystals, which are negatively birefringent and may be extracellular or may occur within polymorphonuclear leukocytes [*see Figure 1*]. The leukocyte count in most gouty synovial fluid rises to a range of 10,000 to 60,000/mm^3, but it may be much higher in some patients.

Intercritical Gout

After the initial attack of gout subsides, the clinical course of gout may follow one of several patterns. A minority of patients never have another attack of gout, and some may not have another attack for several years. Most patients, however, have recurrent attacks over a period of years. In a study done before the use of hypouricemic agents, 78% of patients had a second attack within 2 years and 93% had a second attack within 10 years.[27] In many patients, symptom-free intervals between attacks become progressively shorter as episodes of acute arthritis increase in frequency. In chronic disease, soft tissue swelling and joint effusions persist for longer periods after each attack. Finally, after 10 to 20 years of recurrent gouty attacks, patients typically develop chronic tophaceous gout.

Chronic Tophaceous Gout

Persistent hyperuricemia with increasingly frequent attacks of gout eventually leads to joint involvement of wider distribution and chronic joint destruction resulting from deposition of massive amounts of urate in and around joints [*see Figure 2a*]. Without therapy to lower serum uric acid levels, the average interval from the first gouty attack to the development of chronic arthritis or tophi is about 12 years.[28] After 20 years, 75% of patients have tophi; patients with the highest urate levels are at highest risk. In

Figure 2 **Tophaceous gout, demonstrating chronic swelling in and around the joints of the hand caused by bone destruction and tophaceous deposits in the hands (*a*). Tophi may also be found in extra-articular areas, such as the pinna of the ear (*b*).**

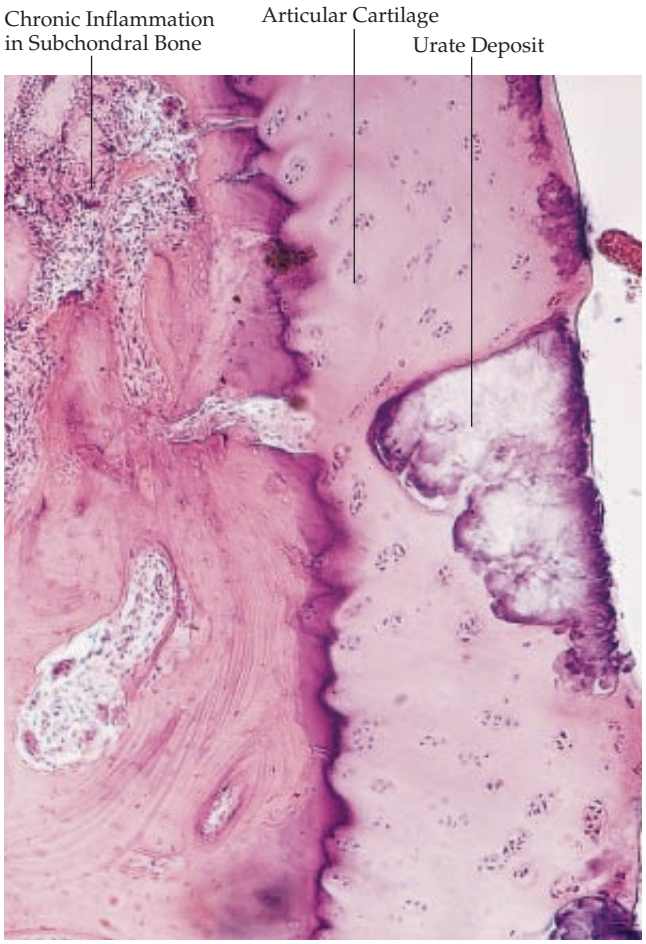

Figure 3 **Microscopic appearance of sodium urate deposits causing a defect in articular cartilage and chronic inflammation in the subchondral bone.**

elderly patients, particularly women, tophi may appear earlier in the course of the disease, sometimes in patients without a history of gouty attacks.[25]

Subcutaneous tophi begin to appear in periarticular and bursal tissues, especially around the knees and elbows, along tendons of the hands and feet, and around the interphalangeal and metacarpophalangeal joints of the hands. Tophaceous deposits are usually firm and movable, and the overlying skin may be normal or thin and reddened. When close to the surface, deposits exhibit a characteristic chalky appearance and may be cream-colored or yellowish. Tophi have also been described in areas not associated with joints, such as the pinna of the ear [*see Figure 2b*], and in unusual visceral locations, such as the myocardium, pericardium, aortic valves, and extradural spinal regions.

Destruction of the articular cartilage and subchondral bone eventually occurs in patients with chronic articular involvement [*see Figure 3*]. Erosive bony lesions may be seen on x-rays as well-defined punched-out lesions in periarticular bone, often associated with overhanging edges of bone.[29] These erosions are usually 5 mm or more in diameter and are larger than those seen in rheumatoid arthritis. Bone mineralization appears to be generally normal in chronic tophaceous gout, and periarticular osteopenia, which is seen in rheumatoid arthritis, is usually not present. The distribution of destructive joint disease in gout is often asymmetrical and patchy.

Associated Conditions

A number of chronic illnesses may be associated with gout and hyperuricemia, either in primary or secondary form. The best-known association is with renal disease, which frequently occurs in patients with gout.[30,31]

Most cases of renal disease in patients with primary forms of gout are believed to be the result of nephrosclerosis related to hypertension. However, experimental evidence suggests that hyperuricemia may play a direct pathogenetic role in the development of renal disease and hypertension.[32] In addition, the presence of intrarenal urate deposits associated with an inflammatory reaction in some patients and the improvement of renal function associated with control of uric acid levels suggest that urate has a causal role in the renal disease seen in patients with chronic tophaceous gout.[33,34]

Renal stones occur in 10% to 25% of patients with gout.[35] Most stones in patients with gout are composed of uric acid. However, some are composed of calcium oxalate and other constituents, and hyperuricemia is believed to contribute to the formation of these stones as well.[36]

An acute urate nephropathy associated with the tumor lysis syndrome has been described in patients with leukemia or lymphoma who are undergoing chemotherapy.[37] This condition is associated with acute oliguria and an elevated urinary urate-to-creatinine ratio (> 1.0) and is usually treated prophylactically with allopurinol and vigorous hydration. An association of gout with renal disease and chronic lead intoxication has been noted in some populations (saturnine gout).[38] In the United States, this association has most often been attributed to the drinking of illicit whiskey produced in lead-lined stills, but it has also been attributed to occupational lead exposure.

Gout has long been associated with obesity, diabetes mellitus, hyperlipidemia, and atherosclerotic cardiovascular disease. The association with diabetes has been variously reported; in lipid disorders, the association is primarily with hypertriglyceridemia, which may in turn be linked to alcohol intake.[39] In addition, a correlation has been found between hyperuricemia and the insulin-resistance syndrome (also referred to as the metabolic syndrome), possibly associated with body-fat distribution and triglyceride levels.[40,41] The association of gout and hyperuricemia with cardiovascular disease appears to be related to the link between these metabolic disorders and hypertension.[42]

Alcohol consumption has long been associated with the precipitation of gouty attacks in susceptible patients. In addition, long-term heavy alcohol consumption promotes hyperuricemia by interfering with renal excretion and increasing production of urate; some alcoholic beverages, particularly beer, serve as a source of dietary purine.[9] Patients with gout have an increased prevalence of hypothyroidism, and urate levels have been shown to decrease with the institution of thyroid replacement therapy, probably through a renal mechanism.[43]

DIAGNOSIS

A diagnosis of gout can be made with certainty only by confirmation of the presence of monosodium urate crystals in synovial fluid or tissue. Elements of the patient's history, physical examination, and laboratory studies can be very helpful in diagnosing gout [*see Table 2*].[44] A typical presentation of podagra in a middle-aged man with known hyperuricemia may be sufficient for an initial tentative diagnosis of gout, particularly if the condition responds well to colchicine. Nodular deposits on the olecra-

Table 2 Diagnosis of Gout

Test	*Sensitivity*	*Specificity*	*Comments*
Microscopic examination of synovial fluid by polarized microscopy	High during acute attacks; some potential between attacks	100% specific	Presence of needle-shaped, negatively birefringent urate crystals is diagnostic
Serum uric acid levels	Unreliable, even during attacks (elevated levels are a risk factor for, but not diagnostic of, gout)	Low in unselected patients (only 30% of people with uric acid > 10 mg/dl will have gout over 5 yr)	Serum levels are lower during attacks in some studies; serial serum levels over months and years may suggest risk of gout and severity
X-rays	Moderate, only in patients with chronic disease; even typical erosions may be difficult to differentiate from other erosions (e.g., as seen in rheumatoid arthritis)	Moderate, depending on nature of changes; otherwise may be difficult to differentiate from other forms	May be useful in patients with chronic disease if interpreted carefully (see text)

non processes, dorsal aspects of the fingers, or finger pads should be sought, particularly in patients with a history of joint problems. Patients with gout may have a normal serum urate level at the time of an attack. With most patients, however, a review of old records reveals a history of chronic hyperuricemia. Radiographs are seldom useful during an acute attack, unless previous attacks have occurred in the area examined and unless, after years of disease, well-defined erosions in or around joints, with characteristic overhanging edges, can be seen.

The detection of needle-shaped, negatively birefringent urate crystals in synovial fluid examined under polarized light microscopy is the definitive diagnostic finding for gout. Although this test is best done on fluid obtained during an acute attack, aspiration of synovial fluid from previously affected joints or aspiration of a subcutaneous nodule suspected of being a tophus may be helpful.[45,46] The synovial fluid should be examined by someone experienced in crystal identification, because an inexperienced person may not recognize the presence of crystals.[47]

Alternative diagnoses should be considered in all patients suspected of having gout. Acute arthritis can be caused by infection, other crystal-induced arthropathies, or other diseases. A Gram stain and culture of the synovial fluid and radiographs may be needed in some patients to rule out these disorders. Gout can be accompanied by fever, particularly during polyarticular attacks, and should be considered in patients suspected of having acute bacterial arthritis whose cultures are negative.[26] In addition, gout and infection can coexist in the same joints, making therapeutic decisions difficult in individual cases. Thus, synovial fluid cultures are essential in any patient who is suspected of having gout and who has fever or purulent-appearing synovial fluid. Pseudogout [*see* Pseudogout (Calcium Pyrophosphate Dihydrate Deposition Disease), *below*] may cause acute monoarthritis or oligoarthritis that is similar to gout. Radiographs in such patients may show chondrocalcinosis, and CPPD crystals in the synovial fluid are usually easily distinguishable from urate crystals. However, some patients may have both gout and pseudogout in the same joint.

TREATMENT

The goals of therapy for patients with gout include termination of the acute attack, prevention of further attacks during the intercritical period, assessment for associated and contributing factors, and consideration of long-term hypouricemic therapy.[48,49] Each aspect of therapy should be considered separately, and there should be no confusion between efforts to suppress inflammation in acute attacks and efforts to lower serum urate levels, decrease the frequency of attacks, and prevent complications in the future.

Acute Gout

Treatment of acute gout should be initiated as early in the attack as possible. Agents available for terminating the acute attack include colchicine, nonsteroidal anti-inflammatory drugs (NSAIDs), adrenocorticotropic hormone (ACTH), and corticosteroids [*see Table 3*]. Each agent has a toxicity profile, with advantages and disadvantages applicable to individual circumstances. The patient's overall health and coexistent medical problems, particularly renal disease and gastrointestinal disease, often dictate the choice among these approaches. Corticosteroids and ACTH have been used more often in recent years in patients with multiple comorbid conditions because of the relatively low toxicity profile of these agents.

Colchicine has been used for centuries to treat acute attacks of gout. Given in oral dosages of 0.6 to 1.2 mg initially, followed by 0.6 mg every 2 hours, colchicine begins relieving most attacks of gout within 12 to 24 hours. However, most patients experience nausea, vomiting, abdominal cramps, and diarrhea with these dosages. Colchicine should be given more cautiously in elderly patients and should be avoided in patients with renal or hepatic insufficiency and patients already on long-term colchicine therapy.[50] Intravenous colchicine has been used for acute attacks, but recognition of the potential for bone marrow suppression and other systemic toxicities has resulted in guidelines for restricting dosage and even in a lack of availability in some countries.[51,52]

NSAIDs are useful in most patients with acute gout and remain the agents of choice for young, healthy patients without comorbid diseases. Indomethacin has been the most widely used agent over the years; it usually begins to provide relief within hours after the initial oral dose. Most NSAIDs are comparable in efficacy, although studies comparing NSAIDs in acute gout are few. The use of all NSAIDs is limited by the risks of gastric ulceration and gastritis, acute renal failure, fluid retention, interference with antihypertensive therapy, and, in older patients, problems with mentation. Aspirin is usually avoided because of its dose-related and variable effect on urate excretion. Newly developed NSAIDs with a high specificity for cyclooxygenase-2 are now available for the treatment of rheumatoid arthritis and osteoarthritis. These agents are generally much less toxic and ap-

Table 3 Drug Treatment of Acute Gout

Drug	*Dosage*	*Relative Efficacy*	*Comments*
Colchicine	0.6–1.2 mg p.o. initially, then 0.6 mg p.o., q. 2 hr	Moderate efficacy in high dose, but low threshold for toxicity	Common side effects are nausea, vomiting, cramps, and diarrhea; use with caution in elderly; avoid in patients with renal or hepatic insufficiency and those already on long-term colchicine Reasonably effective in low dose (q.d.–b.i.d.) as prophylaxis for future attacks
NSAIDs		Moderately effective; most are comparably effective	NSAIDs carry risk of gastric ulceration, gastritis, acute or chronic renal failure, fluid retention, congestive heart failure interference with antihypertensive therapy; risk of mentation problems in elderly COX-2–specific agents reduce risk of GI complications but not other complications
Indomethacin	50–75 mg b.i.d., t.i.d.		
Ibuprofen	600–800 mg t.i.d., q.i.d.		
Naproxen	500 mg b.i.d., t.i.d.		
Diclofenac	75 mg b.i.d		
Piroxicam	20 mg q.d.		
Meloxicam	15 mg q.d.		
Nabumetone	1,500 mg q.d.		
COX-2 inhibitors			
Rofecoxib	25–50 mg q.d.		
Celecoxib	200 mg q.d., b.i.d.		
Valdecoxib	20 mg q.d., b.i.d.		
Corticosteroids		Moderately to extremely effective	Caution in patients with brittle diabetes; some caution in patients with fluid retention or hypertension; overall, safer than NSAIDs or colchicine in these patients
Triamcinolone acetonide (and others)			
Intra-articular	5–10 mg for small joints; 40–60 mg for large joints		
Intramuscular	40–60 mg		
Prednisone (oral)	40–60 mg p.o. per day to start, taper over 5–14 days		
ACTH intramuscular	40–60 mg single dose		

ACTH—adrenocorticotropic hormone COX-2—cyclooxygenase-2 NSAIDs—nonsteroidal anti-inflammatory drugs

pear to have very low potential for gastrointestinal toxicity and inhibition of platelet function in clinical studies. These cyclooxygenase-2–specific NSAIDs should be useful in treating acute gout, and possibly in long-term prophylaxis, in patients at risk for gastrointestinal toxicity from the currently available NSAIDs.[53]

Corticosteroids have become more widely used in the treatment of acute gout in recent years.[54] Intra-articular steroids after arthrocentesis are extremely useful in providing relief, particularly in large effusions, in which the initial aspiration of fluid results in rapid relief of pain and tightness in the affected joint. The dosage of the steroid triamcinolone depends on the size of the joint, ranging from 5 to 10 mg for small joints of the hands or feet to 40 to 60 mg for larger joints, such as the knee. Systemic corticosteroids may also be useful in patients for whom colchicine or NSAIDs are inadvisable and in patients with polyarticular attacks. Oral prednisone, administered in tapered doses starting at 40 to 60 mg daily, and single intramuscular injections of ACTH (40 units) or triamcinolone (40 to 60 mg) have all been shown to be as effective as NSAIDs in treating acute gout. In most studies of systemic steroids for acute gout, only a small proportion of patients have required repeated therapy for rebound attacks in the first several days after therapy.

Interval Follow-up and Evaluation

Patients remain at increased risk for another attack of gout for several weeks after resolution of the initial attack; prophylaxis with small doses of colchicine or NSAIDs should be used for most patients. Colchicine (0.6 mg one or two times a day) prevents attacks in over 80% of patients. Prophylaxis should be continued for 1 to 2 months after an acute attack and for several months in patients with a history of frequent attacks; it should also be employed when urate-lowering drugs are initiated.[55] The dose of colchicine should be reduced or the duration of therapy shortened in patients with reduced renal function because bone marrow suppression and myoneuropathy have been reported in patients on long-term low-dose colchicine therapy with a creatinine clearance of less than 50 ml/min.[56]

After an acute attack of gout, a patient can be monitored for recurrent attacks and assessed for potential underlying causes of hyperuricemia. A spot midmorning urine sample to determine the ratio of urinary uric acid per deciliter of glomerular filtrate (urinary urate × plasma creatinine/urinary creatinine) or a 24-hour urine collection helps to classify the patient as an overproducer or underexcretor of urate; this is useful in identifying the optimal drug treatment for lowering serum urate levels, if indicated [*see Sidebar* Determining Overproducers and Underexcretors of Uric Acid].[1,57] If urinary urate excretion exceeds 0.6 mg/dl of glomerular filtrate or 600 to 700 mg a day, allopurinol is the most appropriate agent for lowering urate levels, by decreasing

Determining Overproducers and Underexcretors of Uric Acid

Urinary urate × plasma creatinine/urinary creatinine
- > 0.6 highly suggestive of overproducer
- < 0.6 suggestive of underexcretor

Urate present in 24-hour urine collection
- > 600–700 mg confirms overproducer status
- < 600 mg evidence of underexcretor if serum urate level is elevated

Table 4 Drug Treatment of Chronic Gout (Urate-Lowering Agents)

Drug	*Dosage*	*Relative Efficacy*	*Comments*
Probenecid	1–2 g/day in divided doses	Modest	Limited benefit to patients with decreased renal function; risk of renal stones
Sulfinpyrazone	Up to 400–800 mg/day in divided doses	Modest	Limited benefit to patients with decreased renal function; risk of renal stones
Allopurinol	300–600 mg/day; 200 mg for patients with GFR < 60 ml/min; 100 mg for patients with GFR < 30 ml/min	Extremely effective in lowering serum urate levels	Inhibits metabolism of azathioprine and other drugs; may cause hypersensitivity reaction (discontinue immediately if rash develops)

GFR—glomerular filtration rate

urate production; with lower excretion levels, a uricosuric drug may be useful.

Management after an acute attack should include a review of the patient's overall health, which may reveal important coexistent diseases, medications, and habits that could contribute to hyperuricemia. In particular, alcohol consumption should be discussed as an important factor in hyperuricemia and the precipitation of attacks. A review of the patient's diet may reveal heavy consumption of purine-rich foods, such as organ meats, seafood, or various legumes or other vegetables. In addition, the intercritical period is an excellent time to assess for obesity, hyperlipidemia, and hypertension, which often accompany gout and are correctable risk factors for premature cardiovascular mortality. Although the purine content of the diet usually contributes only about 1.0 mg/dl to the serum urate concentration, a diet that emphasizes calorie reduction, complex carbohydrates, and unsaturated fats will reduce urate levels and improve lipoprotein profiles in patients with gout.[48,58,59] Weight loss and physical activity are important strategies for lowering cardiovascular risk in obese patients; however, evidence suggests that increased physical activity is the perferred treatment[48,58,59]; sedentary, obese patients who have had an acute attack of gout should be strongly encouraged to increase their level of physical activity [*see CE:IV Diet and Exercise*].

Chronic Hyperuricemia

In general, patients with asymptomatic hyperuricemia should not be treated with hypouricemic agents. However, patients with persistent marked hyperuricemia (levels > 10 mg/dl) or hyperuricosuria (levels > 1,000 mg/24 hr) should be followed carefully for manifestations of gout or renal stones. Drug therapy to lower urate levels should be considered for patients who have had crystal-proven gout with recurrent attacks and persistent hyperuricemia despite efforts to identify and correct contributing factors [*see Table 4*]. Patients who have had more than two or three attacks, who have tophi or radiographic evidence of joint damage, or who have chronic renal insufficiency and recurrent gout should be treated with hypouricemic therapy if they are willing to comply with a long-term regimen. Reduction of serum urate levels to well into the normal range (i.e., < 6.0 mg/dl) eventually leads to prevention of further attacks and resorption of tophi.[42] Low-dose colchicine or NSAIDs should be used to prevent attacks that can occur for several months after hypouricemic therapy is started.[60]

Agents that increase renal excretion of urate (i.e., uricosuric drugs) can be used in patients with normal renal function who have no history of nephrolithiasis and whose 24-hour excretion of urate is less than 700 mg/day. Probenecid (1 to 2 g/day) is the most commonly used agent in this class, although sulfinpyrazone (up to 400 to 800 mg/day) can be used as well. Both agents are of limited use in patients with decreased renal function and carry a risk of precipitating renal stones. High urine volume and alkalinization with bicarbonate intake decrease this risk.

In up to 25% of patients, urate levels are not well controlled with uricosuric drug therapy. Benzbromarone is a uricosuric agent that has been available in Europe for over 20 years but is not available in the United States. Studies have shown that this agent may be useful in lowering uric acid levels in some patients with renal disease.[61]

Allopurinol, the only available inhibitor of xanthine oxidase, reduces serum urate levels in almost all compliant patients and may be used in overproducers or underexcretors. A daily dose of 300 mg is standard in patients with normal renal function, although some patients may require as much as 600 mg to achieve optimal serum urate levels. The dose should be reduced to 200 mg in patients whose glomerular filtration rate (GFR) is less than 60 ml/min and to 100 mg in those whose GFR is less than 30 ml/min. The dose of some other drugs, particularly azathioprine, must be reduced in patients receiving allopurinol, because allopurinol inhibits metabolism. Approximately 2% of patients taking allopurinol develop a hypersensitivity rash that progresses to a severe exfoliative dermatitis.[62] This disorder is more likely to occur in patients taking ampicillin or in those with renal insufficiency. Severe rashes may be accompanied by a syndrome of vasculitis, hepatitis, and interstitial renal disease, with a mortality risk of 20% reported in some series. Because of this risk, allopurinol should be discontinued in any patient who experiences a rash. Allopurinol may be reinstituted in such patients if the rash is mild. Reinitiation of allopurinol therapy should be gradual, starting with oral doses of 50 µg daily and increasing to 100 mg daily over a 4-week period; this strategy effectively desensitizes the majority of patients with prior hypersensitivity reactions to allopurinol therapy.[63]

Pseudogout (Calcium Pyrophosphate Dihydrate Deposition Disease)

DEFINITION AND CLASSIFICATION

CPPD crystals may be found in deposits in and around joints and are characterized by calcification of articular cartilage, menisci, synovium, and other periarticular tissues. McCarty and colleagues first described CPPD crystals in synovial fluids from patients with goutlike attacks in 1962.[2] They used the term pseudogout for this new arthropathy, which is characterized by intra-articular calcifications (chondrocalcinosis), crystals in the synovial fluid, and acute arthropathy. Since then, other clinical presentations and a variety of disease processes have been asso-

ciated with CPPD crystals. Thus, the term CPPD deposition disease has come to include the various clinical presentations as part of the same general clinical syndrome.

EPIDEMIOLOGY

CPPD deposition disease is generally a disease of the elderly; the average age of patients is approximately 70 years.[64] The prevalence of articular chondrocalcinosis is very low in people younger than 40 years but increases with age and is quite common in older populations. When multiple radiologic studies are obtained, the documented prevalence in the general population is 10% to 15% in those 65 to 75 years of age and over 40% in people older than 80 years.[65,66] CPPD deposition occurs in males and females in differing distribution in different studies, but there does not seem to be a major gender predominance. An increased prevalence of CPPD deposition in certain diseases and familial groups has been reported.

PATHOGENESIS AND ETIOLOGY

The metabolic basis for CPPD formation and deposition is less well understood than that for urate crystals. CPPD crystal formation occurs almost exclusively in the articular and periarticular tissue, most often near the surface of chondrocytes.[64,67] Crystal formation is enhanced by elevated levels of either calcium or inorganic pyrophosphate (PP_i) within local tissues or local factors in the cartilage matrix that promote crystal formation. An abnormal substrate of matrix collagen and proteoglycan, as well as variations in mineral content, may promote crystal deposition. Local elevations of PP_i levels appear to be related to two factors: the overactivity of a cell surface enzyme (ectoenzyme) known as nucleoside triphosphate pyrophosphohydrolase (NTPPH), which catalyzes the extracellular hydrolysis of ATP, and the extracellular transport of PP_i by the transmembrane protein ANK.[68] In addition, some of the excess PP_i production may take place intracellularly through NTPPH or as a by-product of cellular proteoglycan and protein synthesis. Other factors that may contribute to excess PP_i and crystal formation include decreased activity of pyrophosphatase, degenerating cellular debris, abnormal matrix collagen, and even the local influence of growth factors (i.e., transforming growth factor and insulinlike growth factor). The mechanisms by which CPPD crystals induce inflammation are believed to be similar to those observed in gout.

CLINICAL VARIANTS

Most joints with radiographically observed chondrocalcinosis are asymptomatic, although subtle articular symptoms are more common in asymptomatic patients with chondrocalcinosis than in patients without these findings.[69] Clinically symptomatic CPPD deposition disease may take any of several forms that tend to present in acute or chronic fashion, mimicking other arthropathies.

Acute Pseudogout

Acute pseudogout is slightly more common in males than in females. Attacks of this form of CPPD deposition disease are usually acute, increase in intensity over 12 to 36 hours, and last for a few days to a few weeks. Most acute attacks of pseudogout are less intense than attacks of gout. The most commonly involved joint is the knee (seen in over half of patients), followed by the wrist and ankle. In rare cases, attacks in the first metatarsophalangeal joint may be seen.[64] Affected joints previously involved are more likely to be involved in subsequent attacks. Attacks may occur in clusters over short periods, and polyarticular attacks occur in a few patients. A moderate synovial fluid leukocytosis is common, and marked elevations in the white blood cell count, mimicking a septic joint, may be seen in some patients. Mild fever and leukocytosis have been described, but not as frequently as in gout.[70] Between attacks, the joint is usually asymptomatic unless there is coexistent osteoarthritis. As in gout, attacks of pseudogout seem to be precipitated in some patients by stressful events, such as surgery, trauma, and acute medical illness. The intra-articular injection of hyaluronate for the symptomatic treatment of osteoarthritis has also been reported to trigger attacks of acute pseudogout.[71]

Table 5 Conditions Associated with Calcium Pyrophosphate Dihydrate Deposition Disease*

Definite association	Possible or doubtful association
Hemochromatosis	Gout
Hyperparathyroidism	Familial hypocalciuric hypocalcemia
Hypophosphatasia	Acromegaly
Hypomagnesemia	X-linked hypophosphatemic rickets
Probable association	Neuropathic joints
Hypothyroidism	Amyloidosis
	Trauma

See reference 62.
*As pseudogout or radiographic chondrocalcinosis.

Chronic Rheumatoid-like Arthritis

About 5% to 10% of patients with CPPD deposition disease experience a polyarticular process resembling rheumatoid arthritis. The disease is indolent, symmetrical in distribution, and characterized by inflammation. Chronic swelling, morning stiffness, and predominant wrist and knee involvement are seen in this group of patients. Because of the relatively high frequency of incidental chondrocalcinosis and positive rheumatoid factors in elderly persons, differentiating CPPD deposition from rheumatoid arthritis can be difficult. A history of acute exacerbations in these patients may help suggest CPPD deposition, whereas the presence of subcutaneous nodules and very high titers of rheumatoid factor favor a diagnosis of rheumatoid arthritis.

Osteoarthritis and CPPD Deposition

About half of patients with CPPD deposition have a chronic degenerative arthritis involving multiple joints, usually in a symmetrical pattern. Women predominate in this group of patients.[64] The knees are most commonly involved, followed by the wrist, metacarpophalangeal joints, hips, spine, and shoulders. CPPD-associated osteoarthritis may be differentiated from typical osteoarthritis by the presence of changes in atypical joints, such as the wrists, elbows, and shoulders. Some patients in this group may not have chondrocalcinosis, but CPPD crystals may be found in the synovial fluid of most of those patients without radiographic findings. In addition, radiographic features of predominantly patellofemoral involvement and femoral cortical erosions in the knee suggest CPPD deposition.[72]

Conditions Associated with CPPD Deposition Disease

Most cases of CPPD deposition disease are sporadic. However, a number of kindreds with familial forms of disease and asso-

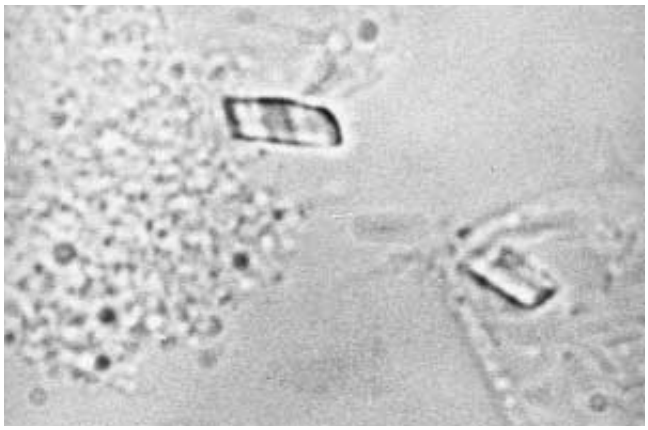

Figure 4 **Calcium pyrophosphate dihydrate crystals typical of pseudogout are rhomboid and demonstrate a weakly positive birefringence under polarized light.**

ciations with metabolic diseases have been reported. Most of the familial forms have shown an autosomal dominant transmission but have displayed a variety of clinical presentations, and most appear to involve single gene mutations.[73,74] Associations with several endocrine and metabolic conditions have been reported, many of which probably represent no more than a chance occurrence of common age-related conditions [*see Table 5*].

Definite associations exist between CPPD deposition disease and hemochromatosis, hyperparathyroidism, hypophosphatasia, and hypomagnesemia. A distinct form of arthritis associated with hemochromatosis was first reported in 1964.[75] This arthropathy is similar to osteoarthritis and rheumatoid arthritis and may be the initial presenting feature in some patients. The most frequently involved joints are the metacarpophalangeal joints (primarily the second and third), wrists, and hips; radiologic changes consisting of hooklike osteophytes at the metacarpal heads are a characteristic finding. CPPD deposition has been described in 20% to 30% of patients with primary hyperparathyroidism, more often in older patients.

Attacks of acute pseudogout after parathyroidectomy have been described and are often the first manifestation of CPPD deposition in these patients.[76] Reports have described pseudogout in patients with hypomagnesemia after liver transplantation, possibly related to tacrolimus therapy.[77]

DIAGNOSIS

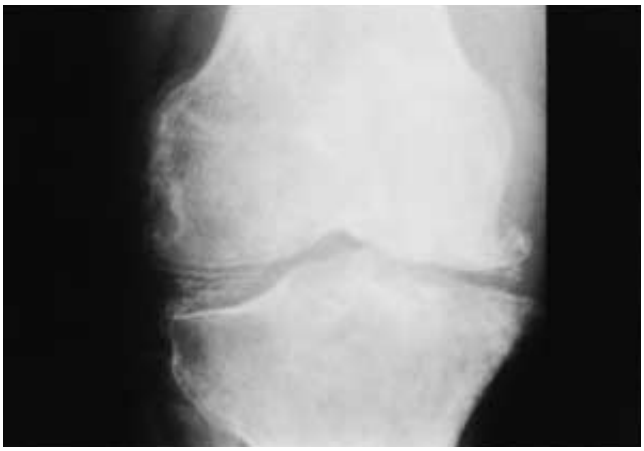
Synovial fluid aspiration and examination for crystals are essential to the diagnosis. The synovial fluid in pseudogout is usually inflammatory but may be hemorrhagic. A leukocyte count of about 10,000 to 20,000 cells/mm^3 is the rule, but in the small joints, such as the wrist, very high counts may be seen. Synovial fluid should be examined first under regular microscopy, because CPPD crystals are weakly birefringent under polarized microscopy. The crystals are rhomboid or rod-shaped and may be intracellular or extracellular [*see Figure 4*]. Because of their weak birefringence, CPPD crystals may be missed on initial examination, so it is essential that someone experienced in crystal identification examine the fluid.

Radiographic studies of affected joints often reveal chondrocalcinosis of the articular cartilage. The fibrocartilage of the menisci in the knees [*see Figure 5a*] or of the triangular ligament at the radioulnar joint at the wrist [*see Figure 5b*] may have punctate or linear calcifications; similar changes may be seen in the symphysis pubis, shoulder, hip, and intervertebral disks. Linear calcification of the hyaline cartilage in these joints may be seen as well. Other features may include narrowing and sclerosis of the radiocarpal and patellofemoral joints, femoral cortical erosions above the knee, and extra-articular calcifications involving tendons or ligaments.

TREATMENT

Management of the patient with pseudogout is similar to management of the patient with acute gout, with the main goal of therapy being control of the acute inflammatory reaction.[49] Rest of the inflamed joint (or joints) and administration of NSAIDs or intra-articular corticosteroid preparations are the mainstay of therapy. Aspiration of the joint is sufficient to significantly relieve pain and discomfort in some patients. Colchicine is effective in patients with acute pseudogout but should be used cautiously in older patients. At lower doses of 0.6 mg one or two times a day, colchicine can be helpful in preventing further attacks.[78] In some patients, intramuscular or subcutaneous ACTH (40 units) or intramuscular triamcinolone (60 mg) can control the acute inflammatory reaction.[79] For those with chronic pain and inflammation,

a



b

Figure 5 **Typical radiographs of chondrocalcinosis seen in CPPD deposition disease, with evidence of intra-articular calcification in the meniscus and hyaline cartilage of the knee (*a*) and the triangular cartilage of the wrist (*b*).**

alternatives for management are physiotherapy, analgesics, and NSAIDs. An evaluation of the patient for underlying metabolic abnormalities, particularly hemochromatosis and hyperparathyroidism, should be considered. However, successful treatment of these associated conditions has not been shown to alter the radiographic or clinical course of CPPD deposition disease.

Other Forms of Crystal-Associated Arthritis

BASIC CALCIUM PHOSPHATE DEPOSITION

A group of apatitelike (basic calcium phosphate) crystals has been identified in pathologic synovial fluids and articular and periarticular tissues in a variety of musculoskeletal disorders. These crystals may be found in 30% to 60% of synovial fluids from patients with osteoarthritis and may contribute to the low-grade inflammatory process and cartilage destruction seen in typical osteoarthritis.[80,81] A severe destructive arthropathy of the shoulder and knee, known as the Milwaukee shoulder-knee syndrome, predominantly affects older women.[82] This process is associated with rotator cuff degeneration and rupture, joint instability, and periarticular calcification. The synovial fluid may be serosanguineous and contains few cells; hydroxyapatite crystals may appear as clumps or may look like intracellular shiny coins, but they are not birefringent under polarized-light microscopy. The treatment of this condition is difficult, but joint aspiration and intra-articular corticosteroid injections have been helpful in some patients.

Basic calcium phosphate crystals are also associated with acute calcific periarthritis that may affect the shoulder or other joint areas in periarticular structures. In patients with this condition, periarticular calcific deposits may be found in the shoulder; near the lateral trochanter of the hip; around the wrists, fingers, or knees; or in the ankle and foot. These deposits may be well defined radiographically at the beginning of attacks but often disappear over several weeks. NSAIDs and local corticosteroid injections are usually useful in the treatment of this condition.

OTHER CRYSTALS FOUND IN SYNOVIAL FLUID

A variety of other crystals in synovial fluid have been described. Cholesterol crystals may be seen in some chronic effusions and are most often associated with chronic rheumatoid bursal effusions.[83] Other lipid crystals have been seen after joint trauma, and another type of lipid crystal, which resembles a Maltese cross, has been described and may be responsible for an acute inflammatory reaction in rare cases. In addition, calcium oxalate crystals have been found in the synovial fluid of patients with end-stage renal disease and in soft tissues of patients with primary hyperoxaluria and may cause articular symptoms.[84] The pathogenetic significance of each of these types of crystals is uncertain; they most probably represent incidental secondary phenomena.

The author has received grants for clinical research from Amgen Inc., Abbott Laboratories Inc., Isis Pharmaceuticals, Inc., and Bristol-Myers Squibb Company and has served as a consultant for TAP Pharmaceutical Products Inc.

X OSTEOARTHRITIS

Christopher Wise, m.d.

Definition

Osteoarthritis is a common form of arthritis characterized by degeneration of articular cartilage and reactive changes in surrounding bone and periarticular tissue. The disease process results in pain and dysfunction of affected joints and is a major cause of disability in the general population. Osteoarthritis is also frequently referred to as degenerative joint disease; other terms that have been used include osteoarthrosis, hypertrophic arthritis, and atrophic arthritis.

Classification

primary osteoarthritis

Patients without a specific inflammatory or metabolic condition known to be associated with arthritis and without a history of specific injury or trauma are considered to have primary osteoarthritis. However, a number of underlying processes are considered to be important in patients with primary osteoarthritis [*see* Etiologic Factors, Risk Factors, *below*]. In most patients, involvement is limited to one or a small number of joints or joint areas. In some patients, however, multiple joint areas are involved, and these patients are considered to have a separate variant called primary generalized osteoarthritis. Another variant, termed erosive osteoarthritis, is characterized by polyarticular involvement of the small joints of the hand and tends to occur more often in middle-aged and elderly women.

secondary osteoarthritis

Secondary osteoarthritis has been associated with several conditions that cause damage to articular cartilage through a variety of mechanisms, including mechanical, inflammatory, and metabolic processes [*see Table 1*]. Acute trauma, particularly intra-articular fractures and meniscal tears, can result in articular instability or incongruity and can lead to osteoarthritis years after an injury.

The role of chronic trauma from certain occupational or avocational activities is not as well established as the role of acute trauma in the development of secondary osteoarthritis. Neurologic disorders that result in the loss of sensory nerve function may be associated with a particularly destructive type of degenerative arthritis (i.e., neuropathic arthritis and Charcot joint) in which cartilage and bone fragmentation are seen with relatively little pain.

Many types of inflammatory arthritis can cause destruction of articular cartilage. The best example of cartilage damage is seen in chronic rheumatoid arthritis, but similar cartilage damage can be seen in postinfectious arthritis, psoriatic arthritis, reactive arthritis, and ankylosing spondylitis.

Congenital and developmental diseases that cause joint incongruity may result in osteoarthritis. This condition is best recognized in epiphyseal dysplasia, Perthes disease, and other processes affecting the femoral head and hip and has also been associated with generalized joint hypermobility, as seen in Ehlers-Danlos syndrome.

Primary bone disorders that affect the mechanics and articular surfaces of nearby joints may also lead to degenerative cartilage changes, particularly around major joints such as the shoulder, hip, and knee. Several metabolic and endocrine disorders have been associated directly or indirectly with the development of osteoarthritis, often with atypical patterns or in unusual locations. In most of these conditions, cartilage damage is associated with the accumulation, in articular cartilage, of a particular substance associated with the metabolic condition (e.g., uric acid or iron). In hemochromatosis, the mechanism of joint damage may also be related to an association with calcium pyrophosphate crystal deposition. In acromegaly, overgrowth of articular cartilage and subsequent mechanical problems appear to be important in the pathogenesis of the disease.

Epidemiology

Osteoarthritis is the most common type of arthritis, and it is one of the most common causes of disability and dependence in the United States.[1,2] Estimating the prevalence of osteoarthritis in the general population is difficult because of the high prevalence of asymptomatic radiographic changes of osteoarthritis and differences in case definition. The prevalence of radiographic changes of osteoarthritis in the population in general, regardless of symptoms, is roughly 30% for the hands, 21% for the feet, and

3% for the knees and hips. In persons older than 65 years, changes are seen in the knee in 33% and in the hands in almost 100%. Fortunately, most patients with radiographic changes found in population-based surveys have few symptoms or functional limitations. Men and women 30 to 60 years of age have equal overall prevalence of symptomatic osteoarthritis (approximately 6% have affected knees and 4% have affected hips). For adults older than 60 years, however, the prevalence of symptomatic osteoarthritis (all joints) increases to 17% in men and 30% in women.[1,2]

Men and women tend be affected equally by osteoarthritis in middle age, but after 50 years of age, women are affected more often, particularly in the interphalangeal joints of the fingers.[3] Osteoarthritis is seen in all population groups, although prevalence can vary with certain geographic areas and ethnic groups. For example, osteoarthritis of the hip is least common in Japanese, Saudi Arabian, Chinese, and African populations; and knee involvement is most common in African-American women. Comparisons of osteoarthritis prevalence have shown that hip involvement is less common, but knee involvement is more common, in Chinese men and women than in white men and women in the United States.[4-6]

Etiologic Factors

RISK FACTORS

A number of risk factors are believed to contribute to the development of primary osteoarthritis, including age, obesity, joint malalignment, bone density, hormonal status, nutritional factors, joint dysplasia, trauma, occupational factors, and hereditary factors.[2,7]

Age is the factor most strongly associated with radiographic and clinically significant osteoarthritis, with an exponential increase seen in more severely involved joints. The cellular or biomechanical changes in articular cartilage that occur with aging are not necessarily those seen in osteoarthritis. However, it has been speculated that these changes may facilitate the development of disease.

Obesity is clearly associated with osteoarthritis of the knee. The increased load carried by obese persons and the alterations in gait and posture that redistribute the load contribute to cartilage damage. A study in young men suggested that each increase in weight of 8 kg results in a 70% increase in the risk of symptomatic arthritis of the knee in later years.[8] This association is particularly high in patients with varus malalignment of the knee, and obese patients with malalignment are at risk for more rapid progression of established osteoarthritis in the knee.[9,10] Most of the association of obesity with osteoarthritis of the knee appears to be related to environmental, rather than genetic, factors.[11] The relation of obesity to osteoarthritis in other weight-bearing joints is not as clear-cut and may not be much of a factor at all for hip involvement.

An association between increased bone density and osteoarthritis has been noted in several studies.[12,13] Women with osteoporosis and hip fractures have a decreased risk of osteoarthritis, and those affected by osteoarthritis have significantly increased bone density. This negative association suggests that soft subchondral bone absorbs impact and protects articular cartilage better than dense bone. Paradoxically, however, estrogen deficiency may contribute to the increased prevalence of osteoarthritis in women who have recently entered menopause.[2] In addition, a study showing that patients with low dietary vitamin D intake have more rapid progression of disease suggests that strong subchondral bone may be particularly important in preventing progression of osteoarthritis once it is established.[14]

Chronic repetitive impact loading is known to cause rapid degenerative changes in articular cartilage in laboratory animals. This mechanism probably accounts for the high frequency of osteoarthritis in certain occupational and athletic settings. In particular, occupational activities that require frequent knee bending increase the risk of knee involvement, and frequent lifting appears to be a risk factor for hip involvement.[15,16] Long-term weight-bearing sports activity is associated with an increased risk of developing radiographic evidence of osteoarthritis. In patients without a history of injury, clinical symptoms do not always correlate well with radiographic changes, and radiographic changes do not often progress significantly, even in older long-distance runners.[17,18] However, a history of specific joint injury, usually related to sports and recreational activities, is an important risk factor for knee and hip disease.[19-21]

Decreased strength and proprioception have been demonstrated in patients with osteoarthritis and likely play a role in pathogenesis of the disease. Patients with radiographic changes of osteoarthritis and no pain have decreased muscle strength in the affected leg, and decreased proprioception has been demonstrated in unaffected knees of patients with unilateral disease.[22,23] In addition, local injection to relieve pain will only partially improve muscle activity and proprioceptive and gait defects.[24] The importance of muscle strength and proprioception to the health of normal cartilage has been further suggested in studies demonstrating cartilage thinning after spinal cord injury.[25,26]

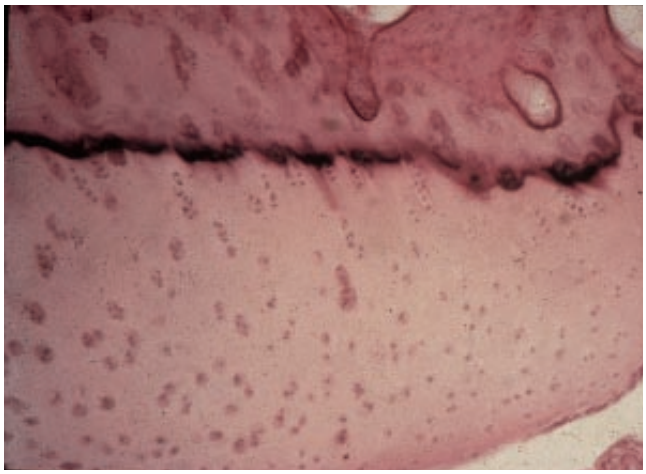
Many patients with osteoarthritis have a family history of the disorder, and multiple genetic factors may be responsible in various forms of osteoarthritis.[27] Osteoarthritis with finger joint involvement in women is probably the best recognized form of arthritis with familial associations,[28] but hereditary factors are also important in osteoarthritis of the hip.[29,30] Metabolic abnormalities related to the hereditary component of osteoarthritis have been found in a number of studies. These abnormalities include associations between variations of collagen genes in familial osteoarthritis and lumbar disk disease; between estrogen and vitamin D receptor genes and osteoarthritis of the knee; and between a gene linked with hemochromatosis in older patients and hand involvement.[31-35] The significance of these findings in relation to osteoarthritis in the general population are uncertain.[36] In addition to the known heritable and acquired joint dysplasias that cause secondary osteoarthritis, subclinical degrees of dysplasia may be a factor in patients with primary osteoarthritis, particularly of the hip.[37] Many different chromosomal markers have been associated with various patterns of osteoarthritis, suggesting that the genetic component in osteoarthritis most likely involves multiple genes.[38-40]

NORMAL ARTICULAR CARTILAGE

Articular cartilage is specialized connective tissue that covers the weight-bearing surfaces of diarthrodial joints. It is composed of sparsely scattered cells (chondrocytes) within an extracellular matrix composed of collagen, proteoglycans, and water, with a very small component of calcium salt.[41]

Most of the collagen in cartilage is type II collagen, which is arranged in thick bundles and is parallel to the surface of the cartilage in outer portions and more perpendicular to the surface in deeper layers. This arrangement of collagen serves as a

a



b

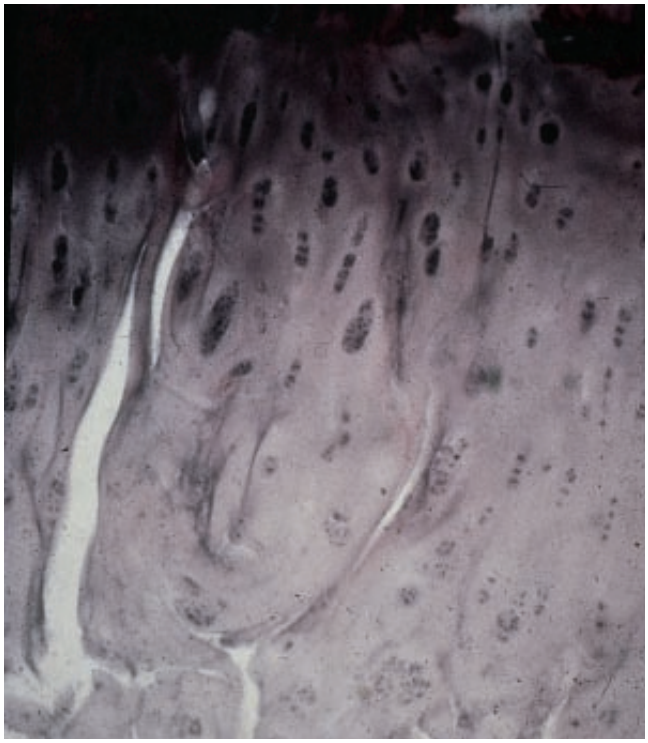


Figure 1 **Microscopic appearance of normal articular cartilage (*a*) and osteoarthritic (*b*) articular cartilage. In normal cartilage, the cartilage surface is smooth and chondrocytes are regularly arranged, mostly as single cells; the background proteoglycan staining is homogeneous; and the subchondral bony plate is intact. In osteoarthritis, there is splitting fissuring of the surface, proliferation and clustering of the chondrocytes, and decreased and irregular staining of the background proteoglycan.**

limiting membrane, distributes compressive forces, and tethers the uncalcified cartilage to the more basilar calcified cartilage and subchondral bone.

The proteoglycan component of the matrix of articular cartilage is composed predominantly of a large molecule called aggrecan, which consists of a large core protein with covalently attached side chains of glycosaminoglycans, most of which are chondroitin sulfate and keratan sulfate. A link protein connects aggrecan to hyaluronic acid, a long, unbranched polysaccharide molecule that can bind several hundred aggrecan molecules. This aggregate of aggrecan molecules forms a very large molecule with a molecular weight of 100 million daltons or more. The molecule has a high fixed negative charge, which allows the retention of large amounts of water.

The collagen matrix and hydrophilic proteoglycan component form a resilient tissue that holds water under pressure and is capable of dissipating much of the force of weight bearing, protecting soft tissues and subchondral bone.

In normal cartilage, the turnover rate of collagen is relatively slow, whereas proteoglycan turnover is rapid. The normal turnover of these matrix components is mediated by the chondrocytes, which synthesize the components and the proteolytic enzymes responsible for their breakdown. Chondrocytes are, in turn, influenced by a number of factors, including polypeptide growth factors and cytokines, structural and physical stimuli, and even the components of the matrix itself.

CHANGES IN OSTEOARTHRITIC CARTILAGE

Pathologic findings suggest that articular cartilage is the site of the primary abnormality in osteoarthritis. There is a loss of homogeneity, and disruption and fragmentation of the surface occur. Uneven staining for proteoglycans is seen in the matrix, and the deeper layers of cartilage are invaded by capillaries from the calcified cartilage. Chondrocytes, which exist as isolated cells in normal cartilage, begin to proliferate and are found in large clusters and clones, and osteophytes are formed, which are covered by irregular hyaline and fibrocartilage [*see Figure 1*].

In early osteoarthritis, the water content of diseased cartilage increases and the cartilage swells, and the collagen fibers are usually smaller and not as tightly organized. The proteoglycan content of cartilage decreases markedly as disease progresses, with shortening of the glycosaminoglycan chains and impaired molecular aggregation.

Osteoarthritic cartilage is characterized by an increase in anabolic and catabolic activity. In the early stages, the synthesis of collagen, proteoglycans, and hyaluronate is increased and chondrocytes tend to replicate. At the same time, synthesis of degradative enzymes such as collagenase, stromelysin, gelatinase, and hyaluronidase is increased, whereas some of the substances that inhibit cartilage destruction are themselves destroyed or inhibited. In the later stages, the anabolic activities of the chondrocytes become insufficient to keep up with the degradative process. The final result is a matrix that is less structurally sound and less well organized on a macromolecular basis, decreasing its ability to withstand the forces required of articular cartilage.

The biochemical and metabolic changes in cartilage that are considered to be potential etiologic factors in osteoarthritis include abnormalities in collagen structure, crystal deposition, inflammatory mediators, and chondrocyte metabolism. The discovery of a familial form of osteoarthritis associated with a specific genetic defect in collagen has led to speculation that similar abnormalities in collagen or other structural components of cartilage may have etiologic importance. In addition, the association of deposition of hemosiderin, copper, or various crystals with secondary forms of osteoarthritis suggests that substances that alter matrix composition can be responsible for degenerative changes.

The relation of calcium-containing crystals to osteoarthritis is complex.[42] Both calcium pyrophosphate dihydrate and basic calcium phosphate crystals have been associated with osteoarthrit-

ic cartilage. In vitro measurement of the by-products of cartilage breakdown suggests that these crystals magnify the degenerative process by stimulation of mitogenesis in fibroblasts and secretion of proteases by cells that ingest the calcium-containing crystals.

The reasons for the increased anabolic and catabolic activities of chondrocytes in osteoarthritis are not well understood.[41] Chondrocytes are influenced by a number of humoral, mechanical, synovial, and cartilage matrix mediators. In particular, prostaglandins, nitric oxide, interleukin-1 (IL-1), transforming growth factor–β, estrogen, and insulinlike growth factor–1 have a variety of stimulatory and inhibitory effects that may be pathogenetically important. In addition, the finding of increased leptin levels in cartilage and synovial fluid of osteoarthritic joints has suggested a role for this substance in the development of osteoarthritis and a role in the relationship between obesity and osteoarthritis.[43,44] Whether the observed abnormalities in these factors are etiologic or merely represent the response of the chondrocyte to other injury is not yet known.[45] The role of inflammation and the potential for damaged cartilage to invoke a more intense inflammatory response than normal cartilage are also areas of ongoing research.[46,47]

The pain of osteoarthritis appears to be derived from inflammation of soft tissue structures surrounding bone, as well as from edema of subchondral bone.[48,49] In addition, edema in subchondral bone is associated with further progression of cartilage damage over time.[50]

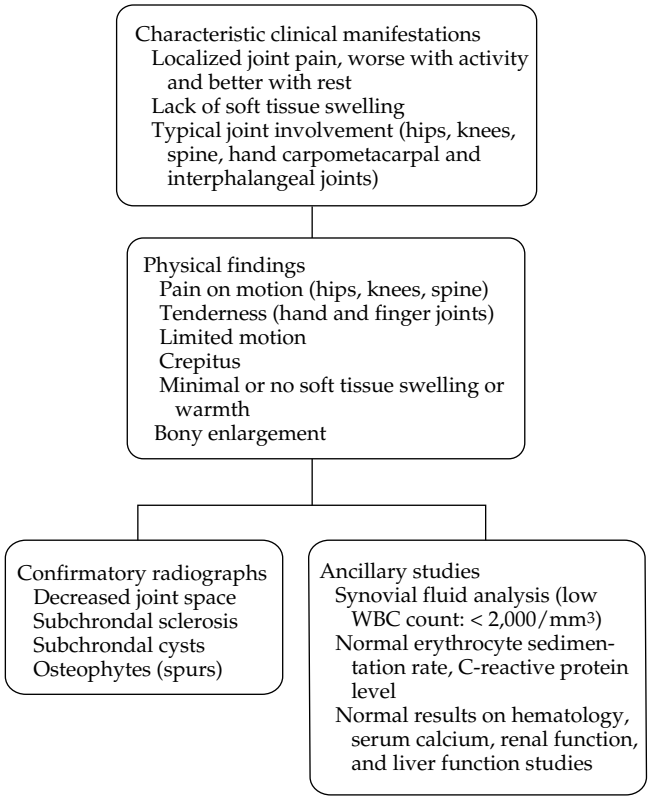

Figure 2 **Diagnosis of osteoarthritis.**

Diagnosis

Characteristic radiographic features are usually considered essential for diagnosis but should be corroborated by the presence of compatible symptoms [*see Figure 2*]. Laboratory studies are useful in the evaluation of patients with osteoarthritis only in that they help to exclude other diagnoses. Thus, the erythrocyte sedimentation rate (ESR), rheumatoid factor, and routine hematologic and biochemical parameters should be normal in patients with osteoarthritis unless the osteoarthritis is attributable to comorbid conditions. Synovial fluid from involved joints is noninflammatory, with leukocyte counts of less than 2,000 cells/mm^3 in most patients. The presence of birefringent calcium pyrophosphate dihydrate crystals is diagnostic of a separate process that frequently is concurrent with typical osteoarthritis. Basic calcium phosphate crystals, which are not birefringent, may be seen frequently in typical osteoarthritis if special stains are used.

Even though some patients have multiple joint involvement, specific joints should be considered individually so that no important problem-causing nonarticular or superimposed process is overlooked.

CLINICAL MANIFESTATIONS

General

Typical symptoms of osteoarthritis include pain, stiffness, swelling, deformity, and loss of function. Pain is usually chronic and localized to the involved joint or joints or referred to nearby areas. Pain may be mild or moderate early in the disease but tends to worsen gradually over many years. Most of the pain is made worse with activity and improves with rest. Morning stiffness is not as prolonged as in patients with inflammatory diseases; morning stiffness in patients with osteoarthritis usually lasts less than an hour. Many patients complain of stiffening, or so-called gelling, during the day, particularly after sitting for extended periods of time. Swelling tends to be mild or moderate and is often related to bony enlargement rather than soft tissue edema. Deformity and loss of function are later manifestations, occurring after many years of disease.

Physical findings in osteoarthritis include crepitus, pain on motion, bony enlargement, and periarticular tenderness. Synovial effusions may be present, particularly in the knee. Erythema and warmth are unusual and should suggest the presence of coexistent crystal-induced inflammation or other conditions. In more advanced disease, limited range of motion, deformity, and instability may become more prominent findings.

Specific Joint Involvement and Complications

Osteoarthritis has a characteristic pattern of involvement in most patients. Joints frequently involved include the distal and proximal interphalangeal joints, as well as the first carpometacarpal joints in the hands, the cervical and lumbar spines, the hips, the knees, and, less commonly, the small joints of the feet or the acromioclavicular joint. The wrists, metacarpophalangeal joints, elbows, shoulders, and ankles are usually not affected unless there is a history of injury to the specific joint, occupational overuse, or underlying condition that might be a cause of secondary osteoarthritis.

Hands The most commonly affected joints in the hands in patients with osteoarthritis are the distal and proximal interphalangeal joints, in which bony enlargement occurs (i.e., Heberden and Bouchard nodes, respectively) [*see Figures 3 and 4*]. The progressive enlargement of these joints occurs slowly over many

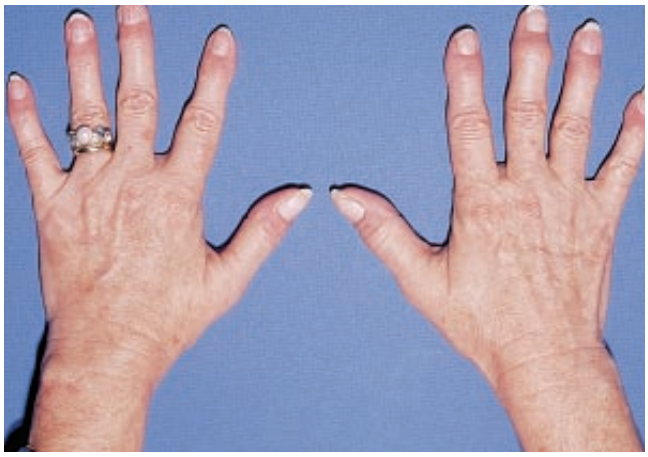

Figure 3 **The hands of a patient with typical primary osteoarthritis show bony enlargement of multiple distal interphalangeal joints (Heberden nodes), mostly on the right, and early bony enlargement of the proximal interphalangeal joints (Bouchard nodes) on the left.**

Figure 4 **Severe destructive changes involving all of the distal interphalangeal joints and some of the proximal interphalangeal joints are characteristic of erosive osteoarthritis. Osteophytes are present at the margins of involved joints. Sharply demarcated bone erosions are seen in several distal interphalangeal joints, and bony fusion is seen in the proximal interphalangeal joint of the left second digit.**

years, is frequently familial, and occurs most often in middle-aged or elderly women. Individual joints may go through inflammatory phases with redness and increased swelling and pain, most of which eventually subsides to a bony enlargement. Small gelatinous cysts may develop over the dorsal aspect of the distal interphalangeal joints and either persist or resolve spontaneously. Many patients with Heberden and Bouchard nodes have very little pain most of the time and therefore may not seek medical attention. The carpometacarpal joint of the thumb is another frequently involved joint, either by itself or along with the more distal joints; in such cases, patients experience pain, bony enlargement, and limited motion of the thumb.

Knees Osteoarthritis frequently affects the knees and may be a cause of significant disability. Most patients present with pain that is worse with activity and improves with rest; they report difficulty getting out of chairs or going up steps. Osteoarthritic knees will almost always have crepitus, limited motion, and pain on motion; effusions may or may not be present. In more advanced disease, bony enlargement, instability, and varus angulation may be present. Many patients have involvement of the patellofemoral compartment, but isolated disease in this area should suggest the presence of calcium pyrophosphate deposition disease.

Hips Osteoarthritis of the hips is another common cause of significant pain and disability [*see Figure 5*]. Most patients experience a progressive disabling pain, usually in the upper thigh or inguinal region, sometimes radiating to the knee. Pain is worse with ambulation and may cause the patient to limp. Patients may also complain of difficulty with activities such as tying shoes, and limited hip motion is found on physical examination.

Spine Osteoarthritis of the cervical and lumbar spine is referred to as spondylosis. Involvement of the intervertebral disk spaces or the posterior spinal facet joints may cause chronic back or neck pain that worsens with activity and improves with rest. Disk degeneration may be complicated by protrusion of the nucleus pulposus, causing nerve root compression with radicular pain or muscle weakness. In patients with extensive degenerative changes with fibrosis and osteophytes, stenosis of the spinal canal can occur, resulting in chronic cord compression in the cervical spine or compression of the cauda equina in the lumbar region. Lumbar spinal stenosis, causing chronic radicular leg pain that is worse with activity and better with rest (neurogenic claudication), is a common complication in elderly patients. A variant of spinal osteoarthritis occurring in the thoracic spine,

Figure 5 **The hip is a common site of involvement in osteoarthritis. Joint space narrowing is most prominent at the superior and lateral aspects of the joint. Increased bony density (sclerosis) is seen in the subchondral bone on both sides of the joint, along with early subchondral cysts and osteophytes (bony spurs) over the superior and inferior aspects of the acetabulum.**

known as diffuse idiopathic skeletal hyperostosis (DISH), is characterized by extensive bridging osteophytes and may cause loss of motion but little pain.

Radiologic Features

Typical radiographic findings in osteoarthritis include joint space narrowing, subchondral bone sclerosis, subchondral cysts, and osteophytes (bony spurs) [*see Figure 5*]. Joint space narrowing, resulting from loss of cartilage, is often asymmetrical and may be the only finding early in the disease process. In weight-bearing joints such as the knees, narrowing may be seen only in a standing view and may be missed in a radiograph obtained with the patient in the recumbent position. In more chronic disease, the hypertrophic features of subchondral sclerosis and osteophyte formation become more prominent, and subluxations or fusion of the joint may become apparent in more severely affected joints. In the small interphalangeal joints of the fingers, central erosions may be seen within the joint space; these erosions should be easily distinguishable from the periarticular erosions of rheumatoid arthritis.

Differential Diagnosis

Because of the high frequency of incidental radiographic changes in the general population, it is important not to attribute all musculoskeletal pain to osteoarthritis, even in patients with radiographic abnormalities. Alternative diagnoses should be made or coexistent conditions suspected in patients who are considered to be at low risk for osteoarthritis (e.g., younger patients) or in those who present with atypical pain patterns or atypical joint involvement. Patients with a relatively sudden onset of pain or with severe pain early in their presentation most often have something other than osteoarthritis. Problems in the wrists, elbows, shoulders, or ankles should raise concerns about other types of arthritis or secondary types of osteoarthritis.

Crystal-induced arthritis should always be considered in patients with acute pain, particularly if swelling and erythema are prominent. Calcium pyrophosphate deposition disease is common in the knees and hips and often coexists with osteoarthritis. Other joints frequently involved are the wrists and shoulders. Detection of chondrocalcinosis on x-ray or of crystals in synovial fluid confirms the diagnosis. Gout usually affects foot and ankle joints in early disease and is not often confused with osteoarthritis, but involvement of the knees is common in later disease. In addition, elderly women with Heberden and Bouchard nodes in the hands may have superimposed attacks in these joints as an initial manifestation of gout. Thus, examination of fluid from these joints for urate crystals may be essential in differentiating gout from an inflammatory flare of erosive osteoarthritis.

Rheumatoid arthritis can usually be distinguished from osteoarthritis on the basis of a different pattern of joint disease, more prominent morning stiffness, and soft tissue swelling and warmth on physical examination. In some patients, the patterns of joint disease may overlap, particularly in the proximal interphalangeal joints, hips, and knees. Thus, in some patients, the presence of an elevated ESR, a high-titer rheumatoid factor, or periarticular erosive changes may be the only way to distinguish these two common conditions.

Polymyalgia rheumatica is a disease of the elderly and is often seen in patients with underlying osteoarthritis. Patients typically have a change in the pattern of pain, more localized to the shoulder and hip girdles, with few peripheral joint symptoms. Morning stiffness is a prominent feature, and the diagnosis is usually more likely if the ESR is markedly elevated. However, because modest elevations of ESR are seen in many normal elderly individuals, the differentiation of this condition from osteoarthritis is often difficult. In some patients, a rapid response of symptoms to a low dose of corticosteroid is helpful in making a diagnosis.

Ankylosing spondylitis is usually a disease that first manifests in young adulthood and should not be confused with spinal osteoarthritis. However, some patients have only mild levels of pain and may not seek medical attention until later years. In such patients, the radiographic changes in the cervical and lumbar spine in the two conditions should make differentiation between them relatively easy.

Psoriatic arthritis, when present in a classic distribution in the distal interphalangeal joints of the fingers, may mimic Heberden nodes. Psoriatic arthritis usually occurs in younger persons and is more common in males, but differentiation between psoriatic arthritis and Heberden nodes may still be difficult. In young patients with arthritis of the distal interphalangeal joints, a careful search for psoriatic skin lesions and nail changes is essential. On physical examination, the swelling of involved joints is usually greater in the soft tissues, with less bony enlargement. Radiography will usually show more erosive changes and fewer osteophytic changes than in typical osteoarthritis.

Disorders of bone near joints can be confused with osteoarthritis. Osteonecrosis of the hip, knee, or shoulder may cause pain and restricted motion without significant signs of inflammation. Radiographs may be normal initially, and follow-up radiographs or magnetic resonance imaging may be necessary to differentiate this condition from osteoarthritis. Paget disease or osteoporotic fractures may cause pain in the back and hip girdle that is similar to that of osteoarthritis, although the pain is often more severe and acute in patients with fractures.

Nonarticular pain syndromes involving tendons, bursae, peripheral nerves, and internal joint structures may cause pain similar to that of osteoarthritis. Examples include de Quervain tenosynovitis or carpal tunnel syndrome in the hand, trochanteric bursitis or meralgia paresthetica in the hip, anserine bursitis or meniscal tears in the knee, and plantar fasciitis and interdigital neuromas in the feet. Knowledge of nonarticular pain syndromes and the characteristic patterns of symptoms and physical findings in each is essential to diagnosing and differentiating these syndromes from osteoarthritis in the same area.

Management

There is no cure for osteoarthritis and no therapy known to prevent or retard the degenerative biologic process in articular cartilage. Thus, the treatment of osteoarthritis is focused primarily on relieving symptoms and improving function.[51-53] Treatment decisions should be based on the severity and distribution of joint involvement, considered in the light of the patient's other medical problems that might affect the safety and effectiveness of any chosen therapy [*see Table 2*].

NONPHARMACOLOGIC MEASURES

Nonpharmacologic measures that have the potential to improve outcomes in osteoarthritis include patient education, physical and occupational therapy assessment and interventions, exercise, weight loss, and dietary measures.[7] Exercise, in particular, should be a part of the therapeutic regimen in every

Table 2 Treatment of Osteoarthritis

Treatment Type	*Useful for What or Whom?*	*Measure*	*Comments*
Nonpharmacologic	All patients	Exercise	Range of motion and strengthening of muscles around affected joints
		Weight loss	Particularly valuable in patients with involvement of weight-bearing joints
		Dietary measures	Adequate intake of calcium, vitamin C, and vitamin D
Pharmacologic	Most or all patients	Simple analgesics	Acetaminophen, tramadol, narcotics in selected cases
		NSAIDs	Nonselective NSAIDs for patients at low risk for GI complications; otherwise, consider addition of misoprostol, a proton pump inhibitor, or an H_2 antagonist or use of a cyclooxygenase-2–specific NSAID (coxib)
Ancillary medical and surgical	Selected joints or patients	Splints	Specific for each joint
		Canes or other orthotics	—
		Corticosteroid injections	Knees, fingers; other joints in selected cases
		Hyaluronic acid injections	Knees in some patients
		Arthroscopic surgery	For patients with mechanical symptoms or findings
		Osteotomy	Knees in selected patients
		Total joint replacement	—

NSAIDs—nonsteroidal anti-inflammatory drugs

patient. Quadriceps weakness contributes significantly to disability in patients with osteoarthritis of the knee, and exercises designed to strengthen quadriceps have potential to lessen pain and disability.[54] In addition, aerobic exercise, such as a walking program, can improve function and reduce pain. Most studies of patients with osteoarthritis have found that regular activity is associated with a better outcome.[55-57] However, compliance with exercise programs is often low, and regular supervised follow-up may be helpful.

The role of obesity as an etiologic factor in osteoarthritis of the knee is well established, and some data suggest that weight loss may reduce the risk of development of symptoms in patients predisposed to osteoarthritis. Even though few prospective studies have been done, patients with osteoarthritis of the knees and hips should be encouraged to lose weight if they are above ideal body weight. In addition, epidemiologic studies have suggested a role for adequate dietary vitamin C and D intake in reducing the risk of progression of established osteoarthritis.[14,58] In some patients, measures designed to alter the biomechanical forces on diseased joints should be considered, including patellar taping, wedged insoles, bracing, canes, and crutches.

PHARMACOLOGIC THERAPY

The primary goal of drug therapy in osteoarthritis is to relieve pain. Acetaminophen may be as effective as nonsteroidal anti-inflammatory drugs (NSAIDs),[59] so it should be prescribed initially in most patients. In most cases, up to 3,000 to 4,000 mg of acetaminophen a day can be given. Doses should be limited in patients with exposure to other potentially hepatotoxic substances. In particular, patients who take acetaminophen regularly should be advised to limit alcohol ingestion and be warned about the increased risk of acetaminophen hepatotoxicity in heavy drinkers. Opioids are generally avoided in osteoarthritis but may be useful in selected patients. However, these agents should be used with caution in elderly patients.[60] Tramadol, a centrally acting analgesic with dual mechanisms, may give relief comparable to that achieved with acetaminophen and codeine. Topical capsaicin may be useful in some patients, especially those with involvement of the knees and hands.

A number of other nutritional supplements and topical therapies have been investigated for the treatment of osteoarthritis. These studies have been poorly controlled or limited, however. Little evidence exists to support widespread use of any of these alternative or complementary therapies.[61,62]

NSAIDs are useful in osteoarthritis mostly for their analgesic effects and, in most patients, are more effective than acetaminophen.[63-65] Unfortunately, NSAIDs are associated with an increased risk of gastric ulcers and bleeding, particularly in patients with a history of gastrointestinal disease, those on concomitant steroids or anticoagulants, and those older than 65 years. Strategies to reduce this toxicity include the use of lower doses of NSAIDs or concomitant use of misoprostol, histamine$_2$ receptor antagonists, and proton pump inhibitors. The cyclooxygenase-2 (COX-2)–specific NSAIDs (celecoxib and valdecoxib) have been shown to reduce the risk of serious gastrointestinal complications, compared with the nonselective COX inhibitors. The association of cardiovascular events with the prolonged use of the COX-2 inhibitor rofecoxib (Vioxx) prompted the withdrawal of the drug from the global market in 2004.[66] The Adenomatous Polyp Prevention on Vioxx (APPROVe) study documented that patients taking the drug for 18 months were twice as likely to experience cardiovascular events as patients taking placebo (after 3 years, the rates of cardiovascular events were 1.5% for rofecoxib and 0.7% for placebo).[66] Data from several sources are consistent in finding an increase of hypertension and congestive heart failure in patients taking rofecoxib.[67-69] There is scant evidence to assess the long-term risk of other COX-2 inhibitors. When prescribing COX-2 inhibitors, clinicians should weigh the potential cardiovascular risks against anticipated benefits and consider issues such as dose and comorbid conditions.

Intra-articular corticosteroid injections may be useful in treating selected joints, particularly during exacerbations characterized by increased pain and effusion, and injections in symptomatic knees every 3 months may be a safe and effective means of reducing pain and improving function over longer periods of time.[70] Some animal and in vitro studies have suggested that steroids have a detrimental effect on articular cartilage, but there are few clinical data to support this concern in patients with osteoarthritis. Intra-articular hyaluronic acid derivatives (Hyalgan and Synvisc), given in a series of three to five weekly injections, have been shown to be superior to placebo in most studies and may be useful in relieving pain in selected patients with less advanced disease.[71,72]

SURGERY

In patients with badly damaged knees and hips, total joint replacement is an effective option. Almost all patients experience significant pain relief, and some have improved range of motion. Joint loosening and infection are potential late complications in prosthetic joints but are uncommon. Arthroscopic debridement of affected joints is no better than placebo in unselected patients with osteoarthritis of the knee.[73] Thus, this procedure should be reserved for patients with mechanical symptoms suggesting internal derangement. Realignment of a degenerative knee to allow redistribution of forces is sometimes attempted by a high tibial wedge osteotomy, particularly in younger patients with valgus deformities.

Biologic approaches to the surgical treatment of osteoarthritis have been explored. These include local enhancement of bone marrow progenitor cells and various forms of cartilage transplantation.[51] In addition, stem cell transplantation has been investigated in animal models of osteoarthritis.[74] Most of these approaches are in early stages of development, and none is likely to enter clinical use in the foreseeable future.

PROTECTING CARTILAGE

Therapies with potential to prevent or retard the progression of articular cartilage breakdown have received a great deal of attention in recent years.[75] Agents considered to have so-called chondroprotective potential include tetracyclines, protease inhibitors, glycosaminoglycan compounds, growth factors, and cytokine inhibitors. Oral glucosamine and chondroitin sulfate have been promoted as health food supplements to improve cartilage, but most of the clinical studies with these agents have demonstrated only modest pain relief, compared with placebo, and studies to assess the effect on cartilage are ongoing.[76-79] Inconsistent dosages in studies and lack of standardization of available preparations have complicated assessment of these agents' value.

Tetracyclines have been shown to reduce the severity of osteoarthritis in animals, probably by inhibiting metalloprotease activity, and are being studied in early human trials. Other approaches to disease modification being investigated in animal models include other agents that inhibit metalloproteases or nitric oxide synthase inhibitors.[80]

Biologic therapies designed to augment growth factors or inhibit cytokines have also been investigated in animal models of osteoarthritis. These have included attempts to introduce growth factors or IL-1 receptor antagonist through the use of gene therapy.[81]

Prognosis

Osteoarthritis is a slowly progressive condition with a variable prognosis.[2] Radiographically, most joints will either remain stable or gradually worsen over a 5- to 15-year period. In most patients, symptoms evolve over many years and may spontaneously remit for long periods of time without explanation. Progression of osteoarthritis of the hand is particularly hard to measure because pain levels frequently improve after involved joints become fused. Disease may progress more rapidly in the hips and knees of older women with osteopenic bone. However, in general, predicting the prognosis in patients with osteoarthritis is difficult.

The author has received grants for clinical research from Abbott Laboratories, Amgen, Inc, Bristol-Myers Squibb Co., and Isis Pharmaceuticals, Inc., and has served as advisor or consultant to TAP Pharmaceutical Products, Inc.

XII BACK PAIN AND COMMON MUSCULOSKELETAL PROBLEMS

CHRISTOPHER WISE, M.D., F.A.C.P.

A large proportion of the musculoskeletal problems for which patients seek medical attention are related to periarticular structures and do not represent a true articular process or a more generalized systemic illness.[1] Knowledge of the common nonarticular regional rheumatic disorders is important because of their high prevalence in primary care practice, the dependence on clinical findings for diagnosis, and the high cost that can result from unnecessary laboratory evaluations. The ability to recognize important patterns of pain and associated physical signs is essential to making a correct diagnosis; in most cases, radiographic and laboratory studies are not needed. Diagnostic studies should be utilized judiciously and must be interpreted in the light of existing clinical findings and prestudy suspicion for specific diagnoses.

Most regional rheumatic disorders respond to local measures, such as application of heat or cold, splinting, and injection of glucocorticoids. Nonsteroidal anti-inflammatory drugs (NSAIDs) or mild analgesic medications are often helpful therapeutic adjuncts. Referral for surgical intervention may be indicated for patients with certain conditions. For example, in cases of cervical or lumbar disk disease or spinal stenosis with definite nerve entrapment or spinal cord compression, well-timed decompression may be necessary to restore function or prevent further functional impairment. Arthroscopic intervention is sometimes useful to better define and treat refractory knee and shoulder pain syndromes. Surgical release is indicated for entrapment neuropathies when there is evidence of motor dysfunction. Surgical consultation may be useful for a variety of other syndromes when the response to conservative measures proves to be less than optimal. Physical therapy and occupational therapy are useful for many patients—particularly those patients who have persistent back and shoulder pain—though these therapies may constitute an important part of the treatment of almost any refractory regional pain syndrome.

Definitions

Common regional rheumatic disorders include various types of bursitis, tendinitis, tenosynovitis, myofascial pain, and entrapment neuropathies. Bursitis results from mechanical or inflammatory changes of one of the many bursae in the body. Bursae are synovia-lined sacs around the joints that serve to minimize friction between tendons, ligaments, and bony structures. Tendinitis usually results from trauma or overuse of tissues near sites where tendons attach to bone or at the musculotendinous junction. Myofascial pain originates at sites within muscle groups and surrounding fascial tissues that become tender and painful as a result of localized injury or overuse. Entrapment neuropathies occur at sites where peripheral nerves are compressed as they traverse periarticular areas that allow relatively little room for free movement of the affected nerves.

Neck Pain

Neck pain may result from degenerative changes in the cervical disks and zygapophyseal (facet) joints or from a variety of muscular, ligamentous, and tendinous conditions.[2] In whiplash injuries occurring after rapid acceleration or deceleration and hyperextension of the head in motor vehicle accidents, a number of structures may be injured.[3] Recovery from whiplash injuries is often incomplete, and a combination of physical and psychosocial factors may contribute to prolongation of pain.[4] Judicious use of analgesics, muscle relaxants, and physiotherapy proves helpful in some patients. The zygapophyseal joints may be the source of pain, and local nerve block with an anesthetic or ablation may be helpful in selected patients.

The term cervical sprain denotes transient neck pain associated with muscle tenderness and spasm. Cervical sprain usually responds to heat, rest, and, occasionally, immobilization and traction. Manual therapy, range-of-motion or strength-training exercises, or acupuncture may provide relief in some patients.[5-7] In cervical disk herniation, nerve root impingement results in pain, paresthesia, and sometimes muscle weakness in the distribution of the affected nerve (usually at the C5 to C7 level). In such patients, radiographic documentation and surgical decompression are sometimes needed if symptoms do not improve with rest or traction or if significant neurologic deficit is present. In some patients with long-standing cervical spondylosis, cervical stenosis may cause chronic compression of the spinal cord (most often at the C3 to C5 level). Surgical decompression is indicated in patients with evolving myelopathy.

Back Pain

Low back pain is the most common musculoskeletal complaint requiring medical attention; it is the fifth most common reason for all physician visits.[8-10] Over half of the general population will seek medical attention for back pain at some point in their lives. An increased risk of back pain is associated with male sex, smoking, frequent lifting of heavy objects, poor general health and conditioning, and certain occupational and sports activities. In addition, preexisting psychological distress, compensation issues, other chronic pain, and job dissatisfaction may play a role in persistent back pain.[11,12] In most patients, the cause of pain cannot be determined with any degree of certainty and is usually attributed to muscular or ligamentous strain, facet joint arthritis, or disk pressure on the annulus fibrosus, vertebral end plate, or nerve roots.[13]

ACUTE BACK PAIN

Diagnosis

For patients with acute back pain, the initial history should be used to identify those who are at increased risk for serious underlying conditions, such as fracture, infection, tumor, or major neurologic deficit[8] [*see Table 1*]. The presence of such factors in patients with acute back pain may indicate the need for radiographic and laboratory studies earlier than in patients without such factors. The initial physical examination should include

Table 1 Indications That Acute Back Pain May Involve Underlying Conditions

Patient demographics	Age > 70 yr History of cancer Glucocorticoid or immunosuppressive drug therapy Alcohol or I.V. drug abuse
Historical features	Weight loss Fever Pain increased by rest
Neurologic symptoms	Bowel or bladder dysfunction Saddle block anesthesia Progressive motor weakness

evaluation for areas of localized bony tenderness and assessment of flexion and straight leg raising. Because acute low back pain will improve within a month in over 90% of patients, further evaluation is usually unnecessary. Plain radiographs should be reserved for patients at high risk for more serious underlying conditions [*see Table 1*], because abnormal findings on plain films are common and do not correlate with back pain. Early use of magnetic resonance imaging or computed tomography has not been shown to change treatment choices or outcomes; consequently, these studies should be reserved for patients with persistent pain and sciatica.[14,15]

Treatment

A number of therapeutic interventions are available for acute back pain, but data supporting efficacy are minimal for most therapies. Strict bed rest should be kept to a minimum (no more than 2 to 4 days), and the continuation of normal activities within the limits permitted by pain should be encouraged. Mild analgesics (including NSAIDs) and muscle relaxants may be useful for early symptom control; opiates should be used sparingly.[16] Spinal manipulation, massage or other physical therapy, graded activity, self-management, or other specific exercise programs may be effective in acute back pain, but most controlled studies suggest little to no advantage of any particular regimen.[17-21] Patient education about the natural history of back pain may result in fewer demands for further diagnostic tests and physician visits and should improve patient satisfaction.

CHRONIC BACK PAIN

Diagnosis

Patients whose pain persists after 4 to 6 weeks of conservative treatment measures should be reassessed. Plain radiography and basic laboratory studies (e.g., complete blood count, erythrocyte sedimentation rate or C-reactive protein level, chemistry profile, and urinalysis) should be considered to screen for systemic illnesses. A herniated lumbar disk should be considered in patients with symptoms of radiculopathy, as suggested by pain radiating down the leg with symptoms reproduced by straight leg raising. MRI may be necessary to confirm a herniated disk, but findings should be interpreted with caution because many asymptomatic persons have disk abnormalities.[22] Electromyography may be useful in differentiating lumbar radiculopathy from other causes of radicular leg pain. Most lumbar disk herniations producing sciatica occur at the L4-L5 and L5-S1 levels. Surgical intervention is indicated in patients with persistent sciatica and clear-cut evidence of a herniated disk on MRI or myelography–CT scanning.

Treatment

A number of nonpharmacologic approaches to therapy have been studied in patients with chronic low back pain, but no specific regimen appears to be superior to others. Most analyses of prior studies suggest that individualized programs promoting strength and range of motion have modest efficacy.[23-25] Behavioral therapies and using a mattress of medium firmness may provide short-term improvement in some patients, as well.[26,27] Judicious use of analgesics, NSAIDs, and tricyclic antidepressants may help the patient function more fully and may improve outcome.[28] Local therapies in the form of local injections of intradiscal or periarticular steroids, hypertonic irritant solutions (prolotherapy), or acupuncture are no more effective than placebo in most studies.[29-31]

Lumbar Stenosis

Lumbar spinal stenosis, usually a result of extensive degenerative disk disease and osteophytes, should be suspected in elderly patients with chronic back pain associated with sciatica.[32] Patients typically complain of pain, numbness, and weakness in the buttocks that extends to one or both legs. Symptoms are usually brought on by standing or walking and improve when the patient stoops forward, sits, or lies down (i.e., neurogenic claudication or pseudoclaudication). The diagnosis may be confirmed by MRI or myelogram–CT scanning.[33] Conservative measures are helpful in many patients, allowing stable or improved function. Surgical decompression by multilevel laminectomy and fusion should be considered in patients with poor response to conservative measures or progressive functional deterioration.[34-36]

Shoulder Pain

Shoulder pain is one of the most common musculoskeletal problems seen in the outpatient setting.[37] Most shoulder pain results from conditions of the periarticular structures of the joint; true arthritis of the glenohumeral joint is uncommon [*see Figure 1*].

The initial evaluation of shoulder pain should include consideration of pain that may be referred from the neck, thorax, or abdomen. The examination should assess active and passive range of flexion, abduction, and internal and external rotation of the shoulder, along with forward elevation. In addition, areas of localized tenderness may help differentiate the various potential causes of shoulder pain. Plain radiographs are seldom diagnostic but are indicated in patients with a history of trauma or refractory pain or when true glenohumeral joint disease is suspected. For patients who respond poorly to conservative therapy, a variety of specialized tests (e.g., arthrography, arthroscopy, and MRI) are available for further definition of lesions that may require surgery.

ROTATOR CUFF TENDINITIS (IMPINGEMENT SYNDROME)

Rotator cuff tendinitis, or impingement syndrome, is often associated with bursitis of the overlying subacromial bursa and is the cause of most nontraumatic cases of shoulder pain. Rotator cuff tendinitis results from inflammation, degeneration, and attrition of the rotator cuff by mechanical impingement on the acromion, coracoacromial ligament, and sometimes the acromioclavicular joint.

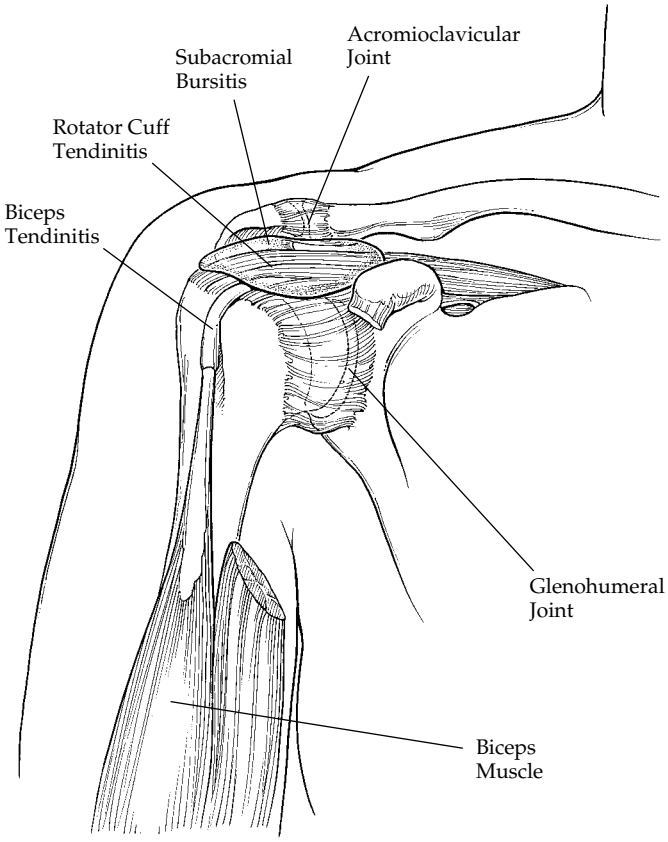

Figure 1 **Tendinitis of the rotator cuff and subacromial bursitis cause pain that is felt over the lateral aspect of the shoulder, whereas bicipital tendinitis, acromioclavicular joint disease, and glenohumeral joint disease cause anterior shoulder pain.**

Rotator cuff tendinitis is seen most commonly in patients 35 to 60 years of age and appears to be partially related to work or activities performed with the arms in highly elevated positions.[38] Younger patients may be affected as a result of athletic activities involving overhand throwing. Patients report an insidious pain that may be diffuse over the lateral deltoid or more localized to the anterior acromial region. Pain worsens with reaching and may be accompanied by a catch as the patient brings the arm into an overhead position. Rotator cuff pain is often particularly bothersome at night and interferes with sleep. On examination, pain may limit movement and may be reproduced by resistance of active movement. The so-called impingement sign is elicited by forced forward elevation of the arm with the scapula stabilized from behind. A coexistent rotator cuff tear may be suspected if the patient cannot hold the arm in a horizontal position against gravity.

The goal of therapy for rotator cuff tendinitis is to relieve pain and maintain or restore range of motion. Treatment should begin with rest and a progressive program of stretching and strengthening exercises, facilitated by an NSAID.[39] Injection of glucocorticoids and local anesthetic into the subacromial space or glenohumeral joint may result in dramatic relief of symptoms and may allow a more rapid, full recovery in some patients.[40,41] Avoidance of repetitive overhead activities of the arms is necessary during recovery, and job modification may be needed to prevent recurrence. In refractory cases, surgical division of the coracoacromial ligament or acromioplasty may be indicated.

CALCIFIC TENDINITIS

Calcific tendinitis is the cause of pain in a subset of patients with apparent rotator cuff disease. In most cases, a more chronic tendinitis is implicated, with associated deposition of calcium in the rotator cuff; calcification in the subacromial space is apparent radiographically. Patients usually have a more acutely painful condition, similar to that seen in crystal-induced arthritis. NSAIDs and local glucocorticoid injections are usually helpful, and surgery is indicated in selected cases. Ultrasound therapy has been shown to provide short-term improvement in symptoms and radiographic signs of calcification, as compared with placebo.[42]

BICIPITAL TENDINITIS

Bicipital tendinitis occurs in the region of the anterior shoulder, where the long head of the biceps tendon passes through the bicipital groove of the humerus and through the joint to insert over the glenoid cavity. Diagnosis is based on the localization of tenderness anteriorly, though this condition may coexist with rotator cuff tendinitis. Rupture of the tendon may occur occasionally, particularly in older patients, and often presents as a bulge in the biceps muscle. Treatment with local measures and range-of-motion exercises is effective, as in rotator cuff disease. Surgical repair of a ruptured tendon is indicated only in younger patients with acute rupture.

FROZEN SHOULDER (ADHESIVE CAPSULITIS)

Frozen shoulder, or adhesive capsulitis, is characterized by progressive pain and global loss of motion in the shoulder. This condition is usually seen in patients with an underlying rotator cuff tendinitis or bicipital tendinitis but has also been associated with stroke, myocardial infarction, cervical radiculopathy, and pulmonary disease. The pathophysiology of frozen shoulder is unclear, and controversy exists as to how significantly capsular inflammation or fibrosis really contributes to the loss of motion that is characteristic of the condition. Treatment is directed toward pain relief and restoration of function, often with a combination of exercises, local heat, ultrasonography, and NSAIDs or mild analgesic medications. Maximal rehabilitation of a frozen shoulder often requires 1 to 2 years. Suprascapular nerve blockade, short courses of systemic steroids, and joint distention with intra-articular steroids have been shown to provide short-term benefit in some studies.[43-45] Manipulative therapy or intra-articular steroid injections combined with physical therapy may provide improvement over longer periods.[46,47] Surgical procedures and capsular distention with saline injection have reportedly proved useful in individual cases.

MYOFASCIAL SHOULDER PAIN SYNDROME

Myofascial shoulder pain syndromes are characterized by pain over the trapezius or medial or lateral scapular borders posteriorly, with the finding of reproducible trigger points. These poorly characterized syndromes usually respond to local injection with glucocorticoids and an anesthetic, though local modalities may be needed in more chronic cases.

Chest Wall Pain

Musculoskeletal chest wall pain syndromes account for about 10% to 15% of cases in which adults are seen for chest pain in the emergency department setting, and they account for about 15% to 20% of patients who have had chest pain but whose coronary angiograms are negative.[48] The diagnosis of musculoskeletal

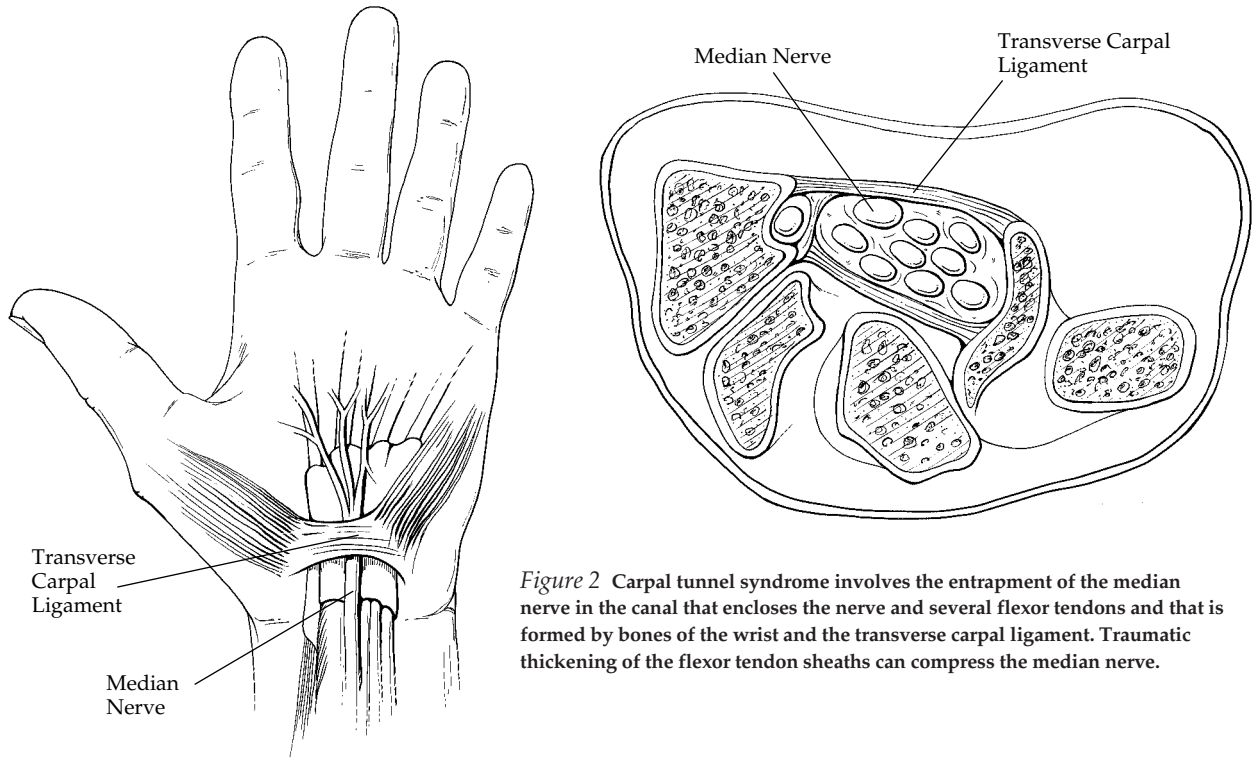

Figure 2 **Carpal tunnel syndrome involves the entrapment of the median nerve in the canal that encloses the nerve and several flexor tendons and that is formed by bones of the wrist and the transverse carpal ligament. Traumatic thickening of the flexor tendon sheaths can compress the median nerve.**

chest wall pain requires the finding of consistent areas of tenderness that reproduce the patient's pain. In rare cases, chest pain may result from Tietze syndrome—a benign, painful, nonsuppurative localized swelling of the costosternal, sternoclavicular, or costochondral joints, most often involving the area of the second and third ribs. In most cases, only one area is involved. Young adults are more commonly affected.

More often, patients with musculoskeletal chest wall syndromes have a more diffuse pain syndrome, termed costochondritis or costosternal syndrome, the specific etiology of which is not well understood. Areas of tenderness are not accompanied by warmth, erythema, or swelling; multiple areas of tenderness are found, usually in the upper costochondral or costosternal junctions. A number of less common chest wall syndromes have been described, each defined by the area of tenderness (e.g., xiphoidalgia, sternalis syndrome, and slipping rib syndrome). Musculoskeletal chest wall syndromes are usually self-limited and respond to analgesics, local heat, stretching exercises, and local glucocorticoid injection.

Elbow Pain

The most common nonarticular syndromes of the elbow include epicondylitis, olecranon bursitis, and ulnar nerve entrapment.

EPICONDYLITIS

Epicondylitis is caused by an inflammation at the origin of the tendons and muscles serving the forearm; it is usually caused by overuse or by repetitive activity. Patients typically complain of elbow and forearm pain with activity. When the extensor muscles are involved (i.e., tennis elbow), tenderness is maximal over the lateral epicondyle and aggravated by extension of the wrist against resistance. A similar, less common process may affect the flexor muscles originating at the medial epicondyle (i.e., golfer's elbow).

Epicondylitis usually responds to rest, local heat or ice, NSAIDs, and forearm support to reduce tension at the epicondyle. Local infiltration of glucocorticoids and lidocaine often results in more rapid improvement than other measures in the first month or two but does not appear to affect the outcome over 6 to 12 months.[49,50]

OLECRANON BURSITIS

Olecranon bursitis presents as a discrete swelling with palpable fluid over the tip of the elbow. Traumatic bursitis is characterized by minimal heat or surrounding erythema. The fluid aspirated is noninflammatory and often contains multiple red cells. Infectious bursitis—usually caused by gram-positive skin organisms—is accompanied by heat, erythema, and induration. When infection is suspected, prompt aspiration and culture of the fluid are mandatory. Antibiotics should be started empirically, and the bursa should be reaspirated frequently until the fluid no longer reaccumulates and cultures are negative.[51] Olecranon bursitis may also be part of rheumatoid arthritis or gout, usually in a patient in whom a diagnosis has already been made. On occasion, an initial diagnosis of gout is made by examination of bursal fluid for urate crystals.

ULNAR NERVE ENTRAPMENT

Ulnar nerve entrapment is caused by compression of the ulnar nerve as it passes through the ulnar groove at the elbow[52] [*see 11:II Diseases of the Peripheral Nervous System*]. Patients typically complain of pain and numbness that radiates from the elbow to the little finger and the medial side of the hand. An increase in paresthesia with elbow flexion is helpful in making the diagnosis, but nerve conduction studies are often needed to confirm the diagnosis. Conservative therapy with a loose cast may help limit elbow flexion and improve symptoms in some patients; surgical decompression is indicated in patients with disabling pain or weakness.

Hand and Wrist Pain

Painful conditions of the tendons and tendon sheaths of the hand and wrist are often related to repetitive or unaccustomed activities. The resultant edema, inflammation, and fibrosis of the structures interfere with the normal function of the tendon as it moves within the sheath.

DE QUERVAIN TENOSYNOVITIS AND FLEXOR TENOSYNOVITIS

De Quervain tenosynovitis affects the abductor pollicis longus and extensor pollicis brevis. Typical symptoms are pain over the radial aspect of the wrist during activities and tenderness that is usually found over the affected tendons proximal to the level of the carpometacarpal joint of the thumb. Pain is reproduced by stretching the tendons with the thumb inside a closed fist (i.e., the Finkelstein maneuver). Flexor tenosynovitis, or trigger finger, is caused by involvement of the flexor tendons of the digits, usually at the level of the metacarpophalangeal joint. Patients complain of locking of the affected digit in a flexed position, often with a sudden painful release on extension. Treatment of de Quervain tenosynovitis and flexor tenosynovitis may require rest, local heat, immobilization with a splint, or local infiltration with glucocorticoids. Surgical release is rarely required.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is caused by compression of the median nerve at the wrist as it courses with the flexor tendons[53] [*see Figure 2 and 11:II Diseases of the Peripheral Nervous System*]. Entrapment is usually associated with flexor tenosynovitis related to overuse, vibratory tool use, or trauma.[54] In addition, an association has been observed with cigarette smoking, body weight, and such medical conditions as diabetes mellitus, rheumatoid arthritis, pregnancy, and hypothyroidism, as well as with rare conditions such as amyloidosis, acromegaly, and localized infection.

Carpal tunnel syndrome is relatively common in the general population. A 1999 study found that 14% of the general population has symptoms suggestive of carpal tunnel syndrome; such symptoms were confirmed by clinical examination and electrophysiologic studies in 2% to 3% of the patients studied.[55] In addition, 18% of asymptomatic persons were found to have electrophysiologic evidence of median nerve entrapment. Carpal tunnel syndrome is more common in persons with occupations that require repetitive wrist movements, awkward wrist positions, or the use of vibrating tools or great force. Patients report numbness, tingling, and pain over the palmar radial aspect of the hand; these symptoms are often worse at night or after use. Reproduction of paresthesia with maximal wrist flexion (i.e., the Phalen test) or tapping over the volar aspect of the wrist (i.e., the Tinel sign) are often considered to be helpful clinical findings. However, a review of published studies suggests that the pattern of pain and findings of decreased sensation and weakness of thumb abduction are the most reliable diagnostic findings.[56] Because of the uncertainties in the reliability of diagnostic findings, electrodiagnostic testing is usually necessary to confirm a diagnosis, particularly when surgical intervention is considered.

Conservative treatment measures include use of NSAIDs and placement of a wrist splint in a neutral position. Local injection of glucocorticoids affords short-term relief in most patients, but long-term improvement is less predictable.[57,58] Surgical decompression by sectioning of the volar carpal ligament results in excellent outcome in 67% to 80% of patients; it is indicated in patients whose conditions respond poorly to conservative therapy, patients with chronic or recurrent symptoms, or patients with weakness or atrophy of the thenar muscles.[59] Predictors of less favorable surgical outcome include poor upper extremity function; alcohol use; worse mental health status; and, in workers, involvement of an attorney.[60]

DUPUYTREN CONTRACTURE

Dupuytren contracture is a fibrosing condition of the palmar and digital fascia that results in thickening and puckering of the palmar skin with subcutaneous nodules and often in flexion contracture of the underlying digit. Dupuytren contracture may be associated with other fibrosing syndromes; with an autosomal dominant inheritance pattern; and possibly with liver disease, epilepsy, and alcoholism. Although spontaneous improvement may be seen, surgical intervention to improve function may be useful in individual cases.

STIFF-HAND SYNDROME

The stiff-hand syndrome, resembling scleroderma, is characterized by thickening of the skin and subcutaneous tissues and generalized limitation of hand and wrist motion. This condition is seen almost exclusively in young patients with long-standing type 1 diabetes mellitus.[61]

Hip Girdle Pain

Pain around the hip girdle is a common complaint in clinical practice. Patients with pain resulting from diseases of the hip joint usually describe pain in the anterior thigh or inguinal region that worsens with weight bearing. More commonly, patients with a chief complaint of hip pain have a problem in one of the nonarticular structures of the hip girdle, usually located posteriorly or laterally [*see Table 2*]. A multitude of bursae have been described in the hip girdle region. Pain in the upper buttock in and around the gluteal muscles is often referred to as myofascial hip pain or gluteal bursitis. Pain in this area is often difficult to differentiate from referred lumbar pain. Local therapy with heat,

Table 2 Differential Diagnosis of Hip Girdle Pain

Clinical Syndrome	*Location of Pain*	*Diagnostic Features and Comments*
Acetabular joint pain	Anterior hip (inguinal)	Worse with weight bearing Radiographic confirmation
Ileopectineal bursitis	Anterior hip (inguinal)	Pain with extension Normal radiograph ? Ultrasound or CT scanning
Meralgia paresthetica	Anterior hip (midthigh)	Numbness and tingling Normal hip movement
Trochanteric bursitis	Lateral hip, posterior hip, or both	Normal hip movement Point tenderness Relief with glucocorticoid injection
Myofascial pain	Posterior hip	Localized tenderness Relief with glucocorticoid injection ? Mimics lumbar disease
Gluteal bursitis	Posterior hip	Localized tenderness Relief with glucocorticoid injection ? Mimics lumbar disease
Ischiogluteal bursitis	Posterior hip	Normal hip movement Point tenderness

stretching, or glucocorticoid injection is usually helpful, but many patients require long-term therapy.

TROCHANTERIC BURSITIS (GREATER TROCHANTERIC PAIN SYNDROME)

Trochanteric bursitis is probably the most common cause of hip girdle pain, although a study using MRI suggests that most patients with this pain syndrome may have tendinitis or a partial tear of the gluteus medius tendon.[62] Patients typically complain of pain over the lateral aspect of the hip girdle, sometimes radiating down the thigh, that is worse at night when they lie on the affected side. Pain is sometimes present when the patient arises from a chair, but it tends to improve with ambulation. Point tenderness over the lateral or posterior aspect of the greater trochanter is usually diagnostic, though some patients with referred lumbar facet or disk disease may have a similar presentation. Patients with more severe pain may have a positive Trendelenburg sign on physical examination. Local heat and NSAIDs may be helpful, and a local glucocorticoid injection is curative in most patients. In refractory cases, repeated injections, physical therapy, and, in rare instances, surgical excision of the bursa may be indicated.

ISCHIOGLUTEAL BURSITIS

Ischiogluteal bursitis results from an irritation of the bursa in the area of the attachments of the hamstring and gluteal muscles at the ischial tuberosity. The condition may be brought on by prolonged sitting or by pressure in the area and usually responds to local heat, stretching, or glucocorticoid injection.

ILIOPECTINEAL BURSITIS

Iliopectineal bursitis, which is caused by irritation of the bursa between the iliopsoas muscle and the inguinal ligament, is an uncommon cause of inguinal pain and may mimic true hip joint disease. The diagnosis is suggested by the presence of inguinal pain that is aggravated by extension of the hip (in a patient whose hip x-ray is normal). Confirmation by ultrasonography or CT scanning may be required. Treatment is usually with local measures or, in rare cases, by means of surgical excision.

MERALGIA PARESTHETICA

Meralgia paresthetica is characterized by intermittent paresthesia, hypoesthesia, or hyperesthesia over the upper anterolateral thigh. The syndrome is caused by an entrapment of the lateral femoral cutaneous nerve at the level of the anterosuperior iliac spine where the nerve passes through the lateral end of the inguinal ligament. Causes include local trauma, rapid weight gain, and the wearing of constrictive garments around the hips. Useful therapies include avoidance of pressure in the area, weight loss, and local infiltration of glucocorticoids at the level of the nerve exit.

Knee and Lower Leg Pain

Clinically, the differentiation of articular knee pain from nonarticular pain can be difficult. Most patients with articular knee pain have a relatively diffuse pain that is not well localized to one area of the knee. Physical examination shows loss of motion, crepitus (in osteoarthritis), warmth (in inflammatory arthritis), or the presence of effusion. If knee pain is localized or if the knee has full range of motion without warmth, crepitus, or effusion, one of the following nonarticular syndromes should be considered: infrapatellar tendinitis, Osgood-Schlatter disease, prepatellar bursitis, anserine bursitis, anterior knee pain syndromes, and restless legs syndrome.

INFRAPATELLAR TENDINITIS

Infrapatellar tendinitis, or jumper's knee, causes anterior knee pain below the patella and is often related to athletic activities. Tenderness is localized to the infrapatellar tendon, with no associated swelling, and conservative measures almost always result in resolution of symptoms.

OSGOOD-SCHLATTER DISEASE

Osgood-Schlatter disease is characterized by pain and swelling over the tibial tubercle at the tendon insertion point. This condition is seen predominantly in adolescent males and is thought to represent a traumatic avulsion injury. Symptoms usually resolve with temporary immobilization and slow resumption of activities.

PREPATELLAR BURSITIS

Prepatellar bursitis, or housemaid's knee, causes pain and swelling in the anterior knee superficial to the patella and infrapatellar tendon. An area of localized fluid collection is usually detectable; aspiration is often needed for diagnosis. As in olecranon bursitis of the elbow, prepatellar bursitis may be associated with trauma, localized bacterial infection, and, less commonly, gout, rheumatoid arthritis, and atypical infections. The differentiation between trauma and infection is particularly important for initiation of appropriate therapy.

ANSERINE BURSITIS

Anserine bursitis, which is caused by irritation of the bursa near the attachment of the sartorius and hamstring muscles at the medial tibial condyle, is a common cause of medial knee pain. Patients with this condition complain of pain at night or when climbing stairs, and an area of localized tenderness can be found on examination. Coexistent osteoarthritis of the knee joint is present in many patients, and relief with local heat or injection of glucocorticoids and anesthetic may be helpful both diagnostically and therapeutically.

ANTERIOR KNEE PAIN SYNDROMES

Anterior knee (patellofemoral) pain syndromes usually manifest themselves as pain and crepitus associated with activities that require knee flexion under load conditions (e.g., stair climbing). Physical findings that help with diagnosis include (1) reproduction of pain with pressure over the patella during knee motion and (2) tenderness over the medial surface of the patella. The cause of most anterior knee pain syndromes is uncertain, but the pain may be related to misalignment of the quadriceps with lateral patellar subluxation, patella alta, hypermobility, or findings of chondromalacia of the patella on arthroscopic evaluation. Local measures and an exercise program that emphasizes isometric quadriceps strengthening is helpful in most patients. Some patients require arthroscopic intervention to diagnose and correct articular irregularities or patellar misalignment.

Ankle and Foot Pain

Nonarticular foot and ankle pain is best approached with a consideration of the region affected: the forefoot, midfoot, or hindfoot [*see Figure 3*].

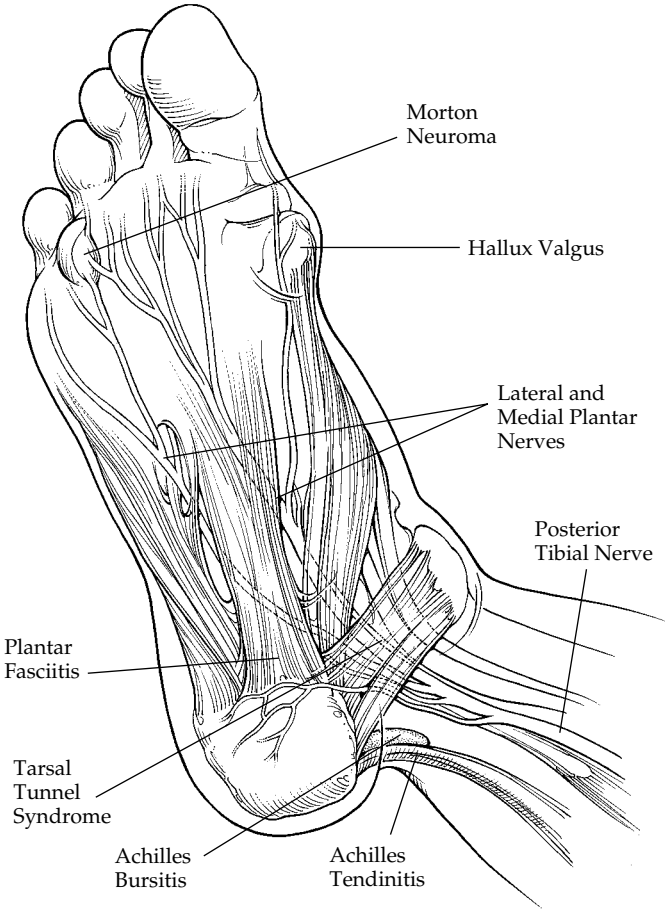

Figure 3 **In the anterior foot, hallux valgus may cause diffuse pain, whereas Morton neuroma is usually localized. Tarsal tunnel syndrome causes paresthesias over the medial and plantar aspects. Plantar fasciitis and Achilles tendinitis are common causes of posterior foot pain.**

FOREFOOT PAIN

Hallux valgus is the leading cause of forefoot pain. It is a common deformity that causes pain because of direct pressure over the first metatarsophalangeal joint resulting from footwear or because of pressure over the lateral toe joints caused by crowding of the toes. In the lateral toes, hammer toe (i.e., plantar flexion of the proximal interphalangeal joint), claw toe (i.e., plantar flexion of the proximal and distal interphalangeal joints), or mallet toe (i.e., isolated flexion contracture of the distal interphalangeal joint) may be associated with a dorsiflexion contracture of the metatarsophalangeal joint. Initial treatment of these problems should begin with adequate footwear that allows ample width for the metatarsal heads, individualized orthoses, and surgical correction (reserved for patients with persistent pain). Morton neuroma is an entrapment neuropathy of the interdigital nerve, with or without an associated plantar neuroma, that is most commonly seen between the third and fourth metatarsal heads. Patients report pain and paresthesia radiating into the affected toes; tenderness between the metatarsal heads that reproduces the described symptoms will also be found. Orthoses to decrease pressure in the area, local glucocorticoid injection, or surgical excision of the neuroma may be needed to relieve symptoms.

MIDFOOT PAIN

Midfoot pain is usually the result of deformities of the arch of the foot or arthritic changes of the midfoot joints. Patients with a cavus foot deformity, peripheral neuropathies, or previous ligamentous injuries from sprains may be predisposed to excessive stresses on the midfoot and early osteoarthritic changes. Tarsal tunnel syndrome is caused by entrapment of the posterior tibial nerve under the flexor retinaculum on the medial side of the ankle. Symptoms of pain and paresthesia over the plantar and distal foot and toes are usually present, and the Tinel sign may be positive. Tarsal tunnel syndrome is much less common and more difficult to diagnose than carpal tunnel syndrome in the wrist. Treatment consists of splinting and NSAIDs. Local glucocorticoid injection and surgical decompression are not as predictably successful as in carpal tunnel syndrome.

HINDFOOT PAIN

Plantar fasciitis is one of the most common causes of hindfoot pain, accounting for up to 15% of all foot symptoms requiring medical attention.[63] The condition is more common in runners and military personnel; other risk factors include obesity, prolonged standing, pes planus, and reduced ankle motion. Patients report pain over the plantar aspect of the heel and midfoot that worsens with walking. Although radiographic spurs in the affected area are common, they may also be seen in asymptomatic persons and are therefore not diagnostic. A majority of patients (approximately 80%) improve regardless of therapy within 12 months of onset. Orthoses, night splints, plantar and heel cord stretching exercises, NSAIDs, and local glucocorticoid injection may be helpful, but few studies have shown conclusive results with any single therapy. Surgical release may be useful for carefully selected patients with poor response to conservative measures. Posterior heel pain is usually caused by Achilles tendinitis or by bursitis of the bursae that lie superficial or deep to the insertion of the Achilles tendon at the calcaneus. Although usually associated with running and other sports activities, Achilles tendinitis may also be part of ankylosing spondylitis and Reiter syndrome and has been reported in association with fluoroquinolone therapy and treatment with systemic or local steroids.[64,65] NSAIDs and orthoses designed to reduce stress on the tendon (e.g., heel lifts) are usually helpful. In most cases, glucocorticoid injections in the Achilles tendon area should be avoided because of the risk of tendon rupture.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XIII FIBROMYALGIA

JOHN BUCKNER WINFIELD, M.D.

Definition

Fibromyalgia is a chronic syndrome that occurs predominantly in women and is marked by generalized pain, multiple defined tender points [*see Figure 1*],[1] fatigue, disturbed or nonrestorative sleep, and numerous other somatic complaints. It is not a discrete disease; rather, it lies at the far end of a continuum of psychological distress and chronic pain in the population. Currently, fibromyalgia is best classified as one of a series of disorders that are variously termed symptom-based conditions,[2] functional somatic syndromes,[3] or affective spectrum disorders.[4] Advances in our understanding of the psychophysiologic dysregulation[5] in these illnesses undoubtedly will lead to revision of such classification in the future. There appear to be discrete subgroups of patients with respect to pain sensitivity and psychological factors,[6,7] and these subgroups vary in response to therapy and in prognosis.[8]

Fibromyalgia largely overlaps with other syndromes with unexplained symptoms, such as chronic fatigue syndrome and irritable bowel syndrome, all of which are related to, but not fully dependent on, depression and anxiety.[9] Fibromyalgia frequently coexists with organically defined disease, such as systemic lupus erythematosus (SLE) or rheumatoid arthritis.

Epidemiology

Otherwise-unexplained widespread pain occurs in about 10% of the general adult population in Western countries, with approximately half of those, mostly women, meeting American College of Rheumatology classification criteria for fibromyalgia.[10]

Fibromyalgia becomes more common after 60 years of age but occurs not infrequently in children. On a typical day, primary care physicians should expect to interact with several patients with fibromyalgia, many of whom will be seeking care for illness other than fibromyalgia. For example, more than 25% of patients with SLE exhibit painful tender points and other clinical and psychological features of fibromyalgia.

Etiology

The cause of fibromyalgia is unknown. Despite extensive research, no definitive organic pathology has been identified. Psychological factors associated with chronic distress appear to be very important.[11] Most researchers believe that pain in fibromyalgia reflects an abnormality of central pain processing, but there is no consensus regarding the mechanism. Nevertheless, current research-based biomedical and sociobehavioral data are now sufficient for a clinically useful understanding of some of the variables that contribute to chronic pain and fatigue in this disorder.

BIOPSYCHOSOCIAL MODEL

At one level, the pain and associated symptoms of fibromyalgia can be viewed according to Engel's biopsychosocial model[12] of chronic illness: health status and outcomes are influenced by the interaction of biologic, psychological, and sociologic variables. Important biologic variables are genetics, gender, sleep, physical condition, stress/neuroendocrine and autonomic dysregulation, and central sensitization to pain. Psychological (cognitive-behavioral) variables contributing to the chronic pain and fatigue of fibromyalgia include pain beliefs/attributions, mood, depression, anxiety, personality traits/disorders, pain behaviors, hypervigilance, coping strategies, and perceived self-efficacy for pain control. Sociologic (environmental and sociocultural) variables consist of experiences influenced by life and culture that have impact on the course of chronic pain and fatigue, such as psychosocial experiences during childhood, family support, work environment, job satisfaction, and ethnologic factors.

Biologic Variables

Genetics Genetic analysis of community-based populations[13] and twins[14] suggests that somatic symptoms, such as pain and fatigue, are etiologically distinct from symptoms of anxiety and depression and reflect, at least in part, the action of genes. The short (S) allele of the promoter region of the serotonin transporter gene *5-HTT* has been associated with depres-

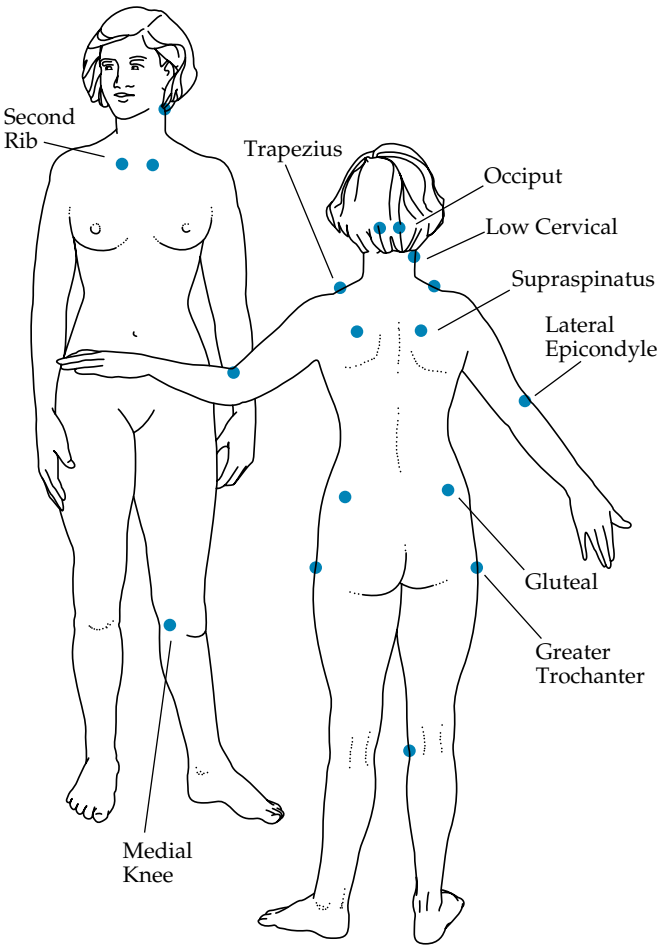

Figure 1 **Tender points in fibromyalgia.**

sion and suicidality in response to stressful life events,[15] and a higher frequency of the S/S genotype has been reported in patients with fibromyalgia than in healthy control subjects.[16] An association with *5-HTT* or its alleles is not evident in fibromyalgia without accompanying depression and psychological distress, however. Other susceptibility genes undoubtedly will be discovered in the near future.

Female gender In general, females exhibit higher pain sensitivity than males and are at greater risk for many pain conditions.[17] Central pain-modulatory systems and inflammatory cytokine levels in females are influenced by phasic alterations in reproductive hormone levels; and females appear to lack diffuse noxious inhibitory control (DNIC), a pain-inhibitory mechanism that is found in normal males.[18] Stressful or aversive stimuli evoke greater sympathetic nervous system, neuroendocrine, and psychological responses in females than in males. Reporting of unexplained symptoms, independent of psychiatric morbidity, also is more common in females.[19] Certain data suggest that the neural circuits activated by emotional experiences and those involved in encoding of emotional experiences into memory show much more overlap in females than in males.[20] Together with the higher prevalence of abuse in women, these biologic variables may explain, at least in part, the increased susceptibility to fibromyalgia in women.

Sleep disturbance Poor sleep is almost universal in fibromyalgia, but fibromyalgia is not primarily a sleep disorder, as had been thought. Pain interferes with sleep, and disturbances in sleep contribute to the experience of pain.[21] In turn, nonrestful sleep and pain underlie the experience of fatigue.

Psychological distress and the stress response system The number of painful tender points in patients with fibromyalgia correlates strongly with their levels of psychological distress.[22] Much evidence suggests that there is an association between chronic, unrelieved psychological stress/distress and functional alterations of the stress-response system (the autonomic nervous system and hypothalamic-pituitary-adrenocortical [HPA] axis) that, in turn, contributes to symptoms of anxiety, pain, and fatigue.[5,23,24] It is unclear, however, whether abnormalities in the stress-response system reflect preexisting vulnerability to fibromyalgia or are a consequence of chronic pain and fatigue.

External triggers Fibromyalgia patients often have fixed beliefs that minor traumatic events, pathogens, chemicals, or other physical agents caused their illness. The available evidence does not support any of those factors as causes, and furthermore, such beliefs can be a barrier to recovery.

Psychological Variables

Cognitive-behavioral variables play a central role in the development and maintenance of persistent pain and functional disability. For example, negative emotions (depression and anxiety), other negative psychological factors (loss of control, unpredictability in one's environment), and certain cognitive aspects (negative beliefs and attributions, catastrophic interpretation of events) can lower pain thresholds and tolerances.[25] Pain behaviors are the actions or expressions by which an individual communicates feelings of pain to the outside world. The response of the outside world (e.g., spouse, physician, employer) then positively or negatively reinforces the pain experience.

Environmental and Sociocultural Variables

Multiple experiences related to forces in the environment, life, and culture can influence the course of chronic pain and fatigue. These influences can be either positive (e.g., good job satisfaction in a patient with work-related back strain) or negative (e.g., a physician's suggestion that a minor traffic accident may have left the patient with long-term damage). In the United States, negative sociocultural elements include the promotion of fear and suggestibility by the media and by society in general, as well as focus on definable causes by patients, physicians, and attorneys. Adverse experiences during childhood, such as poor family environment or childhood sexual abuse, increase susceptibility to the development of chronic pain in adulthood.[26]

Pathophysiology

There are four principal categories of pain: nociceptive, neuropathic, psychogenic, and chronic pain of complex etiology. Nociceptive pain involves stimulation of peripheral pain receptors during inflammation, injury, or destruction of tissues, and it is characterized by a pain experience that corresponds with the noxious stimulus. Neuropathic pain results from direct injury to nerves, such as the radiculopathic pain of degenerative spondylosis. Psychogenic pain occurs in more strictly psychiatric illness, such as somatization disorder or hysteria. Chronic pain of complex etiology is the type of pain characteristic of fibromyalgia, as well as of various regional pain syndromes.

Although chronic pain of complex etiology is as yet incompletely understood, many of the biologic elements operant in the abnormal pain modulation and the associated symptoms seen in fibromyalgia have been identified. Such elements include increased levels of inflammatory cytokines, decreased serotonin levels, increased levels of substance P in the cerebrospinal fluid, deficiency of biogenic amines that normally regulate the release of substance P, glial activation,[27] decreased somatomedin C levels, intrusion of alpha waves into the brain's electrical field during non–random eye movement sleep, and dysregulation of the stress response system. Such dysregulation may manifest as neurally mediated hypoten-

Table 1 Symptoms of Fibromyalgia Syndrome[48]

Musculoskeletal	Pain at multiple sites Stiffness "Hurt all over" Swollen feeling in soft tissues
Nonmusculoskeletal	Fatigue (most times of the day) Morning fatigue (symptom of nonrestorative sleep) Poor sleep Paresthesias
Associated symptoms	Self-assessed anxiety Headaches Dysmenorrhea Irritable bowel syndrome Self-assessed depression Restless legs syndrome Sicca symptoms Raynaud phenomenon Female urethral syndrome

sion; a hypofunctional sympathetic reflex response to stressors; or abnormalities of the HPA axis and other neuroendocrine axes, such as growth hormone secretion in response to exercise.

In fibromyalgia, negative psychological elements constituting stress and distress are a major contributor to the development of increased pain sensitivity and myriad other symptoms. Functional magnetic resonance imaging of the brain during the application of painful pressure in fibromyalgia patients has demonstrated augmented central pain processing.[28] There is no consensus, however, regarding the relative contribution to pain in fibromyalgia of so-called central sensitization (enhanced excitability of dorsal neurons of the spinal cord), dysfunction of descending inhibitory pain control systems (e.g., DNIC), windup (temporal summation of second pain, described as "dull," "aching," or "burning"), thalamic activity, neuroglial activation,[29] and genes.

Diagnosis

CLINICAL MANIFESTATIONS

Pain is the hallmark of fibromyalgia. The pain radiates diffusely from the axial skeleton and is localized to muscles and muscle-tendon junctions of the neck, shoulders, hips, and extremities. Fibromyalgia patients describe the pain with such terms as exhausting, miserable, or unbearable. Generalized hyperalgesia is a cardinal feature. Patients frequently complain that even gentle touch is unpleasant, a condition known as allodynia—pain from normally nonpainful stimuli.

In addition to their persistent widespread pain, fibromyalgia patients experience severe fatigue, insomnia, and low mood or depression [*see Table 1*]. Fatigue occurring most times of the day on most days, together with subjective weakness and nonrestorative sleep, is almost universal. Cognitive complaints, such as difficulties with concentration and memory, may be prominent. Depression, anxiety disorders, and personality disorders contribute to ongoing psychological distress. Other complaints result from somatization, which can be defined as translating psychological distress into somatic symptoms (which are considered more socially acceptable) and seeking care for those symptoms.

Patients with fibromyalgia have a strong tendency toward external attribution of symptoms, with fixed beliefs that minor trauma, viruses (e.g., Epstein-Barr), *Candida,* mold (e.g., so-called black mold), toxic chemicals, or other physical agents (e.g., silicone breast implants) caused their illness. This can be a barrier to recovery, as can ongoing litigation regarding causation of fibromyalgia, disability determination proceedings, or workers' compensation claims.

Functional impairment is usually present, at least in patients with fibromyalgia who seek care. Patients report difficulty doing usual activities of daily living and lack of exercise—indeed, fear and avoidance of exercise.

Regional pain syndromes, such as headache, temporomandibular joint syndrome, or irritable bowel syndrome, are extremely common in fibromyalgia. It is essential that the physician not automatically attribute all such symptoms to fibromyalgia, however, because fibromyalgia frequently coexists with other organically defined disorders. Optimum therapy requires recognition of both fibromyalgia and comorbid disease.

In taking the history, the physician should inquire about sleep quality, ongoing and past stressors, and feelings of anxiety or depression. Recognition of difficulties in these areas is essential in the overall management of chronic pain and fatigue. Onset of fibromyalgia usually antedates clinical diagnosis by years. Exploration of life events surrounding the onset often reveals major stressors, such as breakup of marriage, loss of job, or bankruptcy. The open-ended question, "During your childhood, did you have any bad experiences, such as physical, emotional, or sexual abuse?" not infrequently leads to a catharsis of a significant psychological burden. Current research on the biology of emotion suggests that traumatic experiences during childhood, a period when the brain is still developing, profoundly shape emotions and the subsequent development of functional somatic pain in adulthood. The consequences of abuse are not limited to children; adult domestic violence is an important antecedent of fibromyalgia.[30]

It is valuable to ask whether the patient has previously sought treatment for manifestations of fibromyalgia. Discussion of what treatments have been prescribed and how the patient responded can guide the physician in developing a therapeutic plan. Narcotic use and unsuccessful prior referrals to multidisciplinary pain centers suggest a poor prognosis. Fibromyalgia patients are especially likely to use complementary and alternative medicine (CAM), in part because of the limited efficacy of conventional medical care. Because some CAM agents are not safe and many have the potential to interact with conventional pharmacologic agents, questions about CAM use are an important part of the history.

PHYSICAL EXAMINATION FINDINGS

A patient with uncomplicated fibromyalgia will have normal results on general physical examination. This reassures both the physician and the patient that a significant alternative cause for the symptoms is unlikely. Evidence of synovitis (joint effusion, warmth over joint, pain on joint motion), objective muscle weakness, or other definite physical or neurologic signs suggests the presence of either comorbid disease or an alternative diagnosis. It is essential to identify concomitant painful diseases such as osteoarthritis of individual joints, degenerative spondylosis, bursitis, or other inflammatory soft tissue conditions, because the nociceptive pain from such common problems is amplified in fibromyalgia. Many patients exhibit signs of regional pain syndromes that are often associated with depression or anxiety, such as tenderness in the jaw area (temporomandibular disorder), subtle lower abdominal tenderness to palpation (irritable bowel syndrome), psychomotor slowing (depression), and irritability or hostility (anxiety, panic disorder, or personality disorder).

Tender Points

Eighteen specific tender points have been identified in fibromyalgia [*see Figure 1*].[1] A patient with fibromyalgia will have pain, not just tenderness, on palpation at many of these tender points. Palpation is performed with the thumb, using approximately 4 kg of pressure—about the pressure necessary to blanch the examiner's thumbnail. Attempting to confirm pain at all 18 tender points is not necessary for diagnosis and is often uncomfortable for patients, many of whom find tender-point palpation quite distressing. If an algometer is available, it can provide semiquantitative information regarding pressure pain threshold at tender points. Some fibromyalgia patients complain of pain when pressure is applied anywhere on the body, even relatively insensitive areas such as the forehead or

thumbnail. Unfortunately, in situations of potential secondary gain (e.g., injury litigation, pending disability determination), the physician must be alert for malingering; some of these patients are well informed regarding the location of tender points. Firm pressure over the trapezii or posterior thorax with a stethoscope, rather than a thumb, can provide insight in such cases.

LABORATORY TESTS

There are no specific laboratory test abnormalities in fibromyalgia. Nevertheless, it is appropriate to conduct limited screening for commonly associated disorders and for other diseases that can cause pain and fatigue.

Blood Tests

Useful tests in fibromyalgia include the following: antinuclear antibody (ANA), complete blood count, erythrocyte sedimentation rate (ESR) or C-reactive protein, thyroid-stimulating hormone (TSH), creatine kinase (CK), aspartate aminotransferase, and alanine aminotransferase. Tests for Lyme disease, Epstein-Barr virus infection, and endocrinologic status (e.g., measurement of estrogen, testosterone, growth hormone, and dehydroepiandrosterone) are usually unnecessary.

Other Tests

Urinalysis may be useful. Tests for autonomic dysfunction (tilt-table test), studies of nerve conduction velocity and electromyography, and imaging studies should not be done unless there is a specific indication.

Differential Diagnosis

The differential diagnosis of fibromyalgia is very broad [*see Table 2*]. Nevertheless, extensive laboratory testing or imaging studies should not be done unless the patient has objective indications of other disease on physical or neurologic examination. Major causes of diffuse musculoskeletal pain and key clinical and laboratory features are as follows:

- Fibromyalgia (diffuse pain, tenderness, fatigue, stiffness, tender points, normal laboratory findings)
- Rheumatoid arthritis (symmetrical synovitis, presence of rheumatoid factor, elevated ESR and C-reactive protein)
- SLE (constitutional symptoms, rash, arthralgias, presence of ANA and other autoantibodies)
- Polymyalgia rheumatica (age greater than 50 years, shoulder and hip girdle pain, very high ESR)
- Spondyloarthropathy (morning back pain and stiffness, asymmetrical oligoarthritis, sacroiliitis on pelvic x-rays)
- Inflammatory myopathy (muscle tenderness, objective proximal muscle weakness, elevated serum CK)
- Hypothyroidism (myalgias, weight gain, dry skin, fatigue, cold sensitivity, hyporeflexia, elevated TSH level)
- Osteomalacia (diffuse bone pain and tenderness, proximal myopathy with weakness, low serum phosphate and 25-hydroxyvitamin D levels)

It is usually not helpful clinically to distinguish fibromyalgia from chronic fatigue syndrome or the many regional pain syndromes. Giving patients a name for their illness, however, often enables them to concentrate on getting better, rather than continuously searching for a cause and cure.

Treatment

Four principles govern the treatment of fibromyalgia: (1) validation of distress, (2) diagnostic and therapeutic conservatism, (3) an individualized combination of pharmacologic and nonpharmacologic measures, and (4) care rather than cure. Validation of the patient's symptoms and distress begins with the initial history and physical examination, when the physician explores adverse developmental, social, and behavioral variables and past and current stressors. Failure to provide validation, initially or later in the therapeutic relationship, serves only to perpetuate pain and fatigue and may constitute an insurmountable barrier to treatment.

Strong evidence for therapeutic efficacy in fibromyalgia on the basis of randomized, controlled trials has been difficult to obtain. Confounding factors include the current poor understanding of the syndrome's origin and pathophysiology, the complexity of its symptoms, lack of consensus regarding nosology and clinically meaningful outcome measures, small sample size, short trial duration, and a strong placebo effect because of the close attention patients receive in trials. Much current treatment is empirical and based on proposed, rather than established, models of pathophysiology. Nevertheless, a wealth of published information on treatment of fibromyalgia is now available, including two monographs[31,32] and a series of systematic reviews and meta-analyses of controlled trials.[33-35] Clinical practice guidelines are pending from the American Pain Society[36] The available data suggest that the pain, fatigue, non-

Table 2 Differential Diagnosis of Fibromyalgia

*Common alternative diagnosis.

restorative sleep, depression, and anxiety respond to a multifaceted therapeutic approach that combines drug therapy with physical, psychological, and behavioral treatments. An overarching goal of therapy is the promotion of self-efficacy—the patient's firmly held belief that he or she can control symptoms of pain and fatigue.

TREATMENT IN GERIATRIC AND PEDIATRIC CASES

Treatment of diffuse pain in older persons[37] and in children[38] requires special approaches. Pain in older persons is often neglected or ignored. Compared with younger persons, older persons exhibit more physical abnormalities, are more sensitive to opioids, have lower self-efficacy, and use fewer cognitive coping methods. There are many barriers to accurate pain assessment in older persons, including fear of diagnostic tests or medications and reluctance to report pain because pain is an expected part of aging.

The general principles of treatment in the elderly are as follows: discuss goals, hopes, and trade-offs openly; start medications at a low dose and raise the dose slowly; pay attention to timing of medications; be aware of economic barriers; include nonpharmacologic treatment as an integral part of management; and educate the patient and caregiver.

In the pediatric population, unexplained diffuse or localized pain is most common in preadolescent to adolescent girls, often in association with incongruent affect; disproportionate impairment of performance in school; and psychological distress in the child, the family, or both. Key aspects of therapy in this population are discontinuance of all medications, psychological evaluation and psychotherapy if necessary, and a program of intense exercise. Prognosis is good for most children with persistent unexplained pain.

PHARMACOLOGIC MANAGEMENT

Diffuse Pain

A well-established conventional approach to initial therapy is the use of a tricyclic antidepressant (TCA) at bedtime. Amitriptyline, starting at 10 mg and escalating slowly to 50 mg, is a common choice. In approximately one third of fibromyalgia patients, low doses of amitriptyline produce moderate short-term improvements in pain, disturbed sleep, patient and physician global assessments, physical status, psychological status, and capacity for activities of daily living. Improvements in fatigue, tenderness, and stiffness are more modest. Long-term improvement with TCAs superior to that with placebo has not been established, however, and patient acceptance of these agents is poor because of their anticholinergic and sedative effects and tendency to cause weight gain. The selective serotonin reuptake inhibitors (SSRIs) fluoxetine[39] and citalopram have proved effective in randomized, controlled trials, and the combination of a TCA with an SSRI typically produces greater improvement in pain, sleep, and overall well-being than either drug used alone. Dual-action (serotonin/noradrenaline) reuptake inhibitors (SNRIs), such as venlafaxine and the investigational agents duloxetine and milnacipran, also show promise. Centrally acting skeletal muscle relaxants (e.g., cyclobenzaprine, baclofen, tizanidine) generally are not effective as single agents for the diffuse pain of fibromyalgia, although such usage is common practice and is supported by a few clinical trials. However, muscle relaxants given at low doses and in combination with a TCA or SSRI may provide some benefit, at least over the short term. Topical capsaicin is useful when gently massaged into painful areas twice a day. The patient should be informed that the initial discomfort often encountered with capsaicin will subside with time and that beneficial effects may not be apparent until after 3 to 4 weeks of therapy.

Table 3 Selected Antiepileptic Drugs for Treatment of Fibromyalgia Pain

Agent (Trade Name)	*Dosage*
Gabapentin (Neurontin)	300 mg h.s. to 600 mg t.i.d.; escalate over several weeks
Topiramate (Topamax)	25–50 mg h.s. to 200 mg b.i.d.; escalate by 25–50 mg at weekly intervals
Tiagabine (Gabitril)	2–4 mg h.s. to 56 mg q.d. in two to four divided doses; escalate by 4–8 mg at weekly intervals

Addition of an antiepileptic drug (AED) is indicated in patients with marked allodynia and hyperalgesia. AEDs have efficacy for pain sensitivity and as adjunctive medications for disturbed sleep and depression. Many choices are available, including gabapentin, topiramate, and tiagabine [*see Table 3*]; the experimental AED pregabalin has also shown promise for this purpose. Adjunctive therapy with anxiolytic drugs is often beneficial. Many choices are available, including benzodiazepines, buspirone, or SSRIs [*see 13:VIII Anxiety Disorders*]. AEDs may have anxiolytic effects, as well. Other drugs that may improve pain through effects on the abnormal central nociceptive processing in fibromyalgia include mexiletine, clonidine, and competitive antagonists of 5-hydroxytryptamine-3 [5-HT_3], such as tropisetron.

Opioids should be avoided if at all possible. A few patients can achieve a reasonable quality of life and daily functioning in no other way, however, so blanket interdiction of all opioid medications in fibromyalgia is inappropriate. When opioids prove necessary, they must of course be used with extreme caution. Patients must be closely monitored, agree to seek psychotherapy, and complete a signed promise to use only one prescribing physician and one dispensing pharmacy. So-called doctor shopping is not uncommon, especially among patients taking fentanyl or oxycodone-containing preparations, which are associated with increased psychological dependency. Tramadol, methadone, and hydrocodone are preferable.

Comorbid Nociceptive or Neuropathic Pain

When patients have discrete sources of pain, such as osteoarthritis, inflammatory arthritis, or degenerative disk disease, treatment should include nonsteroidal anti-inflammatory drugs (NSAIDs), with or without opioid or nonopioid analgesics. Analgesic drugs should be given in a stepwise approach on the basis of pain intensity and response. Clonidine (0.1 mg three times a day) and various AEDs [*see* Diffuse Pain, *above*] are helpful in neuropathic pain. Clonidine also is useful in decreasing withdrawal symptoms when opioids are being tapered. Different combinations of corticosteroid injections, activity modification, splints, local heat or cold, and other physical-therapy modalities may be indicated, depending on the specific musculoskeletal disorder.

Fatigue

Fatigue generally improves with effective treatment of pain, depression, and sleep disturbances in combination with a grad-

ed aerobic exercise program. Modafinil,[40] SSRIs, or 5-HT_3 receptor antagonists may benefit patients in whom overwhelming fatigue is a persistent complaint.

Poor Sleep

Sleep disturbances should be managed aggressively, beginning with instruction in the elements of good sleep hygiene, such as avoidance of daytime naps and caffeine. Most patients require medication. A single bedtime dose of a TCA can be given; other drugs that can be given in addition to or instead of a TCA include alprazolam, cyclobenzaprine, temazepam, trazodone, triazolam, and zolpidem.

Clonazepam or levodopa-carbidopa at bedtime may be effective for restless legs syndrome, which is very common in patients with fibromyalgia. A formal sleep study to identify sleep apnea and restless legs syndrome is indicated when the above simple measures are ineffective [*see 11:XIII Disorders of Sleep*].

Depression

Depression requires aggressive pharmacologic treatment. Many well-tolerated drugs are available [*see 13:II Depression and Bipolar Disorder*]. Both SNRIs (e.g., venlafaxine) and certain SSRIs (fluoxetine, citalopram, fluvoxamine) have been shown to improve pain and overall well-being in fibromyalgia independently of their effects on depression. Antidepressant drug treatment should be combined with psychotherapeutic management (formal or informal counseling) [*see 13:II Depression and Bipolar Disorder*].

NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic treatments generally have been of greater benefit in fibromyalgia than pharmacologic treatments alone.[34,41] Nondrug treatments may include exercise, meditation, yoga, biofeedback and stress management, counseling, and support groups. Patient education is important [*see Sidebar* Recommended Internet Sites on Fibromyalgia]. Optimum management of pain and fatigue in many patients is best achieved by interdisciplinary interaction of the primary care physician with allied health professionals and psychologists. Of particular efficacy are such approaches as biofeedback training and water aerobics, which promote active and independent participation by the patient, thereby enhancing self-management and self-efficacy. Conversely, referral of patients to so-called pain clinics that focus on various types of injection therapies and other passive procedures contributes little to the outcome of diffuse pain syndromes.

Biofeedback and Exercise

Significant improvement in physical status and self-reported fibromyalgia symptoms has been achieved by biofeedback training, alone or in combination with relaxation training and aerobic exercise. A systematic review of published trials indicates that supervised aerobic exercise training has beneficial effects on physical capacity, pain threshold, and global well-being.[42] Unfortunately, prescription of progressive home-based aerobic exercise is of limited efficacy unless the patient is highly motivated and has effective coping skills. Exercise should be of graded intensity; high-intensity fitness programs should be avoided.

Psychological Intervention

Psychotherapeutic counseling is helpful for many patients. Although formal cognitive-behavioral therapy is theoretically attractive, its cost-effectiveness and additional benefit over other interventions have not been established. Other psychological interventions, such as guided imagery, may improve self-reported pain over the short term.

TREATMENTS OF UNCERTAIN BENEFIT

Trigger-point injections, botulinum toxin injections, ultrasound, laser therapy, sphenopalatine blocks, and numerous other interventions have been advocated for fibromyalgia. These modalities either have no place in the treatment of fibromyalgia or are of questionable benefit.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

CAM is used almost universally by patients with fibromyalgia, at least in part because of distrust of physicians and frustration with the limited efficacy of much of traditional care. Acupuncture, hypnotherapy, relaxation techniques (e.g., yoga, tai chi, meditation), certain herbal and nutritional supplements (magnesium, S-adenosylmethionine [SAMe]), and massage may be of benefit [*see CE:XII Complementary and Alternative Medicine*]. Vegetarian diets, magnet therapies, and chiropractic manipulation are not recommended.[43-45]

WHEN TO REFER

Consultative referral to a rheumatologist familiar with fibromyalgia is indicated when the diagnosis is unclear, when fibromyalgia is complicated by comorbid autoimmune or musculoskeletal disease, and when response to therapy is poor. Psychiatric referral is essential for severe depression with suicidal ideation and for comorbid psychosis.

Complications

Marital and other personal relationships, family health, and capacity to work productively are all threatened by severe fibromyalgia. Addiction to such drugs as opioids, benzodiazepines, and muscle relaxants is a rare but real risk in fibromyalgia patients. Nevertheless, the physician should be cognizant that drug-seeking behavior is often a sign of inadequate symptom control (pseudoaddiction) rather than drug dependency. Abrupt cessation of such medications may be associated with withdrawal symptoms. Exacerbation of symptoms often is iatrogenic—an unsympathetic, uninformed physician who is dismissive of fibromyalgia as a diagnostic entity and who fails to validate suffering can be a major perpetuating factor in this illness.

Prevention

Physicians may unwittingly contribute to the development of chronic pain in patients with acute pain from neck strain—typically, incurred in a minor traffic accident—by diagnostic indecision that permits patients to misconstrue the severity of their condition. In these cases, it is important for physicians to avoid such measures as open-ended referral for physical therapy, prolonged release from work, prescription of a neck brace, and failure to reassure the patient that recovery will be rapid and full. The term posttraumatic fibromyalgia should not be used.

Prognosis

Although improved treatment provides optimism for better outcomes in fibromyalgia, prospective long-term longitudinal studies in academic medical centers have shown little improvement in health status, disease severity, health service utilization, and costs, with approximately 25% of patients with fibromyalgia receiving disability or other compensation payments.[46,47] Persons with fibromyalgia suffer much more than those with other chronic rheumatologic diseases, such as rheumatoid arthritis.

Even though hyperalgesia and allodynia cannot be reversed entirely, most patients can expect substantial improvement in symptoms and in overall quality of life. Resolution of ongoing stress and promotion of the patient's self-efficacy for control of pain are of pivotal importance. Prognosis varies among three fairly distinct subsets of patients, who have been termed adaptive copers, interpersonally distressed, and dysfunctional.[6] Adaptive copers, many of whom do not seek care for fibromyalgia, do well with respect to self-reported pain, disturbed sleep, and fatigue. Interpersonally distressed patients also respond to a comprehensive interdisciplinary therapeutic approach. Dysfunctional patients with high levels of pain, anxiety, and opioid dependence do poorly, as do patients with pending litigation. The treatment goal that responds least to therapy is improvement in daily functioning.

INTRODUCTION TO WOMEN'S HEALTH: THE PRIMARY CARE OF WOMEN

JANET B. HENRICH, M.D.

Definition of Women's Health

Women's health can be defined as diseases or conditions that are unique to women or that involve gender differences that are particularly important to women.[1] This definition acknowledges the increasing scientific evidence supporting a focus on sex and gender and expands the concept of women's health beyond the traditional focus on reproductive organs and their function.[2,3] Over time, the definition has come to include an appreciation of wellness and prevention, the interdisciplinary and holistic nature of women's health, the diversity of women and their health needs over the lifespan, and the central role of women as patients and as active participants in their health care.[4]

This broader interdisciplinary perspective has important implications for clinicians providing care to women. In addition to understanding basic female physiology and reproductive biology, clinicians need to appreciate the complex interaction between the environment and the biology and psychosocial development of women. When dealing with conditions that are not specific to women, clinicians need to be aware of those aspects of disease that are different in women or have important gender implications. The ability to apply this information requires that clinicians adopt attitudes and behavior that are culturally and gender sensitive. Clinicians also must understand the changes that are occurring in women's patterns of health-seeking and forms of communication and interaction with the health care system.

Goals of the Women's Health Section

The women's health section in *ACP Medicine* is intended to furnish clinicians with the knowledge base and conceptual framework needed to provide comprehensive care to female patients of all ages. Chapters on reproductive function are written for generalists in practice and discuss normal and abnormal menstruation and common problems in younger reproductive-age women, including the aspects of fertility and pregnancy that are under the purview of generalist clinicians. Other chapters discuss the conditions that cause the greatest morbidity and mortality in women as they age; many of these conditions are linked to the menopause and the decline in estrogen levels that accompany waning ovarian function. This chapter contains additional information on some of these topics, as well as links to other chapters in *ACP Medicine* covering important women's health topics.

Factors That Influence Women's Health

HORMONAL INFLUENCES

A dominant theme in women's health is the effect of marked changes in endogenous hormone levels that occur throughout a woman's lifetime. A health-issue category unique to women is the influence, during the reproductive years, of sex hormones on sexual development and reproductive function. As women grow older and sex hormone levels decrease with menopause, women's risk factors for certain diseases increase dramatically and become more similar to those of men. Although women develop the same diseases that affect men, biologic mechanisms and psychosocial factors influence the course of disease differently in women.

SOCIAL FACTORS

One of the important social trends over the past 50 years is the increasing participation of women in the workforce. Currently, it is estimated that 59% of women 16 years of age and older are in the workforce—including 71% of women with children younger than 18 years—and 60% of working women are employed full time throughout the year.[5] The cumulative effects of playing multiple roles, work stress, and new environmental exposures on women's health and reproductive status are largely unknown, but they are certain to have important health and social ramifications.

Paralleling the growing numbers of women in the workforce is the increasing number of single-parent families headed by women, especially minority women. Many of these families live in poverty. Increasing evidence indicates that socioeconomic factors are major indicators of health and that, for some health outcomes, poverty and lack of education are more important determinants of health than ethnicity.[6] However, socioeconomic status cannot wholly explain important ethnic and racial differences that remain in women's susceptibility and response to certain diseases. For example, the mortalities associated with coronary heart disease (CHD), stroke, and breast cancer are higher in black women than in white women, whereas the mortality associated with lung cancer is higher in white women.[6] Regardless of their racial or ethnic designation, minority-group women have a lower life expectancy than white women and experience greater health problems. The differences are most pronounced in areas related to reproductive issues and childbearing, the occurrence and course of chronic disease, the incidence and outcome of cancer, and the risk of interpersonal violence.[6]

MORBIDITY AND MORTALITY IN WOMEN

At the beginning of the 20th century, the average lifespan of women in the United States was 48 years, compared with 46 years for men. Since then, the life expectancy for women has increased more than 30 years and is currently close to 80 years, compared with 74 years for men.[6] The dramatic increase in overall life expectancy is thought to be related to lower infant mortality, control of infectious diseases, and progress in the treatment of chronic diseases, such as diabetes and cardiovascular disease.

Despite a dramatic decline in mortality from heart disease that has occurred in both sexes over the past 2 decades, heart disease remains the leading cause of death for women, accounting for 30% of all deaths in women [*see Table 1*]. Heart disease occurs in women 10 to 15 years later than it does in men. This delayed onset, which is attributed primarily to the protective effect of estrogen, accounts for the fact that 90% of heart disease–related mortality in women occurs after the menopause. Evidence suggests that heart disease in women is more serious than that in

men, resulting in higher mortality. In addition to being affected by biologic factors, the poorer survival of women may stem from the older age and increased prevalence of comorbid conditions in women at the time of diagnosis, as well as to less well defined social factors that influence the diagnosis and treatment of heart disease in women.

Cancer is the second leading cause of death in women and is the most common cause of premature death. Whereas death rates for all cancers combined changed little for women during the last half of the 20th century, major advances in the diagnosis and treatment of cervical and uterine cancers were offset by an increase in mortality from lung and breast cancer. Although breast cancer is the most common cancer diagnosed in women, lung cancer is the overall leading cause of cancer deaths.

Death from breast cancer is the second overall leading cancer death in women and the most common in women younger than 55 years. Although the incidence of breast cancer continues to rise, mortality has begun to decline for the first time since cancer registries began tracking this disease in the 1940s. This divergence is thought to be related partly to the widespread use of screening mammography and the detection of cancers in earlier stages that have a more favorable prognosis.

There are significant racial differences in breast cancer incidence. White women continue to have the highest rates of breast cancer, followed closely by black women. Hispanic and Asian/Pacific Islander women are at intermediate risk, and Native American women are at lowest risk.[6]

There are also significant racial differences in breast cancer mortality. Although the incidence of breast cancer is 22% higher in white women than in black women, mortality is 36% higher in black women.[6] The reasons for the racial differences with breast cancer incidence and mortality are unclear, but the differences may be related to socioeconomic and biologic factors, as well as to certain health behaviors, such as participation in screening mammography.

Although stroke-related deaths have declined by more than 60% in the United States over the past 25 years, stroke still causes 8% of all deaths in women and ranks third as the cause of death for all persons in the United States. Striking racial differences exist in stroke mortality, which is almost twice as high in black women as in white women throughout most of the lifespan.[6] Most of the fatal strokes in women result from thromboembolic disease and occur in older women.

Death rates from chronic lower respiratory diseases have increased steadily for both women and men during the past 25 years; however, the increase has been greater in women. Because this increase has been linked to patterns in cigarette smoking—during the past century, smoking rates rose later in women than in men—the increase in death rates in women for pulmonary disease, as well as for lung cancer, are expected to continue to rise.

The reported mortality of diabetes is most likely underestimated because of its strong association with other life-threatening medical conditions, such as cardiovascular disease, stroke, and kidney failure. Eight percent of all women 20 years of age and older have diabetes; however, prevalence rates are higher in black, Hispanic, and Native American women.[6] In addition to its mortality, diabetes is a significant cause of morbidity and, in women of childbearing age, has important adverse effects on pregnancy and pregnancy outcome, resulting in an increased risk of toxemia, macrosomia, hydramnios, congenital malformations, cesarean section, and fetal and perinatal mortality.

Table 1 Leading Causes of Death and Number of Deaths in Women in the United States in 2002[6]

Cause of Death	*Number of Deaths*	*Total Deaths (%)*
All causes	1,244,123	100.0
Heart disease	356,014	28.6
Cancer	268,503	21.6
Stroke	100,050	8.0
Chronic lung diseases	64,103	5.2
Alzheimer disease	41,877	3.4
Diabetes	38,948	3.1
Unintentional injuries	37,485	3.0
Pneumonia/influenza	36,763	3.0
Kidney disease	21,279	1.7

Although the mortality associated with HIV infection and AIDS began to decline in the mid-1990s as a result of highly effective combination treatment for HIV infection and better prevention of opportunistic infections, HIV remains a leading cause of death in younger women. Women overall account for an increasing proportion of AIDS cases, and ethnic-minority women are disproportionately affected.[6] As the features of this epidemic change, with heterosexual transmission accounting for the majority of new HIV cases in women, these rates are expected to continue to rise.

Mortality data alone do not provide a complete picture of women's health status. Although women live longer than men, overall measures of health status are worse in women. Estimates from the 2002 National Health Interview Survey suggest that more women than men report symptoms of or seek care for acute medical conditions and that women are more disabled by these self-limited illnesses, as measured by the number of days spent in bed or lost from work.[6] In addition, several chronic conditions occur more frequently in women and cause significant disability, such as arthritis, chronic pain syndromes (including migraine and neck, back, and facial pain), and chronic respiratory disorders (including chronic bronchitis, sinusitis, and asthma).[6] Women are also more likely than men to experience severe psychological stress.[6] Data from the National Institute of Mental Health show that affective disorders, especially major depressive episodes, and the anxiety disorders are significantly more prevalent in women.[7]

WOMEN'S HEALTH ACROSS THE LIFESPAN

Many of the important health issues in women have their onset or greatest impact at certain ages and are intricately linked with women's psychosocial and sexual development. To develop a more integrated concept of women's health, it is instructive to look at the important health issues in women within the major lifespan groups.[8]

Birth to Young Adulthood

As girls reach puberty, the health issues that emerge are related primarily to developmental changes involving physical and sexual growth and changing relationships within and outside the family. Central to the psychosocial development of young

women is the process of gender identification and orientation and the development of self-esteem. Intentional and unintentional injuries, including an increasing frequency of acts of physical and sexual violence, are the primary cause of death and disability in young women. Chronic disease or disability develops in a small proportion of girls. Most of these conditions (e.g., lupus erythematosus, juvenile rheumatoid arthritis, and thyroid disease) have an autoimmune component. Because of hormonal influences, many of these conditions first occur or are exacerbated during puberty.

15 to 44 Years

The second lifespan group stretches from ages 15 to 44. As women progress through this age group, cancers of the breast and reproductive tract emerge as the leading cause of death, followed by unintentional injury and heart disease. Of the unintentional and intentional injuries, motor vehicle accidents, homicide, and suicide account for three fourths of all injury-related deaths.[6] Death rates from homicide and suicide have shown a downward trend in young women. Nevertheless, black women, like black men, are more likely than members of other races to be homicide victims, and firearms are used in more than half of those deaths. Intimate partners play a substantial role in violence against women; one third of murders of women are perpetrated by an intimate partner.[9]

The most dramatic trend in this age group, beginning in the 1980s and peaking in the mid-1990s, was the emergence and rapid rise of HIV infection as a major cause of death. Although overall AIDS incidence and death rates have decreased yearly since 1996, the rate of decline has been smaller in women. The consequences of this disease for gynecologic care and reproductive counseling for women are unique. Because HIV can be transmitted during pregnancy and more than 40% of pregnancies are unintended, routine medical care should include discussions about effective contraceptive methods, the effects of pregnancy on HIV infection and treatment, and the potential for perinatal transmission of HIV. Treatment strategies for women who may become or who are pregnant should take into consideration regimens that maximally suppress maternal viral load and reduce transmission to the fetus while minimizing toxicity. A three-part regimen of zidovudine (AZT) reduces the risk of perinatal transmission by 70% and is effective even in women with advanced disease.[10] United States Public Health Service recommendations for antiretroviral chemoprophylaxis to reduce perinatal HIV transmission are evolving rapidly and take into consideration the now standard use of more aggressive combination drug therapies to treat HIV, as well as the clinical status and antiviral drug history of the woman. Zidovudine should be part of the antepartum drug regimen in all pregnant HIV-infected women, if feasible. Treatment guidelines are updated periodically and are available on the Internet (http://AIDSinfo.nih.gov).

An important role of clinicians in the care of young women is to recognize and reduce risk-taking and other unhealthy behaviors. For example, early or unprotected sexual activity increases women's risk for sexually transmitted diseases (STDs). Not only are these diseases transmitted more easily from men to women, but women are disproportionately affected because of infectious complications that can lead to disorders of reproductive function, such as pelvic inflammatory disease and subsequent ectopic pregnancy or infertility. Unfortunately, efforts at risk reduction, particularly in the use of harmful substances, are hampered by industry and market forces and other social factors that influence women's lives. For example, the adverse effects of cigarette smoking on lung cancer and other respiratory diseases, heart disease, osteoporosis, and pregnancy are well documented, yet 20% of women continue to smoke and 18% of teenage mothers smoke during pregnancy.[6]

Social and cultural factors have also contributed to the increasing prevalence of dieting and eating disorders. It is estimated that up to 4% of young women suffer from anorexia nervosa or bulimia, and an additional 5% have less specific eating disorders that are characterized by aberrant eating patterns and weight-management habits.[11] These statistics most likely underestimate the prevalence of eating disorders in young women. According to findings from the 2003 Youth Risk Behavior Surveillance System developed by the Centers for Disease Control and Prevention, during the month before the survey, 56% of adolescent women had attempted dieting, 18% had gone more than 24 hours without eating, 11% had taken diet aids without professional advice, and 8% had induced vomiting or taken laxatives for weight control.[12]

The female lifespan group of 15 to 44 years of age delineates the reproductive years. In addition to having the traditional childbearing and family responsibilities, women are increasingly assuming new, additional roles. The effect of multiple and often conflicting roles on women's mental and physical health remains to be determined, but it is almost certainly closely linked to reproductive freedom and health. Thus, clinicians need to understand the safety and effectiveness of current methods of contraception, including extended oral contraception and emergency contraception, as well as the acceptability of these methods to women of various cultures.[13-15]

Many common disorders of reproductive function are not exclusively gynecologic problems. For example, polycystic ovary syndrome is associated with insulin resistance and an increased risk of diabetes and cardiovascular disease[16] [*see 16:V Polycystic Ovary Syndrome*].

Autoimmunity is a common theme in many of the medical disorders that have the highest prevalence in women 15 to 44 years of age. Most of the autoimmune diseases occur more often, as well as cause greater morbidity, in women than in men. Many of these diseases are influenced by changes in estrogen levels, particularly during pregnancy. The prevalence rates of collagen vascular diseases such as rheumatoid arthritis, systemic lupus erythematosus, and scleroderma are three to nine times higher in women than in men. Many autoimmune-related endocrinopathies, such as Hashimoto thyroiditis and Graves disease, have a female-to-male ratio as high as 10:1. Less well recognized is the role of autoimmunity in recurrent pregnancy loss and infertility in women.

Among the mental disorders, depressive illnesses are twice as common in women as in men. Each year, an estimated 6.5% of women experience a major depressive episode, and twice that many have chronic low-grade depression. The increased risk of depression in women begins at puberty and declines after the menopause. In addition, many women experience mood, cognitive, or behavioral changes associated with cyclic changes in hormone levels during the menstrual cycle or with the marked changes in hormone levels that occur during the postpartum period and the menopausal transition. The genetic, biologic, and environmental contributions to women's susceptibility to depression are not fully understood; however, hormonal factors are thought to play a major role. Women are also twice as likely as men to be diagnosed with an anxiety disorder, including pan-

ic disorder, posttraumatic stress disorder, generalized anxiety disorder, agoraphobia, and simple phobia.[7]

A major cause of psychosocial morbidity in women is physical and sexual abuse. According to the National Violence Against Women Survey conducted by the National Institute of Justice and the Centers for Disease Control and Prevention in 1998, 52% of women have been physically assaulted at some time during their life, and 18% have experienced a rape.[17] Young women are at particular risk for rape; of those women who have been raped, more than half were younger than 18 years when rape first occurred.[17]

Physical and sexual assault of women is primarily a problem of partner violence. Three fourths of women who experience physical or sexual abuse after 18 years of age are assaulted by a current or former spouse or a male intimate. Unfortunately, clinicians often fail to recognize or address symptoms of abuse, whether because of inadequate knowledge of physical and sexual violence, misconceptions about it, or inadequate training in its management. Adequate screening tools are especially crucial in the emergency department, where up to one third of women who have been assaulted seek care.

45 to 64 Years

Death rates for women 45 to 64 years of age have declined by 30% in the past 25 years. Previously, the leading cause of death in this age group was heart disease; however, cancer is now ranked number one. This shift in mortality reflects primarily a decline in death rates for heart disease—a decline that has been observed in both sexes and that is attributed to changes in lifestyle, better control of hypertension, and lower blood cholesterol levels.

Many of the important chronic conditions in women first appear in this age group; some of them, such as heart disease, osteoporosis, and cancer, are inextricably linked to the menopause and the associated marked decline in estrogen levels. Hormone replacement is the most effective therapy for vasomotor and vaginal symptoms associated with the menopause; in addition, hormone therapy (HT) decreases bone loss and the risk of osteoporotic fractures and colon cancer. However, because of the adverse effects of HT shown in the Women's Health Initiative Trial (i.e., an increased incidence of breast cancer, heart disease, stroke, dementia, and urinary problems),[18-24] HT should not be used as preventive therapy in postmenopausal women [*see 16:XI Menopause*].

Although the menopause encompasses many of the physiologic changes that define this period, women also experience major transitions in social roles and life circumstances that profoundly affect their physical and mental health: children leave home; many women become widowed or divorced; parenting roles change as women are called upon to care for aging parents; and disabilities increase, making it difficult for some women to function within and outside the home. An understanding of these life events is essential to the comprehensive care of mature women.

65 Years and Older

Heart disease is the leading cause of death in women 65 years of age and older, followed by cancer and stroke. Mortality for all three disorders rises steeply after 65 years of age and begins to approach the rates for men.

As the longevity of women increases, they bear the burden of illnesses that are seen primarily in the very old. Of these, the neurologic degenerative diseases, such as dementia, sleep disorders, and neurosensory and movement disorders, are particularly common in women. Unfortunately, the added years of life in women are often spent in a frail or dependent state and often result in institutionalization.

The social and psychological changes that women experience as they age add to the burden of illness. Social isolation increases because of the death of loved ones, loss of financial stability, and increasing physical disabilities. In addition to an increasing incidence of dementia with age, mental health problems become more prevalent or serious. The role of primary care clinicians is to recognize and help reduce the impact of these accumulated conditions on women's ability to function and on their quality of life.

Clinical Evaluation of Women

HISTORY

Most elements of the medical history are similar for women and men. Those that are unique to women or are different in women are discussed here.

The goal of the dietary, exercise, and weight history in women is to identify patterns that may indicate an eating disorder or weight-management problem [*see 13:IX The Eating Disorders*]. An assessment of calcium and vitamin D intake is important for bone health at all ages—including the teenage years and 20s, when peak bone mass is built—as is questioning about folic acid supplementation in women of childbearing age to help prevent development of fetal neural tube defects in early pregnancy.

The menstrual and reproductive history, including past and current forms of contraception and hormone use, is important in evaluating current problems and in assessing risk for future conditions. The focus of the sexual history varies depending on age, with an emphasis on STD and pregnancy risk assessment in young women, the identification of medical conditions that may adversely affect fertility and pregnancy outcome in women who are considering pregnancy [*see 16:IX Medical Complications in Pregnancy*], and conditions that may interfere with healthy sexual function in older women. Symptoms of urinary incontinence and pelvic floor dysfunction should be sought specifically [*see 16:XII Urinary Incontinence and the Overactive Bladder*]. The need for Papanicolaou (Pap) smear screening—and, at an appropriate age, screening mammography—should be ascertained.

Screening questions for depression and interpersonal violence are appropriate in women of all ages and socioeconomic class because of the high prevalence of these conditions in women.

Primary clinicians are in a unique position to identify patients at risk for inherited cancer syndromes. Careful questioning about a family history of breast, ovarian, and related cancers can identify women at high risk for the breast cancer susceptibility genes *BRCA1* and *BRCA2* who may benefit from genetic testing and subsequent preventive measures if they test positive for a mutation [*see 3:VIII Genetic Diagnosis and Counseling*].

When obtaining the medication history, clinicians need to be aware of important sex differences in the effects of certain classes of medications that may put women at increased risk for adverse drug reactions.[25,26] For example, because women have longer baseline QT intervals than men, the use of drugs that further prolong the QT interval, such as certain antibiotics, antihistamines, antiarrhythmics, and antipsychotics, may put women at increased risk for torsade de pointes, a potentially lethal ventric-

ular arrhythmia.[27,28] The University of Arizona maintains an online registry of drugs that prolong the QT interval or induce torsade de pointes (http://www.arizonacert.org/medical-pros/drug-lists/drug-lists.htm). Also, women with depressed left ventricular function who use digoxin for heart failure are at greater risk of death than men with a similar diagnosis.[29] This risk is attributed partly to higher serum digoxin levels in women. Because of this potential harm, clinicians are advised to weigh carefully the risks versus benefits of digoxin therapy in women with heart failure.[30]

The hepatic cytochrome P-450 family of enzymes is involved in the metabolism of endogenous and exogenous steroids and many other drugs. Anticonvulsants can lead to oral contraceptive (OC) failure by inducing the cytochrome P-450 enzyme system to metabolize estrogen more rapidly. A similar mechanism has been attributed to antibiotics, leading to drug warnings about the risk of pregnancy when antibiotics are prescribed to women on OCs. Because the evidence supporting drug interactions between antibiotics and OCs is weak,[31] the Council on Scientific Affairs of the American Medical Association convened a panel to review the data and provide recommendations. The panel concluded that rifampin, acting primarily as an inducer of the cytochrome P-450 3A4 isoenzyme, is the only antibiotic tested that significantly reduces plasma concentrations of OC-derived estrogens and increases OC failure rates.[32] However, women using several other commonly prescribed antibiotics have wide variations in OC-derived hormone levels; some women have elevated follicle-stimulating hormone levels or breakthrough bleeding, suggesting that ovulation may occur. On the basis of these findings, the panel concluded that even though the risk of OC failure with these antibiotics is very small, some women may be at risk, particularly those using low-dose or very low dose OCs. The panel recommended nonhormonal contraceptive methods for women who are concomitantly using OCs and rifampin, as well as for women who are taking other antibiotics and are concerned about a small risk of pregnancy, have had previous contraceptive failure, or develop breakthrough bleeding.[32]

Because women are generally smaller and have more body fat than men, there is an increased risk of bleeding in women who are on anticoagulants if doses are not carefully adjusted for body size. Women also have an enhanced response to certain fat-soluble drugs, such as antipsychotics.[25] High body weight by itself can influence drug efficacy in women. For example, women who weigh 70.5 kg or more are at increased risk for contraceptive failure on OCs—particularly with low-dose and very low dose OCs.[33] This effect is attributed to lower circulating drug levels as a result of higher metabolic rates in women with a large body habitus, increased absorption of OCs by fat cells in women with high fat levels, or both.

PHYSICAL EXAMINATION

Most primary clinicians include the breast and pelvic examinations as part of the routine physical examination in women. Skill in these examinations requires an appreciation of the spectrum of normal findings in women of different age groups and the ability to recognize pathology. Clinicians who wish to increase their skills in performing the breast and pelvic examination can attend workshops or training sessions in one of several teaching associate programs affiliated with academic medical centers or can study teaching modules developed by the American College of Physicians and other professional organizations.

LABORATORY TESTS

Routine Blood Tests

Body structure and hormones, particularly estrogen, affect routine blood test results in women. Serum creatinine and creatine kinase (CK) levels are generally lower in women than in men because women have less muscle mass. The MB fraction of CK (CK-MB) is specific for cardiac tissue and is used as a marker for cardiac injury. CK-MB reference limits for diagnosing acute coronary syndromes are lower in women than in men because women generally have smaller hearts. There is also a small contribution to CK-MB from skeletal muscle, leading to higher levels in men.[34] Premenopausal women have lower serum uric acid levels than men because estrogen increases renal urate excretion.

Alkaline phosphatase levels increase gradually with aging in both women and men and can reach levels that are 50% higher than those reported in young adults. The source of the increase in postmenopausal women is bone; the liver is the source in older men.

Estrogen and the serum estrogen receptor modulators tamoxifen and raloxifene increase thyroid-binding globulin levels in women, resulting in an increase in total thyroxine (T_4) and triiodothyronine (T_3) concentrations but not in the free concentrations of thyroid hormones; thus, thyroid function remains normal.

Women have lower ferritin levels than men as a result of iron losses during menses, pregnancy, and lactation, and a high proportion of women have absent iron stores, resulting in lower red blood cell (RBC) measures (e.g., hemoglobin concentration, hematocrit, and RBC count). Because anemia is defined as RBC values more than two standard deviations below the mean, normal ranges for women are lower than they are for men; however, these differences diminish with age, because RBC measures decline in both women and men as part of normal aging.

Breast Cancer Screening

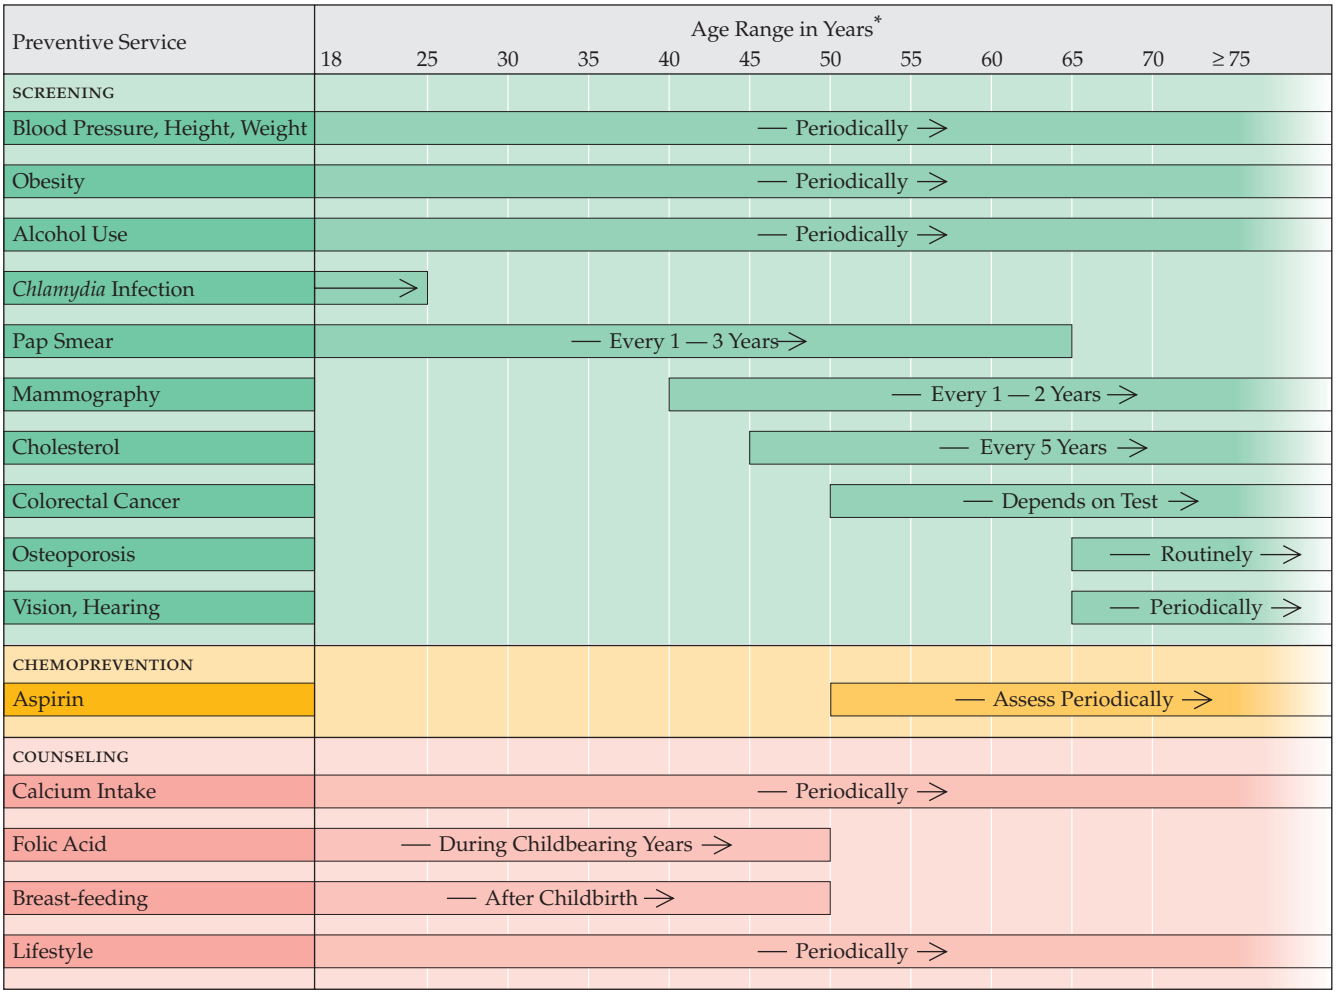
Primary care clinicians need to be familiar with the risks and benefits of screening mammography and of newer breast cancer screening technologies offered to high-risk women, including breast magenetic resonance imaging[35-38] [*see 12:VII Breast Cancer*]. Many clinicians do a clinical breast examination (CBE) before ordering a screening mammogram to help prevent the possibility of a biased exam if the mammography report is normal. A mass found on CBE should be investigated further even if it is not identified by mammography[39] [*see 16:XIV Approach to the Patient with a Breast Mass*].

Osteoporosis Screening

Clinicians should be knowledgeable about the indications for bone densitometry and should be able to interpret a woman's fracture risk on the basis of her bone mass and other factors that influence the risk of hip and other fractures [*see 3:VI Diseases of Calcium Metabolism and Metabolic Bone Disease*].

Cardiovascular Disease Testing

Noninvasive tests for CHD generally have lower diagnostic accuracy in women than in men. Consequently, clinicians should be familiar with the sensitivity and specificity of exercise testing and of newer imaging techniques whose accuracy is lower in women [*see 16:XIX Cardiovascular Disease in Women*].



* Upper age limits should be individualized for each patient.
For cardiovascular disease, when indicated by risk assessment.
Tobacco cessation, drug and alcohol use, sexually transmitted diseases and HIV, nutrition, physical activity, sun exposure, oral health, injury prevention, and polypharmacy.

Figure 1 **United States Preventive Services Task Force guidelines for preventive primary care in women.[42] These recommendations are conservative and represent the minimum level of preventive services that should be offered.**

Cervical Cancer Screening

Cervical cancer screening requires proficiency in obtaining the traditional Pap smear or in using liquid-based cytology or other new cervical cancer screening technologies. Knowledge of the Bethesda system for reporting results of cervical cytology is essential to interpreting Pap test results and in managing patients with atypical cells, including DNA testing for high-risk types of human papillomavirus (HPV).[40,41]

Vaginitis and Sexually Transmitted Disease Testing

Because STDs are often asymptomatic in women, screening is vital for preventing their spread, as well as their progression to pelvic inflammatory disease. Nonculture technologies have become the preferred method for diagnosing *Chlamydia* infections and gonorrhea in women and in identifying the cause of genital ulcers [*see 7:XXII Vaginitis and Sexually Transmitted Diseases*]. Clinicians need to be familiar with the use of these tests and the proper way to collect specimens. None of these newer technologies, however, replace the simple saline wet mount as a valuable tool for establishing the cause of a vaginal discharge.

Primary Prevention Guidelines in Nonpregnant Women

Many of the conditions that cause the greatest morbidity and mortality in women can be prevented or delayed by the early recognition and treatment of risk factors and the identification of individuals who might benefit the most from early intervention. The United States Preventive Services Task Force (USPSTF) publishes primary preventive guidelines that can assist clinicians in providing care to women [*see Figure 1*].[42] These guidelines are available online (http://www.ahrq.gov/clinic/uspstfix.htm). The recommendations are conservative and represent the minimum level of preventive services that should be offered.

The USPSTF recommends that all women have periodic measurement of blood pressure, height, and weight, as well as undergo screening for obesity and depression. Cervical cancer screening with Pap smears is recommended in sexually active women. Although other policy-making organizations offer different guidelines about when to start or stop Pap smear screening and the optimal screening interval in low-risk women, the USPSTF recommends initiating screening 3 years after sexual activity begins or at age 21, whichever occurs first, and screening

low-risk women at least every 3 years after two or three annual normal Pap smears. Routine screening is not recommended for low-risk women after age 65 if they have had adequate recent screening or for women who have had a total hysterectomy for benign conditions.

Newer screening methods using liquid-based cytology offer advantages over conventional Pap smears, such as the option of reflex HPV testing, but are more expensive. Until more information is available from trials assessing the role of HPV testing in cervical cancer screening, the USPSTF holds that the evidence is insufficient to recommend the use of this new technology over the routine Pap smear. Sexually active women younger than 25 years should be screened routinely for *Chlamydia*; screening for *Chlamydia*, gonorrhea, syphilis, and HIV should be done in any woman with risk factors for these diseases.

The USPSTF recommends that breast cancer screening with mammography, with or without clinical breast exam, be done every 1 to 2 years starting at age 40, although women 50 to 65 years of age and those at increased risk for breast cancer benefit the most [*see CE:V Adult Preventive Health Care*]. Clinicians should discuss the risks and benefits of breast cancer chemoprophylaxis with women who are at high risk for breast cancer. Routine screening for ovarian cancer is not recommended.

According to the USPSTF, women should receive cholesterol screening every 5 years starting at age 45; women with risk factors for cardiovascular disease, such as hypertension or hyperlipidemia, should be screened further for diabetes. As with men, colorectal screening is recommended beginning at age 50. Routine screening for osteoporosis in women is recommended starting at age 65. Many younger women, however, have conditions that put them at increased risk for osteoporotic fractures; in these women, screening is recommended to be started at age 60. Periodic vision and hearing screening is recommended for both women and men after age 65.

On the basis of findings from studies that were conducted primarily in men, the USPSTF currently recommends that clinicians discuss the use of aspirin for the primary prevention of CHD with postmenopausal women and with younger women with risk factors for CHD. However, results from the first randomized trial that assessed the risks and benefits of aspirin as chemoprevention for CHD in women found a beneficial effect only in women 65 years of age and older.[43] In younger women, aspirin reduced the risk of thromboembolic stroke but had little effect on CHD, findings opposite to those described in men. As in men, the use of aspirin in older women was associated with an increased risk of hemorrhagic stroke and major gastrointestinal hemorrhage. Until more information is available about aspirin's effects in women, discussions about its use should be individualized for each patient.

The USPSTF recommends counseling women of childbearing age about folic acid supplementation to reduce the risk of neural tube defects and recommends counseling women of all ages about adequate calcium and vitamin D intake. All women should be counseled about tobacco and other substance use, strategies to decrease the transmission of STDs, effective methods of contraception, a healthy diet and increased physical activity, and injury prevention. In older women, counseling should focus on prevention of falls and the potential dangers of multiple medication use.

I AMENORRHEA

Robert L. Barbieri, m.d.

The menstrual cycle is orchestrated through the interaction of the hypothalamus, pituitary gland, ovaries, and uterus. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the pituitary to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH stimulate follicular growth, ovulation, corpus luteum formation, and the secretion of estradiol and progesterone by the ovaries, which leads to the cyclic growth and shedding of the uterine endometrium. At the endometrial level, the menstrual cycle has three key phases: estradiol stimulates endometrial growth, progesterone induces differentiation of the endometrium, and withdrawal of estradiol and progesterone results in sloughing of the endometrium and menstrual bleeding.

Failure of any part of this process can result in the absence of menstruation. A girl may not start to menstruate when she reaches puberty (primary amenorrhea); or as is far more common, a woman who has been menstruating may have her cycles cease (secondary amenorrhea).

Pathophysiology

The hypothalamus contains approximately 10,000 GnRH-secreting neurons that drive the menstrual cycle by secreting pulses of GnRH. The embryonic precursors of the GnRH neurons develop in the olfactory bulb and migrate to the arcuate and preoptic nuclei. Improper development of the olfactory bulb in early embryogenesis can result in both anosmia and amenorrhea because of the absence of the GnRH neurons (Kallman syndrome).

The main function of the GnRH neurons is to receive neural signals from the brain and transform them into an endocrine output, the pulsatile release of GnRH. This conversion of electrical signal into endocrine output takes place in the arcuate nucleus. To determine the appropriate pulse frequency and amplitude of GnRH secretion, the hypothalamus monitors numerous environmental cues, including body composition, stress, nutritional status, and emotion. From a teleologic perspective, it is inefficient to ovulate and reproduce if the environment is hostile to the nurturing of a newborn.

The hypothalamus is the conductor that sets the tempo for the menstrual cycle. When the hypothalamus secretes GnRH at a low pulse frequency and amplitude, the pituitary gland is not driven to secrete LH and FSH, so the ovary and endometrium become quiescent. This causes amenorrhea. When the hypothalamus secretes GnRH at an abnormally elevated pulse frequency and amplitude, there is an exaggerated secretion of LH, causing the ovary to become androgenic and secrete testosterone. Follicular growth is blocked and no ovulation occurs. This results in the polycystic ovary syndrome (PCOS), which can be associated with oligomenorrhea or amenorrhea.

The pituitary gland is the main link between the brain and ovarian function. Secretion of the gonadotropins LH and FSH by the pituitary gland is not only stimulated by GnRH from the hypothalamus but also modulated by the negative feedback of steroid and protein hormones from the ovaries, especially estradiol, progesterone, and inhibin A and B [*see Figure 1*]. Estradiol and inhibin A are secreted by growing follicles and the corpus luteum. Inhibin B is secreted by the small antral follicles and growing follicles. Progestersone is secreted by the corpus luteum.

The follicle is the functional unit of the ovary. At puberty, the ovary contains approximately 300,000 follicles, of which only a few hundred will be ovulated in the woman's lifetime. The follicle has three components: an outer shell of thecal cells that respond to LH and secrete the androgen precursor androstenedione; an inner cell mass of granulosa cells that respond to FSH by converting androstenedione to estradiol; and, at the center of the follicle, the oocyte [*see Figure 2*]. Resting fol-

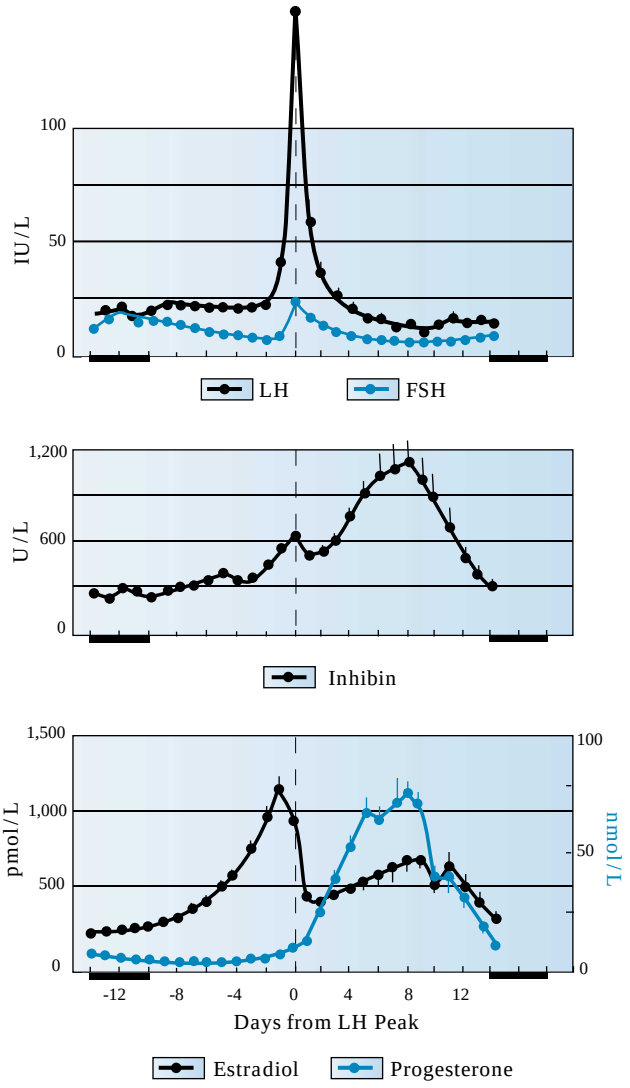

Figure 1 **Interaction between pituitary and ovarian hormones. The surge of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which prompts ovulation, is followed by an increase in inhibin and progesterone secretion and a decrease in estradiol.[28]**

licles are recruited into a cohort of active follicles, only one of which will be destined to ovulate each cycle; the remainder undergo atresia. Under FSH stimulation, granulosa cell numbers increase dramatically, from approximately 10 cells in the primordial follicle to approximately 50 million cells in the preovulatory dominant follicle. The dominant follicle, which is the one destined to ovulate, can be identified early in its development by three characteristics: it has captured large amounts of FSH in its follicular fluid, it has the optimal number of granulosa cells for its size, and it produces much more estradiol than testosterone. Excess stimulation by LH results in an androgen-dominant follicle, which is characterized by thecal cell overactivity and a preference to produce testosterone over estradiol. In PCOS, the ovary contains many androgen-dominant follicles that do not have the potential to ovulate.

The purpose of the menstrual cycle is to generate a single oocyte for fertilization and to prepare the endometrium for implantation. Estradiol stimulates endometrial proliferation, gland formation, and vascular growth in the endometrium.

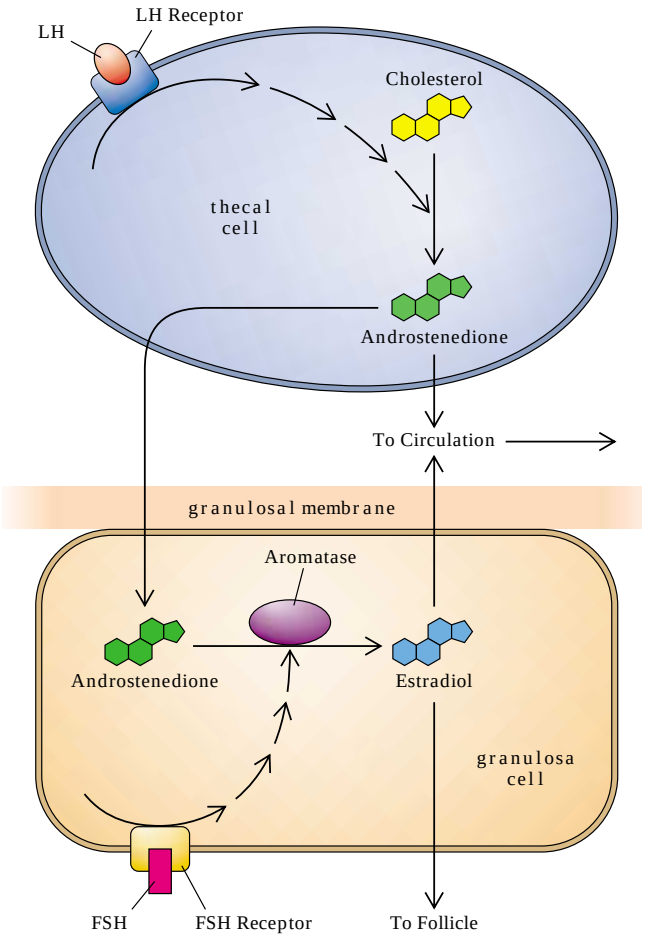

Figure 2 **Relationship between granulosa cells and thecal cells of the ovarian follicle. Luteinizing hormone (LH) stimulates thecal production of androstenedione, which diffuses to the granulosa cells. In the granulosa cells, follicle-stimulating hormone (FSH) stimulates the conversion of androstenedione to estradiol.[29]**

When stimulated by estradiol, the endometrium increases production of its own intracellular estrogen receptors, which augment its response to estradiol; it also produces more progesterone receptors. After ovulation, progesterone causes gland development and differentiation of the endometrium; in addition, glycogen is stored in preparation for embryo implantation. If pregnancy does not occur, the decline in ovarian production of estradiol and progesterone causes vasospasm of the endometrial blood vessels and sloughing of the endometrium, resulting in menstrual bleeding.

Abnormalities in GnRH secretion, LH or FSH secretion, ovarian follicular function, or endometrial function can cause amenorrhea or oligomenorrhea. In a given patient, the differential diagnosis—and hence the evaluation—depends on whether the amenorrhea is secondary or primary.

Secondary Amenorrhea

Secondary, or adult-onset, amenorrhea is present when a woman who had been menstruating has no menses for longer than three of her previous cycles, or 6 months. Determining the cause of secondary amenorrhea starts with measuring serum levels of human chorionic gonadotropin (hCG), prolactin, FSH, and testosterone and calculating the body mass index (BMI) [*see Figure 3*].

The most common cause of secondary amenorrhea is pregnancy. Pregnancy is best diagnosed by measuring the serum or urine hCG level. The hCG pregnancy test is one of the most accurate in medicine, with a sensitivity and specificity exceeding 99%.

In women who are not pregnant, the most common causes of secondary amenorrhea are as follows: hypothalamic dysfunction (low GnRH pulse frequency, amplitude, or both), pituitary dysfunction (low LH and FSH production), loss of all ovarian follicles (ovarian failure), PCOS, Asherman syndrome (intrauterine adhesions), and thyroid disease [*see Table 1*].[1]

amenorrhea caused by hypothalamic dysfunction

Low GnRH Secretion

Low BMI, vigorous exercise, psychosocial stress, and nutritional abnormalities decrease GnRH production. This reduces LH and FSH secretion and can cause amenorrhea.

Diagnosis The patient typically has a history of regular vigorous exercise, psychosocial stress, or reduced caloric intake. On physical examination, the BMI is often less than 20 kg/m^2 [*see Figure 4*]. Serum FSH, prolactin, and testosterone levels are usually reported as normal in women with secondary amenorrhea caused by low GnRH secretion. Women with secondary amenorrhea from hypothalamic hypofunction should be screened for eating disorders; the prevalence of eating disorders in this population is 5% to 10%. Rarely, hypothalamic dysfunction can be caused by structural abnormalities of the hypothalamus, including lymphoma, histiocytosis X, sarcoidosis, and hypothalamic cysts.

The absence of menses in association with hypothalamic hypofunction suggests severe estrogen deficiency, although varying degrees of hypoestrogenism may be present. The severity of the hypoestrogenism can be tested by performing a progestin withdrawal test [*see Figure 5*].[2] Serum estradiol assays are not sufficiently accurate for this purpose. Women with amenorrhea

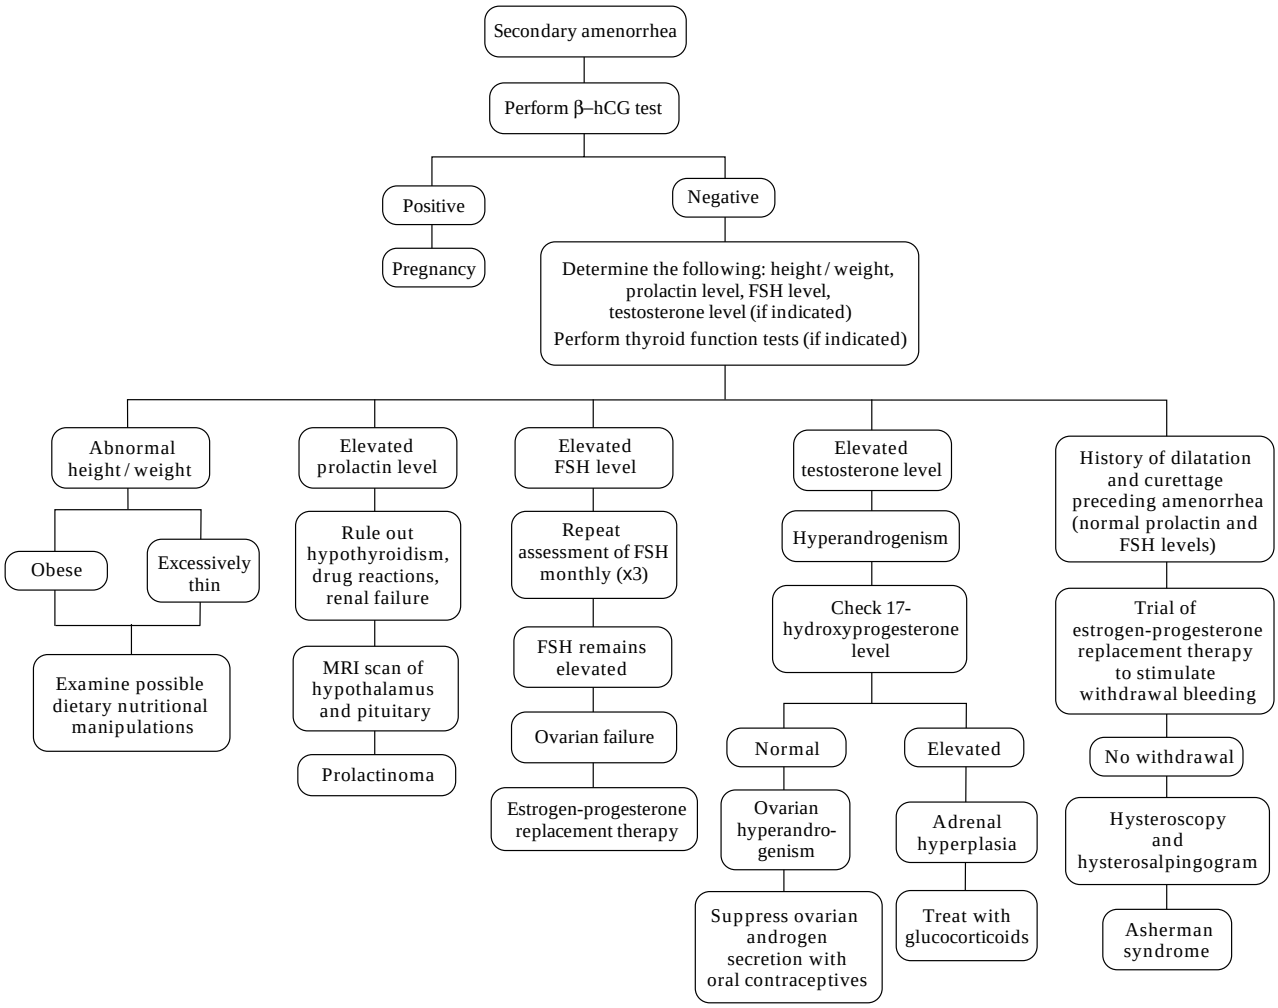

Figure 3 **Diagnosis and treatment of secondary amenorrhea. (β-hCG—β-human chorionic gonadotropin; FSH—follicle-stimulating hormone)**

resulting from hypothalamic hypofunction often have triiodothyronine (T_3) levels less than 70 ng / dl, reverse T_3 levels greater than 40 ng / dl (similar to those of nutritionally deprived individuals), and elevated levels of cortisol secretion (as seen in depressed women or women under significant stress).

Treatment Reversing the underlying cause of hypothalamic hypofunction (reducing psychosocial stress, gaining weight, lowering exercise intensity) often results in resumption of ovulatory menses. However, many women with amenorrhea from low GnRH secretion prefer to maintain the exercise and nutritional regimens that cause the amenorrhea, and those with an eating disorder may not respond to treatment of it. These women are best treated with hormone replacement. Therapeutic choices include oral contraceptives and low-dose hormone replacement, such as a standard combined continuous regimen of conjugated estrogens, 0.625 mg, plus medroxyprogesterone acetate, 2.5 mg, daily. Cyclic hormone replacement may also be used. The use of sustained-release vaginal gel to supply the progesterone component of hormone replacement therapy has been reported.[3] Vitamin D (400 IU / day) and calcium (1,200 to 1,500 mg / day) supplements should be administered to slow the rate of decline in bone mineral density associated with low estrogen levels.

amenorrhea caused by pituitary dysfunction

The most common pituitary diseases that cause secondary amenorrhea are prolactin-secreting pituitary tumors (prolactinomas), the empty sella syndrome, Sheehan syndrome, and other pituitary tumors, such as those that secrete adrenocorticotropic hormone (ACTH) or growth hormone.

Prolactin-Secreting Pituitary Tumors

Most pituitary tumors are monoclonal, which indicates that they arise from a somatic mutation in a single progenitor cell. In general, pituitary tumors are benign and slow growing.

Diagnosis The most common causes of an elevation in the serum prolactin level are, in order of frequency, advanced pregnancy; the use of psychotropic medications that are

Table 1 The Most Common Causes of Secondary Amenorrhea in Women Who Are Not Pregnant

Organ	*Cause*	*Relative Frequency (%)*
Hypothalamus	Abnormalities of height / weight and nutrition	15

	Ovarian tumors	< 1

ACTH—adrenocorticotropic hormone GH—growth hormone

dopamine antagonists, such as haloperidol; prolactin-secreting pituitary tumors; hypothyroidism; and renal failure. After excluding those causes, the workup should focus on the pituitary.

A magnetic resonance imaging scan of the hypothalamus and pituitary can confirm the diagnosis of prolactinoma. The MRI is also used to determine whether the diameter of the tumor is less than 10 mm (microprolactinoma) or greater than 10 mm (macroprolactinoma), because this measurement has clinical implications. Finally, the MRI can assess for possible involvement of the sella turcica and the optic chiasm.

If the MRI shows a pituitary tumor, it is important to also measure serum insulinlike growth factor–1 (IGF-1). IGF-1 levels will be elevated in patients whose pituitary tumor secretes growth hormone; this is a more reliable test than measurement of growth hormone itself.

Treatment In general, microprolactinomas have a benign course and can be managed by the patient's primary care physician. Observational studies indicate that over a period of 4 to 6 years, 95% of microprolactinomas do not increase in size.[4,5] Macroprolactinomas, however, can be associated with significant complications, such as pituitary apoplexy and compression of the optic chiasm, and should be managed by an endocrinologist. The initial treatment of both microprolactinomas and macroprolactinomas should be medical therapy, not surgery.

The two best approaches to management of microprolactinomas in women with amenorrhea are low-dose oral contraceptives and a dopamine agonist (bromocriptine, pergolide, or cabergoline). Both contraceptives and dopamine agonists can initiate regular withdrawal bleeding and prevent osteoporosis. In women with microprolactinomas, treatment with an estrogen-progestin oral contraceptive is safe and is not associated with clinically significant tumor growth.[6]

Women with amenorrhea caused by a prolactinoma who wish to become pregnant should receive treatment with a dopamine agonist to induce ovulation. Dopamine agonists directly suppress prolactin production by the tumor and cause an increase in endogenous GnRH secretion, which stimulates pituitary secretion of LH and FSH and consequently induces follicle development and ovulation. In addition, dopamine agonists decrease the size of prolactin-secreting pituitary tumors.[7,8]

Bromocriptine has been used to induce ovulation in women with hyperprolactinemia for more than 25 years.[9] In one study of 280 women with hyperprolactinemia, bromocriptine normalized the circulating prolactin level in 82% of the women.[10] The main side effects associated with the use of bromocriptine are nausea, vomiting, and orthostatic hypotension. To minimize these potential side effects, it is recommended that bromocriptine be initiated at a dose of 1.25 mg at bedtime. After 1 week, the dosage can be increased to 1.25 mg twice daily. The dosage can then be increased to 2.5 mg twice daily, a standard dosage that successfully reduces serum prolactin in most women with hyperprolactinemia.[10] Long-acting oral and injectable forms of bromocriptine have been developed,[11,12] but those are not yet available in the United States.

Pergolide, an ergot dopamine agonist, has been approved by the Food and Drug Administration for the treatment of Parkinson disease but not for the treatment of hyperprolactinemia. Unlike bromocriptine, pergolide can be given once a day. Pergolide is the least expensive of the dopamine agonists; its cost is about one sixth that of cabergoline.

Cabergoline is a non-ergot dopamine agonist that is administered once or twice a week and causes less nausea than bromocriptine or pergolide.[13] The FDA-approved dosage of cabergoline is 0.25 mg twice a week. Many clinicians start cabergoline at a dosage of 0.5 mg a week, then increase the dosage to 1 mg once or twice a week, depending on the response of the serum prolactin level (see below). In about 25% of women, the serum prolactin level returns to normal through therapy with cabergoline at a dosage of 1 mg a week; in these patients, the dosage can be reduced to 0.5 mg a week and the serum prolactin level will remain normal. About one half of women who do not respond to bromocriptine treatment will respond to treatment with cabergoline.[14] Many authorities believe that cabergoline is more effective than bromocriptine in treating hyperprolactinemia.[15] In a series of 459 women with hyperprolactinemia and amenorrhea, 83% of the women treated with cabergoline experienced normalization of their prolactin levels, compared with 52% of those treated with bromocriptine.[16] Cabergoline is significantly more expensive than bromocriptine, however.

With dopamine agonist therapy, near-maximal decreases in serum prolactin levels are typically achieved after 4 weeks of treatment. Serum prolactin levels should be measured approximately 1 month after initiating therapy and about 1 month after a change in dose or drug. If the serum prolactin concentration is normal and no side effects have occurred, the initial dose should be continued. If serum prolactin has not decreased to normal and no side effects are present, the dose should be gradually increased. Maximal dosages of the dopamine agonists are as follows: bromocriptine, 5 mg twice daily; pergolide, 0.25 mg once daily; and cabergoline, 1.5 mg two or three times weekly. If the serum prolactin level does not decrease to normal, switching to a different dopamine agonist may be effec-

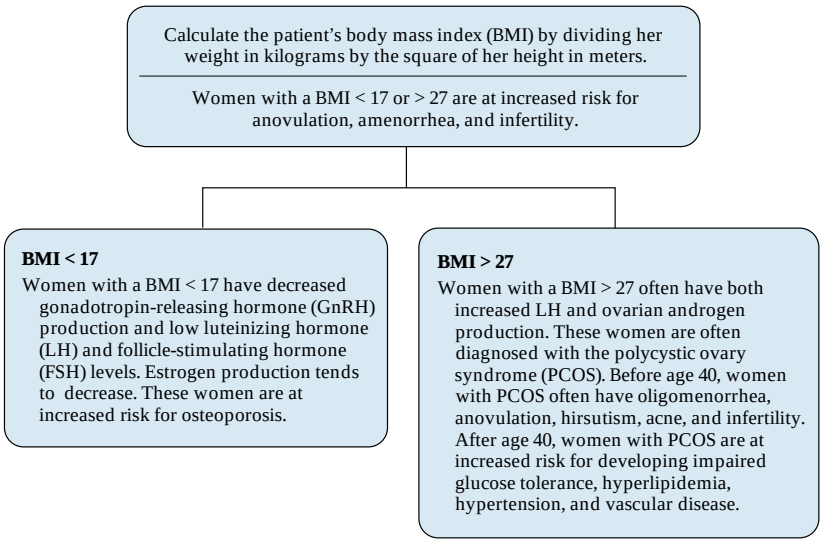

Figure 4 **Relation of body mass index to anovulation.**

tive. If the patient cannot tolerate the side effects of the dopamine agonist initially prescribed, a different dopamine agonist may be tried. If the patient experiences side effects with all the dopamine agonists, then vaginal administration of bromocriptine can be tried.[17] If all attempts at medical therapy fail, transsphenoidal surgery is indicated. Successful removal of the tumor will result in the normalization of the prolactin secretion level and resumption of ovulatory menses.

After correction of hyperprolactinemia, about 80% of women will ovulate; cumulative pregnancy rates of 80% are commonly observed.[18] Treatment is usually discontinued once a pregnancy is diagnosed. However, in women with a macroprolactinoma, therapy should be continued throughout pregnancy to reduce the risk that the tumor will grow and cause neurosurgical complications, such as compression of the optic nerve.

Empty Sella Syndrome

The roof of the pituitary gland (the diaphragm of the sella) is perforated by the pituitary stalk, which connects the hypothalamic median eminence to the pituitary. If the perforation in the diaphragm of the sella is excessively large, the pia mater and accompanying cerebrospinal fluid can herniate into the pituitary fossa. Herniation of this fluid, which is under reasonably high pressure, can produce compression atrophy of the pituitary gland, resulting in hypopituitarism and amenorrhea.

The empty sella syndrome can be diagnosed on the basis of high-resolution MRI or computed tomography of the pituitary. Therapy is directed to the specific replacement of documented hormonal abnormalities.

Sheehan Syndrome

Sheehan syndrome is the onset of hypothalamic and pituitary dysfunction after severe obstetric hemorrhage and maternal hypotension at delivery. During pregnancy, the pituitary volume increases by approximately 100%. The increase in pituitary size and the low-flow, low-pressure nature of the portal circulation may make the pituitary and parts of the hypothalamus susceptible to ischemia brought on by obstetric hemorrhage and hypotension. Worldwide, Sheehan syndrome is the most common cause of hypopituitarism.

Diagnosis Every possible pattern of pituitary hormone deficiency has been reported in Sheehan syndrome, but growth hormone and prolactin deficiencies are the most common presentations. In a study of 10 African women with Sheehan syndrome, all had both prolactin and growth hormone deficiency, nine had cortisol deficiency, eight had TSH deficiency, seven had LH deficiency, and four had FSH deficiency.[19] Clinical studies have demonstrated that many women with Sheehan syndrome also have mild defects in vasopressin secretion.[20] The best test to diagnose Sheehan syndrome is to administer thyrotropin-releasing hormone (TRH), 100 µg intravenously, and measure prolactin at 0 and 30 minutes. The ratio of prolactin at 30 minutes to prolactin at 0 minutes should be greater than 3.[21] If the ratio is less than 3, the patient should undergo a complete evaluation for panhypopituitarism.

Treatment Treatment of Sheehan syndrome is with hormone replacement. The particular regimen is based on the patient's pattern of hormone deficiency.

Premature Ovarian Failure

Ovarian failure is the loss of all functional ovarian follicles. Ovarian failure in patients younger than 40 years is termed premature ovarian failure. The causes of premature ovarian failure include genetic abnormalities (e.g., microdeletions of the X chromosome), autoimmune processes (e.g., polyglandular autoimmune disease and myasthenia gravis), chemotherapy (especially with alkylating agents), and pelvic radiotherapy (> 500 cGy to the ovaries).

Diagnosis Loss of all follicles results in a decrease in estradiol and inhibin B production. In the absence of the negative feedback effect of these two hormones, FSH secretion increases markedly. Therefore, ovarian failure is most accurately diagnosed by measurement of serum FSH. Complete ovarian failure is associated with serum FSH levels greater than 25 U/L. In

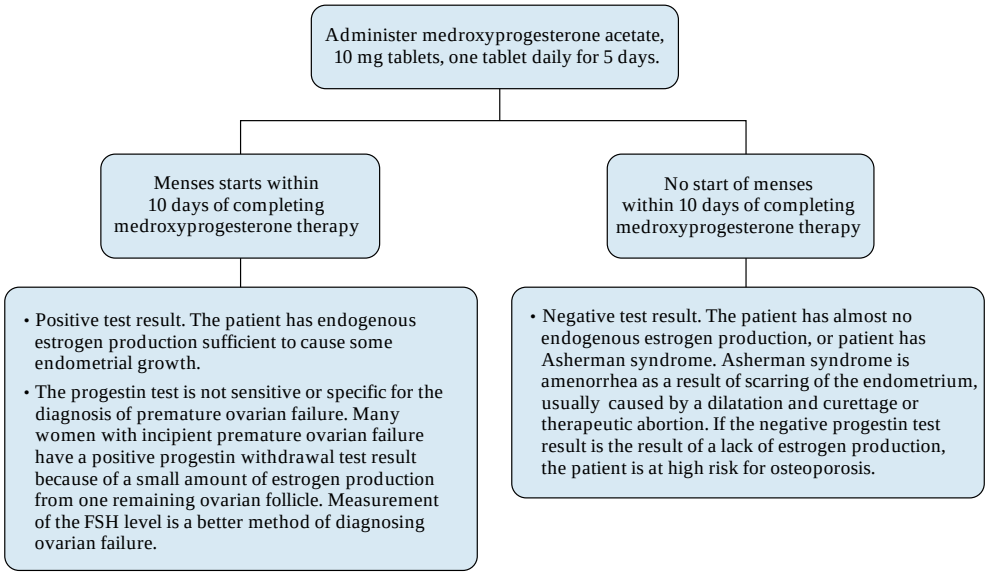

Figure 5 **The progestin withdrawal test. (FSH—follicle-stimulating hormone)**

women with incipient ovarian failure, FSH levels are often between 15 and 25 U/L and can fluctuate.[22] Clinically, women with premature ovarian failure often experience vasomotor symptoms (hot flashes) or vaginal dryness.

Treatment There are no proven therapies specifically for ovarian failure. Because women with premature ovarian failure (like all women with estrogen deficiency) are at high risk for osteoporosis, they should be treated with estrogen-progestin replacement. Although women with ovarian failure are by definition infertile, they may be able to bear a child through oocyte donation. In this process, a donor egg and sperm from the woman's partner are incubated in vitro. The embryo is then transferred to the woman's uterus, after she undergoes treatment with estrogen and progesterone to mature the endometrium.

Hyperandrogenism and the Polycystic Ovary Syndrome

Hyperandrogenism is marked by clinical evidence of excess androgens, including severe hirsutism, and elevated serum androgen levels. PCOS causes 80% of hyperandrogenism; idiopathic hirsutism causes 15%, and nonclassical adrenal hyperplasia (NCAH) causes 4%. Rare causes, such as androgen-secreting ovarian or adrenal tumors, account for 1% of cases. Idiopathic hirsutism is hirsutism associated with regular menses and therefore is not a cause of amenorrhea. PCOS, NCAH, and androgen-secreting tumors can all cause amenorrhea. Women who have amenorrhea with hyperandrogenism are at increased risk for endometrial carcinoma.

Diagnosis Androgen-secreting tumors are usually associated with circulating testosterone levels greater than 200 ng/dl. In menopausal women, small ovarian hilar cell androgen-secreting tumors can be associated with elevations in the serum testosterone level in the range of 150 to 200 ng/dl. In most women with PCOS, the serum testosterone level ranges from 50 and 200 ng/dl. The 17-hydroxyprogesterone level, when measured at 8:00 A.M., is greater than 4 ng/ml in women with NCAH and is less than 4 ng/ml in women with PCOS. A sonogram that shows multiple small ovarian follicles can support the diagnosis of PCOS.[22]

Treatment Ovarian hyperandrogenism, such as PCOS, is treated by suppression of ovarian androgen secretion with oral contraceptives. Adrenal hyperplasia is treated with glucocorticoids.

Table 2 The Most Common Causes of Primary Amenorrhea

Cause	*Rate of Occurrence (%)*
Gonadal dysgenesis, including 45X (Turner syndrome)	45

Hyperprolactinemia	1
Adrenal hyperplasia	1
Hypothyroidism	1
Pituitary tumors	1
Craniopharyngioma	1

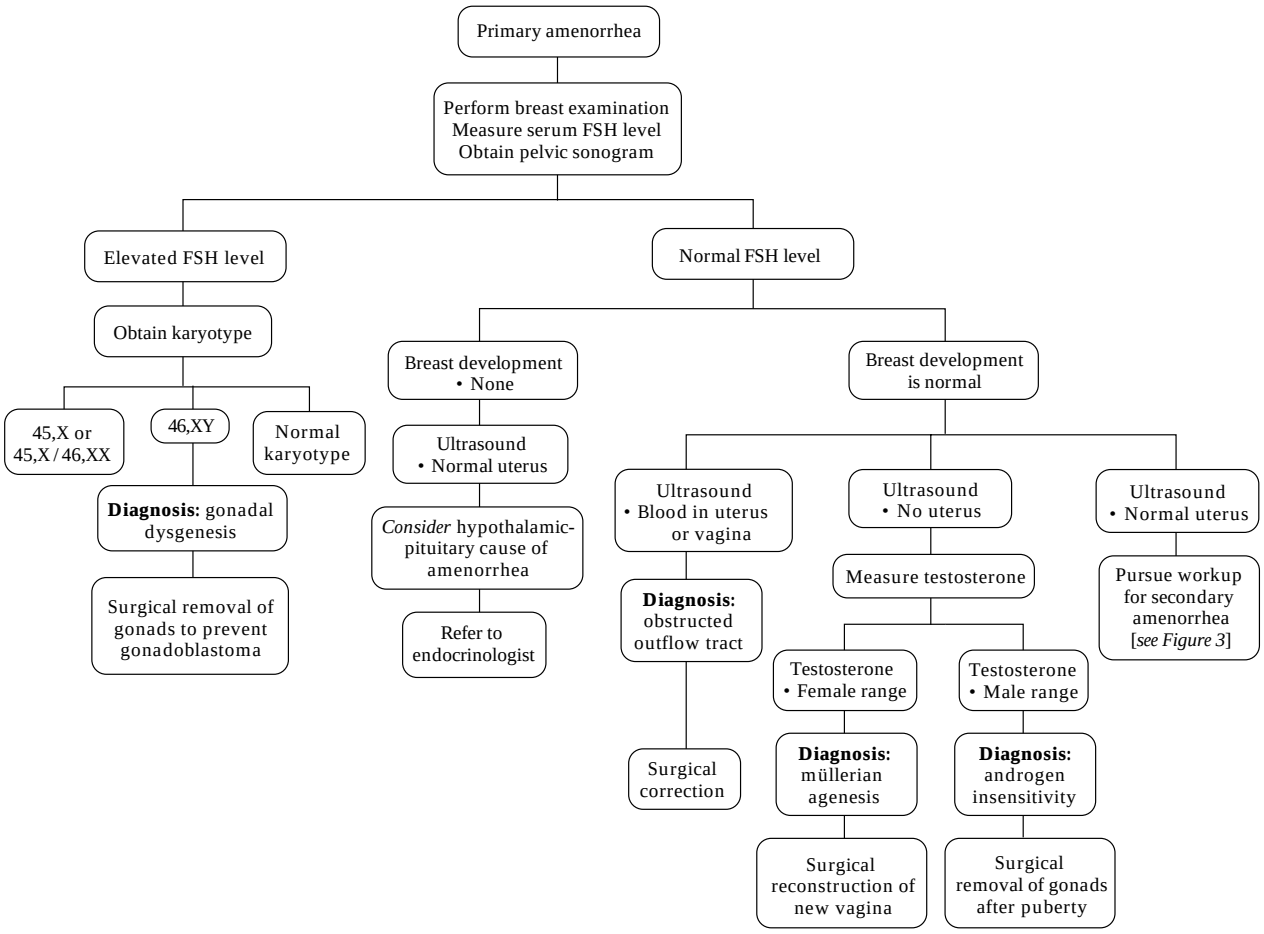

Figure 6 **Diagnosis and treatment of primary amenorrhea. (FSH—follicle-stimulating hormone)**

Asherman Syndrome (Intrauterine Adhesions)

Asherman syndrome is the presence of intrauterine scar tissue that interferes with normal endometrial growth and shedding. In women with this condition, intrauterine scar tissue usually develops after vigorous curettage of infected endometrium early in pregnancy.

Diagnosis The history is an important clue to Asherman syndrome. For patients whose history is suggestive, a commonly used way to assess endocrine function is to prescribe conjugated estrogens, 2.5 mg for 35 days, plus medroxyprogesterone acetate, 10 mg daily, on days 26 to 35. The estrogen and progestin are then discontinued. Absence of withdrawal bleeding after such a challenge strongly suggests Asherman syndrome. The diagnosis can be confirmed radiologically by hysterosalpingogram or by direct visualization of the scar tissue with hysteroscopy.

Treatment The treatment of Asherman syndrome involves surgical lysis of the intrauterine adhesions by operative hysteroscopy, followed by stimulation of endometrial growth with estrogen. Some women who become pregnant after treatment experience placental defects such as placenta accreta. This is probably the result of disruption of function of the endometrial stroma by the disease and treatment.

Primary Amenorrhea

Primary amenorrhea is present when the first menses has not occurred by the time a girl reaches 16 years of age. Girls who reach 14 years of age and have no breast development should also undergo a workup similar to that for primary amenorrhea.[23] Primary amenorrhea is usually caused by genetic or congenital disorders and is often associated with developmental problems during puberty.[24] These developmental problems include delayed height and weight gain, delayed breast development, and delayed development of pubic and axillary hair.

In a large case series, the most common causes of primary amenorrhea were found to be gonadal dysgenesis resulting from chromosomal abnormalities such as 45,X, 45,X/46,XX, and 46,XY (45% of cases); physiologic delay of puberty (20% of cases); müllerian agenesis (15% of cases); transverse vaginal septum or imperforate hymen (5% of cases); absence of hypothalamic GnRH production, such as seen in Kallman syndrome (5% of cases); anorexia nervosa (2% of cases); and hypopituitarism (2% of cases).[25] Less common causes of primary amenorrhea are hyperprolactinemia, hypothyroidism, pituitary tumors, Cushing disease, and craniopharyngiomas [*see Table 2*].

Primary amenorrhea is evaluated by focusing on the serum FSH level; breast development; and the presence of the cervix

and uterus, as determined by an imaging study (pelvic sonogram or MRI) [*see Figure 6*].

If the FSH level is elevated, a diagnosis of gonadal dysgenesis can be made in most cases. A karyotype should be obtained in such cases to determine whether a Y chromosome is present. Girls with gonadal dysgenesis and a Y chromosome on the karyotype have a high rate of malignant transformation of the gonad to a dysgerminoma or a gonadoblastoma. In these cases, the ovaries need to be removed surgically.

If the FSH level is normal, then breast development should be assessed, and it should be determined whether a uterus and a cervix are present. If breast development is absent and a uterus is present, the differential diagnosis includes hypothalamic and pituitary causes of amenorrhea; the patient should then be referred to an endocrinologist. If breast development is normal and a uterus is present, the differential diagnosis is the same as that for secondary amenorrhea (see above). However, if the pelvic ultrasound shows not only that the patient has a uterus but that the uterus or vagina is dilated by blood, the diagnosis is a blocked reproductive outflow tract (transverse vaginal septum or imperforate hymen). Surgical relief of the outflow tract is necessary to prevent the development of hematocolpos, hematometria, and endometriosis.[26]

If breast development is present and no uterus is present on ultrasound, then the serum testosterone level should be assessed. If the testosterone level is in the normal range for a girl, the likely diagnosis is müllerian agenesis.[27] Treatment of müllerian agenesis is surgical construction of a new vagina, which should be scheduled for the time when the patient is expected to begin having sexual relations.

In a patient with breast development, no uterus, and a testosterone level that is elevated to the male range, the likely diagnosis is androgen insensitivity. Females with androgen insensitivity usually do not have pubic or axillary hair. Breast development is usually normal because in the absence of a tissue androgen receptor, low levels of estrogen have a markedly stimulating effect. Although the karyotype in these patients is 46,XY, their likelihood of developing a gonadoblastoma is low until after puberty. Removal of the gonads is typically delayed until puberty is complete.

II ABNORMAL VAGINAL BLEEDING

Alan H. DeCherney, m.d.

Definition

Abnormal vaginal bleeding is classified on the basis of the duration, amount, and frequency of bleeding. The duration of a menstrual cycle is defined as the length of time between the first day of bleeding of one menstrual cycle and the first day of bleeding of the next cycle. The normal menstrual cycle lasts about 28 days (plus or minus 7 days). Any deviation in cycle duration is considered abnormal. Polymenorrhea refers to an abnormally shortened menstrual cycle, with bleeding occurring every 21 days or sooner. A cycle duration of 35 days or longer is also considered abnormal and is termed oligomenorrhea.

Women with normal menses bleed for a maximum of 7 days, losing a total of 60 ml of blood. Menstruation that occurs at regular intervals but lasts for more than 7 days and involves the loss of more than 80 ml of blood with each menstrual cycle is called menorrhagia. In contrast, women with a decrease in monthly blood loss are considered to have hypomenorrhea.

Intermenstrual bleeding, metrorrhagia, and menometrorrhagia are other abnormal bleeding patterns. Intermenstrual bleeding is bleeding that occurs between regular menstrual periods. Metrorrhagia refers to bleeding that is frequent and irregular. When this pattern of bleeding becomes prolonged, it is called menometrorrhagia.

Etiology

Abnormal vaginal bleeding occurs in women of all ages and can result from a number of causes, including anatomic abnormalities, pregnancy complications, malignancies, infections, systemic diseases, and endocrinologic disturbances [*see Table 1*]. The physician must be able to recognize all causes of this condition and treat the specific underlying cause. The bleeding pattern experienced by a woman and the age at which it occurs may be indicative of the cause. It is thus useful to distinguish between premenopausal vaginal bleeding [*see Figure 1*] and postmenopausal vaginal bleeding [*see Figure 2*]. Once the cause of bleeding is identified, treatment can be started and tailored to meet the needs of the patient.[1,2]

Premenopausal Vaginal Bleeding

PREGNANCY

An abnormal pregnancy is the first possibility to consider when a patient in her reproductive years presents with abnormal vaginal bleeding. The complications of pregnancy associated with abnormal vaginal bleeding include threatened, incomplete, and undetected abortions; ectopic pregnancies; trophoblastic disease (a benign or malignant tumor arising in placental tissue); and other abnormalities of placental location. These conditions can be fatal if not treated in an expeditious and judicious manner. Thus, early diagnosis and treatment are critical [*see 16:VIII Ectopic Pregnancy and Spontaneous Abortion*].

NONPREGNANT PATIENTS

A detailed history and physical examination are essential for making an accurate diagnosis. Inspection of the vagina and external genitalia can easily establish the diagnosis in patients whose bleeding is caused by either trauma or the presence of a foreign body, as well as in some patients with anatomic abnormalities. Treatment in such cases is specific to the lesion.

Adjunctive blood tests (e.g., for anemia or clotting abnormalities) and imaging studies are also essential in most patients. Pelvic ultrasonography and hysteroscopy may be useful in differentiating anatomic from nonanatomic causes of bleeding.[3,4]

In a premenopausal woman older than 35 years who experiences changes in her menstrual bleeding pattern, a Papanicolaou (Pap) smear and endometrial biopsy should also be obtained. These tests will reveal whether premalignant or malignant cells are present. Although these tumors are more common in postmenopausal women, premenopausal women should always be evaluated.

Anatomic abnormalities of the uterus (e.g., polyps, uterine myomas, adenomyosis, and endometriosis) should be considered when abnormal bleeding occurs in an ovulatory woman. Pelvic ultrasonography, hysterosalpingography, or diagnostic laparoscopy or hysteroscopy may aid in the diagnosis of anatomic uterine abnormalities. Surgical correction of the anatomic problem is usually necessary to alleviate and ultimately resolve the bleeding disorder.

Reproductive Tract Diseases

Malignancy Vaginal bleeding may be an initial symptom of malignancies involving the cervix, endometrium, vagina, vulva, or ovaries. The incidence of these malignant tumors increases with advancing age. Identification of a malignancy warrants intervention with radiotherapy, chemotherapy, surgery, or a combination of these modalities.

Infection Lower or upper genital tract infection may result in abnormal bleeding. Urethritis, cervicitis, erosions of the cervix

and vagina, and emerging pelvic inflammatory disease can cause menstrual irregularities. Affected patients often experience pelvic and lower abdominal pain, fever, chills, and bloody vaginal discharge.

Diagnosis is usually made with vaginal and cervical cultures and an endometrial biopsy. Ultimately, treatment is targeted at the causative organism [*see 7:XXII Sexually Transmitted Diseases*].

Systemic Disease

Systemic diseases, including coagulation defects, liver failure, and thyroid dysfunction, can manifest as abnormal vaginal bleeding. In such cases, other manifestations typically point to the diagnosis.

Coagulation defects Patients with coagulopathies usually bruise easily and bleed from numerous sites, including the nose, gingiva, uterus, urinary tract, and gastrointestinal tract. The cessation of menstruation relies partly on a normal coagulation profile and the body's ability to form clots. Thrombocytopenia, von Willebrand disease, and other disorders of coagulation disrupt this natural process. Because coagulation disorders generally become apparent at the time of menarche, adolescents who display uncontrolled menorrhagia should be evaluated for these conditions[5] [*see 5:VI Disorders of Hemostasis and Coagulation*].

A coagulation defect is detected in 5% to 20% of adolescents who are hospitalized for abnormal vaginal bleeding. Von Willebrand disease is the most common inherited bleeding disorder in women and is believed to occur in 0.1% to 0.8 % of the population.[6,7] Acquired and congenital deficiencies of coagulation factors are less frequent but should not be overlooked. It is imperative that an accurate diagnosis be made so that appropriate treatment can be administered.

Liver failure Cirrhosis of the liver may affect vaginal bleeding in two ways. First, estrogen metabolism may be compromised in advanced liver disease, leading to elevated levels of free estrogen. Second, the liver produces components of the intrinsic pathway of the coagulation cascade. When production of these factors becomes compromised, bleeding irregularities occur.

Thyroid dysfunction Hypothyroidism can cause menstrual disturbances. The prevalence of hypothyroidism in women with menorrhagia is about 2.5%. Patients who complain of weight gain, fatigue, cold intolerance, and constipation may have a thyroid disorder and warrant further evaluation. The thyroid-stim-

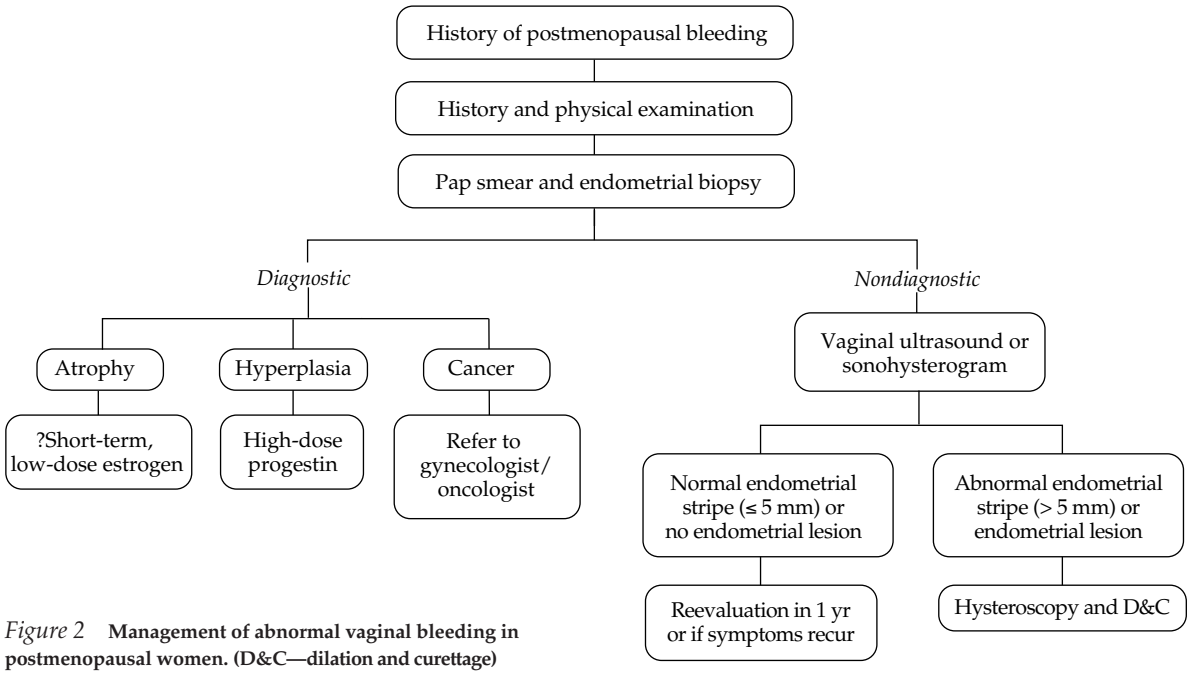

Figure 2 **Management of abnormal vaginal bleeding in postmenopausal women. (D&C—dilation and curettage)**

ulating hormone (TSH) level should be determined during the initial workup. Treatment entails oral administration of exogenous thyroid hormone. The dosage should be titrated until symptoms resolve and the TSH level becomes normal.

Hyperthyroidism can also cause abnormalities in menstrual bleeding. Uncommonly, women with hyperthyroidism experience menorrhagia. Patients should be treated with propylthiouracil until a normal TSH value is obtained. Beta blockers should be considered for patients with severe tachycardia. Treatment for hyperthyroidism is discussed in detail elsewhere [*see 3:I Thyroid*].

Iatrogenic Causes of Vaginal Bleeding

Women who use medications that contain estrogen and progesterone may experience changes in their bleeding pattern. Long-acting contraceptives such as depot medroxyprogesterone acetate and levonorgestrel-releasing implants commonly cause irregular menses and eventually amenorrhea in patients who use these medications for longer than 6 months. Other pharmacologic agents that cause menstrual disturbances are digitalis, phenytoin, anticoagulants, corticosteroids, and psychotropic agents. A detailed account of the patient's current medication usage will reveal risk for iatrogenically induced uterine bleeding.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) is the term used to describe uterine bleeding that is not caused by an anatomic lesion. Two variations of AUB exist, ovulatory and anovulatory. Prostaglandins have been implicated as a cause of AUB. As the menstrual cycle progresses to the luteal phase, the production of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) from arachidonic acid increases. $PGF_{2\alpha}$ causes vasoconstriction of the spiral arteries, whereas prostaglandin E_2 (PGE_2) induces vasodilation. In normal menstruating women, the level of $PGF_{2\alpha}$ relative to PGE_2 increases steadily during the menstrual cycle.

Another hypothesis regarding the regulation of menstrual bleeding considers the role of matrix metalloproteinase–2 (MMP-2). This enzyme initiates menstruation when progesterone is withdrawn from decidualized endometrial stroma. MMP-2 acts on the vascular and epithelial basement membrane of the endometrium, causing breakdown and shedding of the endometrium during a normal menstrual cycle.[8]

Ovulatory AUB Ovulatory AUB is caused by an abnormality in the ratio of $PGF_{2\alpha}$ to PGE_2. The production of $PGF_{2\alpha}$ in ovulatory AUB is reduced, while the synthesis of PGE_2 and prostacyclin is increased. This distortion in prostaglandin synthesis leads to abnormal uterine bleeding, despite the presence of a luteinized endometrium.

Anovulatory AUB In most cases, AUB arises from anovulation. Anovulatory AUB is especially likely to affect women shortly after menarche and before menopause. When ovulation does not take place, progesterone is not produced, and the effects of estrogen predominate. Continuous unopposed estrogen production causes the endometrial lining to proliferate without undergoing cyclical changes. Eventually, the endometrial lining outgrows its blood supply, which results in focal areas of necrosis and bleeding. Because a uniform shedding of the endometrial lining does not occur, a prolonged and abnormal bleeding pattern may develop. In addition, the $PGF_{2\alpha}$ production decreases and PGE_2 production remains the same, stimulating heavier bleeding.

Treatment of AUB Nonsteroidal anti-inflammatory drugs (NSAIDs) can reduce the amount of uterine bleeding in ovulatory and anovulatory women. These drugs inhibit the activity of cyclooxygenase and therefore block the production of prostaglandins [*see 16:IV Dysmenorrhea*]. Thromboxane is a prostaglandin that promotes platelet aggregation, and prostacyclin is a prostaglandin that inhibits platelet aggregation. The benefit of NSAIDs may derive from an alteration in the ratio of thromboxane to prostacyclin. Women with AUB who are treated with NSAIDs may experience as much as a 50% reduction in blood loss during their menstrual period.[9] There is no reason to

and
Nonsteroidal anti-inflammatory drugs

AUB—abnormal uterine bleeding

choose one NSAID over another,[10] although some reports have suggested that naproxen may be superior. Cyclooxygenase-2 (COX-2) inhibitors are still being evaluated for this indication.

Management of anovulatory AUB is accomplished with hormone therapy, not by curettage. In treating anovulatory AUB, NSAIDs should be combined with either oral contraceptives or progestin therapy to optimize the control of bleeding [*see Table 2*]. Combination oral contraceptive therapy is preferred to other treatments because of its superior efficacy in controlling menstrual bleeding. Abnormal bleeding will usually cease within 24 hours after the start of this regimen.

Cyclic progestin can also be used to control anovulatory bleeding. Progesterone prevents endometrial proliferation, and its withdrawal causes an organized breakdown and uniform slough. Progesterone also increases the formation of arachidonic acid and the production of $PGF_{2\alpha}$, inducing vasoconstriction of the spiral arteries. Together, these two effects of progesterone cause an organized slough of the endometrium and a swift termination of bleeding.

Progesterone can be administered orally as medroxyprogesterone acetate, 10 mg a day for 7 to 14 days, or intramuscularly as a single dose of 50 mg progesterone in oil every 28 days. Alternatively, a single dose of a long-acting progesterone (e.g., depot medroxyprogesterone acetate, 150 mg) can be given once every 3 months.

Some patients have acute, heavy bleeding as a result of decreasing estrogen levels. Provided the patient is hemodynamically stable, she can be treated with estrogen alone, either intravenously or orally.[11] Therapy with progestins should not be used, because these agents are ineffective in controlling acute and heavy bleeding. When bleeding is pronounced and leads to hypovolemia, dilation and curettage (D&C) should be performed before the induction of medical therapy. However, a D&C should not be performed routinely for anovulatory bleeding.

Conjugated estrogen is usually administered intravenously in doses of 20 mg every 4 hours over 12 to 24 hours. After completion of intravenous estrogen administration, oral supplements with 2.5 to 3.75 mg of conjugated estrogen should follow for 3 weeks before the addition of progesterone supplements to obtain a withdrawal bleed. The use of estrogen without progesterone is not the preferred treatment for anovulatory AUB.

Women who fail to respond to medical management should be considered for surgical therapy. Conservative surgery with endometrial ablation can be used to treat women who wish to retain their uterus.[12] Heavy bleeding recurs in nearly half of these women within 1 year after the procedure, however, and it may need to be performed several times before the bleeding disorder is corrected. Ablation of the endometrium should not be performed on women who desire future pregnancies or on those who have not tried other medical modalities.

Hysterectomy is the ultimate and most definitive treatment for AUB. The removal of the uterus should be reserved for women with ovulatory AUB in whom all other therapies have failed. If an alternative indication for performing this procedure coexists with AUB, a hysterectomy should be performed.

Postmenopausal Bleeding

Bleeding in postmenopausal women is most often caused by atrophic changes of the endometrium. Endometrial atrophy accounts for 45% of such cases. Polyps, submucous myomas, and proliferative changes of the endometrium each account for about 10%, and endometrial hyperplasia accounts for another 15%. Thus, all postmenopausal women who experience an episode of bleeding should be evaluated promptly [*see Figure 2*].

DIAGNOSTIC EVALUATION

The evaluation should begin with a thorough history and physical examination. A detailed account of current medications should be obtained.

Women who use hormone replacement therapy (HRT) may experience episodes of uterine bleeding.[13] In most cases, bleeding that occurs with HRT is the result of an anatomic structural abnormality and not cancer. Although HRT is thought to reduce the risk of endometrial cancer, this possibility should still be considered in the differential diagnosis.

A Pap smear and endometrial biopsy should be obtained. These tests are diagnostic if they show atrophy, hyperplasia, or endometrial cancer. An endometrial biopsy cannot detect an intracavitary mass, however, so pelvic sonography or sonohysterography should be performed in patients with nondiagnostic results, to evaluate the endometrial cavity and search for an intracavitary mass.[14,15] If an endometrial biopsy cannot be performed in the office, such as in the case of a patient with a stenotic cervical os, an ultrasound should be obtained to evaluate the thickness of the endometrial lining. An endometrium that is less than 5 mm thick is considered normal and unlikely to harbor a malignancy. However, 4% of endometrial cancers will be missed by this criterion, with a false positive rate as high as 50%, so endometrial thickness measurement in symptomatic women does not reduce the need for invasive diagnostic testing.[16]

MANAGEMENT

Postmenopausal bleeding should be treated on the basis of the predisposing etiology. If a submucous myoma or polyp is responsible, surgical removal of the lesion should be considered. Endometrial atrophy is not amenable to treatment; some gynecologists use short-term, low-dose estrogen for this purpose, but there are no data to support this practice. High-dose progestin therapy should be instituted for women with endometrial hyperplasia. Women with endometrial cancer should be treated according to the stage and grade of the cancer detected.

If an identifiable cause of bleeding is found, such as a polyp or myoma, hysteroscopy should be performed. Hysteroscopy should also be done, followed by a D&C, when an ultrasound obtained during a screening reveals an abnormally thickened endometrial lining.

III PREMENSTRUAL SYNDROME

Sarah L. Berga, m.d.

Premenstrual syndrome (PMS) is a recurrent constellation of affective and physical symptoms that begin during the luteal phase of the menstrual cycle and resolve completely or almost completely during the follicular phase. The number, severity, and duration of symptoms occur along a spectrum. It is estimated that 20% to 40% of women report premenstrual symptoms during the luteal phase, but only 5% to 10% of women report symptoms severe enough to significantly interfere with their lifestyle. The long-term natural history of PMS is unclear.

The fourth edition of the *Diagnostic and Statistical Manual* of the American Psychiatric Association (DSM-IV) has defined a related syndrome, premenstrual dysphoric disorder (PMDD), to facilitate an accurate psychiatric diagnosis [*see Table 1*].[1] The criteria for PMDD are also used to define research populations so that therapeutic responses can be quantitated and generalized. PMDD is often considered a variant of depression, an impression buttressed by the treatment efficacy of antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs), in women who meet the criteria for PMDD.[2-4]

Pathogenesis

Most evidence suggests that PMS/PMDD is caused by aberrant responses of target tissues, particularly the brain, to normal fluctuations in serum levels of ovarian gonadal steroids.[5-7] The causes of the untoward central nervous system responses are not firmly established[8] [*see Table 2*], but several pathogenic mechanisms are currently being explored. Altered metabolism of progesterone by the CNS may lead to altered CNS reactivity and neurotransmission. Specifically, one of the principal metabolites of progesterone, allopregnanolone, decreases anxiety. Women with PMS show lower levels of allopregnanolone during their luteal phase[9]; they may instead produce a predominance of anxiogenic progesterone metabolites.

PMS/PMDD may involve alterations in CNS neurotransmission that cause heightened reactivity to normal excursions in gonadal steroid levels. This exaggerated reactivity may be inherited or acquired. An acquired cause of altered CNS neurotransmission is chronic stress. Chronobiologic disturbances documented in women with PMDD have been interpreted as evidence of an underlying aberration in CNS function.[10] High levels of estrogen or of estrogen and progesterone may elicit or aggravate this underlying brain dysfunction, which would explain why symptoms are greatest during the luteal phase or at ovulation. In women with PMS/PMDD, but not in women without it, the symptom complex can be replicated by exposure to, followed by withdrawal from, exogenous estrogen and progesterone.[11] There is also an association between PMS and dysmenorrhea, further suggesting that PMS is an exaggerated tissue response to normal hormonal changes.

Diagnosis

To warrant medical attention, evaluation, and intervention, premenstrual symptoms must be recurrent and sufficiently severe to interfere with daily work and social activities. To establish the diagnosis of PMS/PMDD, the clinician must confirm that the patient has the characteristic manifestations of the disorder at the appropriate time in her menstrual cycle.

It is also important to identify any concurrent conditions likely to complicate treatment [*see Table 3*]. Many women with PMS/PMDD have a personal or family history of alcoholism. A history of sexual abuse, particularly in childhood or adolescence, may be common in women with severe PMS.[12] This population also has an increased personal and family history of posttraumatic stress disorder, mood disorders, schizophrenia, eating disorders, postpartum depression or psychosis, personality disorders, and anxiety disorders. A positive family history does not necessarily imply an inherited biologic vulnerability, because persistent exposure to dysfunctional family interactions is a chronic stress that can alter underlying CNS function.

Conclusive diagnosis of PMS or PMDD requires the documentation of concordance between symptoms and the luteal or periovulatory phase. The diagnosis of PMS/PMDD cannot be made in an anovulatory patient. Ideally, symptoms and menstrual dates should be followed prospectively to establish synchrony between the luteal phase and increase in symptoms. Two or more cycles and at least five symptoms [*see Table 1*] should be charted before the diagnosis is made. However, with a patient who is suffering severe psychological distress, there may not be time for prospective evaluation. Immediate referral to a psychiatrist may be indicated to prevent suicide or homicide.

If the menstrual cycle is irregular (menstrual cycle is ordinarily between 26 and 30 days) and there is no clear pattern of symptoms, the progesterone level should be measured weekly

Table 1 DSM-IV Criteria for Premenstrual Dysphoric Disorder

Symptoms occur in the luteal phase, with prospective confirmation of a 30% increase in symptoms during the luteal phase above the level in the follicular phase

Not an exacerbation of major depression, panic dysthymia, or personality disorder

Marked disturbance in functioning

At least five of the following

- Marked lability
- Marked irritability
- Marked anxiety
- Markedly depressed mood
- Decreased interest
- Lethargy
- Difficulty concentrating
- Food craving
- Hypersomnia or insomnia
- Physical symptoms (breast tenderness or swelling, headache, joint or muscle pain, bloating, weight gain)
- Avoidance of social activities
- Decreased productivity
- Increased sensitivity to rejection
- Feeling overwhelmed
- Feeling out of control
- Increased interpersonal conflict

Table 2 Potential Causes of PMS/PMDD

Aberrant responses of target tissues, especially the brain, to normal gonadal steroid exposures mediated by the following:
- Opioid withdrawal
- Serotonergic imbalance
- Entrainment to endogenous cycles
- Chronobiologic disturbance
- Membrane effects of steroids or steroid metabolites
- Genomic effects of steroids
- Variation in steroid metabolism

throughout a cycle to determine whether there is a luteal phase. A progesterone concentration greater than 5 ng/ml, or 15 nmol/L, is generally considered evidence that a woman is in the luteal phase and ovulation is impending. No rise in progesterone indicates anovulation, which may be stress induced. These patients may require further evaluation [*see 16:I Amenorrhea*]. Symptoms should be charted concurrently with progesterone levels. To meet the criteria for PMS/PMDD, the patient's symptoms should become at least 30% more severe during the luteal phase (or when the progesterone concentration is greater than 5 ng/ml) than they were in the follicular phase.

DIFFERENTIAL DIAGNOSIS

If a patient has regular menses and severe dysmenorrhea but no behavioral symptoms, she should be evaluated for possible endometriosis [*see 16:X Endometriosis*]. As with all psychiatric diagnoses, it is important to exclude organic causes. In PMS/PMDD, it is especially important to exclude thyroid dysfunction (hyperthyroidism or hypothyroidism) and drug abuse or dependence as contributing factors.

Premenstrual changes in hormone levels can exacerbate underlying medical conditions, including migraine, epilepsy, asthma, irritable bowel syndrome, and diabetes mellitus.[13] This is not PMS but may resemble it.

If behavioral symptoms are severe and are present throughout the menstrual cycle and if there is no clear pattern of increase in symptom severity during the luteal phase, another psychiatric diagnosis must be considered. The following psychiatric disorders must be excluded: major depression, panic and anxiety disorders, dysthymia, and personality disorder. Such patients should be referred to a psychiatrist for definitive diagnosis and treatment. The most important condition to exclude is depression.

Treatment

Available therapies for PMS/PMDD range from lifestyle modification to surgery. Sustained improvement in a woman with PMS/PMDD generally requires a combination of modalities. The severity of a patient's symptoms and her response to particular modalities should guide the choice of therapies and the pace of their introduction. Mild cases can be treated with lifestyle modification and nonpharmacologic options; severe cases deserve immediate and aggressive intervention.

NONPHARMACOLOGIC THERAPY

Lifestyle interventions for PMS include institution of good sleep patterns and regular exercise. The patient should reduce or eliminate the use of tobacco, alcohol, and other drugs.

Dietary treatment helps some patients. Calcium supplementation may be beneficial.[14] It has been suggested that diets high in carbohydrates and protein buttress the serotonergic axis.[15] A diet high in tryptophan, a precursor of serotonin, may also be of benefit for mild PMS.[16]

Full-spectrum bright-light therapy given in the evening has been shown to markedly reduce symptoms of PMS/PMDD. Its use can be limited to the luteal phase.[17,18]

Stress management is integral to lifestyle treatment. Biofeedback,[19] massage,[20] and other relaxation methods may be helpful. Education, emotional support, and attention from the physician or therapist are instrumental. However, almost any intervention can be temporarily helpful, as the placebo response is quite high in this disorder.

Some women may wish to treat their PMS with herbal remedies, such as oil of primrose, chaste tree berries, or St. John's wort [*see Clinical Essentials:XII Complementary and Alternative Medicine*]. The use of herbal medicine and other complementary and alternative measures for PMS/PMDD has not been strongly validated in randomized, controlled trials, however.[21]

Behavioral Therapy

Patients with PMS may benefit from cognitive-behavioral therapy or interpersonal therapy. These are formal, structured psychotherapies designed to help patients institute behavioral changes and address cognitive patterns that sustain maladaptative behavior. Response to treatment may take as long as 6 months, but the effects persist indefinitely. If a patient is having difficulty coping with her symptoms during the early months of psychotherapy, there is no reason not to add pharmacologic treatment. The effects of medication are more rapid in onset than those of psychotherapy, but the effects persist only as long as the patient takes the medication. The model of combined psychotherapy and pharmacotherapy is considered the most effective approach to major depression; it has not been formally tested in PMS/PMDD, but there is no reason to believe it would not work well in this disorder, given the similarities between depression and PMS/PMDD.

Disposition

Benefit from nonpharmacologic interventions should be evident within two menstrual cycles. If the patient has shown no improvement at all during that time, the clinician should move on to pharmacotherapy. Complete recovery is not to be expected, however; that seldom or never occurs, regardless of the therapy chosen. Nevertheless, it is unwise for the clinician to lower the patient's expectations about these modalities, because enthusiasm inspires patients to participate in therapy and enhances the placebo effect. To set the stage for follow-up without lowering expectations, the clinician can tell the patient,

Table 3 Pertinent History in PMS/PMDD

- Dysmenorrhea
- Psychosocial adjustments and stressors
- Diet
- Exercise
- Sleep
- Drug, alcohol, and medication use
- Endocrine disorders
- Family and personal history of psychiatric disorders

"I want to see how you are doing in 2 months. If you are feeling perfectly fine and don't want to come back in, just give me a call. In case you aren't perfectly fine, though, I would rather see you back."

It is reasonable to wait more than 2 months for a response in a patient who has initiated behavioral therapy in a formal psychiatric setting. On the other hand, with a patient who is in severe psychological distress, 2 months may be too long to wait. The worst-case scenario is that such a patient will interpret a prescription of lifestyle modification and a distant follow-up appointment as a dismissal by her physician and, in the meantime, commit suicide or a homicide or ruin her life in some way. Clinicians who have limited psychiatric expertise or who practice in a stringent managed-care setting that severely restricts follow-up should refer severely distressed patients to a psychiatrist.

Pharmacologic Therapies for Somatic Symptoms

Bromocriptine (2.5 mg/day orally) has been promoted as treatment for breast tenderness. Spironolactone (25 to 50 mg/day orally) has been given to alleviate bloating. Nonsteroidal anti-inflammatory drugs can be effective treatment for dysmenorrhea [*see 16:IV Dysmenorrhea*].

Progesterone treatment has been shown to be ineffective for PMS.[22] Oral contraceptives are likely to aggravate rather than attenuate PMS/PMDD symptoms.

Pharmacologic Therapies for Affective Symptoms

Because the pathogenesis of PMS/PMDD probably involves an aberrant CNS response to normal ovarian function, the first-line treatment is to buttress CNS function with antidepressants. The SSRIs fluoxetine and sertraline have been shown to be effective[2-4]; other agents in this class presumably would work but are not as well studied. Although use of SSRIs can be limited to the luteal phase (10 to 14 days), that approach is impractical for many patients, who may have difficulty determining when to start the drug. It is simpler for patients simply to take the medication every day.

Sertraline has a shorter half-life than fluoxetine. The advantage of a shorter half-life is that if the patient experiences unacceptable side effects, the side effects will fade more rapidly once the medication is discontinued. The most prominent side effect of SSRIs in patients with PMS/PMDD—and a common reason for poor compliance with SSRI therapy for the disorder—is sexual dysfunction.[23] Some patients are willing to accept impaired libido as a trade-off for the relief of their symptoms. Buspirone is mildly effective for PMS/PMDD and may be a useful alternative in patients who find the sexual side effects unacceptable.[24] Classified as an atypical antidepressant, buspirone tends to be used for the anxious variety of depression.

Benzodiazepine therapy with alprazolam, taken during the luteal phase, is appropriate for patients whose main symptom is anxiety.[25] However, alprazolam has many more side effects than do SSRIs, even though the dose can be titrated to minimize side effects.

Pharmacologic Interventions That Alter Ovarian Steroid Exposure

Patients with PMS/PMDD who fail to respond adequately to lifestyle modification and SSRI therapy or who refuse or are unable to follow such measures can be treated with gonadotropin-releasing hormone (GnRH) agonist therapy (e.g., leuprolide, nafarelin, or goserelin).[26-29] GnRH agonists effect a medical oophorectomy. They cannot be continued indefinitely without hormone replacement therapy because of concerns about the long-term deleterious effects of sustained hypoestrogenism. Add-back hormone regimens generally involve continuous exposure to small amounts of both estrogen and progestin,[29] thereby obviating the hormonal changes associated with a menstrual cycle.

There is a variety of hormonal preparations available for add-back regimens. It is usually a good idea to administer the estrogen and progestin separately at first, so that the response to each can be monitored. The progestin dose must be large enough to prevent endometrial hyperplasia but below the threshold for triggering PMS symptoms. Ongoing exposure to even small amounts of progestin (e.g., oral medroxyprogesterone acetate, 2.5 mg daily) may provoke symptoms, however.

The synthetic androgen danazol can be used to temporarily suppress endogenous ovarian function and provide an androgenic environment. However, its side effects may be as problematic as the PMS/PMDD symptoms. The androgenic side effects of danazol include voice changes, hirsutism, and breast regression, all of which may be permanent.

Surgical Therapy

GnRH agonist therapy is expensive, so if a patient is responding very well to a GnRH agonist and has completed her childbearing, oophorectomy and hysterectomy may be a reasonable step. Surgery may also be the therapy of choice for patients who have sustained improvement with GnRH-agonist therapy but experience recurrent symptoms with add-back hormone regimens. Postoperatively, these patients are given hormone replacement therapy with continuous estrogen alone. Continuing SSRI therapy may be indicated.

IV DYSMENORRHEA

Alan H. DeCherney, m.d.

Dysmenorrhea—colicky pain in the lower abdomen and pelvis around the time of menses—is a common condition that disturbs the lives and families of the women who suffer from it. Severe pain and discomfort often lead to absenteeism from work or school, resulting in an overall reduction in productivity and enormous economic loss.

Dysmenorrhea can be classified as primary or secondary, depending on its cause. Secondary dysmenorrhea results from a known pathologic process occurring within the pelvis. Primary dysmenorrhea does not have an anatomic cause.

Because many women seek help for this disorder, the physician should be sensitive to the concerns of each patient and provide a treatment that is specific to each patient's needs. The goal of therapy is to enable the patient to resume her daily life without the fear of being disabled by pain.

Primary Dysmenorrhea

The prevalence of primary dysmenorrhea is between 40% and 90%, with an average of 75%. It occurs predominantly in women younger than 25 years.

pathogenesis

Primary dysmenorrhea results from tissue hypoxia and ischemia. An elevation in the basal tone of the uterus, combined with an increase in contraction strength and frequency, leads to vasospasm and a reduction in uterine blood flow.[1] Increased levels of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), leukotrienes, and vasopressin are responsible for these alterations [*see Figure 1*].[2] It is important to note that this abnormality in prostaglandin production occurs only in endometrial tissue that has been exposed to both estrogen and progesterone.

diagnosis

Diagnosis of primary dysmenorrhea is based on patient history; results of physical examination are usually normal. Symptoms characteristically begin within 6 to 12 months after menarche, as ovulatory cycles become established. The pain occurs only during ovulatory cycles and lasts about 48 to 72 hours each month. In most patients, the pain starts a few hours before menstruation or at the onset of menstruation.

The degree of pain suffered is variable, but fewer than 15% of women with primary dysmenorrhea have severe pain. Patients with severe pain may also experience other symptoms, such as nausea, vomiting, dizziness, and diarrhea.

treatment

Treatment of primary dysmenorrhea includes nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives, and transcutaneous electrical nerve stimulation (TENS).[3] Other nonpharmacologic approaches that may be effective are the use of a lower abdominal heating pad,[4] supplemental vitamin B_1 (100 mg daily) or magnesium (400 mg daily),[5] and a low-fat vegetarian diet.[6]

NSAIDs inhibit the action of cyclooxygenase and prevent the conversion of arachidonic acid into prostaglandins (PGs). NSAIDs significantly alleviate pain in approximately 75% of patients. The fenamates (e.g., mefenamic acid) are considered the

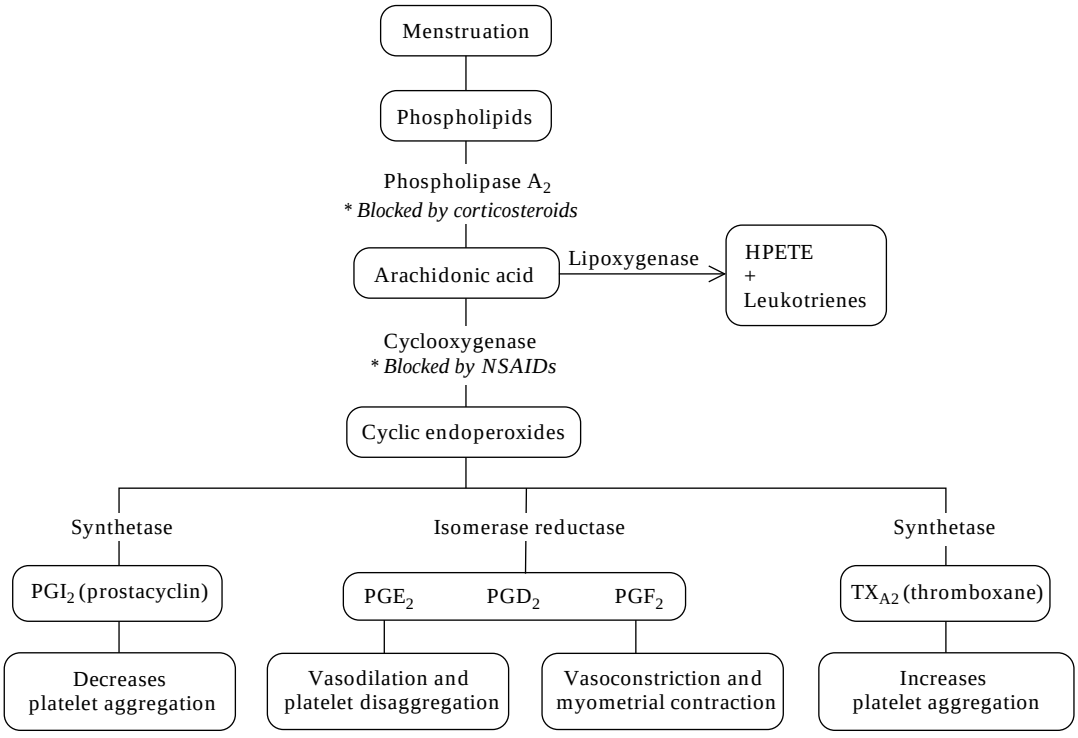

Figure 1 **Prostaglandin synthesis. (HPETE—hydroperoxyeicosatetraenoic acid)**

Table 1 Common Prostaglandin Synthesis Inhibitors

Chemical Group	*Derivative*	*Usual Dosage*
Benzoic acid	Acetylsalicylic acid (aspirin)	650 mg p.o. every 4 hr
Fenamates	Mefenamic acid	250 mg p.o. every 6 hr
	Meclofenamate sodium	100 mg p.o., t.i.d., for up to 6 days
Indoleacetic acid	Indomethacin	25–50 mg p.o. every 8 hr
Arylpropionic acid	Ibuprofen	400–800 mg p.o. every 4 hr
	Naproxen	250–500 mg p.o. every 12 hr
	Naproxen sodium	275–550 mg p.o. every 12 hr
Cyclooxygenase-2 (COX-2) inhibitors	Celecoxib	200 mg p.o., b.i.d.
	Rofecoxib	50 mg p.o., q.d.
	Valdecoxib	20 mg p.o., b.i.d.

best choice of NSAIDs because they act as antiprostaglandins, preventing both the production of PGs and the binding of the PG to its receptor [*see Table 1*].[7,8] Therapy with NSAIDs should be discontinued if adverse side effects occur.[9] Definitive research on the use of cyclooxygenase-2 (COX-2) inhibitors (e.g., celecoxib [Celebrex] or rofecoxib [Vioxx]) in dysmenorrhea has not been completed, but these agents seem promising for this purpose.

If NSAIDs are ineffective or poorly tolerated, the next step is the use of combined estrogen-progestin oral contraceptives. In a normal menstrual cycle, the progesterone level increases after ovulation and steadily decreases during the luteal phase. As the level of progesterone decreases, lysosomal enzymes within the endometrial cells are released, causing an increase in the production of PGs. Oral contraceptives prevent fluctuations of endogenous progesterone levels, reducing the amount of pain and symptoms associated with primary dysmenorrhea.[10] Regular-cycle oral contraceptives are not usually effective for treatment of primary dysmenorrhea; continuous oral contraceptives are preferable. Many patients consider continuous oral contraceptives unnatural but are willing to compromise by taking long-cycle contraceptives, so that they have three or four menses a year [*see 16:VI Contraception*].

If neither NSAIDs nor oral contraceptives alone alleviate primary dysmenorrhea, the two can be used together. If combination therapy also fails, the patient should be reevaluated and a diagnostic workup initiated for secondary dysmenorrhea.

Secondary Dysmenorrhea

The pain associated with secondary dysmenorrhea is the direct result of a pathologic process. Unlike primary dysmenorrhea, secondary dysmenorrhea varies with regard to the patient's age at onset and the causative condition. Some of the conditions that can cause secondary dysmenorrhea include endometriosis, adenomyosis, pelvic adhesions and infection, pelvic congestion, cervical stenosis, psychological stress, and psychological disturbances.

endometriosis

Endometriosis is the presence of endometrial glands and stroma outside the uterus [*see 16:X Endometriosis*]. Approximately 7% of women in the United States suffer from this disorder. Endometriosis causes intra-abdominal hemorrhage, fibrosis, and adhesion formation. Consequently, dyspareunia, infertility, and pelvic pain occur.[11]

The pain usually begins 2 to 3 days before menses and worsens during menstruation. Tender nodules along the uterosacral ligament, a posteriorly fixed uterus, and enlarged cystic ovaries are characteristic findings; however, results of physical examination are often normal. Definitive diagnosis requires direct visualization during laparoscopy, with or without a tissue biopsy.

Treatment may entail either medical intervention or surgery. Oral contraceptives, intramuscular injection of leuprolide acetate depot, oral danazol, or high-dose progestins (oral or intramuscular) are all beneficial in suppressing the endometrial implants and relieving the symptoms of pain.

adenomyosis

Adenomyosis is the presence of ectopic endometrial glands and stroma in the myometrium of the uterus. Unlike the ectopic glands in endometriosis, the ectopic glands in adenomyosis do not undergo monthly cyclical changes.

Symptoms of adenomyosis classically include dysmenorrhea and menorrhagia (heavy menstrual bleeding). As the disease progresses, so does the dysmenorrhea. On physical examination, the uterus is soft, globular, and uniformly enlarged. Typically, the uterus is tender just before and during menstruation.

Diagnostic aids include pelvic sonography, magnetic resonance imaging, and hysterosalpingography. Unfortunately, most cases go undiagnosed until histologic evaluation is made at the time of a hysterectomy.

Treatment starts with medical suppression of ovarian function and culminates in hysterectomy if symptoms do not abate. Thermal balloon ablation of the endometrium, which is an effective treatment for some patients with dysmenorrhea from other causes,[12] does not work in adenomyosis.

cervical stenosis

When menstrual flow is impeded at the level of the internal cervical os, intrauterine pressure increases and pelvic pain occurs. A narrow or stenotic os may be a congenital abnormality or the result of trauma, infection, or surgery.

The diagnosis of cervical stenosis should be considered in women who have a history of hypomenorrhea and severe pelvic pain during menses or if the diameter of the external cervical os is less than 5 mm.

During the physical examination, the physician should attempt to pass a uterine sound into the endometrial cavity. Inability to document a clear passage through the cervical canal warrants further investigation. Diagnostic workup with hysterosalpingography may reveal a narrow cervical canal.

Treatment consists of dilating the cervical canal with laminaria tents or performing a formal dilatation and curettage (D and C) under anesthesia. These procedures have limited therapeutic benefit and need to be repeated frequently. Complete resolution of symptoms typically occurs with pregnancy and vaginal delivery, which therefore is considered the ultimate therapy.

pelvic inflammatory disease

Most pelvic infections are caused by *Chlamydia*, *Neisseria gonorrhoeae*, and mixed microbial organisms. Pelvic anatomy is often distorted as a consequence of dense adhesion formation. During menstruation, adhesion edema and venous congestion

result in severe pelvic pain and discomfort. This pain may eventually become chronic.

Patients at risk for pelvic inflammatory disease (PID) include current or past users of intrauterine devices (IUDs) and women with more than one sexual partner. The workup includes cervical cultures, endometrial biopsy, and pelvic sonography.

Treatment of the dysmenorrhea associated with PID includes NSAIDs for pain management and antibiotics for acute infection. Surgery can be offered to patients with chronic pain and to those with a known tubo-ovarian abscess or hydrosalpinx. Although lysis of adhesions can be performed, results are usually poor because recurrence is high.

pelvic congestion syndrome

Engorgement and thrombosis of the pelvic veins are another cause of dysmenorrhea.[13] The pooling of blood in the pelvic vasculature results in a burning and throbbing pain. The pain is characteristically worse at night and after prolonged periods of standing. Bimanual examination often reveals a uterus that is mildly enlarged and tender to the touch. The diagnosis of pelvic congestion syndrome is made almost exclusively during laparoscopic evaluation.

Although the underlying cause of pain is not well understood, treatment often entails NSAIDs and psychological therapy. New treatment approaches that utilize uterine artery embolization show promising results. Hysterectomy should be reserved for patients who do not respond to other therapeutic modalities.

other causes of chronic pelvic pain

Secondary dysmenorrhea can also be caused by psychological problems, including stress, tension, and abnormal conditioned behavior. For these patients, resolution of symptoms is best achieved through lifestyle and behavior modification. Chronic pelvic pain, rather than acute pain, is more common among women with psychological disorders.

Patients who have pain for more than 6 months are considered to have chronic pelvic pain. In addition to a gynecologic cause of the pelvic pain, the physician should always consider other causes. The basic workup should include gastrointestinal, urologic, musculoskeletal, and psychological evaluations. Once a diagnosis has been established, treatment should focus on correcting the underlying disorder. Treatment should be initiated with medical therapy. If this fails, more aggressive treatment can be attempted, including presacral neurectomy or a laparoscopic uterine nerve ablation (LUNA) procedure.[14-16]

V POLYCYSTIC OVARY SYNDROME

Robert L. Barbieri, m.d.

Polycystic ovary syndrome (PCOS) is defined as hyperandrogenism and reduced frequency of ovulation in the absence of other hyperandrogenic disorders. The clinical manifestations of PCOS in women with hyperandrogenism are cosmetic and reproductive. These patients present with hirsutism, acne, and irregular menstrual periods; ovulation may be infrequent or absent, and infertility can occur.

When assessing a patient with possible PCOS, the physician must rule out other conditions that can produce clinical hyperandrogenism, such as androgen-secreting tumors and nonclassic congenital adrenal hyperplasia. It is also necessary to identify patients whose hirsutism or acne results from increased sensitivity to normal androgen levels.

Epidemiology

PCOS is one of the most common endocrine disorders of women. In three population-based studies, the average prevalence of PCOS in women of reproductive age was reported to be about 6%.[1-3] Among anovulatory women, the prevalence of PCOS is approximately 30%.[4]

Pathophysiology

In women, luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH) normally drive the secretion of androgens by the ovaries and adrenal glands, respectively. PCOS is caused by abnormally increased secretion of LH, insulin, or both. Increased levels of those hormones stimulate the ovarian theca and stroma to produce excess quantities of androgen, including testosterone and androstenedione. Elevated ovarian androgen secretion tends to block the growth of a dominant ovarian follicle. Instead, many small follicles accumulate; these follicles range in size from 4 to 8 mm in diameter. In the absence of a dominant follicle, an LH surge is not triggered, and ovulation does not occur regularly.

About 95% of women with PCOS have elevated levels of LH secretion, and 50% have hyperinsulinemia.[5] Those rates are influenced by body mass and genetics. In a population with a high prevalence of obesity, up to 100% of the women with PCOS will have hyperinsulinemia. Indeed, there may be two major phenotypes of PCOS: (1) lean women with markedly elevated levels of LH secretion and minimal or no insulin resistance and (2) obese women with slightly elevated or normal levels of LH secretion and insulin resistance and with markedly elevated levels of insulin secretion.

Women with PCOS show an abnormal increase in both the amplitude and the frequency of LH pulses in the early follicular phase of the menstrual cycle.[6] The elevated LH pulse frequency suggests an underlying increase in the pulse frequency of gonadotropin-releasing hormone (GnRH) secretion by the hypothalamus; this in turn suggests that PCOS results from a neuroendocrine disorder. The neuroendocrine mechanisms that raise GnRH pulse frequency are poorly characterized but may include alterations in hypothalamic opioid and catecholamine tone.

The insulin resistance in women with PCOS, as in other patients, has many possible causes, including genetic mutations in the insulin receptor and autoantibodies to the insulin receptor. The most common cause, however, is obesity. When pancreatic function is normal, resistance to the action of insulin in the liver, adipose tissue, muscle, and other insulin-sensitive tissues results in a compensatory and chronic hypersecretion of insulin. Laboratory studies suggest that insulin, especially in high concentrations, can stimulate ovarian androgen secretion.[7] Why insulin resistance develops in muscle and fat but not the ovary remains unclear. It is possible that insulin stimulates ovarian androgen secretion indirectly by binding to the insulin-like growth factor–1 receptor in the theca and the stroma.

Hirsutism

At birth, all areas of the body except the scalp and eyebrows are covered with vellus hair, which is light colored; individual vellus hairs have a very narrow diameter. Androgens can transform vellus hair into terminal hair, which is dark; individual terminal hairs have a thick diameter. The amount of androgen necessary to stimulate this transformation depends on many factors, including the sensitivity of hair follicles to androgens and the site of the hair follicle on the body. When girls reach puberty, small quantities of adrenal and ovarian androgens stimulate the transformation of vellus hair in the pubic region and axilla into terminal hair. Substantially larger amounts of androgen are required to stimulate the growth of terminal hair in a male-pattern distribution—that is, on the face, chest, and abdomen.

The term hirsutism denotes an increase in terminal hair in a male-pattern distribution. Hirsutism varies considerably by race: it is rare in Asian women, for example, because their hair follicles are relatively insensitive to androgens. In some families, women may inherit heightened sensitivity of the follicles to androgens and therefore may experience a degree of hirsutism at normal levels of circulating androgens.

Acne

The hair follicle is part of the pilosebaceous unit, which also contains a sweat or sebaceous gland. Androgenic stimulation of the pilosebaceous unit promotes not only hair growth but also the production of sebum. Blockage of the follicle by excessive sebum (in concert with inflammation from free fatty acids produced by bacteria and yeast in the follicle) produces acne. The pilosebaceous unit is both a target organ responsive to androgen stimulation and a site of androgen production and metabolism.[8] Consequently, acne, like hirsutism, reflects both circulating androgen concentrations and genetic makeup.

Diagnosis

In PCOS, hyperandrogenism and oligo-ovulation or anovulation are present, but other hyperandrogenic disorders, such as androgen-secreting tumors and nonclassic adrenal hyperplasia, are absent.

No single feature is pathognomonic for PCOS. The history, physical examination, and laboratory evaluation can all provide evidence that establishes the diagnosis of PCOS and that excludes other conditions associated with those features. Clinical evidence of hyperandrogenism includes hirsutism, acne, and menstrual irregularity. Laboratory evidence of hyperandrogenism includes an elevated total or free serum testosterone concentration [*see Table 1*].

HISTORY

The history can provide key information in the differential diagnosis of androgen excess (and heightened androgen sensitivity) in women.

Age of Onset

In PCOS, oligomenorrhea, hirsutism, and acne typically begin in the perimenarchal or teenage years. The onset of severe hirsutism in menopause suggests an ovarian neoplasm.

Menstrual History

Patients with PCOS typically experience irregular menstrual cycles starting at menarche. Regular cycles are more consistent with familial or idiopathic hirsutism. A history of initially regular periods followed by onset of oligomenorrhea or amenorrhea and hirsutism with virilization in adult life suggests an androgen-secreting tumor.

Pace of Progression of Hirsutism

In PCOS, hirsutism tends to progress slowly, over many years. Rapid progression to severe hirsutism suggests a virilizing disorder from an androgen-secreting tumor. Patients with androgen-secreting tumors typically report other manifestations of virilization, such as deepening of the voice and secondary amenorrhea. Virilization will be evident on the physical examination (see below).

Family History

Approximately 50% of women with PCOS have a family history of PCOS, type 2 diabetes mellitus, or both. Alternatively, the history may disclose familial hirsutism, which begins at puberty and is accompanied by regular menstrual cycles and normal concentrations of circulating androgens. In the absence of a positive family history, hirsutism that is disproportionate to the patient's racial background and is accompanied by regular periods is considered idiopathic, if laboratory test results are normal (see below).

Medication Use

Some medications appear to cause increased LH secretion and thus promote the development of PCOS. In particular, long-term use of the anticonvulsant valproate is strongly associated with the onset of PCOS.[9]

Cigarette Smoking

Women who smoke have higher concentrations of androstenedione and testosterone than do nonsmoking women.[10] Hence, smoking may contribute to hyperandrogenism.

PHYSICAL EXAMINATION

Hirsutism can be assessed objectively with the Ferriman-Gallwey scoring system [*see Figure 1*].[11] Along with providing a baseline measurement of hirsutism, this system can also be used to follow the efficacy of treatment.

Various physical findings point to insulin resistance [*see Table 2*]. Excess weight is a major determinant of insulin resistance and hyperinsulinemia.[12] Relative weight is best assessed by means of the body mass index (BMI), which is calculated by dividing the patient's weight in kilograms by the square of the patient's height in meters. Women with a BMI of greater than 27 (i.e., those who are overweight) are often insulin resistant and usually demonstrate hyperinsulinemia in response to a glucose stimulus. Women with a BMI of greater than 30 (i.e., those who are obese) are almost always insulin resistant. Women with a BMI of less than 22 are unlikely to be insulin resistant unless they have one of a relatively rare group of acquired or inherited lipodystrophic disorders.

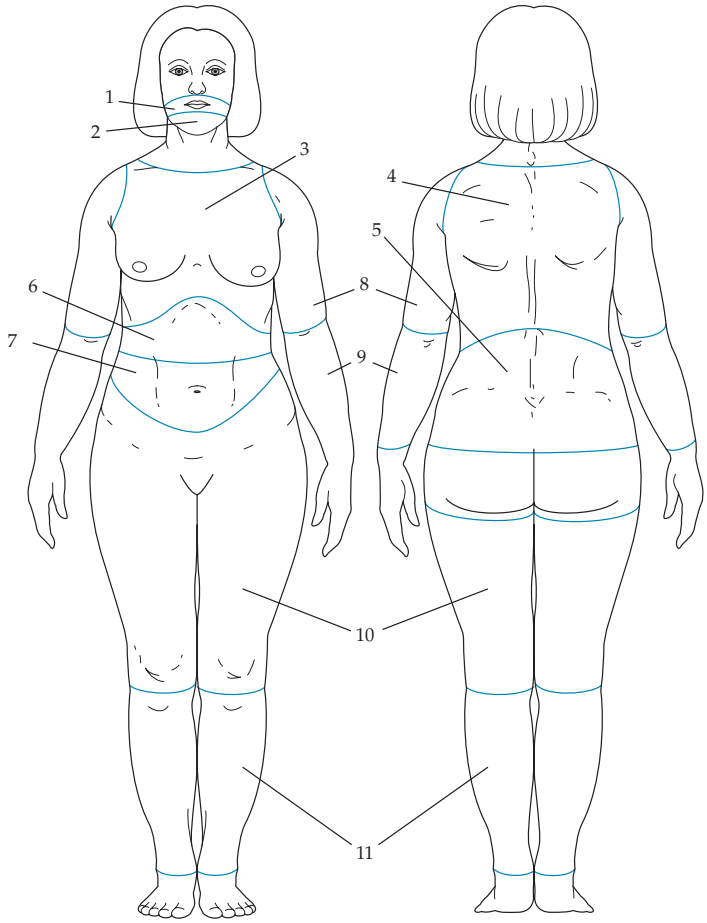
Other physical findings that suggest insulin resistance are a waist-to-hip ratio greater than 0.85 and a waist circumference greater than 90 cm (35.5 in). The presence of acanthosis nigricans or achrochordons (skin tags) suggests hyperinsulinemia. The syndrome of hyperandrogenism, insulin resistance, and acanthosis nigricans (HAIR-AN syndrome) is the most severe form of the insulin-resistant phenotype of PCOS.

Unfortunately, the physical findings that are associated with insulin resistance tend to be specific but not sensitive. For example, patients with acanthosis nigricans are almost always in-

Table 1 Characteristics of Common Causes of Androgen Excess

Diagnosis	*Cause*	*Ovulation Status*	*Testosterone Level*	*8 A.M. Follicular-Phase 17-Hydroxyprogesterone Level*
PCOS	Elevated LH, serum insulin, or both	Anovulation or oligo-ovulation	Elevated (0.75–2 ng/ml)	Normal (< 4 ng/ml)
Idiopathic hirsutism	Elevated production of androgen in the pilosebaceous unit, or a mild form of PCOS	Regular ovulation	Normal (< 0.75 ng/ml)	Normal (< 4 ng/ml)
Adrenal hyperplasia	Decrease in 21-hydroxylase activity because of a gene mutation	Anovulation or oligo-ovulation	Elevated (0.75-2 ng/ml)	Elevated (> 4 ng/ml)
Ovarian or adrenal tumor	Disorder of cell growth	Anovulation	Markedly elevated (> 2 ng/ml)	May be elevated

LH— luteinizing hormone PCOS—polycystic ovary syndrome



Site	Grade	Definition
1. Upper Lip	1	Few hairs at outer margin
	2	Small mustache at outer margin
	3	Mustache extending halfway from outer margin
	4	Mustache extending to midline
2. Chin	1	Few scattered hairs
	2	Scattered hairs with small concentrations
	3 and 4	Complete cover, light and heavy
3. Chest	1	Circumareolar hairs
	2	With midline hair in addition
	3	Fusion of these areas, with three-quarters cover
	4	Complete cover
4. Upper Back	1	Few scattered hairs
	2	Rather more, still scattered
	3 and 4	Complete cover, light and heavy
5. Lower Back	1	Sacral tuft of hair
	2	With some lateral extension
	3	Three-quarters cover
	4	Complete cover
6. Upper Abdomen	1	Few midline hairs
	2	Rather more, still midline
	3 and 4	Half and full cover
7. Lower Abdomen	1	Few midline hairs
	2	Midline streak of hair
	3	Midline band of hair
	4	Inverted V-shaped growth
8. Arm	1	Sparse growth affecting not more than one quarter of limb surface
	2	More than this; cover still incomplete
	3 and 4	Complete cover, light and heavy
9. Forearm	1, 2, 3, and 4	Complete cover of dorsal surface; 2 grades of light and 2 of heavy growth
10. Thigh	1, 2, 3, and 4	As for arm
11. Leg	1, 2, 3, and 4	As for arm

Figure 1 **Ferriman-Gallwey scoring system for quantitating hirsutism. The 11 sites are graded from 0 (no terminal hair) to 4 (severe hirsutism). Women with a total score greater than 8 are considered hirsute.[11]**

sulin resistant, but many women with insulin resistance do not have acanthosis nigricans.[13] Although the identification of severe insulin resistance on the basis of clinical manifestations may be relatively simple, the detection of mild insulin resistance may be difficult.

A key aspect of the physical examination is a search for signs of virilization, such as clitoromegaly, increased upper body muscle mass, and male pattern baldness. These may indicate the presence of an androgen-secreting tumor.

Women with PCOS have enlarged ovaries, although the ovaries typically are not palpable on pelvic examination. If pelvic examination discloses a large, complex mass, the patient may have an adrenal or ovarian tumor.

LABORATORY TESTS

The goals of the laboratory evaluation of hyperandrogenism are to rule out an adrenal and ovarian tumor, assess the severity of the androgen excess, and determine whether the source of the hyperandrogenism is adrenal or ovarian. Laboratory tests that are the most useful in the evaluation of hyperandrogenism include determination of the total serum testosterone level; determination of the 8 A.M. follicular phase 17-hydroxyprogesterone level; determination of the serum dehydroepiandrosterone sulfate (DHEAS) level (if fertility is an issue); and determination of the serum prolactin level (if the patient has amenorrhea).

Testosterone

The serum testosterone concentration provides the best laboratory estimate of the severity of androgen overproduction. Either total or free testosterone can be measured. Total testosterone measurement is performed by all clinical laboratories; these tests are well standardized and are less expensive than free testosterone measurement. However, because the level of sex hormone–binding globulin decreases as testosterone production increases, the total testosterone level does not fully reflect the degree of hyperandrogenism, especially if the overproduction of testosterone is minimal. Many women with mild PCOS have a total testosterone level in the upper end of the normal range. If the total testosterone level is greater than 2 ng/ml (200 ng/dl), the patient probably has ovarian stromal hyperthecosis or an adrenal or ovarian tumor and needs a detailed evaluation, which should include imaging studies of the ovary and adrenal glands.

The free testosterone measurement is more sensitive in detecting mild androgen overproduction. Nevertheless, because the total testosterone adequately identifies women with marked

Table 2 Physical Findings Associated with Insulin Resistance

Body mass index* > 27	Acanthosis nigricans
Waist-to-hip ratio > 0.85	Numerous achrochordons (skin tags)
Waist > 90 cm	

*Calculated by dividing the patient's weight in kilograms by the square of her height in meters.

androgen overproduction who need additional evaluation and because free testosterone is usually more expensive to assay, measurement of free testosterone is not routinely indicated.

17-Hydroxyprogesterone

Approximately 2% of women who present with hyperandrogenism and oligo-ovulation or anovulation have nonclassic adrenal hyperplasia resulting from a 21-hydroxylase deficiency. The prevalence of this congenital disorder varies markedly among different ethnic groups, from below 1% in Hispanic populations to as high as 5% to 8% in Ashkenazi Jewish populations. The decision to screen for the disorder depends on the cost-benefit assessment of detection and the baseline prevalence of the disorder in the patient's ethnic group.

If the 17-hydroxyprogesterone level at 8 A.M. (measured in the follicular phase of the menstrual cycle) is greater than 4 ng/ml, the patient probably has nonclassic adrenal hyperplasia resulting from a 21-hydroxylase deficiency. This diagnosis can be confirmed by a 60-minute ACTH stimulation test. The test utilizes a form of synthetic ACTH (cosyntropin) that contains the first 24 of the 39 amino acids of natural ACTH: 0.25 mg is given intravenously or intramuscularly, and the 17-hydroxyprogesterone level is measured 60 minutes later. A post-ACTH 17-hydroxyprogesterone level greater than 10 ng/ml confirms the diagnosis of nonclassic adrenal hyperplasia resulting from a 21-hydroxylase deficiency.

DHEAS

DHEAS, an androgen prohormone that can be converted to testosterone in the periphery, is secreted almost exclusively by the adrenal glands. The normal DHEAS level in premenopausal women is 0.12 to 5.35 µg/dl. A DHEAS level above 10.70 µg/dl—that is, more than twice the upper limit of normal—should raise concern over a possible adrenal tumor. Many women with PCOS have a DHEAS level in the upper range of normal, for reasons that have not been clearly identified. In infertile women with PCOS whose DHEAS level is greater than 2 µg/ml, the combination of clomiphene and a glucocorticoid may result in higher pregnancy rates than clomiphene alone (see below).

Serum Prolactin

If the patient has amenorrhea, the laboratory workup should include an assessment of the serum prolactin level to rule out a prolactin-secreting pituitary tumor [*see 16:I Amenorrhea*]. Many clinicians also routinely measure serum follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH) levels in amenorrheic patients.

Serum Luteinizing Hormone

The measurement of serum LH presents a special problem in the laboratory evaluation of PCOS. In the research setting—using multiple serum LH measurements (every 10 minutes for at least 8 hours) and a precise and reliable LH assay—elevated LH levels can be documented in about 95% of women with PCOS. However, because LH secretion is pulsatile and the standard commercial assays are not as precise as research assays, measurement of LH in clinical practice is of only modest utility. An elevated LH level is reasonably specific for PCOS, provided the sample was not taken during a preovulatory LH surge. A normal LH value does not necessarily exclude PCOS, however, because the test sample may have been drawn when the patient was at the nadir of an LH pulse. Another important point is that as BMI increases, the normal range for LH decreases [*see Figure 2*].[14] Nomograms that control serum LH for BMI are not widely available.

Pelvic Imaging

Demonstration of polycystic ovaries on pelvic ultrasonography is not essential for the diagnosis of PCOS. Pelvic imaging is indicated only if the ovaries are palpable on physical examination or the total testosterone concentration is greater than 200 mg/dl.

Tests for Detection of Insulin Resistance and Hyperinsulinemia

About 50% of women with PCOS have insulin resistance and hyperinsulinemia. There is no clear consensus on how to detect those conditions. A major problem is that the least resource-intensive laboratory techniques for diagnosing insulin resistance and hyperinsulinemia are specific but not sensitive. Elevation of the fasting serum insulin level or a fasting serum insulin-to-glucose ratio of less than 4.5 is almost always associ-

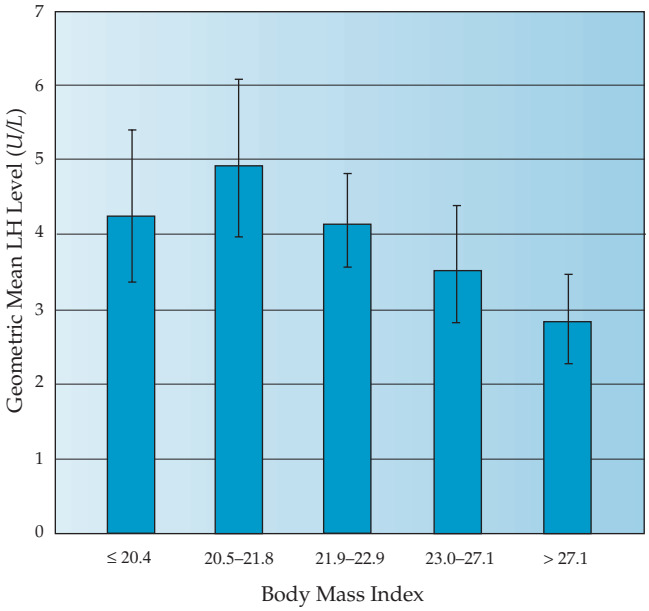


Figure 2 **Relationship between body mass index (BMI) and basal luteinizing hormone (LH) levels in women in the follicular phase of the menstrual cycle.[14]**

ated with insulin resistance, but many insulin-resistant women do not have fasting hyperinsulinemia. Laboratory techniques that are both specific and sensitive for detecting insulin resistance, such as euglycemic hyperinsulinemic clamp studies, are too complex and expensive for application in general clinical practice. Until both specific and sensitive laboratory tests that can be widely applied in practice become available, clinicians should use clinical findings and, if necessary, simple laboratory tests—such as assessment of fasting insulin levels or assessment of insulin response to an oral glucose challenge—to identify women with insulin resistance. Even nonobese women with PCOS have marked increases in circulating insulin after a glucose challenge [*see Figure 3*].[15]

Differential Diagnosis

IDIOPATHIC HIRSUTISM

Idiopathic hirsutism is defined as hirsutism in a woman with regular, ovulatory menstrual cycles. Women with idiopathic hirsutism have circulating testosterone and androstenedione concentrations at the upper limit of the normal range, but in these patients, such levels are lower than the levels observed in women with PCOS. Women with idiopathic hirsutism often have sisters with PCOS, and they tend to have a lower BMI than the sisters with PCOS.[16,17] Many authorities believe that idiopathic hirsutism is a mild form of PCOS in which hyperandrogenism is present but the disease has not progressed to the point where ovulatory menses have become disrupted. Other authorities believe that idiopathic hirsutism is the result of overactive skin conversion of weak precursor androgens (e.g., as androstenedione) to potent androgens (e.g., dihydrotestosterone) directly in the pilosebaceous unit. Regardless of the etiology, idiopathic hirsutism is best treated with the same approach as that for hirsutism in women with PCOS (see below).

VIRILIZATION SYNDROMES

Women with the rapid onset of virilization or a serum testosterone level greater than 2 ng/ml (200 ng/dl) should be evaluated for an adrenal or ovarian tumor. Use of magnetic resonance imaging to screen for an adrenal tumor and use of pelvic sonography to screen for an ovarian tumor are helpful.

Adrenal carcinoma presents with the rapid onset of virilization; it is often associated with systemic symptoms such as fatigue, weakness, and weight loss. DHEAS concentration is often greater than 8 µg/ml, and 24-hour urinary 17-ketosteroid excretion is markedly increased, to about 30 mg/dl.

OVARIAN HYPERTHECOSIS

Careful histologic examination of ovaries from women with PCOS often reveals islands of luteinized, steroid-secreting stromal cells (stromal hyperthecosis) in the medullary portion of the ovary that are not associated with follicular structures.[18] Severely hyperthecotic ovaries may contain only a small number of follicles, each 4 to 8 mm in diameter. PCOS patients with more severe hyperinsulinemia seem to be at highest risk for hyperthecosis.

Only a small subset of women with hyperandrogenism have stromal hyperthecosis. The diagnosis should be considered in a

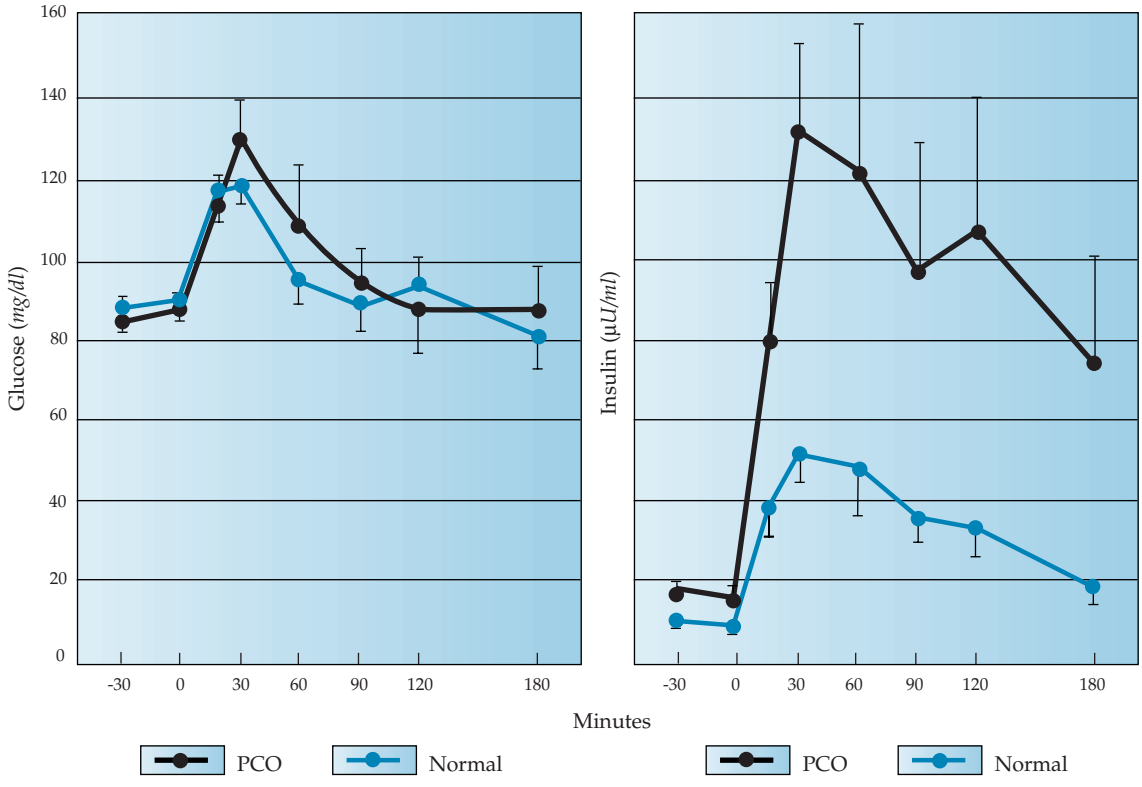

Figure 3 **In response to an oral glucose challenge, nonobese women with PCOS experience an exaggerated increase in circulating insulin compared with weight-matched control subjects; the increase persists for over 3 hours.[15]**

patient who presents with virilization, a total serum testosterone concentration of greater than 2 ng/ml, a normal LH level, and marked insulin resistance and hyperinsulinemia. Pathologic confirmation of the diagnosis, which requires removal of the ovaries, is not necessary.

Differentiation of ovarian hyperthecosis from PCOS is important because women with ovarian hyperthecosis often do not have significant suppression of circulating testosterone when treated with estrogen-progestin contraceptive alone. Instead, treatment with a GnRH analogue (e.g., leuprolide acetate depot, 3.75 mg intramuscularly every 4 weeks) plus an estrogen-progestin contraceptive often results in the normalization of circulating androgens.[19] A possible interpretation of this observation is that LH must be profoundly suppressed to decrease ovarian androgen production in women with hyperthecotic ovaries. Low-dose estrogen-progestin contraceptives alone do not suppress pituitary LH secretion as completely as they do in combination with a GnRH agonist analogue.

Treatment

Treatment for PCOS may be general—directed at the underlying hormonal imbalance—or specific to a particular manifestation (e.g., hirsutism or infertility) [*see Table 3*]. PCOS should be treated, because it poses long-term risks of endometrial cancer, diabetes mellitus, and possibly cardiovascular disease.

Regardless of the patient's presenting complaint, treatment of PCOS in a woman who smokes cigarettes includes smoking cessation. Discontinuance of smoking may result in a reduction in circulating androgens; also, smoking is a contraindication to the use of oral contraceptives, which are often prescribed for patients with PCOS.

TREATMENT OF HIRSUTISM

The mainstay of the treatment of hirsutism resulting from androgen excess is the combination of an estrogen-progestin oral contraceptive (used in regular or long cycles) and an antiandrogen. Patients should be advised that response to therapy tends to be slow; for more immediate results, patients may prefer the use of techniques that directly destroy the hair follicle.

Oral Contraceptives

Cyclic estrogen-progestin oral contraceptives produce multiple beneficial effects in patients with PCOS. These effects include the following: (1) decreased LH secretion, which suppresses ovarian androgen production; (2) increased liver production of sex hormone–binding globulin, which decreases free testosterone concentration; (3) decreased adrenal androgen production, through an unidentified pathway; (4) prevention of endometrial hyperplasia; and (5) regular uterine withdrawal bleeding. Of course, oral contraceptives also prevent pregnancy. The choice of agent does not seem important; it appears that any oral contraceptive, regardless of the estrogen dose or the progestin employed, can be effective in the treatment of hirsutism.

By suppressing both ovarian and adrenal androgen production, oral contraceptives decrease the stimulus to terminal hair growth. In patients with hirsutism, therapy with an oral contraceptive first brings a decrease in the diameter of the hair shaft and in the intensity of pigment in the hair—the unwanted hair becomes thinner and lighter in color. With prolonged treatment, the linear rate of hair growth diminishes. Ultimately, the hair follicle becomes senescent. If no new hair follicle starts to grow, the hirsutism then diminishes.

Long-cycle oral contraceptives When oral contraceptives are used in a standard cyclic manner (21 days of active pills followed by 7 days of inactive pills), LH secretion tends to increase during the 7 days in which inactive pills are taken. This stimulates a small rise in ovarian testosterone secretion, which, in turn, can stimulate hair growth. As an alternative, oral contraceptives can be taken in a continuous manner. In the initial treatment of hirsutism caused by PCOS, use of continuous oral contraceptives may be more effective than use of cyclic oral contraceptives for the suppression of LH and androgen production.[20]

Table 3 Treatment of Hirsutism, Anovulatory Infertility, and Endometrial Hyperplasia in Women with PCOS

Presenting Problem	*Standard Treatment*	*Alternative Treatment*
Hirsutism	Oral contraceptive plus spironolactone Weight loss	Oral contraceptive used in a long-cycle regimen, plus spironolactone Oral contraceptive plus GnRH analogue Insulin sensitizer, preferably metformin Finasteride
Acne	Oral contraceptive	Topical agents, oral antibiotics
Infertility	Weight loss Clomiphene Metformin plus clomiphene Clomiphene plus glucocorticoids Low-dose FSH injections Low-dose FSH injections plus metformin	Ovarian surgery IVF-ET
Endometrial hyperplasia	Oral contraceptives High-dose progestins	Weight loss

FSH—follicle-stimulating hormone GnRH—gonadotropin-releasing hormone IVF-ET—in vitro fertilization with embryo transfer

Most women with PCOS would like to restore a regular pattern of menses. To accommodate this desire while maximally suppressing LH levels, the clinician can employ the following regimen: the patient takes an active pill daily for 63 days (using the active pills from three packs), then takes inactive pills for 7 days. This long-cycle oral contraceptive regimen may induce regular withdrawal bleeding every other month and produce better suppression of LH and testosterone than oral contraceptives used in monthly cycles.

Antiandrogens

Antiandrogens are a cornerstone of therapy for hirsutism. In a 1-year trial, antiandrogen therapy using cyproterone acetate, 50 mg daily, plus ethinyl estradiol on cycle days 16 through 25, was compared with glucocorticoid suppression with hydrocortisone, 20 mg daily. Although hydrocortisone was more effective at normalizing plasma androgen levels, cyproterone provided superior treatment of hirsutism.[21] This study demonstrated that in established hirsutism, suppressing circulating androgens to normal levels is less important than blocking peripheral androgen action in the pilosebaceous unit.

Cyproterone acetate is not available in the United States. However, spironolactone has proved to be an effective antiandrogen, and its effects on hirsutism are similar to those of cyproterone acetate.[22] Because spironolactone has been used for many decades in the treatment of hirsutism and has an excellent safety profile, it should be considered the first-line agent for this indication in the United States. The usual dosage of spironolactone as an antiandrogen is 100 mg once daily.

The 5α-reductase inhibitor finasteride, which the Food and Drug Administration has approved only for treatment of men with benign prostatic hyperplasia, also reduces hirsutism in women.[23] The dosage of finasteride is 5 mg daily.

The androgen receptor antagonist flutamide (Eulexin) is as effective as spironolactone and finasteride in the treatment of hirsutism, but flutamide has liver toxicity and may cause fulminant liver failure.[24] Although the risk of liver failure with flutamide is small, hirsutism is a benign condition, so treatment regimens must have a high degree of safety.

Spironolactone, finasteride, and flutamide are believed to be human teratogens and may induce abnormal genital tract development in male fetuses. Women taking these agents need to use effective birth control. In addition, spironolactone, finasteride, and flutamide do not protect against endometrial hyperplasia and are not likely to induce regular menstrual cycles. These considerations support the use of an oral contraceptive in combination with an antiandrogen in the treatment of hirsutism in women of reproductive age.

Weight Loss

Numerous studies have demonstrated the benefits of weight loss in hyperandrogenic, insulin-resistant women.[25-27] In these studies, mean weight loss ranging from about 10 to 20 kg has been associated with a decrease in insulin levels and testosterone concentration and with ovulation and subsequent pregnancy in many women.[28-30]

Weight loss is difficult to achieve. A structured program that includes consultation with a nutritionist, encouragement by the physician, a low-calorie diet, and initiation of an exercise program may be the most effective nonsurgical approach in these patients. Surgical methods of weight reduction can be very effective, especially in women whose BMI is greater than 40.

Gonadotropin-Releasing Hormone Agonists

Women with hirsutism who do not respond to treatment with an oral contraceptive plus an antiandrogen can often be successfully treated with a combination of a GnRH agonist (e.g., leuprolide acetate) and an oral contraceptive,[31] with or without an antiandrogen. It is likely that the combination of leuprolide and an oral contraceptive produces greater suppression of LH and androgens than the oral contraceptive alone. Leuprolide is not ordinarily recommended as a first-line therapy for hirsutism because it is expensive (costing approximately $400 a month). Also, when used as a single agent, a GnRH agonist produces profound hypoestrogenism and accelerated bone loss. The addition of an oral contraceptive prevents GnRH agonist–induced hypoestrogenism and vasomotor symptoms and preserves bone density.

Glucocorticoids

Treatment with glucocorticoids may be appropriate in women with ACTH-dependent adrenal androgen overproduction, such as those with nonclassic adrenal hyperplasia resulting from 21-hydroxylase deficiency,[32,33] but it is not appropriate for the treatment of hirsutism in PCOS. A major problem with glucocorticoid therapy is that the complete suppression of ACTH production often requires giving more glucocorticoid than would normally be produced by the adrenal glands. As a result, patients receiving long-term glucocorticoid treatment are at increased risk for iatrogenic Cushing syndrome, osteoporosis, and diabetes mellitus. In addition, the corticotropin-releasing hormone–ACTH–cortisol axis may become so suppressed that the adrenal response to stress is blunted. For those reasons, I avoid using glucocorticoids to treat hirsutism. If the clinician does decide to use glucocorticoid therapy, use of low-dose glucocorticoids (5 or 7.5 mg of prednisone daily) or an alternate-day regimen of glucocorticoids may minimize those risks. Also, because almost all women treated with glucocorticoids gain weight and many develop osteoporosis, the clinician should carefully monitor weight and bone density in these patients.

Ovarian Surgery

Ovarian surgery can be used to decrease the mass of androgen-secreting thecal and stromal tissue. No randomized, controlled trials have been published concerning the benefits and risks of ovarian surgery for hyperandrogenism. In my opinion, the risks of ovarian surgery are greater than the potential benefits for women with hirsutism. I recommend ovarian surgery only for women with PCOS and infertility in whom conservative therapy has failed (see below).

Laser, Electrolysis, and Depilatory Treatment

Techniques that directly destroy the hair follicle are helpful in the treatment of hirsutism. Mechanical techniques include plucking, waxing, and shaving. These methods do not lead to a worsening of hirsutism, as some people believe, but may cause skin irritation. Electrolysis can destroy both the hair and the cells responsible for the growth of the hair, thereby producing a more prolonged beneficial effect than mechanical techniques.

Laser therapy is an evolving technique that is highly effective in the treatment of hirsutism. Multiple case series have

been reported using the ruby laser to treat hirsutism. The melanin in the hair is used as a natural chromophore. The energy delivered by the ruby laser causes photothermal damage to the hair and key cells surrounding the hair, which may prevent hair regrowth. In one study, two treatments with the ruby laser resulted in a 50% reduction in hair follicle density.[34] Unwanted side effects of laser treatment of hirsutism include skin hyperpigmentation and hypopigmentation and pitting of the skin surface. Most of these changes resolve spontaneously over 6 months.[35]

A new chemical inhibitor of hair growth is eflornithine 13.9% cream (Vaniqa). Eflornithine irreversibly inhibits the activity of skin ornithine decarboxylase, an enzyme that is necessary for the synthesis of polyamines and hence for hair growth. In clinical studies, which excluded pregnant and nursing women, eflornithine reduced facial hirsutism.[36]

TREATMENT OF ACNE

As with treatment of hirsutism, treatment of acne in PCOS patients begins with an oral contraceptive. Randomized, placebo-controlled clinical trials have demonstrated the benefits of combination estrogen-progestin oral contraceptives for acne after 6 months of treatment.[37,38] Because norgestrel is more androgenic than gestodene and desogestrel, some authorities recommend, on theoretical grounds, that oral contraceptives containing one of the latter progestins be used to treat acne.

Topical agents and oral antibiotics may also be indicated for acne in women with PCOS [*see 2:XII Acne Vulgaris and Related Disorders*].

TREATMENT OF ANOVULATION

Ovulation induction in PCOS follows a stepwise approach [*see Table 4*]. If the BMI is greater than 27, weight loss is an important goal. If normalization of the BMI cannot be achieved, clomiphene citrate is often prescribed because it is relatively inexpensive and has an excellent safety profile. Hyperandrogenic, insulin-resistant women are more likely to fail to ovulate and become pregnant with clomiphene than are women who are not insulin resistant. If both weight loss and clomiphene do not induce ovulation and result in pregnancy, the currently available choices for ovulation induction include insulin-sensitizing agents (for patients with insulin resistance), FSH injections, ovarian surgery, and in vitro fertilization with embryo transfer (IVF-ET).

Table 4 A Stepwise Approach to the Induction of Ovulation in Infertile Women with PCOS*

Step 1: if BMI is > 27, weight loss of at least 10%
Step 2: clomiphene
Step 3: if DHEAS > 2 µg/ml (200 µg/dl), clomiphene plus glucocorticoid therapy
Step 4: metformin for 8 to 12 wk
Step 5: metformin plus clomiphene
Step 6: low-dose FSH therapy
Step 7: metformin plus low-dose FSH therapy
Step 8: in vitro fertilization
Step 9: laparoscopic ovarian surgery to reduce ovarian androgen production

*Steps proceed in order of increasing resource intensity.

Weight Loss

Many women with PCOS are overweight or obese. In such women, weight loss (see above) is associated with a decrease in insulin secretion, a decrease in LH secretion, and a decrease in androgen production. The result is often a resumption of regular ovulation and, in some women, pregnancy.

Clomiphene Citrate

Clomiphene citrate is the most widely used agent for ovulation induction in women with PCOS. The FDA-approved doses for clomiphene are 50 or 100 mg daily for a maximum of 5 days per cycle. After a spontaneous menses or the induction of menses with a progestin withdrawal maneuver (medroxyprogesterone acetate, 10 mg p.o. daily for 5 days), clomiphene (50 mg daily for 5 days) is started on cycle day 3, 4, or 5. In properly selected women, 50% will ovulate through the use of this clomiphene regimen. Another 25% will ovulate if the dose of clomiphene is increased to 100 mg daily. During each cycle, determination of ovulation should be attempted by use of basal body temperature charts, ultrasound monitoring of follicle growth and rupture, or luteal-phase progesterone measurements. Some clinicians use endometrial biopsies to document ovulation in cycles where conception is not attempted. In most women, ovulation occurs approximately 5 to 12 days after the last dose of clomiphene. Measurement of the urinary LH surge is recommended to assist the patient in prospectively determining the periovulatory interval.

Although the FDA has approved maximal clomiphene doses of 100 mg daily, many clinicians have used clomiphene at doses of up to 250 mg daily. Women who fail to ovulate after taking clomiphene in doses of 100 mg daily for 5 days may ovulate if they are treated with clomiphene at doses of 150 mg daily for 5 days. Some authorities advocate use of clomiphene at doses up to 250 mg daily for up to 14 days. As many as 70% of the women who fail to ovulate with doses of 100 mg daily will ovulate with higher doses, but fewer than 30% of those become pregnant. In my opinion, there are few data to support the use of clomiphene at doses greater than 150 mg daily. Women who do not become pregnant at that dose should consider other approaches to ovulation induction (see below).

Clomiphene treatment can be associated with adverse changes in the reproductive tract, including induction of a luteal-phase defect (delay of endometrial maturation) and the creation of a hostile cervical environment from low quantity and quality of cervical mucus. Some clinicians recommend endometrial biopsy in a test cycle of clomiphene treatment to assess whether clomiphene induces luteal-phase deficiency. Many clinicians recommend that a postcoital test be performed during the first clomiphene cycle of treatment to screen for poor cervical mucus properties.

Multiple pregnancy is a well known outcome of clomiphene use. The absolute risk of high-order multiple gestation with clomiphene treatment is low: in a manufacturer's study of 2,369 clomiphene-induced pregnancies, 7% resulted in twins, 0.5% triplets, 0.3% quadruplets, and 0.13% quintuplets. However, because clomiphene is a heavily prescribed medication, the number of triplets resulting from clomiphene is substantial. The rate of spontaneous abortion after clomiphene-induced ovulation

and pregnancy is approximately 15%. The most common side effects of clomiphene include vasomotor symptoms (20%), adnexal tenderness (5%), nausea (3%), headache (1%), and, rarely, blurring of vision or scotomata. Most clinicians permanently discontinue clomiphene in women who experience visual changes from the drug.

Clomiphene plus Glucocorticoid

Anovulatory women with PCOS whose serum DHEAS concentration is above the midnormal range (2 μg/ml) appear to have reduced ovulation and pregnancy rates when they are treated with clomiphene. Some studies suggest that adding a glucocorticoid (e.g., dexamethasone) to clomiphene improves pregnancy rates in these women.[39]

Insulin Sensitizers

A major advance in reproductive endocrinology is the discovery that insulin sensitizers can induce ovulation in infertile women with oligo-ovulation, hyperandrogenism, and insulin resistance. Insulin sensitizers that have been approved for the treatment of diabetes include metformin, rosiglitazone, and pioglitazone. The insulin sensitizer D-chiro-inositol has been demonstrated to induce ovulation in hyperandrogenic insulin-resistant women, but it is currently available for use in research trials only.[40]

Metformin An oral biguanide antihyperglycemic agent approved for the treatment of type 2 diabetes mellitus, metformin has been evaluated in multiple studies for its ability to induce ovulation in women with hyperandrogenism and insulin resistance.

Metformin decreases blood glucose by inhibiting hepatic glucose production and enhancing peripheral glucose uptake. It increases insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal. Unlike the sulfonylureas, metformin's mechanism of action does not involve increased insulin secretion.

Metformin increases the number of ovulatory cycles in infertile women with hyperandrogenism and insulin resistance. When used together with clomiphene, metformin significantly increases the rate of ovulation and of pregnancy resulting in live-born singleton births.[41-44] Metformin has also been shown to enhance response to the induction of ovulation with FSH injections in oligo-ovulatory, hyperandrogenic, insulin-resistant women.[45]

Metformin is commonly used at a dosage of 500 mg three times daily. To minimize gastrointestinal side effects, such as nausea, many clinicians start metformin at 500 mg daily for the first week, then increase the dosage to 500 mg twice daily for the second week, and then increase the dosage again to 500 mg three times daily. After the full dosage is reached, some clinicians switch to a regimen of 850 mg twice daily to enhance compliance. Although metformin is not approved for ovulation induction by the FDA, it may be significantly less expensive than FSH injections, ovarian surgery, or IVF-ET and may have fewer serious side effects than these treatments.

The most common side effects associated with metformin are GI disturbances, including diarrhea, nausea, vomiting, and abdominal bloating. In rare cases, metformin treatment has caused fatal lactic acidosis, but most of these patients had some degree of renal insufficiency or were severely hypoxic. Before starting treatment with metformin, it is advisable to confirm that the patient's serum creatinine level is less than 1.4 mg/dl.

If a patient has not ovulated after 5 to 10 weeks of metformin treatment, clomiphene can be added (see above). If the patient becomes pregnant, metformin can be discontinued, although it is a category B drug for pregnant women and has been used by some clinicians to treat diabetes in pregnant women.[46]

Thiazolidinediones The thiazolidinediones increase cellular sensitivity to the effects of insulin. Agents in this category include pioglitazone, rosiglitazone, and troglitazone. Several studies of troglitazone reported a decrease not only in fasting insulin but also in LH and testosterone levels, along with an increase in ovulatory cycles.[47-49] Troglitazone was reported to induce ovulation in obese, infertile women with hyperandrogenism and severe insulin resistance who had previously failed to ovulate when treated with clomiphene.[50] In this study, some women ovulated and became pregnant with troglitazone alone, whereas others responded to troglitazone plus clomiphene.

Troglitazone was removed from the market because of its association with the risk of death from liver failure.[51] The risk was extremely small but measurable, affecting approximately 1 in 50,000 patients treated with the drug. Pioglitazone and rosiglitazone, although now widely used in the treatment of diabetes mellitus, have not been extensively studied for their impact on ovulation. One might reasonably assume that they would offer benefits similar to troglitazone. However, until their efficacy and safety in PCOS is well established, it is probably best to use metformin as the main insulin sensitizer in women with PCOS.

Clomiphene plus Gonadotropin Induction

In women who fail to ovulate after therapy with clomiphene alone, gonadotropin injections can be added to clomiphene treatment to induce ovulation.[52] Typically, the injections are started after clomiphene, 100 to 200 mg daily, has been given for 5 days. The main benefit of this combination is that it tends to reduce the quantity of gonadotropins (an expensive medication) needed to induce ovulation during each cycle, because the rise in endogenous LH and FSH levels induced by clomiphene increases the sensitivity of the follicles to the injected gonadotropins. This regimen has been associated with a 50% decrease in the dosage of gonadotropin required to induce ovulation.[53]

Gonadotropins

The gonadotropins currently available for ovulation induction include (1) FSH produced by recombinant DNA technology and immunopurification and (2) LH plus FSH derived from menopausal urine. The recombinant FSH preparations can be given as subcutaneous injections and are available in ampules of 37.5 or 75 IU. FSH is the primary hormone responsible for follicular recruitment and growth in humans; it can be used as a single agent to induce ovulation in most anovulatory women. Women with PCOS generally do not require exogenous LH to induce follicular development, because their levels of LH secretion are already increased.

In women with PCOS, induction of ovulation with long-term, low-dose FSH treatment appears to result in a high pregnancy rate with a low rate of complications such as high-order multiple gestation and ovarian hyperstimulation.[54] In this approach, 75 units of FSH are given daily for the first 14 days; the

dose is then raised by 37.5 units every 7 days until follicular ripening is complete. If FSH treatment fails to result in pregnancy, consideration should be given to the combination of metformin and FSH, ovarian surgery, or IVF-ET.

During gonadotropin induction of ovulation, as many as 20% of patients experience mild to moderate enlargement of the ovaries. Some women treated with gonadotropins develop increased vascular permeability and accumulation of fluid in the peritoneal cavity and pleural space, a condition termed the ovarian hyperstimulation syndrome (OHSS). Clinical manifestations of OHSS include abdominal pain, abdominal distention, nausea, vomiting, diarrhea, and dyspnea. Other physical and laboratory findings of OHSS include weight gain, ovarian enlargement, ascites, pleural effusion, hemoconcentration, electrolyte imbalances, renal dysfunction, and thrombosis.[55] Treatment includes bed rest, maintenance of intravascular volume, prophylaxis against thrombosis, and surgical correction of ovarian torsion.

Before the utilization of repetitive estradiol measurements and sonographic evaluation of the follicular development, OHSS occurred in as many as 5% of women receiving gonadotropin treatment. In recent series that employed intense monitoring with those techniques, the rate of OHSS was approximately 0.5%. OHSS may be more severe and have a longer course if a successful pregnancy occurs. Multiple births occur in approximately 15% of pregnancies that take place after ovulation induction with gonadotropins.

Ovarian Surgery

Many gynecologists recommend that in infertile women with PCOS, ovarian surgery be attempted before FSH injections or IVF-ET. Laparoscopic drilling of the ovary is the most widely studied surgical treatment for ovulation in PCOS; approximately 1,000 cases have been reported, although no controlled studies have been undertaken.[56] These reports demonstrate that surgery to induce ovulation causes a decrease in circulating LH (50% decline) and testosterone (30% decline) and an increase in FSH (30% increase). The pregnancy rate is in the range of 50% at 12 months and 70% at 24 months.

The surgical techniques used for ovarian drilling vary between centers. However, all use a laser or electrosurgery to make multiple millimeter-size punctures in each ovary.[57-59]

In Vitro Fertilization with Embryo Transfer

IVF-ET has recently been demonstrated to be effective in the treatment of infertile women with PCOS who fail to become pregnant with gonadotropin injections.[60] In preliminary reports, IVF-ET treatment of infertile women with PCOS has been associated with a per-cycle pregnancy rate of 0.24 to 0.27.[61,62]

Metabolic Abnormalities Associated with PCOS

DIABETES MELLITUS

Obese women with PCOS may be at high risk for diabetes. In one study, testing in 254 PCOS patients found new-onset diabetes in 7%, most of whom had a BMI greater than 30.[63] Another study showed that by 40 years of age, 10% of women with PCOS will have been diagnosed with diabetes.[64]

It is important to assess for diabetes in an obese infertile woman with PCOS before using an ovulation-inducing agent. Poorly controlled diabetes is associated with a significantly increased risk of fetal malformations. Sacral agenesis and caudal dysplasia are 400 times more common in the offspring of women with diabetes than in those of women with normal glucose metabolism. Other anomalies associated with diabetes include anencephaly, open spina bifida, renal agenesis, ventricular septal defects, and transposition of the great vessels. Control of diabetes before conception decreases the risk of fetal malformations.

HYPERLIPIDEMIA

Women with PCOS have hyperandrogenism, and obesity and insulin resistance are common. These conditions are often associated with hyperlipidemia. In one study, levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides were higher in obese women with PCOS than in weight-matched control subjects. Elevated LDL levels were the predominant lipid abnormality observed in women with PCOS, independent of obesity.[65] High-density lipoprotein (HDL) cholesterol levels were also higher, however, which could provide some degree of protection against cardiovascular disease. One epidemiologic study that included a 30-year follow-up of women with PCOS found no increase in mortality from cardiovascular disease.[66]

VI CONTRACEPTION

Sarah L. Berga, m.d.

Contraception means to prevent conception, but in common medical usage, it also refers to methods that prevent implantation. The goal of contraception is to make every child a wanted child. Most methods of contraception (e.g., barrier methods and hormone preparations) also reduce the risk of sexually transmitted diseases (STDs), but intrauterine devices (IUDs) may increase the risk of STDs or their consequences.

Contraceptive methods are generally categorized as reversible [*see Table 1*] or irreversible. Irreversible methods are often referred to as sterilization procedures. Pregnancy termination is not typically regarded as contraception, but the availability of medical methods of abortion has blurred this distinction. Emergency postcoital contraceptive methods are also available.

Most methods of contraception are designed for use by women. Hormonal methods of male contraception are under development, but they are not yet commercially available.[1] In any case, unless such products prove to be almost free of side effects, their acceptance by men is likely to be limited.

Historically, methods to prevent or terminate pregnancy have been subject to intense legal regulation. In the United States, legal regulations vary widely from state to state regarding the provision of services to minors, waiting periods for termination and sterilization, husband and parental consent, reporting of complications and deaths, and restrictions on advance directives by pregnant or potentially pregnant women. Some states also have regulations regarding the type of practitioner or the type of facility in which contraceptive and fertility management procedures can be provided, but no state currently bans the use of reversible contraceptives. Medical insurance coverage for contraception varies widely.

The percentage of women using a contraceptive method rose from 56% in 1982 to 64% in 1995.[2] The most widely used methods in 1995 were female sterilization, combined estrogen and progestin oral contraceptives (COCs), and the male condom. Male condom use is common among unmarried couples; this popularity is due in part to the protection its use affords against certain STDs, particularly HIV infection.

Combined Estrogen-Progestin Contraceptives

COCs are formulated with estrogen (in the form of ethinyl estradiol), in doses ranging from 20 to 35 μg, and a variety of progestins derived from 19-nortestosterone. Individual formulations may have a fixed dose of progestin (monophasic) or may have doses that vary by cycle phase (triphasic). Two preparations contain varying estrogen doses.

efficacy and mechanism of action

Combined estrogen and progestin oral contraceptives are a highly effective method of birth control. Theoretical efficacy is about 99.9%, but the typical efficacy is around 97%.[3] The contraceptive effect of COCs derives principally from the suppression of the hypothalamic release of gonadotropin-releasing hormone (GnRH) and the concomitant suppression of the pituitary release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The decrease in LH reduces ovarian androgen secretion. The suppression of GnRH is primarily caused by the progestin component. Estrogen also independently suppresses FSH at the pituitary level, thereby retarding folliculogenesis.

COCs are progestin dominant. Progestin exposure causes endometrial decidualization and atrophy, rendering the endometrium unfavorable for implantation and thickening of the cervical mucus, thereby blocking the entry of sperm and bacteria into the upper genital tract. There are three generations of progestins. Third-generation progestins, which are theoretically less androgenic, include desogestrel, gestodene, and norgestimate. The clinical superiority of one progestin over any other has not been demonstrated.

reduction of androgen exposure

All COC preparations reduce androgen exposure by two mechanisms: (1) suppression of ovarian androgen production, as a result of the reduction in LH stimulation of the ovarian theca compartment and (2) elevation of the level of sex hormone–binding globulin protein, which binds androgens and thereby lowers the unbound fraction of circulating androgens. COCs reduce facial or androgen-dependent hair growth and acne by reducing the circulating concentrations of androgens available to occupy androgen receptors on the pilosebaceous unit. Although women with polycystic ovary syndrome have elevated GnRH and LH levels, COCs containing 30 to 35 μg of estrogen adequately suppress their androgen secretion.[4]

continuous versus cyclic coc regimens

Traditional COCs follow a 28-day cycle, with 21 days of active pills and 7 days of placebo pills. The 7-day placebo window permits significant follicular development, and higher estrogen and progestin doses are then needed to inhibit further folliculogenesis and ovulation. Further, if there is a delay in starting the next pill pack, a so-called escape ovulation may result.

In patients taking COCs to effect ovarian suppression for medical purposes, this 28-day cycle may be ineffective. These patients may benefit from a long-cycle regimen—42 to 105 days of active pills, and then 1 week off—or a continuous regimen.

Table 1 Categories of Commercially Available Reversible Contraceptives

- Barrier methods
  - Condoms
  - Diaphragms
  - Cervical caps
- Hormonal
  - Combined estrogen-progestin preparations
    - Oral
    - Vaginal ring
    - Transdermal
    - Injectable
  - Progestin preparations
    - Oral
    - Injectable
    - Implantable
- Intrauterine devices

For long-cycle regimens, patients use the active pills from several packs; however, a commercial long-cycle preparation that includes 63 days' worth of active pills is under development. The use of continuous COC regimens has not been well studied, but it is common to omit the placebo week in women undergoing hormonal treatment for disorders such as polycystic ovary syndrome or endometriosis, as well as in those who desire amenorrhea or have headaches or other symptoms provoked by estrogen withdrawal during the placebo week. There are several advantages to a continuous approach, including better suppression of ovarian function. Persistent ovarian cysts may be less likely with a continuous regimen than with a cyclic regimen.

Increased breakthrough bleeding is a potential side effect of a continuous regimen as compared with a cyclic regimen. The increase in breakthrough bleeding is attributable partly to the development of fragile endometrial vessels coursing along the surface of the endometrium and partly to impaired local hemostasis.[5] The only near-continuous COC preparation that avoids the increase in breakthrough bleeding while increasing follicular suppression is Mircette, which has 2 placebo days, 5 days of 10 µg estrogen, and 21 days of 20 µg estrogen plus 150 µg desogestrel.[6] One objective of these modifications is to lower overall sex steroid exposure and minimize the unwanted consequences of pill use while minimizing breakthrough bleeding.

nonoral combined contraceptives

Several combined estrogen-progestin contraceptives that do not use the oral route have recently been developed. All offer the convenience of less-frequent dosing.

The hormonal vaginal contraceptive ring (NuvaRing) was approved by the Food and Drug Administration in October 2001. This product is a flexible polymer ring, about 2 in. in diameter, which the patient inserts in her vagina. The ring releases a continuous low dose of estrogen and etonogestrel. The ring is left in place for 3 weeks, then removed for the week during which the patient will have her menstrual period. Neither patients nor their partners can tell that the ring is in place. Comparison of the vaginal ring with a COC has shown a lower incidence of irregular bleeding and a higher incidence of a normal intended bleeding pattern with the ring.[7]

The transdermal contraceptive patch (Ortho Evra) was approved by the FDA in November 2001. The patch delivers estrogen and norelgestromin over the course of a week. Patches are applied once a week for 3 consecutive weeks to the skin of the buttocks, the abdomen, the upper torso, or the upper outer arm.[8] In general, the efficacy and cycle control provided by the patch are comparable to those of COCs, but the efficacy of the patch may be lower in women who weigh 198 lb (90 kg) or more.[9] The overall rate of patch detachment is about 4%; about 2% of users experience skin irritation at the site of application.

An injectable estrogen-progestin contraceptive (Lunelle) is available in the United States. The preparation, which is given intramuscularly once a month, contains medroxyprogesterone acetate and estradiol cypionate in a timed-release form. In clinical trials, efficacy and patient satisfaction have been comparable to that seen with COCs.[10]

side effects

A myriad of serious and nuisance side effects are associated with COCs [*see Table 2*]. Smoking markedly increases the risk of venous thromboembolism. Smoking is a relative contraindication to COC use, particularly in women older than 35 years.[11]

Table 2 Potential Side Effects of Oral Contraceptives

Serious side effects	Metabolic changes Decreased insulin action Increase in clotting factors Elevation of triglyceride levels Increase in the metabolic work load of the liver Increase in renin substrate Clinical manifestations* Venous thromboembolic events Fatty liver or hepatoma Cholestasis or cholecystitis Diabetes mellitus Hypertension Cardiovascular events Exacerbation of depression Drug interactions
Nuisance side effects	Mastodynia Reduced libido Reduced vaginal lubrication Increased appetite Weight gain Fatigue Bloating

*These events are rare in healthy women younger than 50 years.

The crucial clinical issue is to convince the woman who smokes to stop smoking rather than deny her access to an acceptable form of contraception. For nonsmokers who take COCs containing 35 µg or less of estrogen, the risk of nonfatal venous thromboembolism is approximately one half that of pregnancy (60 per 100,000 women) but greater than that observed in healthy women who do not take oral contraceptives (5 per 100,000 women). The alleged excess mortality from venous thromboembolism attributable to third-generation progestins as compared with other progestins is less than two per million women per year.[12] However, women with familial thrombophilia caused by factor V Leiden or prothrombin mutation 20210A have a greatly increased risk of venous thromboembolism when using any oral contraceptive[13] [*see 5:XIV Thrombotic Disorders*]. In white women, the carrier rate of factor V Leiden is approximately 3% and that of prothrombin mutation 20210A is less than 2%, so screening has not been routinely advised.[14] Also, there are other known causes of thrombophilia, but not all the thrombophilias can be detected.

COCs may decrease insulin action, an effect that has been attributed to the progestin component. The use of COCs does not increase the risk of diabetes mellitus in women who do not have other risk factors for the disease. However, in a nonrandomized clinical trial that followed Latin-American women with gestational diabetes for 7.5 years post partum, the rate of development of diabetes mellitus was 8.7% for those given nonhormonal contraception, 10.4% for those who used COCs, and 26.5% for those who used progestin-only pills. Life-table analysis showed an increase in diabetes mellitus within 2 years in the progestin-only group.[15] Given these considerations, it is prudent to avoid prescribing any progestin-only form of contraception in women predisposed to diabetes mellitus or in frankly diabetic women. Fortunately, COC use by insulin-dependent diabetic women does not increase the risk of diabetic retinopathy or nephropathy.[16]

COCs have a negligible effect on the overall risk of cancer.[17] Among women who take oral contraceptives for 8 years, the estimated increase in the number of cases of cancer is 125 per 100,000 for cervical cancer and 41 per 100,000 for liver cancer; those increases are offset, however, by decreases in endometrial cancer and ovarian cancer [*see* Benefits, *below*].[17] Oral contraceptive use does not appear to increase the risk of breast cancer significantly—regardless of the dose, duration of use, or age at use—even in women with a family history of breast cancer.[18] However, the effect of oral contraceptive use on risk of breast cancer in carriers of *BRCA1* and *BRCA2* has not been defined.

Exposure to high doses of estrogen or progestin may provoke depression and mood disturbances, but this effect is limited to women with an underlying diathesis.[19] It is not known whether oral contraceptive use increases the lifetime risk of depression or hastens its onset in women so predisposed.

Progestins have mineralocorticoid activity that results in the retention of up to 2 lb of water in sensitive women. The progestins also increase plasma renin activity; in predisposed women, hypertension may result.

Oral contraceptive use can cause drug interactions by increasing liver production of proteins that bind other drugs, by inhibiting oxidative metabolism in the liver by the P-450 and P-448 cytochrome systems, and by competing for or accelerating conjugation. Conversely, drugs that stimulate the hepatic microsomal system, such as oral antifungal agents or rifampin, may decrease plasma levels of contraceptive steroid and lead to unintended pregnancy. Antibiotics such as ampicillin, tetracyclines, and metronidazole do not interfere with COC efficacy.

contraindications

There are specific contraindications to oral contraceptives [*see Table 3*]. Lactating women should probably not take COCs. Women with hypertension, epilepsy, depression, hepatitis, gallbladder disease, migraine, or premenstrual syndrome (PMS) need to be carefully monitored. Fibroids are not a contraindication to COC use.

benefits

Women use oral contraceptives primarily for birth control. If side effects are tolerable, they are pleased to gain the other benefits [*see Table 4*]. Women generally appreciate the lighter and predictable menses. The option of long cycles or continuous use to schedule or skip bleeding episodes is a major advantage for any busy woman, particularly one who travels or spends time outdoors. Other women use oral contraceptives to treat an underlying disorder, such as polycystic ovary syndrome, dysmenorrhea, endometriosis, or idiopathic hirsutism. In general, the same benefits accrue.

Table 3 Contraindications to Oral Contraceptives

- Active liver or gallbladder disease
- Medically significant hypertriglyceridemia
- Active or past venous thromboembolic events
- Atherosclerotic heart disease
- Undiagnosed vaginal bleeding
- Estrogen-dependent neoplasia
  - Breast cancer
  - Endometrial cancer
- Symptomatic mitral valve prolapse
- Smoking after 35 years of age

Table 4 Potential Benefits of Oral Contraceptives

- Reduced risk of the following disorders:
  - Ectopic pregnancy
  - Benign breast disease
  - Anemia
  - Ovarian cysts and cancer
  - Endometrial cancer
- Lighter and predictable menses
- Reduction or elimination of dysmenorrhea
- Bone accretion

One of the major benefits of COC use is bone accretion. One study showed that as little as 10 µg of estrogen was bone sparing in women older than 40 years, and 5 µg of estrogen plus 1 mg of norethindrone caused bone accretion.[20] Women who are hyperandrogenic but eumenorrheic have greater bone mass than do hyperandrogenic women who are oligomenorrheic. The latter have slightly higher bone mass than eumenorrheic, nonhirsute women. Women with polycystic ovary syndrome or idiopathic hirsutism who take oral contraceptives will have a decrement in endogenous androgen exposure, but COC use in this setting is expected to be bone sparing. Women with hypothalamic hypogonadism, particularly those with an eating disorder, have underlying metabolic disturbances that render their bones less responsive to exogenous steroid exposure. These women may continue to lose or not accrue bone even if they use COCs.

Long-term use of COCs reduces the incidence of endometrial cancer and ovarian cancer. Among women who take oral contraceptives for 8 years, it is estimated that there will be 197 fewer cases of endometrial cancer per 100,000 users and 193 fewer cases of ovarian cancer per 100,000 users.[17] Newer COCs, which contain 20 µg of estrogen, appear to provide identical risk reduction for ovarian cancer as did older formulations, which contained 50 µg or more of estrogen.[21] A recent study showed that oral contraceptives also markedly reduce the risk of ovarian cancer in carriers of *BRCA1* and *BRCA2* mutations (who are at increased risk for ovarian cancer and premenopausal breast cancer). The longer the duration of use, the greater is the protection from ovarian cancer.[22]

Progestin-Only Contraceptives

efficacy and mechanism of action

Two progestin-only contraceptives are commercially available. Norplant is composed of Silastic rods impregnated with the progestin levonorgestrel. The new Norplant system contains only two rods. A single-rod system will soon be available. The rods are inserted subdermally, generally in the upper arm. Diffusion of levonorgestrel through the wall of each capsule provides a continuous low dose of progestin for at least 5 years. The progestin modestly inhibits the hypothalamic-pituitary-ovarian axis to block ovulation; it also induces endometrial shedding, making implantation unlikely, and thickens cervical mucus,

thereby retarding the entry of sperm and bacteria to the upper genital tract. The birth-control efficacy is greater than 99.9%.

Depot medroxyprogesterone acetate (DMPA) is an aqueous suspension of 150 mg designed to be given intramuscularly every 3 months. The birth-control efficacy is greater than 99%.

side effects

Subdermal and injectable progestins have side effects [*see Table 5*]. The principal side effect is breakthrough bleeding caused by the development of fragile endometrial vessels and local derangement of hemostatic mechanisms as a result of excess progestin exposure relative to estrogen exposure.[5] The breakthrough bleeding may respond to the administration of an estrogen such as transdermal estradiol. Progestin implants and injections are relatively contraindicated in women with past or active depression or other psychiatric disorders [*see Table 6*]. There is some suggestion that progestin-only contraceptives are more mood destabilizing than COCs. The long-term effect on bone accretion depends on the extent of ovarian suppression and its attendant decline in estradiol secretion and on the age of the patient. Younger patients who have not attained peak bone mass may be more adversely affected. Levonorgestrel may be more bone sparing than DMPA. Progestin-only contraceptives have been found to increase the risk of diabetes mellitus in Latin-American women who have had gestational diabetes (see above).[15] This may be partly caused by the lack of estrogen, which is an insulin sensitizer. The long-term cardiovascular risks are largely unknown, but in some experimental settings, synthetic progestins provoke vasoconstriction, an effect not seen with progesterone. A recent epidemiologic analysis from the World Health Organization (WHO) found no excess risk of cardiovascular disease with either combined or progestin-only methods other than an increased risk of stroke in hypertensive women who were given the progestin-only contraceptives.[23]

Another common side effect of progestin-only contraceptives is delay in return of menses. DMPA is given at 90-day intervals, but patients who discontinue this method may not experience immediate return of menses because of variability in the metabolism of the depot form and variable sensitivity of the hypothalamic GnRH pulse generator to low levels of progestin.

Intrauterine Devices

IUDs interfere with sperm migration, fertilization, ovum transport, and implantation, presumably by causing a sterile salpingitis, endometritis, or both. The birth-control efficacy is greater than 97%.

One of the principal benefits of IUDs is that they provide a nonhormonal method of birth control. They are ideal for women who have completed childbearing and who desire a low-maintenance, reversible method of contraception. IUDs are also relatively economical.

Table 5 Potential Side Effects of Injectable and Implantable Progestin Contraceptives

Breakthrough bleeding	Mastodynia
Headaches	Acne
Mood changes	Bone loss
Weight gain	

Table 6 Contraindications to Injectable and Implantable Progestin Contraceptives

Active liver disease	Active thromboembolic disease
Diabetes mellitus	Active cardiovascular disease
Unexplained vaginal bleeding	Depression
Breast cancer	Other psychiatric disorders

Two IUDs are currently available: the Copper T 380A, which lasts 10 years, and the 5-year, levonorgestrel-releasing Mirena. With the copper IUD, both the inert plastic device and the copper contribute to the spermicidal effect and prevention of implantation. With the progestin-containing IUD, part of the efficacy is attributed to the effects of the progestin on the endometrium that retard implantation.[24]

The main side effect associated with IUD use is pelvic inflammatory disease (PID). Most of the increased risk of PID occurs in the first 3 weeks after insertion. Women with more than one sexual partner who are at risk for contracting gonorrhea and chlamydial infection also are at increased risk for PID. Patient selection, rigorous aseptic insertion technique, and screening for STDs may minimize this risk. Routine antibiotic prophylaxis during insertion may not be necessary.[25] Uterine perforation is a rare insertion risk. Dysmenorrhea and menorrhagia have been reported with the copper IUD, whereas decreased menstrual flow, dysmenorrhea, and increased risk of ectopic pregnancy have been reported with the progesterone-releasing IUD.

The primary contraindication to IUD use is a history of PID. Nulligravidity is a relative contraindication. Sexual monogamy should be emphasized as a means of minimizing the risk of STDs and PID.

Barrier Methods

Male and female barrier contraceptives are available. When used correctly, the male condom protects against pregnancy and STDs. The theoretical efficacy of barrier methods for birth control is 98%, but the actual efficacy is about 88%. The efficacy gap results from inconsistent use and condom breakage. The female condom is more difficult to use and has not gained popularity. The diaphragm and cervical cap do not protect against STDs as effectively as condoms. When they are used with spermicides, the birth-control efficacy of diaphragms and cervical caps is theoretically 94%; in practice, however, the efficacy is about 82%. Both cervical caps and diaphragms require fitting and a prescription. They also require user training and diligence. Instructions on their use are provided in the products' package inserts. Spermicides may independently decrease the risk of STDs. When used alone, spermicides have a birth-control efficacy of about 79%.[3] Spermicides that also have antimicrobial activity are in development.

Allergic reactions to latex and hypersensitivity to spermicides occur. Diaphragm use may increase the risk of urinary tract infections because the rim presses against the symphysis pubis and urethra, which may cause incomplete emptying of the bladder.

The main contraindication to barrier methods is lack of user motivation and hypersensitivity to spermicides or allergy to latex. The primary benefits of condoms are that they are avail-

able without prescription, inexpensive, relatively easy to use, nonhormonal, and protective against STDs. Other barrier methods are only slightly more difficult to use but require fitting and a prescription, so the need for birth control must be anticipated.

Periodic Abstinence

Periodic abstinence, or natural family planning, depends on recognition of the periovulatory window and avoidance of sexual intercourse during that window. As such, it requires that a woman have highly regular menstrual cycles and that both partners be motivated to avoid intercourse when the woman is fertile. There are several methods of detecting the fertile window, including avoiding intercourse on days 9 to 14 of a 28-day cycle, monitoring cervical mucus and body temperature, and monitoring salivary estradiol levels.

Successful use of fertility-awareness methods for birth control requires not only dedication but education. Family health centers, family planning centers, and church-affiliated centers may offer courses on this subject. Information is available on the Internet at sites such as http://my.webmd.com/encyclopedia/article/1819.51010.

Mastering the concepts of menstrual-cycle physiology can be empowering, and couples can use this information to plan a pregnancy as well as to avoid it. There are no known contraindications. There are no religious prohibitions against periodic abstinence, so it is theoretically available to all women who have predictable cycles.

Periodic abstinence can be frustrating, however, and it is less reliable than other forms of contraception, with an estimated efficacy of 80%. Several factors can interfere with fertility awareness. Even women who usually have very regular cycles may occasionally have a cycle that deviates from normal. Vaginitis may obscure the recognition of midcycle mucus. Fever may mimic the progesterone-induced rise in body temperature that normally indicates the onset of the luteal phase, thereby falsely signaling that the fertile period has passed.

Sterilization

Sterilization procedures generally entail occlusion or ligation of the fallopian tubes in women or the vas deferens in men. The birth-control efficacy of sterilization procedures is greater than 99%; they are meant to be permanent. Reversal procedures are available, but the reversibility of tubal ligation or vasectomy is not guaranteed. Sterilization procedures may fail if the fallopian tube is not properly identified or if it recannulates. Vasectomy failures primarily result from not waiting a sufficient length of time after the procedure before having unprotected sexual intercourse. In women, sterilization procedures can be done post partum, but interval procedures are safer and more effective. Interval procedures employ laparoscopy, with or without general anesthesia. The fallopian tubes are either fulgurated or banded.

Patients may experience feelings of regret after a tubal ligation or vasectomy. Appropriate counseling can minimize this emotional side effect. There is no concrete evidence that vasectomy causes heart disease or prostate cancer. A recent review of tubal ligation found no evidence of increased rates of premenstrual distress, menorrhagia, dysmenorrhea, or menstrual irregularities in women 30 years of age or older who had undergone interval tubal ligation.[26]

The main contraindication to sterilization is ambivalence. In addition, women who undergo laparoscopic procedures must be suitable surgical candidates. The main benefit of sterilization is its permanence. Because sterilization is a one-time procedure with high efficacy, it is highly cost-effective in appropriately selected candidates. Tubal ligation may decrease the risk of PID and ovarian cancer.

Emergency Contraception

Postcoital contraception aims to desynchronize endometrial development and prevent implantation. Various methods have been proposed.[27] They include high doses of COCs taken within 72 hours after intercourse; levonorgestrel taken within 72 hours after intercourse; high doses of estrogen; danazol; mifepristone, as a single 600 mg dose; and insertion of a copper IUD up to 5 days after ovulation. The contraceptive efficacy of mifepristone or IUDs is at least 99%. One study compared a treatment consisting of 100 µg of estrogen plus 0.5 mg of levonorgestrel taken twice, 12 hours apart, with a treatment consisting of levonorgestrel, 0.75 mg, taken twice, 12 hours apart.[28] Both treatments were taken within 72 hours after intercourse. Levonorgestrel alone had an efficacy of 85% and was associated with fewer side effects than the combined therapy, which had an efficacy of 57%. The efficacy of levonorgestrel taken within 24 hours after intercourse was greater than 99%. This would appear to be the treatment of choice because it is inexpensive, widely available, well tolerated, and highly effective. A recent Scottish study also suggested that women given a single emergency contraceptive kit used it correctly without experiencing significant side effects, and they had a lower unintended pregnancy rate.[29] Given the safety and efficacy of emergency contraception, many physicians strongly advocate that it be made available over the counter.[30] Patient information on emergency contraception is available on the Internet at http://ec.princeton.edu.

Choosing a Contraceptive Method

There is no perfect contraceptive; all may fail, and all have drawbacks and side effects. Age, motivation, marital status, partner attitude, perceived risk of pregnancy, frequency of intercourse, medical conditions, costs, cultural considerations, and religious beliefs affect the choice of contraceptive methods. The patient's or couple's medical history and preferences must guide the selection of a contraceptive [*see Table 7*]. Patients should be encouraged to revise their choice on the basis of side effects and changing circumstances.

Patients should be advised to inform the physician of new symptoms before discontinuing a contraceptive method. The physician must remain sensitive to the patient's concerns. Even if a symptom sounds trivial from a medical perspective, it may alarm the patient and cause her to discontinue the method.

The role of condoms and other contraceptives in the reduction of STD transmission must be emphasized so that patients can choose properly from among the available options. Emergency contraception should be discussed and offered to those not seeking long-term contraception.

reversible method desired

The first decision point in the choice of a reversible contraceptive method hinges on whether the patient has more than one sexual partner or is in a long-term monogamous relationship. If

Table 7 Contraceptive Characteristics Affecting Choice[29]

Characteristic	*Method*
High efficacy	Combined oral contraceptives Intrauterine devices Depot medroxyprogesterone acetate Subdermal progestin implants
Limited or no systemic side effects	Barriers Spermicides Periodic abstinence
Minimal effort	Intrauterine devices Subdermal progestin implants Depot medroxyprogesterone acetate
Low cost	Male condom Spermicides Combined oral contraceptives
Nonprescription	Male condom Spermicides Periodic abstinence
No religious prohibitions	Periodic abstinence
Protection against sexually transmitted diseases	
Cervical gonorrhea and chlamydial infection	Barriers
Salpingitis	Barriers, hormone contraceptives
HIV infection	Male and female latex condoms
Other health benefits	Hormone contraceptives
Minimal risk to future fertility	Hormone contraceptives Barriers Periodic abstinence

the patient has more than one sexual partner, condoms with or without hormonal contraception should be recommended. User reluctance and lack of familiarity are the main limitations to condom use. Condoms are ideal for unplanned intercourse.

For healthy women, the ancillary health benefits of combined estrogen-progestin contraceptives should be emphasized. These include a reduced risk of ovarian and endometrial cancer and preservation or accretion of bone mass. The option of using combined hormonal contraceptives to regulate menstrual timing should be discussed as a means of aiding compliance.

COCs, particularly the generic brands, are relatively inexpensive—in the range of $10 to $20 a month. COCs work best if taken daily, and some women find it difficult to remember to do so; they may prefer a vaginal ring, transdermal patch, or injectable contraceptive. Women who do not take the pills reliably will have increased rates of pregnancy and side effects, such as breakthrough bleeding. They should be counseled to use a barrier method or spermicide if they miss two consecutive pills or if they start the next package of pills after a hiatus of 8 or more days. In healthy nonsmokers without predisposing medical conditions, the pill is a safe and highly efficacious method of contraception that can be used in women up to 50 years of age. In women who are approaching menopause, COC use not only provides effective contraception but also can regularize menstrual cycles, relieve vasomotor symptoms, and stabilize bone mass.[31]

Women with epilepsy may need to have their antiseizure medications adjusted when they start oral contraceptive therapy. Not all the newer antiseizure drugs interact with oral contraceptives, however,[32] so patients need to be evaluated on a case-by-case basis. Consultation with a pharmacist may be useful.

Follow-up is important in women who choose hormonal contraceptives. Blood pressure should be measured around 3 months after the start of COCs and annually thereafter. If hypertension results, it is prudent to discontinue COCs. Women using hormonal contraception who develop a severe, unremitting headache should be evaluated for possible stroke and cerebral thrombosis.

With prolonged use of COCs—even on a cyclic regimen—some women develop endometrial atrophy and amenorrhea. Once pregnancy has been excluded, it is prudent to recommend a long-cycle or a continuous regimen or one with a shortened placebo window.

It is prudent for women who develop serious mood disturbances to discontinue COCs. Women with active or past PMS and depression, including postpartum depression, should be advised about the potential for negative mood effects associated with COCs.

Switching to a lower-dosage regimen may reduce nuisance side effects. Physically smaller women or women who metabolize synthetic sex steroids slowly (such as women of Asian descent) should start with a 20 μg pill. Although most women do well on 20 μg pills, there may be a slight increase in breakthrough bleeding with some formulations. The benefit is fewer estrogen-dependent side effects, such as breast tenderness or nausea. Women with a history of headaches may do better on the lowest dose given in a continuous or nearly continuous (Mircette) regimen.

If a patient has a low risk of depression, PMS, and osteoporosis, Norplant or DMPA may be an appropriate method of contraception. The patient must desire extended protection and be willing to undergo the insertion procedure or an injection. Subdermal implants and DMPA are relatively expensive.

The DMPA cannot be removed if a patient experiences adverse effects, and continuance rates are low with DMPA. Insertion of subdermal implants requires training and skill. If adverse effects occur with subdermal implants, a surgical procedure is required for their removal. Removal is often more difficult than introduction because of scarring around the capsules. In appropriate patients, however, subdermal implants provide a long-term, low-maintenance birth-control method.

IUDs, barrier methods, or periodic abstinence may be considered if the patient is not a candidate for hormone contraception and is in a long-term monogamous relationship.

Prospective users of IUDs must be made aware of the attendant risks and benefits. To make an informed decision, users need to understand the risks and potential consequences of PID.

Diaphragms and cervical caps are ideal for highly motivated users who desire a nonhormonal method of birth control. Spermicides increase the efficacy of all barrier methods of contraception but also increase cost and bother. Use of barrier methods is increased by public health education and by suggestion that the barrier method be incorporated into foreplay.

Women who report vaginal pruritus, irritation, inflammation, pain, or discharge associated with the use of a barrier method may have a latex allergy or hypersensitivity to spermicide. Latex allergies are particularly common in health care workers, many of whom are women. Formal allergy testing

can be done to detect latex allergy, but current tests are not highly reliable. Latex allergy can provoke life-threatening anaphylaxis. Although most spermicides contain nonoxynol-9 as the active contraceptive ingredient, the other constituents may vary. Therefore, it may be possible to minimize irritation by switching to a different preparation. Men may also report allergies to latex or hypersensitivity to spermicides. Latex is preferred for condoms and barrier methods because it is impermeable to HIV.

nonreversible method desired

All potential reversible and permanent options must be reviewed before a sterilization procedure is chosen. In general, if a couple seeks sterilization, a vasectomy is recommended because it is safer and less expensive than a laparoscopic tubal ligation. Postpartum tubal ligation is the most risky, least effective, and most likely to cause regret.

Laparoscopic tubal ligation is expensive and must be performed by a skilled surgeon in an appropriate setting, so availability may be limited by cost or access to an appropriate physician. Many states require mandatory waiting periods. Some require spousal consent. Counseling is the cornerstone of success.

VII INFERTILITY

Alan H. DeCherney, m.d.

Infertility is defined as the inability to conceive after 1 or more years of regular coital activity without contraception. Fecundity is the statistical probability of achieving a pregnancy (resulting in a live birth) within 1 month (one menstrual cycle) of unprotected sexual intercourse. Monthly fecundity for a fertile couple ranges from 20% to 35% [*see Table 1*].[1] Within 1 year, more than 85% of all couples trying to conceive will achieve a pregnancy.

The incidence of infertility has been increasing over the past 3 decades. It is estimated that nearly 10% of all couples in the United States have disorders associated with infertility. As a result, about 2.5 million couples seek advice for treatment each year in the United States.[2,3]

The practitioner needs to approach the infertile couple in a rational and organized manner. After the initial evaluation, all the reproductive factors should be assessed and a treatment plan proposed that addresses the risk,[4] benefit, and cost[5] to the couple [*see Figures 1 and 2*]. Couples who go through this process and have little or no success may experience severe emotional and psychological distress. For this reason, patients should be counseled about the probability of their achieving a pregnancy before embarking on this potentially expensive treatment course, and psychological counseling during treatment may be valuable.[6]

Evaluation and Treatment of the Infertile Couple

During the first encounter, both partners should be interviewed. The physician should take note of each partner's age, duration of infertility, past pregnancies, past surgeries, frequency of coital activity, and problems encountered during intercourse (e.g., dyspareunia, impotence, anorgasmia, and lack of libido). All potential problems that are revealed during the initial examination should be addressed and treated accordingly. The initial evaluation should also cover other conditions that can affect fertility rates in women. Obese and sedentary women are at higher risk for infertility,[7] because obesity promotes anovulation. Cigarette smoking[8] and long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs)[9] can contribute to infertility. These effects are most noticeable at the extremes (i.e., marked obesity, heavy smoking, or high NSAID doses).

age

A woman's reproductive capability decreases with advancing age. After women reach 30 years of age, pregnancy rates decrease.[10] By 40 years of age, a woman's monthly fecundity is less than 5%.[11] Poor oocyte quality is the predominant factor responsible for this decline in pregnancy rate.

Male fertility also diminishes with age. Sperm quality declines, and the frequency of ejaculation decreases as men grow older. Nearly 50% of the infertility experienced by couples older than 40 years is caused by problems associated with advancing age.[12] Therefore, age is an independent risk factor that is instrumental in determining a couple's chance of achieving a successful pregnancy.

The duration of infertility may be just as important a risk factor as the age of the couple. The longer the duration of infertility, the lower is the probability of achieving a successful pregnancy.

male infertility

Infertility in the male partner is the primary cause of infertility in approximately 35% of couples who seek help.[10] Any previous testicular injury, infection, surgery, radiation, or chemotherapy should be documented during the initial history. The physical examination should focus on penile and testicular anomalies (e.g., hypospadia, cryptorchidism, and varicoceles). If any such anomaly is present, the patient should be referred to a urologist for evaluation and treatment.

After the initial physical examination, a semen analysis should be performed. The specimen is collected after 48 hours of abstinence from coital activity and evaluated no more than 1 hour after collection.[13] If any parameters are abnormal [*see Table 2*], two additional semen analyses should be performed 2 weeks apart. Persistent abnormalities may warrant urologic evaluation and workup for diabetes mellitus, prolactin elevation, and chromosomal abnormalities.

Other tests that can be performed are the sperm penetration assay and the immunobead-binding assay. These tests can detect abnormalities in sperm penetration and motility, respectively, but may not indicate the true nature of a patient's problem.

If the results of the semen tests are normal and the female partner's evaluation appears normal, a diagnosis of unexplained infertility is appropriate [*see* Unexplained Infertility, *below*].

Idiopathic oligospermia is the most common cause of infertility in men. Although there is no cure for this problem, treatment may include in vitro fertilization (IVF) with microinjection of sperm into egg (intracytoplasmic sperm injection [ICSI]) [*see Table 3*]. In severe cases of infertility, this technique can achieve fertilization rates as high as 65%.[14]

female infertility

Tubal and Pelvic Factors

Nearly 35% of the infertility experienced by couples and 40% of the infertility in women is of pelvic origin. Uterine, tubal, and other pelvic abnormalities are responsible for this type of infertility. The practitioner should elicit information regarding any history of sexually transmitted diseases, pelvic inflammatory disease, appendicitis with rupture, pelvic tuberculosis, or adnexal surgery. Many patients with tubal or pelvic damage have a history that includes a previous diagnosis of endometriosis, ectopic pregnancy, or submucous myomas. Al-

Table 1 Fecundity of Normal Couples over Time

Time (Months)	*Couples Achieving Pregnancy (%)*

3	57
6	72
12	85
24	93

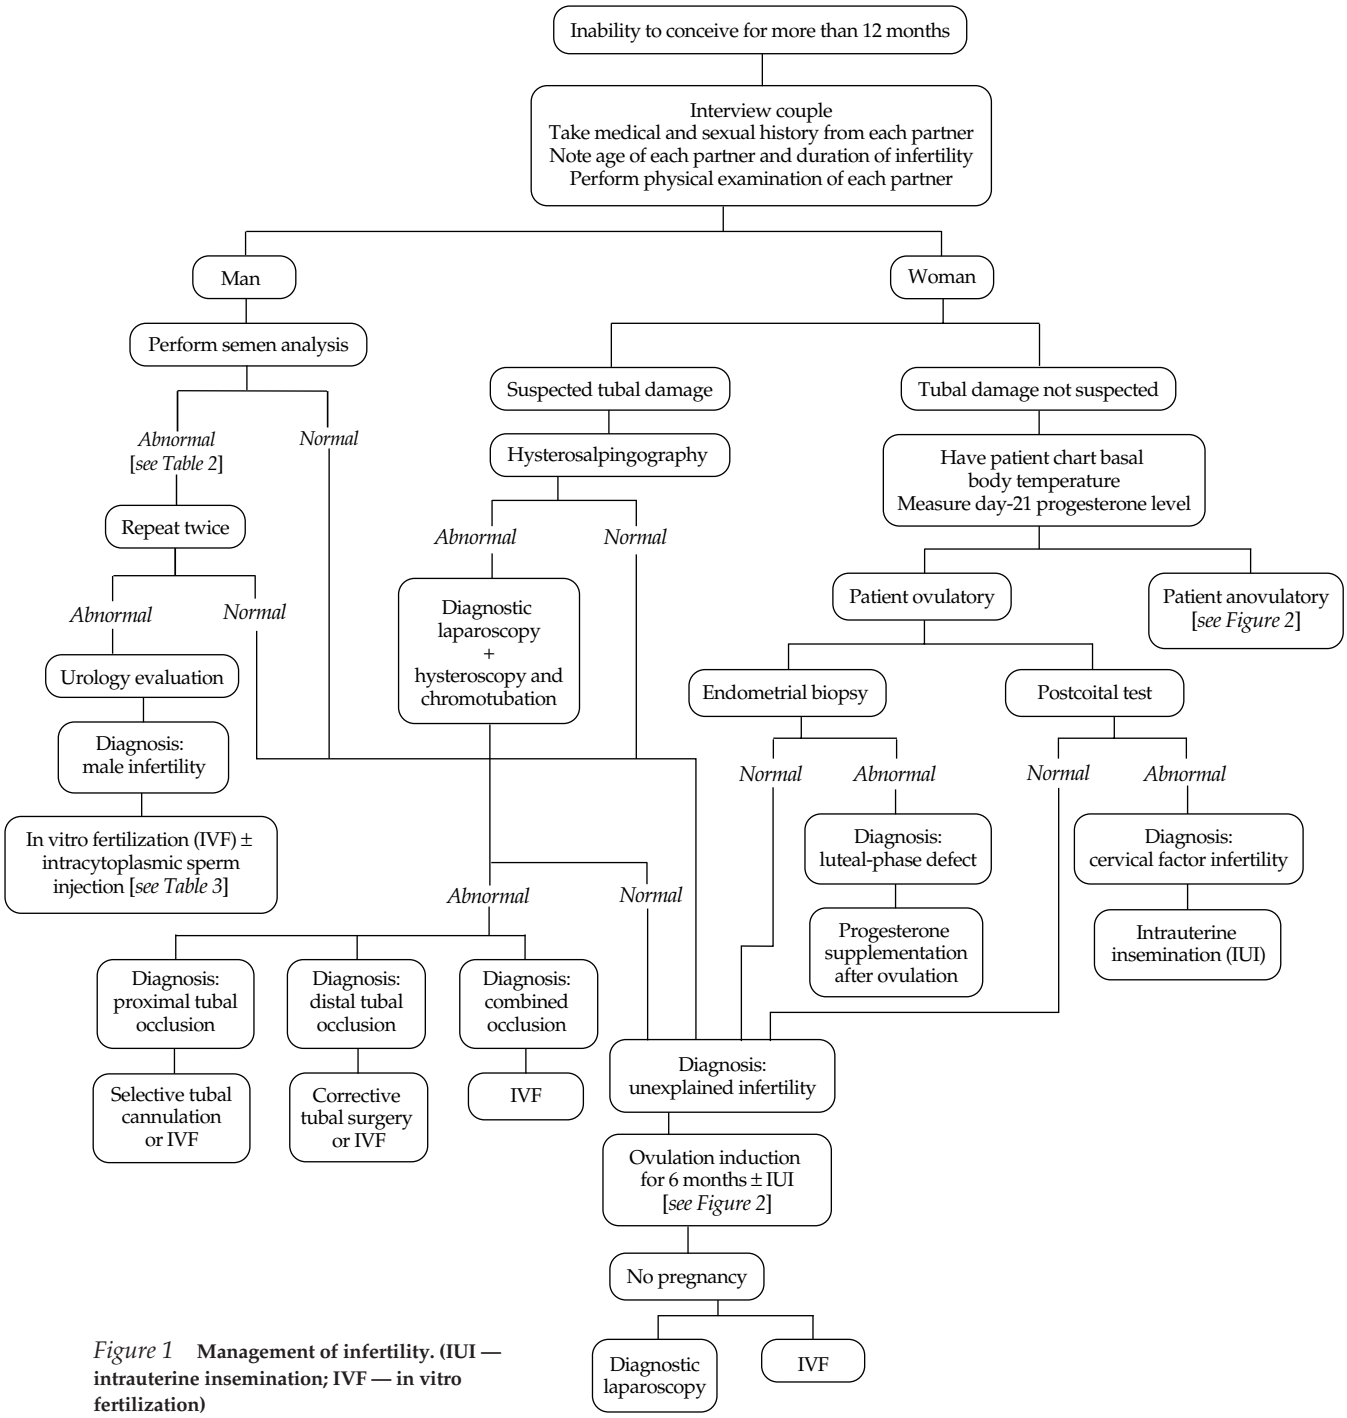

Figure 1 **Management of infertility. (IUI — intrauterine insemination; IVF — in vitro fertilization)**

though uterine myomas seldom cause infertility, they may cause recurrent early pregnancy loss and preterm labor.

Hysterosalpingography (HSG) is one of the initial diagnostic tests used to evaluate uterine, tubal, and pelvic abnormalities. This test is performed during the early proliferative phase, after the cessation of menstrual flow (cycle day 5 to 10). HSG can help identify abnormalities of uterine filling caused by submucous myomas, polyps, uterine synechiae (adhesions), and congenital malformations.

Tubal patency should be evaluated at the time of HSG. A delayed set of radiographs can detect pelvic adhesions and other pelvic abnormalities that prevent the release of contrast material into the pelvis. Once the site of blockage (which may be proximal or distal) has been identified, it can be dealt with accordingly.[15] Patients who are known to be anovulatory may forgo an initial HSG. If ovulation induction is successfully attempted for at least four consecutive cycles and conception does not occur, however, HSG should be performed.

HSG should never be performed on a woman with acute salpingitis, a tender pelvic mass, or allergy to iodine. Women with a known contraindication are better evaluated directly by laparoscopy. Patients who undergo HSG should receive prophylactic treatment for chlamydial infection; oral doxycycline, 100 mg twice daily for 7 days, is effective.

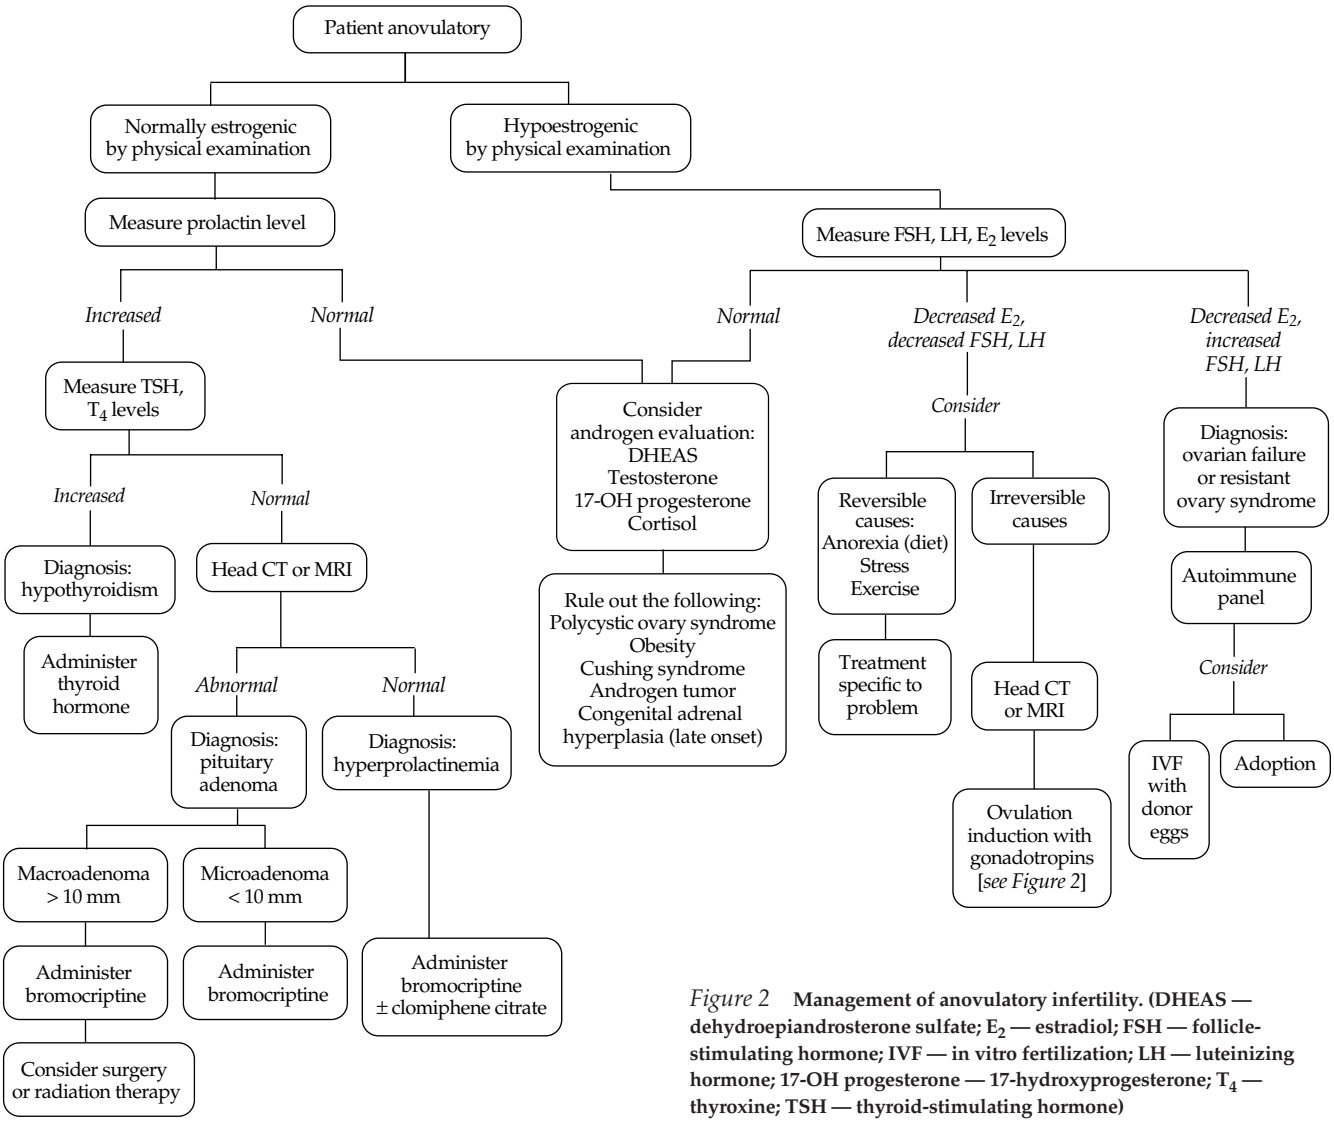

Figure 2 **Management of anovulatory infertility. (DHEAS — dehydroepiandrosterone sulfate; E_2 — estradiol; FSH — follicle-stimulating hormone; IVF — in vitro fertilization; LH — luteinizing hormone; 17-OH progesterone — 17-hydroxyprogesterone; T_4 — thyroxine; TSH — thyroid-stimulating hormone)**

Laparoscopy with chromotubation (intrauterine injection of colored liquid [indigo carmine] to confirm tubal patency) is indicated for patients with abnormal findings on HSG and for patients with unexplained infertility. This procedure may be omitted from the diagnostic workup if IVF is the main focus of treatment. However, surgical resection of the diseased tube should be considered for patients who are diagnosed with a hydrosalpinx on the basis of HSG or laparoscopy. Studies indicate that the mere presence of a hydrosalpinx can adversely affect embryo implantation and the success of IVF.[16]

If the laparoscopy and chromotubation reveal tubal occlusion, surgery may be indicated. Isolated proximal or distal tubal occlusions may be treated by various surgical techniques. However, combined proximal and distal occlusions are not well corrected with surgery, and IVF should be recommended as the treatment of choice to achieve pregnancy in these patients. Age is also important when deciding between tubal surgery and IVF. Older couples should be encouraged to have IVF rather than tubal surgery because the probability of their achieving a pregnancy is higher with IVF.

Cervical Factors

Abnormal cervical mucus is the recognized cause of infertility in 5% to 10% of couples trying to conceive. The postcoital test provides information regarding both the quality of the cervical mucus and its interaction with sperm. This test is performed on cycle day 11 to 13 (24 to 48 hours before ovulation); the male partner must abstain from ejaculation for 48 hours before testing. The cervical mucus is examined 2 to 8 hours after intercourse. The consistency of the cervical mucus is examined and the number of motile sperm per high-power field (hpf) is

Table 2 Semen Analysis Parameters

Parameter	*Normal Value*
Volume of semen	≥ 2.0 ml
pH	7.2–8.0
Sperm concentration	$\geq 20 \times 10^6$ spermatozoa/ml
Total sperm count	$\geq 40 \times 10^6$ spermatozoa/ejaculate

Table 3 In Vitro Fertilization

Step 1	Stimulation of ovulation with injectable gonadotropins.
	Monitoring of follicular development with vaginal ultrasound.
	When mean follicle diameter is ≥ 15 mm, ovulation is triggered with hCG administered intramuscularly.
Step 2	Collection of eggs 34 to 36 hours after hCG injection.
Step 3	Collection of sperm on day of ovum capture or obtain frozen sample.
Step 4	Laboratory (in vitro) incubation of egg(s) with sperm for fertilization and embryo growth.
	If sperm are of poor quality, fertilization is facilitated by microinjection (ICSI) of sperm into egg.
Step 5	Transfer of embryo to uterus 3 to 5 days after oocyte aspiration.
	Administration of progesterone in oil, 50 to 100 mg/day I.M., or vaginal progesterone suppositories.
Step 6	14-day wait for pregnancy or menstruation.
	Measure β-hCG.

hCG—human chorionic gonadotropin ICSI—intracytoplasmic sperm injection

determined. Normal mucus is acellular, clear, thin, and elastic; the mucus should stretch approximately 8 to 10 cm when placed on a glass slide and pulled. This elasticity of the cervical mucus is known as spinnbarkeit. The mucus should also contain at least 5 to 10 progressively motile sperm/hpf.

Cervical mucus that is of poor quality (i.e., thick and nonelastic) will demonstrate a globular rather than a fernlike pattern after drying on a microscope slide. Absent or poor-quality cervical mucus may reflect either inaccurate timing of the test or an abnormality in mucus production. Cervical trauma and infection have been implicated as antecedents to abnormal mucus production.

Sperm that are both shaky and immotile on microscopic inspection are found in the cervical mucus of women who produce antisperm antibodies. When all the sperm from a postcoital test are found to be immotile, the patient should be asked whether lubricants or spermicides were used during coitus.

Intrauterine insemination (IUI) is the treatment of choice for those patients with cervical factor infertility.[17] This procedure bypasses the cervix and allows the physician to place washed sperm directly into the endometrial cavity.[18]

Ovulatory Factors

Ovulatory dysfunction is the cause of 15% of the infertility detected in couples and 40% of the infertility found in women. Anovulation and oligo-ovulation account for most menstrual abnormalities. Shortened menstrual cycles and luteal phase defects are less common causes of ovulatory dysfunction.

A patient's ovulatory status can be determined by several techniques. The cheapest and least invasive technique is to have the patient chart her basal body temperature (BBT). When done correctly, charting can aid the clinician by providing indirect evidence of ovulation. A biphasic temperature curve (i.e., an elevated temperature for at least 11 to 16 days) is an indication that ovulation probably occurred. The patient's own assessment of premenstrual molimina further strengthens the indirect evidence of ovulation.

Measurement of the progesterone level on day 21 of the menstrual cycle also provides an indirect assessment of ovulatory status. This method is less time-consuming than BBT charting. Progesterone values of more than 15 ng/ml are consistent with ovulation. A value of less than 5 ng/ml may indicate that ovulation has not occurred. Because progesterone is secreted in a pulsatile manner, only elevated values of progesterone are diagnostically useful. Levels between 5 and 15 ng/ml probably indicate ovulation but give insufficient information regarding the adequacy of the luteal phase.

Of all menstrual cycles in normally menstruating women, 5% to 30% involve a luteinized unruptured follicle. Although ovulatory symptoms and elevated progesterone levels occur during these cycles, an oocyte is not released and fertilization is impossible. Thus, the predictive value of indirect measures of ovulatory status is limited.

An endometrial biopsy can be performed on cycle days 23 to 26. This test can assess both the ovulatory status of the patient and the adequacy of the luteal phase. A luteal phase defect is defined as a lag in the histologic development of the endometrium by 2 or more days when compared with the cycle day of sampling. This defect in the luteal phase is presumably caused by inadequate progesterone secretion from the corpus luteum.

Treatment has entailed prolonging the luteal phase by administering progesterone either intramuscularly or intravaginally. The benefit of this approach, however, has not been substantiated.

Anovulation

Measurement of the prolactin level should be done during the initial evaluation of patients who are believed to be anovulatory [*see Figure 2*].[19] Elevated prolactin levels have a negative feedback effect on the hypothalamus, preventing the pulsatile release of gonadotropin-releasing hormone (GnRH). This, in turn, prevents secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. Consequently, follicular development and ovulation do not occur.

Hyperprolactinemia is responsible for 15% of all ovulatory disturbances.[20] If the patient has an elevated prolactin level, with or without galactorrhea, the thyroid-stimulating hormone (TSH) level should be measured to rule out primary or secondary hypothyroidism. If the TSH level is normal, a computed tomography scan or magnetic resonance image of the head should be obtained to determine whether the patient has a prolactinoma. Of import is that prolactin levels may also be elevated as a result of the use of specific medications. Pharmacologic agents that deplete dopamine reserves (i.e., antidepressants, antipsychotics, and other psychotropic agents) may also result in hyperprolactinemia and anovulation.

If the CT or MRI findings are abnormal or reveal a pituitary adenoma, the patient should be treated with oral bromocriptine, starting at a dosage of 2.5 to 5 mg daily, or oral cabergoline, 0.25 mg twice weekly [*see 16:I Amenorrhea*]. These medications should be titrated until prolactin levels return to normal. When prolactin levels are normalized, restoration of ovulatory function should occur.[21] Patients with symptomatic macroadenomas may require ablative therapy with either surgery or radiation if medical therapy does not reduce the size of the tumor or if symptoms associated with the tumor persist or worsen.

Patients with hyperprolactinemia and oligomenorrhea (except those with primary and secondary hypothyroidism, who require thyroid hormone replacement) should be treated with bromocriptine only if they are bothered by symptoms (i.e., galactorrhea) or desire fertility. If a patient remains anovulatory despite treatment with bromocriptine, oral clomiphene cit-

rate, starting at a dosage of 50 mg daily for 5 days, can be added as an adjunctive therapy to stimulate ovulation.

If, at the time of initial examination, the patient is determined to be hypoestrogenic (i.e., she has an atrophic vagina and perineum and reports hot flashes and lack of lubrication during coital activity), the clinician should obtain serum levels of FSH, LH, and estradiol (E_2). These values will identify patients with hypogonadotropic hypogonadism and those with ovarian failure. Patients with hypogonadotropic hypogonadism should be evaluated with a GnRH-stimulation test to determine whether the problem is reversible.

Special attention should be given to anovulatory women who have normal levels of estrogen and prolactin and who have signs of hyperandrogenism and virilization. In these patients, measurements should be made of dehydroepiandrosterone sulfate (DHEAS), total testosterone, 17-hydroxyprogesterone, and 8 A.M. free urine cortisol levels. These tests will help to identify patients with polycystic ovary syndrome (PCOS), ovarian and adrenal neoplasms, congenital adrenal hyperplasia, or Cushing syndrome [*see 16:V Polycystic Ovary Syndrome*].

Patients with PCOS that is associated with elevated insulin or glucose levels who wish to conceive may benefit from a combined regimen of oral metformin, 850 mg twice daily, and clomiphene citrate. Studies have shown that women treated with this combination have a higher rate of ovulation than those treated with clomiphene citrate alone.[22] Hirsutism and acne should not be treated medically during ovulatory induction cycles.

Elevated levels of both FSH and E_2 on cycle day 3 signify a decrease in ovarian reserve (i.e., a decrease in the total number of follicles present for maturation and ovulation). The diagnosis of premature ovarian failure is reserved for women who are younger than 40 years and have gonadotropin (FSH and LH) levels in the menopausal range.

Depending on the incipient age of ovarian failure, a complete autoimmune profile and possibly a genetic karyotype should be considered to establish a diagnosis.[23] Women with an autoimmune disorder are at increased risk for developing multiple organ failure and should be screened annually. These women should be counseled to consider IVF with donor eggs or adoption.

UNEXPLAINED INFERTILITY

The incidence of unexplained infertility is estimated to be between 15% and 20%. Couples who do not receive treatment have a monthly fecundity of 3% and a cumulative 3-year pregnancy rate of 60%. However, when a couple has experienced long-standing infertility (> 3 years) and the female partner is older than 35 years, the probability of achieving a pregnancy is markedly reduced.[24]

The treatment for couples with unexplained infertility includes inducement of superovulation with either clomiphene citrate or gonadotropins[25,26] and IUI or one of the assisted reproductive technologies (e.g., IVF, gamete intrafallopian transfer, and zygote intrafallopian transfer).[27] IUI with ovulation induction using gonadotropins produces higher pregnancy rates for couples with male-factor or unexplained infertility than does either procedure performed alone.[17]

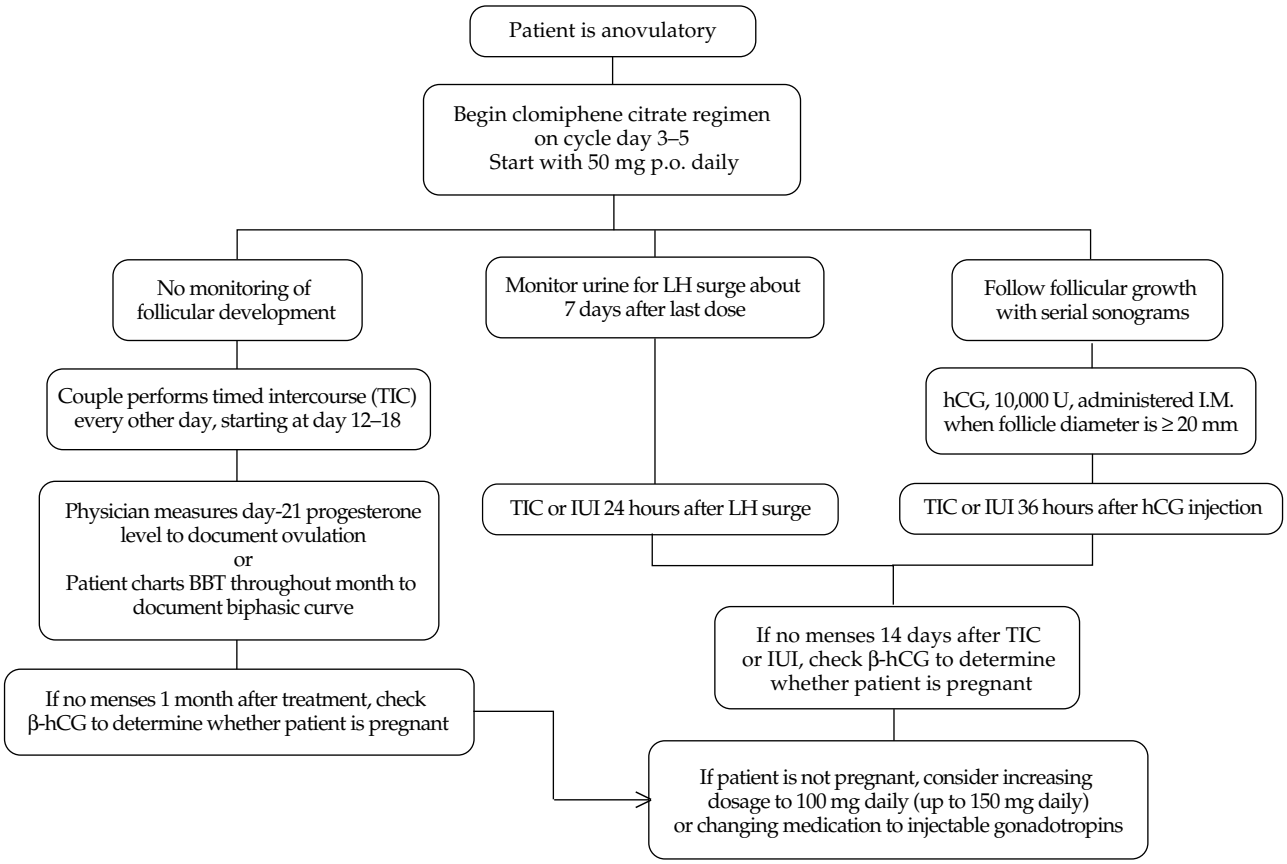

Figure 3 **Ovulation induction with clomiphene citrate. (BBT — basal body temperature; hCG — human chorionic gonadotropin; IUI — intrauterine insemination; TIC — timed intercourse)**

Ovulation Induction with Clomiphene Citrate

To induce ovulation in a woman who has been determined to be anovulatory, clomiphene citrate, 50 mg orally daily, is begun on cycle day 3 to 5 and is continued for a total of 5 days [*see Figure 3*]. The couple and the physician must decide whether to add IUI to the ovulation induction regimen or have the couple perform timed sexual intercourse.

The couple and physician must also decide whether to monitor follicular development and timing for intercourse or IUI and, if so, whether to use a low-, moderate-, or high-technology method for monitoring. Low-technology monitoring entails charting the BBT. A moderate level of monitoring by the patient can be achieved with an LH kit. The kit enables urinary detection of the LH surge, which usually occurs about 7 days after the last dose of clomiphene citrate. High-technology monitoring entails serial vaginal sonography, with administration of human chorionic gonadotropin (hCG) to trigger ovulation when appropriate; hCG is given in a dose of 10,000 units intramuscularly when the follicle diameter is at least 20 mm.

If the clinician is not monitoring follicular development, the couple is directed to perform timed intercourse every other day, starting on cycle days 12 to 18. Timed intercourse or IUI should begin 24 hours after urinary detection of the LH surge or 36 hours after the administration of hCG. One study has shown that in couples with anovulatory, male, or unexplained infertility, clinical pregnancy rates with IUI and clomiphene citrate did not depend on the method used to establish the timing for IUI.[28] Thus, if cost is a consideration for the couple, urinary LH testing may lower the expense by reducing the number of patient visits and eliminating the midcycle ultrasound.

If menses does not begin 14 days after timed intercourse or IUI, the hCG level should be checked to determine whether the patient is pregnant. If the patient is not pregnant but did ovulate, as evidenced by an elevation in the progesterone level on day 21 or a biphasic BBT chart, she should undergo another stimulation cycle with the same dosage of clomiphene citrate. This method can be repeated for as long as 6 months. If pregnancy is not achieved by that time, the use of injectable gonadotropins to stimulate ovulation should be considered [*see 16:V Polycystic Ovary Syndrome*].

It is important for the clinician to realize that the incidence of multiple gestations (e.g., twins) is nearly 8% in patients taking clomiphene citrate and as high as 35% in patients who use injectable gonadotropins.[17] Therefore, extreme caution and judgment should be exercised with these medications.

For patients who do not ovulate with the initial 50 mg/day dosage of clomiphene citrate (as determined on the basis of a low day-21 progesterone level or a monophasic BBT chart), the dose can be increased to 100 or 150 mg daily. If ovulation still does not occur with the higher dosage, ovulation induction with gonadotropins should be employed.[29]

VIII ECTOPIC PREGNANCY AND SPONTANEOUS ABORTION

Alan H. DeCherney, m.d.

Ectopic Pregnancy

Ectopic pregnancy is the implantation of an embryo outside the endometrial cavity (i.e., lining of the uterus). The embryo may be implanted in the fallopian tubes, ovaries, abdomen, or cervix. More than 95% of ectopic pregnancies occur in the fallopian tubes, with nearly 80% of ectopic pregnancies occurring in the ampullary portion of the fallopian tube.

Ectopic pregnancies comprise approximately 2% of all reported pregnancies in the United States. If left untreated, ectopic pregnancy can result in rupture of the fallopian tube, which can lead to hemorrhagic shock and death. For that reason, ectopic pregnancy is a major cause of morbidity and mortality in women of reproductive age. It is the third leading cause of maternal mortality and is responsible for nearly 9% of all pregnancy-related deaths.[1] Between 1970 and 1992, the incidence of ectopic pregnancy increased sixfold, which is consistent with the increased prevalence of important risk factors for ectopic pregnancy (see below).[2]

Improvements in diagnostic skills have enabled physicians to treat ectopic pregnancies at an earlier gestational age and by more conservative approaches. Therefore, it is imperative that the primary care physician be able to diagnose and intervene as early as possible to reduce the incidence of irreversible tubal damage and the risk of future infertility [*see Figure 1*].[3]

DIAGNOSIS

Clinical Manifestations

The principal diagnostic task in ectopic pregnancy is distinguishing it from intrauterine pregnancy or threatened abortion. The symptoms of an ectopic pregnancy [*see Table 1*] vary with its location and the rate of its growth. Nearly all women with ectopic pregnancies complain of a colicky abdominal pain that is vague in location. As the pregnancy grows, capillaries are broken and blood spills into the abdominal cavity. The blood that fills the intraperitoneal cavity causes irritation of the left hemidiaphragm, resulting in left shoulder pain; the liver occupies the space directly under the right hemidiaphragm and prevents the blood from reaching the right hemidiaphragm. Almost one quarter of the patients with ruptured ectopic pregnancies have left shoulder pain.

Amenorrhea, the second most common symptom, occurs in more than 75% of patients. The duration of amenorrhea depends on the site of implantation and usually lasts 6 to 8 weeks before the onset of other symptoms.

Vaginal bleeding is also common and may occur a few days to weeks before the patient's initial visit. The pattern of bleeding is most often described as spotting and usually is preceded by the onset and worsening of abdominal pain.

Other symptoms, which occur less frequently, are dizziness, fainting, nausea, vomiting, other signs of pregnancy, the urge to defecate, and passage of tissue through the vagina.

History and Physical Examination

At the initial visit, the patient's medical history should be taken. Patients in whom ectopic pregnancy is suspected often have a history of infertility, pelvic inflammatory disease, endometriosis, or tubal damage [*see Table 2*]. In rare cases, ectopic pregnancy can occur in patients who have undergone tubal sterilization, even many years after the procedure.[4] If the diagnosis of ectopic pregnancy is suspected, a pregnancy test should be performed (e.g., measurement of the human chorionic gonadotropin [hCG] level in urine). The urine hCG test is extremely sensitive; false negative results are very rare.

Patients who have a negative urine hCG test result should be evaluated for other gynecologic problems, including ovarian torsion, a ruptured ovarian cyst, and pelvic inflammatory disease. Gastrointestinal disorders and possible surgical conditions (e.g., appendicitis) should also be investigated.

If the urine hCG test result is positive, a physical examination should be performed and a pelvic sonogram obtained.[5] The physician should assess the degree of abdominal and pelvic pain experienced by the patient and try to elicit signs of peritonitis, which could indicate rupture of an ectopic pregnancy.

Inspection of the patient's cervix with a speculum can help distinguish ectopic pregnancy from spontaneous or threatened abortion. If the cervical os is open, fetal tissue should be observed at the internal cervical os; the diagnosis of an inevitable abortion or incomplete abortion should be made, and a dilatation and curettage (D&C) should be performed. If the cervical os is closed, the examiner should determine both the amount of blood present in the vagina and the amount emanating from the external cervical os. Most women with ectopic pregnancies do not experience heavy vaginal bleeding and have only a light bloody vaginal discharge. In the case of threatened or complete abortion, the patient should be instructed to have pelvic rest and bed rest until the symptoms resolve.

Laboratory Testing

A pelvic sonogram should be obtained to document whether an intrauterine pregnancy (IUP) or extrauterine pregnancy (EUP) exists. The sonographer should focus attention on the uterus, the adnexa, and the cul-de-sac. The endometrium should be inspected, and the presence of a gestational sac and fetal pole should be verified. Attempts should be made to observe the fetal heartbeat to help distinguish normal from abnormal pregnancies. If nothing is present in the uterus, the adnexa should be inspected. If a gestational sac and fetal pole are identified outside the uterus, the diagnosis of an EUP should be made. The ectopic pregnancy can then be treated by medical or surgical means [*see* Treatment, *below*].

If no IUP or EUP can be documented on sonography, further laboratory evaluation should be pursued. The evaluation should include measurement of the serum β-hCG level, a complete blood count (CBC), and measurement of the prothrombin time (PT) or partial thromboplastin time (PTT). A progesterone assay is optional (see below). A β-hCG value of 1,500 mIU/ml occurs

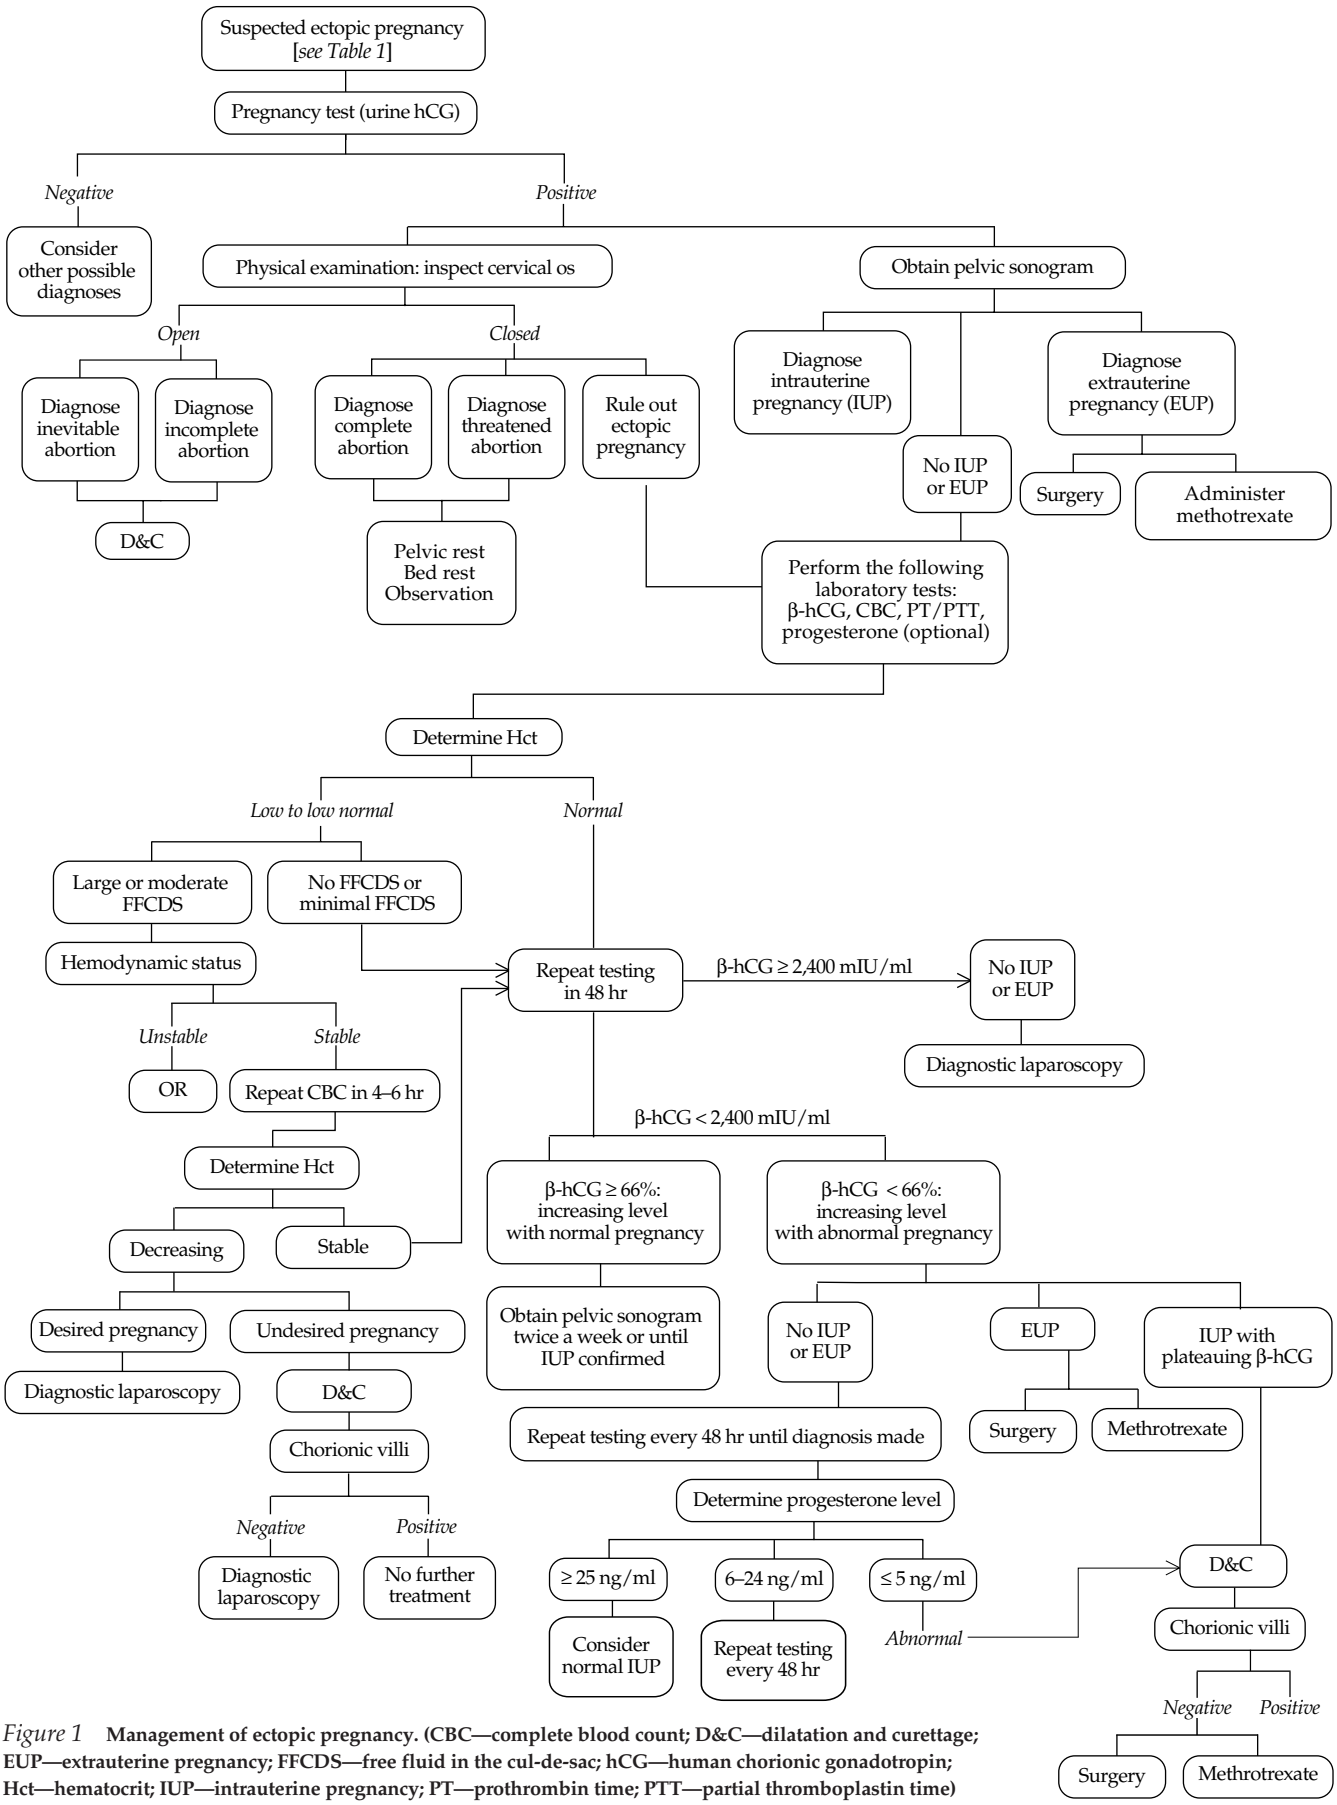

Figure 1 **Management of ectopic pregnancy. (CBC—complete blood count; D&C—dilatation and curettage; EUP—extrauterine pregnancy; FFCDS—free fluid in the cul-de-sac; hCG—human chorionic gonadotropin; Hct—hematocrit; IUP—intrauterine pregnancy; PT—prothrombin time; PTT—partial thromboplastin time)**

Current pregnancy conceived with in vitro fertilization (IVF)
History of endometriosis
Current pregnancy conceived while taking oral contraceptives

around the time a normal IUP first becomes visible on pelvic sonography. If no IUP is observed and the β-hCG value is 2,400 mIU/ml or higher, an ectopic pregnancy should be suspected.

A baseline hematocrit, along with sonographic evaluation of the patient's cul-de-sac, will provide insight for prognosis and possible treatment options. Free fluid in the cul-de-sac may be blood; this finding increases the likelihood of ectopic pregnancy.[6] Patients with aborting ectopic and early nonruptured ectopic pregnancies may present with blood in the cul-de-sac. If the patient has a normal hematocrit and minimal to no free fluid in the cul-de-sac, repeating pelvic sonography and measurements of the β-hCG level and a CBC in 48 hours is recommended. Patients with low to low-normal hematocrits in conjunction with mild to moderate amounts of free fluid in the cul de sac need further evaluation, including a repeat CBC.

If a moderate to large amount of free fluid is found in the cul-de-sac, blood pressure needs to be checked immediately. If the blood pressure is unstable, the patient should be taken to the operating room for an exploratory laparotomy and transfusion with packed red blood cells and crystalloids to replenish intravascular losses.

Some patients require hospitalization for confirmation of hemodynamic stability. The CBC should be repeated within 4 to 6 hours in patients who are hemodynamically stable. If the hematocrit remains stable, the laboratory tests and sonographic evaluation should be repeated within 48 hours (see below).

Patients with decreasing hematocrits should be evaluated with either a D&C or diagnostic laparoscopy, depending on their desire to maintain the pregnancy. When a D&C is performed for removal of fetal tissue, histology of the removed tissue should show chorionic villi. If no villi are obtained, an ectopic pregnancy should be suspected.

Repeat hCG levels The doubling time of the β-hCG level in early pregnancies ranges from 48 to 72 hours. A rise in the β-hCG level of at least 66% in 2 days is generally indicative of a normal IUP. Patients who have normal doubling values of their β-hCG level on repeat evaluation should be followed up in 1 week with a repeat sonogram to confirm a pregnancy in utero.[7]

An abnormally rising β-hCG level (< 66% higher than original values) should be further investigated. Correlation with a repeat sonogram and hematocrit will help guide the clinician to the correct diagnosis and treatment. Although the presence of an ectopic pregnancy should be suspected, an abnormally developing IUP cannot be ruled out. Treatment should be decided not on the basis of only two β-hCG values but, rather, on the entire clinical picture. An abnormally rising β-hCG level that is not substantiated by other laboratory or radiographic evidence should not be treated as an ectopic pregnancy. Surgical or medical treatment of these patients should be considered only when the diagnosis is confirmed and an EUP is documented.

Serum progesterone level Progesterone values can help the clinician determine the viability of a pregnancy, but only in rare instances can they reveal an ectopic pregnancy.[8] A progesterone level of greater than 25 ng/ml is associated with a normal IUP in nearly 97% of cases. Values of less than 5 ng/ml are associated with abnormal pregnancies, and values between 5 and 25 ng/ml are indeterminate. The usefulness of the progesterone assay is limited because more than 85% of the values obtained are between 5 and 25 ng/ml. Furthermore, most centers are unable to process this test in a timely fashion, with results being unavailable for review and interpretation on the same day that the sample is drawn.

TREATMENT

Ectopic pregnancy can be treated medically or surgically. The choice of treatment should be tailored to the patient's clinical circumstances and preferences.[9,10]

Medical Therapy

Methotrexate should be considered as the primary modality of treatment in all patients who meet the criteria for medical therapy [*see Table 3*].[11,12] Methotrexate is an antimetabolite that interferes with the conversion of dihydrofolic acid to tetrahydrofolic acid, inhibiting DNA synthesis and cell division and thereby terminating the pregnancy. Because methotrexate may, in rare cases, produce hepatotoxicity or bone marrow suppression, baseline liver function tests (LFTs) and a CBC, along with a β-hCG level, must

Table 3 Criteria and Contraindications for Methotrexate Treatment

Criteria
Patient is diagnosed with ectopic pregnancy
Patient is reliable and expected to comply with regimen
Patient is hemodynamically stable
The ectopic pregnancy is no greater than 3.5 to 4 cm in diameter
Contraindications
Absolute
Hepatic dysfunction
Moderate to severe anemia
Relative
Human chorionic gonadotropin concentration ≥ 10,000 mIU/ml
Fetal cardiac activity detected with sonography

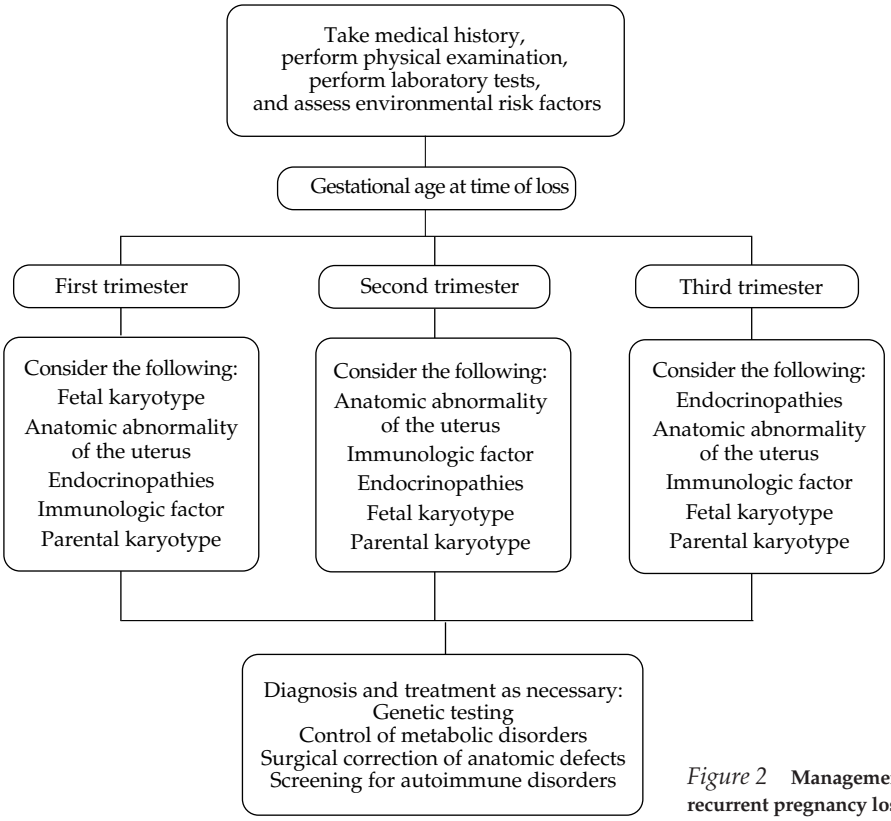

Figure 2 **Management of spontaneous abortion and recurrent pregnancy loss.**

be done in all patients being considered for methotrexate therapy. LFTs and CBCs must be monitored during treatment with repeated doses of methotrexate, and methotrexate should be discontinued if test results become abnormal.

Methotrexate therapy can be given by local injection into the area of the ectopic pregnancy, which requires ultrasound or laparoscopic guidance, or by intramuscular injection as a single-dose or multiple-dose regimen. The multiple-dose regimen is rarely used today, unless the patient fails to respond to the single-dose regimen. The multiple-dose regimen includes citrovorum rescue to protect maternal cells. In the single-dose regimen, 50 mg/m^2 of methotrexate is given and baseline studies are repeated on day 3 or 4. If the β-hCG level decreases by less than 15%, the treatment can be repeated in 1 week. Of the patients who receive methotrexate, 64% are cured with a single dose.[13] An additional 14% require two or three doses. This gives an overall cure rate of 78%. Patients who are cured with methotrexate have fertility rates equivalent to those of patients who are treated surgically. Unfortunately, 20% of the patients whose ectopic pregnancy is treated pharmacologically will ultimately require surgical intervention.

Surgical Therapy

Surgical modalities for ectopic pregnancy include laparoscopy and laparotomy [*see Figure 1*]. Laparoscopy with conservative tubal therapy (salpingostomy or salpingotomy) is the preferred surgical method in hemodynamically stable patients, for the following reasons: (1) Less intraoperative blood loss occurs, (2) less postoperative analgesia is required, (3) the hospital stay is shorter, and (4) the cost savings per patient is greater. After laparoscopy, β-hCG levels should be measured serially until they decrease to nonpregnant levels. If the β-hCG level plateaus, increases, or does not decrease more than 15% in 48 hours, treatment with methotrexate or salpingectomy is required.

In the past, laparotomy and radical tubal surgery (salpingectomy) was recommended for hemodynamically unstable patients. Because of improvements in anesthesia and cardiovascular monitoring, together with advances in laparoscopic surgical skills and experience, operative laparoscopy can now be justified for surgical treatment of ectopic pregnancy even in women with hemodynamic instability.[14] Serial measurement of β-hCG levels is not required after salpingectomy.

Fertility after surgery is not a function of the surgical method employed. Rather, future fertility in these cases depends on three patient factors. The first is a history of infertility; patients with prior infertility have a fourfold lower pregnancy rate than patients without. The second is the status of the contralateral fallopian tube. The third is the extent of adhesions involving the ipsilateral tube.

Spontaneous Abortions

A spontaneous abortion is defined as the spontaneous termination of a pregnancy before 20 weeks' gestation (from the onset of the last menstrual period) or the loss of a pregnancy with a fetal weight of less than 500 g. All pregnancy losses that occur later than 20 weeks' gestational age are termed miscarriages.

Spontaneous abortions occur in about 15% to 20% of all known pregnancies.[15] It has been estimated that more than 50% of all conceptions end in spontaneous abortion. This rate is higher than previous estimates, because spontaneous abortions often

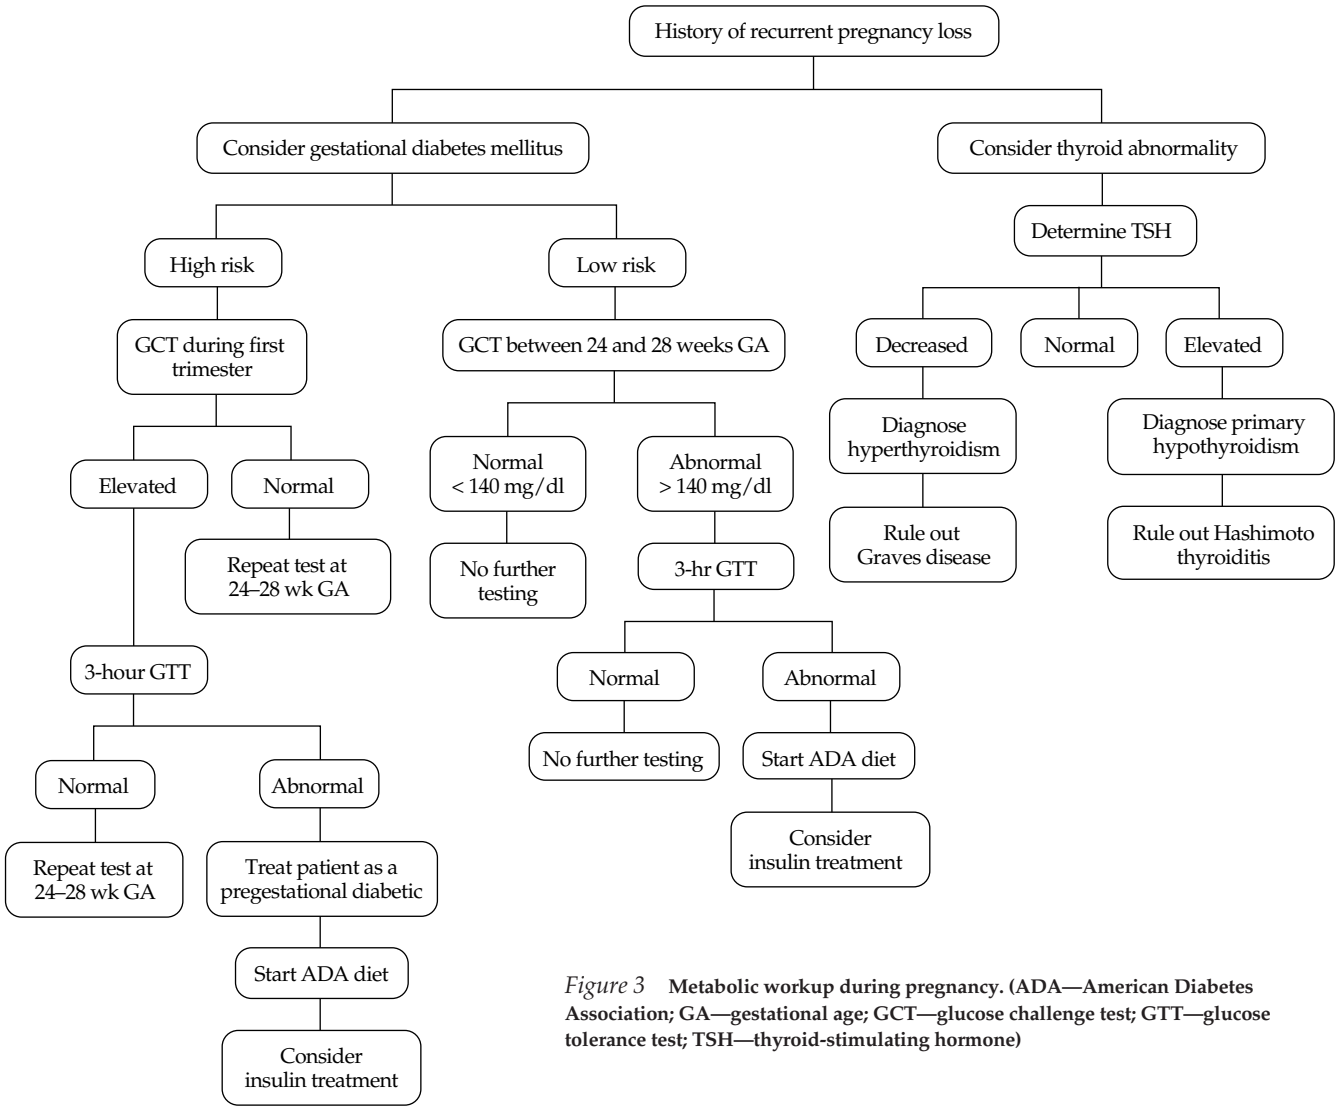

Figure 3 **Metabolic workup during pregnancy. (ADA—American Diabetes Association; GA—gestational age; GCT—glucose challenge test; GTT—glucose tolerance test; TSH—thyroid-stimulating hormone)**

occur around the time of expected menses and are not recognized as abortions.

Traditionally, women who had three or more consecutive pregnancy losses were designated habitual aborters, and it was considered likely that they would continue to have frequent spontaneous abortions. It is now known, however, that in women who have two or more consecutive losses and no history of a live birth, the maximum likelihood that a subsequent pregnancy will result in spontaneous abortion is only about 45%. Women who have at least one live birth before three or more losses have an abortion frequency of less than 30%.[16]

Factors responsible for pregnancy termination vary from one trimester to the next. A strong correlation exists between the gestational age at which the loss occurs and its cause. Therefore, it is important to recognize these potential risks and begin treatment when necessary [*see Figure 2*].

DETERMINING CAUSE OF SPONTANEOUS ABORTION

When a spontaneous abortion has occurred, the physician must investigate the possible causes. A medical history should be taken, possible environmental risk factors should be assessed, and laboratory tests for common infections should be performed.

Depending on whether the abortion occurred during the first, second, or third trimester, the likelihood of genetic, anatomic, or endocrinologic causes varies (see below).

Infections

Organisms that can cause spontaneous abortions include *Ureaplasma, Chlamydia, Listeria,* mycoplasmas, and the TORCH (toxoplasmosis, other [e.g., hepatitis B] rubella, cytomegalovirus, herpes) organisms. Diagnosis is made by cultures of blood or amniotic fluid. Treatments may include antibiotics, γ-globulins, or vaccinations.

Environmental Factors

Cigarette smoking, alcohol consumption, and caffeine consumption can cause spontaneous abortion. The greater the number of cigarettes smoked in a day, the greater the risk of fetal loss. Cleaning solvents and anesthetic gases have been linked to fetal wastage. It is important that pregnant women take precautions and limit their exposure to these agents.

Genetic Factors

Chromosomal abnormalities are responsible for more than 70% of all first-trimester abortions.[17] Aneuploidy problems pre-

dominate, with trisomies as a whole constituting the largest group (nearly 50%). Monosomy X (Turner syndrome) is the single most common chromosomal abnormality, accounting for nearly 25% of spontaneous abortions. Maternal nondisjunction during metaphase I is the most common cause of trisomies. It is estimated that only 30% of second-trimester losses and 3% of third-trimester losses are the result of chromosomal defects.

Balanced translocations are the most commonly transmitted parental chromosomal abnormalities responsible for recurrent losses. Thus, genetic testing should be done in couples who have experienced recurrent spontaneous abortion, to determine whether either partner is a carrier. Genetic testing is often done on spontaneously aborted fetuses.

Endocrine Factors

Patients with uncontrolled diabetes mellitus or thyroid disease have an increased risk of fetal demise and spontaneous abortion. Workup for an endocrine disorder should be considered for all patients with recurrent pregnancy losses. Any history or physical examination that is suspect for a metabolic problem should prompt the physician to investigate immediately.

Second- and third-trimester losses are more often the result of a maternal endocrine abnormality. Recognition and control of the metabolic disturbance are the goals of treatment [*see Figure 3*]. Initial screening begins with a 1-hour glucose challenge test (GCT). This test should be performed in all pregnant women between 24 and 28 weeks' gestational age. A 3-hour glucose tolerance test (GTT) is performed only in women with abnormal GCT values. Evaluation for a thyroid abnormality should be performed at the first prenatal visit. Determining the thyroid-stimulating hormone (TSH) level will distinguish women who have a suspected thyroid dysfunction from those who are euthyroid.[18,19]

Luteal-phase defect is another factor thought to be responsible for early pregnancy loss. Women with this problem characteristically have abnormally shortened secretory phases (< 10 days) or an endometrial lining that is not in phase with the presumed day of the menstrual cycle. An endometrial biopsy that is 2 or more days out of phase with the menstrual cycle is considered diagnostic. Treatment entails the use of progesterone suppositories (25 mg twice daily) to support the luteal phase. However, the benefit of this treatment regimen has not been substantiated.

Anatomic Abnormalities

Uterine cavity malformations are responsible for nearly 15% of recurrent pregnancy losses. Most of these losses occur in the second and third trimesters. Uterine septa are most commonly associated with recurrent abortions. Other causes are submucous myomas, intrauterine adhesions, congenital abnormalities, and cervical incompetence.

A pelvic sonogram and hysterosalpingogram are useful for establishing an initial diagnosis. A magnetic resonance image of the pelvis or a combined laparoscopy and hysteroscopy may be needed for further examination of the uterus. Treatment entails surgical correction of the anatomic defect.

Immunologic Factors

Autoimmune disorders have also been associated with pregnancy losses.[20] These losses commonly occur in the second and third trimesters. Approximately 30% of patients with recurrent pregnancy losses test positive for antinuclear antibodies. Antiphospholipid antibodies, lupus anticoagulants, anticardiolipin antibodies, anti–SS-A (Ro), and anti–SS-B (La) have also been implicated as risk factors. Diagnosis is made by screening the patient for common autoimmune disorders [*see 15:IV Systemic Lupus Erythematosus*].

IX MEDICAL COMPLICATIONS IN PREGNANCY

Ellen W. Seely, m.d.
Jeffrey Ecker, m.d.

Medical complications and intercurrent disease have long presented challenges to obstetricians and other medical providers caring for pregnant women. Contemporary medical practice and treatments have only added to these challenges. Advances in disease management mean that patients with some conditions (e.g., cystic fibrosis) whose life expectancies in the past would have precluded pregnancy are now living to reproductive age. Cures and treatments for other conditions can restore fertility to patients who previously had limited fecundity (e.g., renal transplants in women with renal insufficiency). In vitro fertilization and other assisted reproductive technologies allow the barrier of age, as well as anatomic and genetic barriers, to be surmounted.

All these advances emphasize the need for careful and considered collaboration between clinicians caring for women of reproductive age who are not pregnant and those who care for them during pregnancy. Contraceptive planning and management is vital for patients with significant medical problems, especially those undergoing treatment that is likely to restore fertility (e.g., prescription of metformin for insulin resistance in women with polycystic ovarian syndrome). Primary care clinicians and obstetricians must together evaluate the risk associated with particular diseases in pregnancy and plan for their management, ideally through prepregnancy consultation.

In this chapter, we first review the basic structure and issues for prepregnancy or early pregnancy consultation. We then outline the principles of teratogenesis necessary to evaluate the safety of using medications and other treatments during pregnancy. Next, we discuss the normal physiologic changes of pregnancy. Finally, we discuss specific diseases and conditions that may predate pregnancy or arise as complications of pregnancy and that often require comanagement by obstetricians and medical specialists.

Pregnancy Planning and Counseling

The prognosis for pregnancy complicated by medical conditions is usually improved by pregnancy planning and counseling. In addition, there are a few conditions in which pregnancy may so significantly complicate underlying medical conditions that pregnancy itself is either ill-advised or undertaken only with the greatest of caution. Such conditions include primary pulmonary hypertension and Eisenmenger syndrome (pulmonary hypertension in association with a left-to-right cardiac shunt), each of which carries an approximately 25% to 50% risk of maternal mortality.[1,2] Marfan syndrome with involvement of the aortic root also carries a significant risk of mortality during pregnancy and the puerperium—25% by some estimations.[3] In women with such conditions who have an unplanned pregnancy or who become pregnant in spite of careful contraceptive management, early pregnancy termination should be considered. However, because maternal hormones and physiology change so early in gestation, even early pregnancy interruption does not eliminate all the maternal morbidity and mortality associated with these conditions.

Consultation should also include an evaluation of the risk that a child will inherit the parent's condition. For many disorders, inheritance is defined by mendelian genetics (e.g., autosomal dominant, autosomal recessive, or X-linked disorders). For other conditions that are felt to result from a mix of genetic and environmental exposures (e.g., congenital heart disease), empirical data on inheritance are available. An increasing number of gene defects have been linked to specific disorders, and for many of these, prenatal diagnosis is available. All such diagnoses are facilitated by screening a couple before pregnancy or early in gestation to determine whether genetic testing is informative (i.e., if there is an identifiable mutation or abnormality that can be used in screening DNA from fetal cells). For some couples, family history or ethnic background may indicate the need for screening for specific disorders. The American College of Obstetricians and Gynecologists recommends that white couples with Northern European background be offered screening for cystic fibrosis.[4] Ashkenazi Jews are offered screening for Tay-Sachs disease, Canavan disease, and cystic fibrosis; in addition, Ashkenazi couples may choose screening for an expanded panel of recessive conditions that are more common in this population. Black couples of African background are offered screening to determine whether they are sickle cell carriers. Any fetal testing is facilitated by completing parental screening in advance of pregnancy so that the prospective parents, practitioners, and genetic counselors can anticipate the need for prenatal diagnosis. Such advance planning is essential if couples are considering preimplantation diagnosis, in which embryos created using in vitro fertilization undergo biopsy, their genetic material is studied, and appropriate embryos are transferred for implantation.

Finally, women or couples seeking advice in advance of pregnancy should be counseled about specific dietary or lifestyle changes that may optimize outcome of future pregnancy. Folic acid supplementation of at least 400 μg daily, starting at least 3 months in advance of conception, is recommended to decrease the likelihood of neural tube defects.[5] Planning for a pregnancy may be an impetus to address smoking and the use of alcohol and drugs of abuse. In women with diabetes mellitus (DM), improved glucose control before conception can reduce the risk of birth defects.

Principles of Teratogenesis

Patients and physicians often worry that exposure to medications or environmental agents may increase the risk of birth defects or pregnancy complications. There are, however, few well-designed, prospective studies that address these questions. Such a deficit, while unfortunate, is understandable, because few pregnant women would choose to enroll in prospective, placebo-controlled trials designed simply to examine drug safety. As a result, most of the studies evaluating teratogenesis are retrospective and observational and, therefore, compromised by all the attendant limitations of this approach. In particular, it can be difficult to

separate the effect of medications from that of the condition being treated (e.g., determining whether growth restriction in fetuses of women taking beta blockers for hypertension is caused by the hypertension or the beta blocker). Recognizing the inherent difficulty in human studies, some investigators have turned to animal models; with regard to teratogenesis, however, it is clear that mice are not men (or women). Thalidomide, for example, was not recognized as a teratogen in laboratory animals but proved to cause dramatic phocomelia in humans. Conversely, exposure to steroids in early pregnancy has a much stronger association with cleft lips in mice pups than in humans.

There are several other important challenges in determining whether a particular drug or exposure is teratogenic. Potential teratogenic effects may be small (e.g., lithium is associated with Ebstein anomaly in only one in 1,000 exposed pregnancies) or distant from the incident exposure (e.g., clear cell carcinoma in daughters whose mothers used diethylstilbestrol [DES] occurs decades after the mother's use). In addition, many diseases require treatment with multiple medications. As limited as the data are on individual agents, however, information on outcomes associated with combinations of medications and their potential synergistic effects is even more limited.

Given these recognized limitations, several principles can guide counseling regarding medication use or environmental exposure in pregnancy. Because organogenesis begins in early pregnancy, the first trimester is a critical period for teratogenesis. Early exposure is most directly linked with birth defects; however, later exposure may have adverse effects as well. Use of warfarin or ethanol during the second and third trimester, for example, is associated with clear fetal consequences, because brain development continues well into the neonatal period. Good practice, therefore, recommends that throughout pregnancy, physicians should use the fewest number of medications and the lowest doses appropriate to treat the underlying symptoms or conditions.

There are several resources that providers can use to evaluate exposures in anticipation of or during pregnancy. Databases on reproductive risk are available as online references at many hospitals and health care facilities or by subscription (e.g., the Reprorisk system, which is made up of four such databases, is available online [http://www.micromedex.com/products/reprorisk]. The Food and Drug Administration's classification of drugs according to teratogenic potential [*see Table 1*] and compendia such as the *Physicians' Desk Reference* (PDR) are often used as resources for information on drugs in pregnancy and as guides to patients and providers. Each has important limitations, however. Ratings in the FDA system are often more a reflection of available studies than of evidence of teratogenesis, and the PDR reports all associations between drugs and outcome without rigorously evaluating causality.

The baseline risk of congenital anomalies in the United States is approximately 2% to 3%.[6] To be considered teratogenic, a drug or exposure must be associated with a risk that is higher than threshold, ideally with anomalies clustered in a specific pattern. In fact, only a few drugs are identified teratogens [*see Table 2*].[7] Family history may also increase the risk that a couple will have a child with birth defects. For example, the risk for congenital heart defects is 0.4% to 0.8% in the general population but rises to 3% to 10% if the mother or father had a heart defect at birth.[8] Other maternal characteristics or behaviors may increase the risk of anomalies; for example, maternal obesity is associated with an increased risk of cardiac and neural tube defects.[9] Finally, environmental exposures, such as exposure to heat or ionizing radiation, especially during the critical first trimester, can increase the risk of miscarriage or birth defects such as spina bifida.[10]

Table 1 The Food and Drug Administration Drug Classification System for Pregnancy

Class A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and there is no evidence of a risk in later trimesters; the possibility of fetal harm appears remote.
Class B	Either animal-reproduction studies have not demonstrated a fetal risk (and there are no controlled studies in pregnant women) or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester, and there is no evidence of a risk in later trimesters.
Class C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Class D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Class X	Studies in animals or human beings have demonstrated fetal abnormalities, there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Physiologic Changes in Pregnancy

A variety of physiologic adaptations take place over the course of pregnancy. For example, blood volume increases by as much as 50%; red blood cell mass also increases, but to a lesser extent, resulting in a mild dilutional anemia. Cardiac output rises in compensation. The total blood leukocyte count increases to as much as 15,000 cells/ml in the third trimester. The albumin concentration decreases, which tends to increase free levels of protein-bound drugs. The glomerular filtration rate and the renal plasma flow rate increase until midpregnancy, typically by 40%.

Respiratory changes include an increase in tidal volume. The majority of pregnant women experience dyspnea in the first trimester as a paradoxical result of lower carbon dioxide levels.

Placental secretion of hormones, such as placental lactogen, promotes maternal insulin resistance with subsequent postprandial hyperglycemia; glucose is shunted to the fetus, and the mother uses ketones and triglycerides to meet her metabolic needs.

Liver enzyme levels change during pregnancy. Alkaline phosphatase levels double, whereas there is a slight decrease in levels of aspartate aminotransferase, alanine aminotransferase, γ-glutamyl transpeptidase, and bilirubin.

Changes in the coagulation system include marked increases in levels of fibrinogen and factor VIII, with lesser increases in factors VII, IX, X, and XII; protein S levels (both free and bound) decrease. Together with the increase in venous stasis in the lower extremities, these changes can promote thrombosis.

Cardiovascular Disease

HYPERTENSION

Epidemiology

Up to 5% of pregnant women have chronic hypertension.[11] Moreover, the prevalence of chronic hypertension in pregnancy is increasing, for two reasons: (1) women are having children at older ages, when chronic hypertension is more common, and (2) with the increase in obesity in the general population, chronic hypertension is developing at younger ages.

Diagnosis

Chronic hypertension is defined by the Working Group on High Blood Pressure in Pregnancy as a blood pressure greater than 140/90 mm Hg before pregnancy or in the first half of pregnancy.[11]

Management

Blood pressure should be followed closely throughout pregnancy, to guide decision making about initiation or adjustment of medication. In normal pregnancy, blood pressure falls in the late first trimester and returns to prepregnancy ranges near term. Blood pressure in most women with chronic hypertension follows this pattern.

During pregnancy, blood pressure must be kept high enough to maintain placental perfusion. Consequently, blood pressure goals for pregnant women are higher than those for nonpregnant women. The Working Group on High Blood Pressure in Pregnancy recommends antihypertensive treatment for pregnant women with a diastolic blood pressure of 105 mm Hg or higher to decrease risk of maternal stroke and intracerebral hemorrhage.[11] A meta-analysis of existing studies indicates that antihypertensive therapy in women with mild to moderate chronic hypertension does not influence the risk of developing superimposed preeclampsia.[12]

No antihypertensive medications are designated category A in pregnancy, but methyldopa is recommended as first-line therapy, given its long history of use without adverse effects.[11] However, because methyldopa often causes fatigue and has limited potency, labetalol, beta blockers, or calcium channel blockers are often used. Trials of antihypertensive therapies and trials comparing the effectiveness of different agents in pregnancy are very limited; consequently, few data exist to guide choices among these agents.

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are considered category C in the second and third trimester, because of associated neonatal renal failure.[13,14] Some studies have shown that exposure to ACE inhibitors during the first trimester does not result in ill effects.[13] This finding is important for counseling women who conceive inadvertently while on this class of medication. However, given the number of unplanned pregnancies and the fact that many women do not present for prenatal care in the first trimester, it is prudent that women on these agents be switched to agents of another class when they are planning pregnancy.

Because chronic hypertension in pregnancy is associated with an increased risk of fetal growth restriction and other manifestations of uteroplacental insufficiency, including stillbirth, and because intensive antihypertensive treatment in pregnancy has been associated with intrauterine fetal growth restriction,pregnant women who have chronic hyertension should be carefully monitored. This is usually accomplished by regular evaluation of fetal growth with ultrasonography and, as the pregnancy approaches term, weekly or biweekly evaluation of fetal well-being with nonstress tests (20- to 30-minute evaluations of the pattern of fetal heart rate tracing) or biophysical profiles (ultrasonographic evaluation of fetal movement and amniotic fluid volume). Recognizing the increased risk attendant with these pregnancies, most practitioners plan delivery before the 40th week of gestation even if test results up to that point are reassuring.

Prognosis

Most women with chronic hypertension do well during pregnancy. However, pregnant women with poorly controlled hypertension are at risk for stroke and cerebral hemorrhage, and they are at increased risk for placental abruption.[15] In addition, preeclampsia (exacerbation of hypertension with onset or worsening of proteinuria [*see* Pregnancy-Specific Conditions, Preeclampsia, *below*] develops in approximately 25% of women with chronic hypertension, compared with an overall incidence of 5% in the general population.[15] Preeclampsia has the highest risk of maternal and fetal problems associated with essential hypertension. Despite much research, efforts to decrease the incidence of preeclampsia in women at increased risk for it have been unsuccessful. For these reasons, it is important that women with chronic hypertension be followed more closely during pregnancy. Measuring the 24-hour urinary protein level before pregnancy can facilitate the diagnosis of preeclampsia during pregnancy in women with chronic hypertension.

VALVULAR DISEASE

In general, valvular heart diseases such as pulmonic and tricuspid lesions or mitral valve prolapse or regurgitation are well tolerated during pregnancy. Previously undiagnosed and asymptomatic mitral stenosis, however, may become symptomatic during pregnancy as a result of the increased plasma volume. Women with moderate or severe mitral stenosis are at particular risk in the postpartum period, when the fluid previously sequestered in the placenta or lower extremities returns to the systemic circulation, augmenting the existing increased volume. During labor, careful attention to fluid management and judicious diuresis is required for women with mitral stenosis. Epidural anesthesia may help both by providing vascular relaxation,

Table 2 Selected Drugs with Suspected or Known Teratogenic Potential[7]

Alcohol	Misoprostol
Androgens	Nonsteroidal anti-inflammatory drugs
Danazol	Phenytoin
Angiotensin-converting enzyme inhibitors	Quinolones
Anticholinergic drugs	Retinoids and derivatives
Antithyroid drugs	Acitretin
Methimazole	Etretinate
Propylthiouracil	Isotretinoin
Carbamazepine	Tetracycline
Cyclophosphamide	Thalidomide
Cocaine	Valproic acid
Lithium	Warfarin
Methotrexate	

which slows increases in plasma volume after delivery, and by providing pain relief, which can help slow the patient's heart rate. Lower heart rates in these patients improve the heart's efficiency by promoting adequate atrial filling and the "kick" needed to push blood past the stenotic mitral valve.[16] Symptomatic mitral stenosis has become less common with the fall in the incidence of rheumatic heart disease, but patients who experience critical stenosis can be treated safely during pregnancy with balloon valvuloplasty.[17]

ARRHYTHMIAS

Increased plasma volume may contribute to the onset or worsening of maternal dysrhythmias during pregnancy. Many antiarrhythmic agents are appropriate for use during pregnancy, however, and cardioversion, implantable defibrillators, and pacemakers have all been safely used to control symptomatic dysrhythmias in pregnant women.[18]

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy affects one in 1,500 to 15,000 pregnancies and is marked by heart failure in the months before or after delivery. The cause is unknown. Diagnosis is confirmed by echocardiographic demonstration of decreased ejection fraction in the absence of another recognized etiology.[19] Treatment is supportive and focuses on supplemental oxygen, inotropic medication, and diuresis. With such support, 50% of patients improve over a period of weeks. In those who do not improve, cardiac transplantation may be required. In subsequent pregnancies, women who have previously had pregnancies complicated by peripartum cardiomyopathy demonstrate further decline in left ventricular ejection fraction. Death occurs principally in women who enter their next pregnancy with persistent left ventricular dysfunction; mortality in this group can be as high as 20%.[20]

Diabetes Mellitus

EPIDEMIOLOGY

Approximately 1% to 2% of pregnant women have DM that predates their pregnancy (i.e., pregestational DM). In another 2% to 3%, DM develops during the pregnancy (i.e., gestational DM) [*see* Pregnancy-Specific Conditions, Gestational Diabetes Mellitus, *below*]. As with chronic hypertension, changes in the demographic profile of women who become pregnant have led to an increase in the frequency of type 2 DM in pregnancy.

MANAGEMENT

Women with pregestational DM should receive preconception care that includes counseling about the importance of preconception glucose control. Preconception care improves glucose control and decreases maternal hospitalizations, the need for neonatal intensive care, birth defects, and fetal and neonatal deaths.[21]

Diet therapy is a mainstay of the management of DM outside of pregnancy and is key in pregnancy. Insulin is the preferred agent for the treatment of DM in pregnancy. Women with type 1 DM will already be on insulin; women with type 2 DM who are on oral agents (e.g., hypoglycemics and insulin sensitizers) should be switched to insulin before conception. Insulin therapy should be intensified before conception to achieve a glycosylated hemoglobin level in the normal range, when possible. Neutral protamine Hagedorn (NPH) and regular insulins have a long track record of use in pregnancy. The short-acting insulins, in particular insulin lispro, have been used increasingly in pregnancy and appear to be safe, but long-term follow-up of infants exposed to these agents in utero is not yet available. The long-acting insulins, such as insulin glargine, have not been extensively tested in pregnancy. Goals for whole-blood glucose levels recommended by the American Diabetes Association (ADA) during pregnancy are fasting levels below 95 mg/dl and 1-hour postprandial levels below 140 mg/dl.

Insulin resistance is a hallmark of normal pregnancy, and it occurs in women with DM as well. As a result, insulin requirements typically increase in pregnancy.

Both type 1 and type 2 DM are associated with an increased risk of fetal growth abnormalities. Women with type 1 DM, particularly those with vascular complications, are at risk for fetal growth restriction. Conversely, women with type 2 DM are at risk for large (macrosomic) newborns. In either case, fetal growth in women with diabetes can be monitored with serial ultrasound scans during pregnancy. DM, particularly when poorly controlled, has also been linked to intrauterine fetal demise; accordingly, for pregnant women with diabetes, most practitioners employ a careful program of fetal surveillance that includes nonstress tests, biophysical profiles, and fetal movement counting. As with pregnancies that are at increased risk from other medical complications, delivery is often planned before the 40th week of gestation.

COMPLICATIONS AND PROGNOSIS

DM is associated with increased risks for both the mother and the fetus. For the mother with DM, there may be acceleration of retinopathy and nephropathy during pregnancy. In addition, women with DM are at increased risk for preeclampsia. For the fetus, poor maternal glycemic control at the time of conception may be associated with a birth defect rate as high as 20%. This rate can be reduced to a rate similar to that of the general population if glycemic control is adequate at conception.

Unless insulin doses are increased to compensate for the insulin resistance of pregnancy, women with type 1 DM may experience diabetic ketoacidosis. In the setting of uncontrolled maternal hyperglycemia, the fetus responds by increasing insulin secretion. Insulin acts as a growth factor for the fetus and can cause macrosomia, which increases the chance of injury during vaginal delivery, as well as the need for cesarean section. This elevation in insulin secretion does not resolve immediately with delivery and can lead to neonatal hypoglycemia. The neonates of women who had DM during pregnancy are also at increased risk for respiratory distress syndrome.

Thyroid Disease

EPIDEMIOLOGY

In general, thyroid disease is more common in women than in men. Both hypothyroidism and hyperthyroidism are common in pregnant women.

HYPERTHYROIDISM

Hyperthyroidism complicates about 0.2% of pregnancies.[22] Graves disease is the most common cause of hyperthyroidism in pregnancy.

Diagnosis

The diagnosis of hyperthyroidism during pregnancy is often complicated by the changes in thyroid function that take place in

normal pregnancy. In early pregnancy, the rise in levels of human chorionic gonadotropin, which has thyroid stimulatory activity, results in a compensatory fall in levels of thyroid-stimulating hormone (TSH). Although the fall in TSH concentration is usually within the physiologic range, in some women the TSH falls into the suppressed range. Therefore, the diagnosis of Graves disease should be based not solely on a low TSH level but also on the presence of symptoms of hyperthyroidism and of elevated thyroxine (T_4) levels. Symptoms of hyperthyroidism in pregnancy include weight loss or absence of weight gain, anxiety, and palpitations. Although it is possible that a small degree of thyroid enlargement occurs in normal pregnancy, secondary to increase in plasma volume and thyroid blood flow, a palpable goiter should not be attributed to pregnancy.

Management

Antithyroid medications (thionamides) do cross the placenta, and the fetal thyroid appears to be more sensitive to these agents than the maternal thyroid. Therefore, maternal treatment of euthyroidism is associated with fetal hypothyroidism in about 25% of cases.[23] In addition to fetal and neonatal hypothyroidism, neonatal goiter can be present and can cause respiratory compromise from tracheal compression.

Treatment of maternal hyperthyroidism is recommended only for mothers who are symptomatic. The treatment goal is a T_4 level in the upper range of normal. Hyperthyroidism in pregnancy is one of the few clinical situations in which therapy is guided by the T_4 level rather than the TSH level; normalization of the TSH level is not the goal in these patients.

Propylthiouracil (PTU) and methimazole are the most common drugs used for hyperthyroidism in the United States. There has been some suggestion that PTU crosses the placenta to a lesser degree than methimazole, although the data are limited. Furthermore, methimazole, but not PTU, has been associated with the condition aplasia cutis, a skin defect most commonly involving the scalp. As a result, PTU is the preferred drug for pregnancy. If antithyroid medication does not control the hyperthyroidism and the woman has severe symptoms, thyroidectomy during pregnancy may be required. Radioactive iodine (RAI) ablation is contraindicated during pregnancy, because it can ablate the fetal thyroid and cause congenital hypothyroidism. Concern over uncontrollable hyperthyroidism in pregnancy has led some endocrinologists to recommend RAI thyroid ablation or surgery in women with Graves disease who are planning a pregnancy and in whom control of Graves disease has been difficult, as a result of disease activity or problems with medication. Women with Graves disease who are going to be managed on antithyroid medications should be followed by a clinician with experience in thyroid disease during pregnancy, because the goals of treatment differ from those in nonpregnant patients.

Complications and Prognosis

Severe hyperthyroidism may be associated with stillbirth, preterm delivery, intrauterine growth restriction, preeclampsia, or congestive heart failure.[24] Graves disease usually follows a characteristic course during pregnancy, with exacerbation in the first trimester and improvement or even remission in the third trimester, with exacerbation again about 2 months post partum.

HYPOTHYROIDISM

Maternal hypothyroidism complicates 2% to 5% of pregnancies. For unknown reasons, women with primary hypothyroidism have an increased requirement for thyroid hormone during pregnancy.[25]

Diagnosis

Hypothyroidism is best diagnosed by determination of the TSH level. The upper limit of normal in pregnancy is similar to that outside of pregnancy.

Management

Women with hypothyroidism should have their TSH level measured at the time of a pregnancy test to guide adjustment of their thyroid hormone replacement dose. The TSH level should then be checked at a minimum of each trimester, as well as 4 to 6 weeks after each dose adjustment. Because of the increase in thyroid hormone requirement in pregnancy, some advocate regulating dosing of thyroid hormone before conception to achieve a TSH level of around 1 IU/ml. The increased requirement resolves with delivery, and therefore, the thyroid hormone dose can be reduced to the prepregnancy dose at that time.

Complications and Prognosis

Maternal hypothyroidism has been reported to increase the risk for preeclampsia, placental abruption, and stillbirths. A study of over 400 pregnant women with subclinical hypothyroidism (defined as a TSH level of ≥ 97.5% of the upper range of normal and a T_4 level within normal range) found that rates of hypertension were no different from those in euthyroid pregnant women; however, subclinical hypothyroidism was associated with an increased risk of placental abruption and preterm delivery.[26] The offspring of mothers who were hypothyroid during pregnancy have been reported to have intelligent quotients (IQs) 7 points lower than those of the offspring of euthyroid mothers, although IQs remain in the normal range.[27]

POSTPARTUM THYROIDITIS

The immunologic flare that follows the relative immune suppression of pregnancy may result in thyroiditis. Postpartum thyroiditis is typically transient; it is marked by a period of hyperthyroidism followed by hypothyroidism.

Epidemiology

Postpartum thyroiditis occurs after approximately 8% of pregnancies.[28] Women with type 1 DM are at threefold higher risk; the risk is also higher in women who have had Hashimoto thyroiditis and in those who had postpartum thyroiditis after a previous pregnancy.

Diagnosis

About 2 months after delivery, women with postpartum thyroiditis may experience hyperthyroidism as a result of leakage of thyroid hormone from the inflamed thyroid gland. This phase is often missed because of its short duration (usually 4 weeks or less) and because the patient and her caregivers tend to ascribe its symptoms of anxiety and palpitations to the stress of being a new mother. A TSH level measured at this time will be low. About 6 months after delivery, the hypothyroid phase develops. At this time, patients usually present with fatigue and weight gain or an inability to lose pregnancy-associated weight. Depression can also be a presenting symptom; for that reason, it is important to check the TSH level before making a diagnosis of postpartum depression.

Management

Whether to initiate thyroid hormone therapy in a woman with postpartum thyroiditis depends on the severity of her symptoms. If thyroid hormone replacement therapy is chosen, thyroid hormone can be withdrawn at 1 year post partum to determine whether long-term therapy is indicated. The TSH level should be checked 4 to 6 weeks after stopping therapy, or it should be checked sooner if symptoms of hypothyroidism develop.

Prognosis

In the majority of women with postpartum thyroiditis, thyroid function returns to normal in the ensuing postpartum year. However, some women remain permanently hypothyroid. Overall, approximately 25% of women who have postpartum thyroiditis progress to permanent hypothyroidism in the ensuing 10 years.[28]

Thrombophilia

The risk for thromboembolism during pregnancy is increased, largely as a result of increased venous stasis in the lower extremities and pelvis. In addition, changes in some serum coagulation factors (i.e., elevation of factor VII, factor X, factor VIII, fibrinogen, and von Willebrand factor and decrease of protein S) may contribute to the pregnancy-associated risk for thrombosis. This risk may be particularly prominent in women who have another risk factor for thrombosis, such as inherited or acquired thrombophilia or a history of thrombosis unassociated with trauma—in particular, thrombosis associated with the use of oral contraceptives. Prophylaxis with aspirin or heparin during pregnancy may be indicated for women with any of these risk factors.[29] Although the safety of low-molecular-weight heparin (LMWH) during pregnancy is not definitively established, expert panels have concluded that LMWH may be safely used during pregnancy.[30] Because the timing and course of labor and delivery are not easily predicted and because LMWH has a long duration of action, conversion to unfractionated heparin is generally planned late in the third trimester to minimize bleeding complications from delivery or regional anesthesia. The use of LMWH or unfractionated heparin during pregnancy requires careful monitoring, because changes in plasma volume may affect the usual dosing.[31]

Some studies have suggested that thrombophilias may also be associated with an increased risk of miscarriage and other pregnancy complications, such as stillbirth, growth restriction, and placental abruption.[32] A detailed review of these investigations is beyond the scope of this chapter. Data are, at best, inconclusive, and there is little evidence that intervention (e.g., treatment with heparin, aspirin, or steroids) improves outcome, except possibly in women with antiphospholipid antibody syndrome.[33]

Asthma

As many as 6% of pregnant women have asthma. This disease has a variable course during pregnancy: it is equally likely to worsen, improve, or remain unchanged.[34] In contrast to past reports, current studies indicate that asthma is not associated with an increased risk of preterm delivery and growth restriction.[35] The clinical course in an individual patient may be linked, at least in part, to the patient's and her clinician's willingness to use needed medications during pregnancy. Guidelines from the National Institute of Child Health and Human Development emphasize that continued use of beta agonists and steroids during pregnancy is safe and appropriate.[36] As in nonpregnant women, clinical evaluations such as peak flow measurements can be used to judge disease activity and guide therapy.

Infectious Diseases

Vertical transmission of maternal infection is rare during pregnancy, but some pathogens carry particular pregnancy-associated risks. In addition, infections that are of little or no clinical significance to a woman when she is not pregnant may have serious implications during pregnancy (e.g., parvovirus or cytomegalovirus infection). It is important to note that pregnancy is not a contraindication to most prophylactic measures against infection—including, as appropriate, malaria prophylaxis or vaccination with inactive agents. Seasonal vaccination with influenza is recommended for pregnant women.

HERPES SIMPLEX VIRUS INFECTION

Neonatal infection with herpes simplex virus (HSV) acquired during delivery as a consequence of viral shedding from the cervix and vagina can have devastating consequences for the newborn. Cesarean delivery, especially if performed before active labor when the amniotic membranes are still intact, largely eliminates the possibility of vertical transmission.[37] The risk of delivering an HSV-infected infant is greatest in women with a primary infection with HSV type 1 or 2 at the time of delivery. Although secondary infection carries lower neonatal risk, as a result of the protection afforded by circulating HSV antibodies shared across the placenta with the fetus, cesarean delivery to further limit vertical transmission is still generally recommended when women present in labor with signs or symptoms of secondary infection. To avoid cesarean delivery and reduce neonatal risk, prophylactic treatment with antiviral agents such as acyclovir may be recommended late in the third trimester in an effort to minimize the chances of an outbreak at the time of labor and delivery.[38]

PARVOVIRUS INFECTION

Infection with parvovirus B19, which produces a viral exanthem known as fifth disease, may at times be epidemic in schools or child care settings. Parvovirus infection is usually not of clinical consequence to immunocompetent adults or children. Rarely, fetuses of newly infected pregnant women can develop significant anemia or other complications as a result of transplacental infection. Estimating the precise fetal risk has proved to be challenging, but some series suggest that the risk of the loss of pregnancy when a new maternal infection occurs before the 20th week of gestation may range from 2.5% to 10%.[39] Both early and later infections can result in fetal bone marrow suppression and subsequent anemia; in turn, the anemia leads to pericardial effusion, pleural effusion, and generalized body edema—a condition known as hydrops fetalis. It should be emphasized that such complications are rare, however.[40] Although the anemia is often self-limited, either delivery or in utero fetal red blood cell transfusion may be considered if hydrops fetalis develops.

HIV INFECTION

Although transplacental transmission of HIV infection from mother to fetus has been described, vertical transmission of HIV occurs largely at the time of delivery and is directly linked to maternal viral load. To reduce transmission and optimize maternal

health, antiretroviral regimens that were initiated before pregnancy are continued during pregnancy.[41] Because of mitochondrial toxicity, the combination of didanosine and stavudine should be avoided during pregnancy. Additional concern has been raised about teratogenic effects of efavirenz in animals. For women who have not previously been treated with antiviral agents and whose viral loads and $CD4^+$ T cell counts do not themselves dictate treatment, zidovudine is prescribed during the antepartum and intrapartum period, with postpartum treatment for the newborn, because such treatment has been linked to a reduction of vertical transmission.[42] Cesarean delivery has also been shown to protect against vertical transmission in women with HIV infection and high viral loads.[43] Consequently, cesarean delivery should be offered to patients with more than 1,000 copies/ml.[41] Breast-feeding is not recommended for women with HIV infection if appropriate alternatives (e.g., clean water and formula) exist.[44]

HEPATITIS

Women with active hepatitis B or C are at risk for vertical transmission of such infections to their fetus, particularly if either the presence of e-antigen (in the case of hepatitis B) or copy counts indicate high viral loads. Administration of hepatitis B vaccine and immunoglobulin reduces neonatal infection with hepatitis B by 90%. Cesarean delivery is not routinely recommended in the setting of either of these maternal infections. Breast-feeding is not contraindicated in mothers with hepatitis C, nor is it contraindicated in mothers with hepatitis B whose newborns have received appropriate prophylaxis.

GROUP B *STREPTOCOCCUS* INFECTION

In 20% of women, group B *Streptococcus* (GBS) can be cultured from the rectovaginal area. Such carriage, of no consequence to adults, can result in early- or late-onset GBS sepsis and mortality in three of 1,000 infants delivered to women who are carriers. Screening for GBS colonization is now recommended during pregnancy; when linked with intrapartum treatment, such screening has reduced neonatal infection to less than one in 1,000 deliveries.[45]

Renal Disease

A 1996 study of the outcomes of 87 pregnancies in 67 women with moderate or severe preexisting renal disease described preterm delivery in 59% and fetal growth restriction in 37%—rates considerably higher than those seen in the general population (11% and 10%, respectively).[46] In addition, pregnancy-related loss of renal function was noted in 43% of these women, although distinguishing natural disease progression from progression caused by the pregnancy is extremely challenging at an individual level and can be difficult even at a population level. Accordingly, careful monitoring of both mother and baby are required during such pregnancies. Some conditions (e.g., autosomal dominant polycystic kidney disease and structural anomalies such as single kidney) increase the risk of fetal renal disease.

Renal transplantation can restore fertility in women with end-stage renal disease. However, it is generally recommended that transplant recipients delay conception until graft function has been stable for 1 to 2 years, blood pressure is well controlled, and the immunosuppressive regimen is optimized. In one review of 2,300 pregnancies in 1,600 women who had had a renal transplant, 13% of patients had a spontaneous abortion (a rate similar to that in the general population), and 27% elected pregnancy termination; of pregnancies continuing beyond the first trimester, 92% were termed successful, although many of these were complicated by issues of prematurity and growth restriction.[47] Worsening graft function has been noted during posttransplant pregnancies, but whether the deterioration is any worse than that expected outside of pregnancy remains a matter of debate.

Autoimmune Diseases

Whether pregnancy worsens maternal autoimmune disease, such as systemic lupus erythematosus (SLE), remains controversial. Women with such conditions are at risk for preeclampsia and fetal growth restriction. Outcomes for mother and baby are, in general, felt to be best when maternal disease is quiescent.[48] In some cases, continued treatment with steroids may be needed to maintain quiescence and optimize outcomes. Fetuses of women with SLE or other connective tissue diseases and anti-Ro/SS-A or anti-La/SS-B antibodies are at special risk for neonatal lupus, a condition that may be marked by fetal or neonatal heart block, skin disease, and hepatic inflammation.[49] Testing for these serologic markers is important for guiding both fetal and neonatal care. For example, congenital heart block can be detected in utero, and some have suggested that early detection, when linked with steroid treatment of the mother, can improve outcomes.[50]

Recurrent miscarriage, stillbirth, growth restriction, and preeclampsia more frequently complicate pregnancies of women with antiphospholipid antibodies. In small studies, treatment with heparin, aspirin, or both has been shown to improve pregnancy outcome in some women with symptomatic antiphospholipid antibody syndrome.[51] Such data are limited, however, and treatment should carefully be considered on a case-by-case basis.

Cancer

There is no evidence that pregnancy increases the development, hastens the progression, or promotes the recurrence of any cancer. Cancers, particularly those more prevalent in populations of young women (e.g., breast and cervical cancer), will be found during pregnancy, however. Indeed, given that pregnancy may be one of the few times that many young women seek medical care, the examination and screening conducted during pregnancy may improve detection of incidental malignancies. Appropriate diagnostic studies, including mammography, Papanicolaou smear and colposcopy, and endoscopy should not be deferred because of pregnancy.

Management of cancer that is coincident with pregnancy presents many challenges. Because some forms of cancer and its treatment carry risks for both the woman and her fetus, some women may choose pregnancy interruption. In particular, management of invasive cervical cancer requiring surgical excision presents particular challenges. For other cancers in women who choose to continue their pregnancies, surgical and medical management need not be delayed by pregnancy. Several series describe successful chemotherapeutic treatment of malignancies diagnosed early in gestation, in concert with careful fetal monitoring.[52] For malignancies diagnosed later in gestation, early delivery may be considered so as to facilitate treatment.

Neurologic Diseases

EPILEPSY

The management of epilepsy before and during pregnancy demonstrates the careful balance of risks and benefits attendant with treating women of reproductive age, particularly those who require long-term medication. Most antiseizure drugs are associated with an increased risk of congenital anomalies—6% to 9%, compared with the 3% risk for birth defects in the general United States population. These defects cluster in a characteristic pattern that includes facial defects and microcephaly.[53] The risk is further increased by the need for multiple medications or the use of a few particularly teratogenic medications; for example, valproic acid is associated with a 1% to 3% risk of open neural tube defects. Balanced against these risks are the morbidities associated with seizures if medications are discontinued or are inappropriately dosed during pregnancy. Although pregnancy itself does not appear to either lower seizure thresholds or otherwise increase seizure frequency, changes in plasma volume may require increases in dosing to maintain effective drug levels. With careful monitoring, most women with epilepsy can anticipate healthy outcomes for themselves and their babies.[54]

MULTIPLE SCLEROSIS

Multiple sclerosis generally improves during pregnancy—a time of relative immunosuppression. The disease may flare post partum, however.[55] Although steroids might be used during pregnancy if a woman were to have worsening symptoms, many other contemporary treatments are either poorly studied in pregnancy (i.e., glatiramer acetate) or generally discouraged during pregnancy (i.e., interferons).

MYASTHENIA GRAVIS

Infants of women with myasthenia gravis are at risk for a self-limited neonatal myasthenia syndrome that results when antibodies to the acetylcholine receptor cross the placental circulation. Once delivery and cord clamping interrupt the placental circulation, the newborn clears these antibodies and, over a period of weeks, the syndrome improves. In the interval, affected newborns may require ventilatory and nutritional support until muscles involved in breathing and feeding again function normally.

Substance Use

The use of substances, legal and illegal, can have important consequences for pregnancy. Cigarette smoking is associated with an increased risk of intrauterine growth restriction, preterm delivery, and sudden infant death. Although nicotine is labeled class D (i.e., there is positive evidence of its association with human fetal risk) by the FDA, many clinicians use nicotine replacement to help pregnant women quit smoking.[56] In fact, there is reason to believe that nicotine might carry fewer risks when it is absorbed via transdermal patch or chewing gum than when it is delivered together with the carbon monoxide and other toxins contained in inhaled tobacco smoke.

Although the effects of cocaine on the behavior and neural development of newborns have in the past been exaggerated,[57] the use of cocaine during pregnancy may cause placental abruption. Heroin use may cause fetal growth abnormalities, whereas methadone therapy can be initiated and safely maintained during pregnancy.[58] Infants of mothers who use methadone or other prescription and nonprescription narcotics during pregnancy may be born with drug dependence and require careful monitoring after birth to prevent acute withdrawal. In such newborns, tincture of opium is sometimes given and then slowly titrated to minimize the consequences of acute withdrawal.

Fetal alcohol syndrome—marked by abnormal facial features, growth retardation, and central nervous system disturbances—is a consequence of long-term alcohol use. Although higher frequency and volumes of drinking are associated with an increased risk of fetal alcohol syndrome, no safe level of alcohol use during pregnancy can be defined or recommended.[59]

Data examining the effects of caffeine on pregnancy are indeterminate, but some small studies suggest that high exposures (i.e., more than three to five cups of regular coffee a day) may increase the risk of miscarriage. Prudence therefore argues for moderation in women planning to become pregnant.[60]

Both because of the recognized fetal risks and because prenatal care offers a series of regular practitioner contacts, pregnancy may offer an ideal opportunity to address problems of substance use and abuse. Intervention, however, requires a careful balance that encourages treatment without limiting maternal liberties. Mandated screening and reporting may drive women from prenatal care and otherwise limit the therapeutic opportunity that pregnancy presents.

Intrahepatic Cholestasis

Intrahepatic cholestasis appears to result from impaired processing of bile salts and acids in the liver. The etiology remains uncertain, but evidence suggests a genetic predisposition. Intrahepatic cholestasis occurs in 0.1% to 0.01% of pregnant women. The accumulation of these salts in the skin can cause an intense and characteristic pruritus (worse on palms and soles) without associated skin lesions. Jaundice develops in only about 10% of patients.

Liver function tests in women with intrahepatic cholestasis of pregnancy show elevations in levels of γ-glutamyl transpeptidase, alanine aminotransferase, and aspartate aminotransferase. The most specific test is an elevation in the fasting serum total bile acid concentration.

Whether deposition of bile salts in the placenta results in fetal morbidity and mortality is much debated, but some series indicate an increased risk of stillbirth and postpartum hemorrhage in women with cholestasis. Consequently, many practitioners institute a program of fetal monitoring and maternal prothrombin measurement in cholestatic pregnancies and may recommend induced delivery between 36 and 39 weeks of gestation.[61] Ursodeoxycholic acid can relieve pruritus and help normalize liver enzyme levels and may improve fetal outcome.[62]

Pregnancy-Specific Conditions

There are several medical complications of pregnancy that occur only during pregnancy and that resolve once the pregnancy is completed. Three of these pregnancy-specific conditions are hyperemesis gravidarum, preeclampsia, and gestational diabetes.

HYPEREMESIS GRAVIDARUM

Nausea and vomiting complicate as many as 70% of pregnancies. The cause of these symptoms remains obscure but may be related to levels of human chorionic gonadotropin and other hormones that are affected by pregnancy. Older theories suggesting that nausea and vomiting are a psychosomatic reflection of a woman's rejection of her pregnancy have been discredited. Never-

theless, different cultures and individuals may manage symptoms differently, and in any woman, the symptoms may cause stress.

Unless other findings suggest specific causes for nausea and vomiting (e.g., hyperthyroidism, hepatitis or other viral syndromes, or hydatidiform mole), little testing is required; care is supportive. Women may be reassured that the dietary limitations their symptoms require are unlikely to compromise their pregnancy, and in fact, pregnancies accompanied by nausea and vomiting are more likely to be healthful than those without such symptoms.[63] Several randomized, controlled trials have demonstrated that supplementation with vitamin B_6 (10 to 50 mg two or three times a day) may improve symptoms.[64] Some women may require other medications, including antihistamines and dopamine antagonists, to control symptoms.[65]

Fortunately, in most women, nausea and vomiting abate between the 12th and 16th weeks of gestation. Only rarely is hospitalization or enteral nutrition required.

PREECLAMPSIA

Preeclampsia is defined as the onset of hypertension (i.e., blood pressure greater than 140/90 mm Hg) and proteinuria in the second half of pregnancy.[11] Proteinuria in pregnancy is defined as a finding of more than 300 mg of protein on a 24-hour urine collection. Preeclampsia may also be superimposed on chronic hypertension; in these cases, there is an exacerbation of hypertension accompanied by new-onset proteinuria or worsening of preexisting proteinuria. Preeclampsia complicates 3% to 5% of pregnancies. It occurs most commonly in first pregnancies.

Pathogenesis

The cause of preeclampsia is unknown. At the root of the disorder is endothelial dysfunction and placental insufficiency. Several potential factors in preeclampsia include immune dysregulation, genes, insulin resistance, and placental factors such as soluble fms-like tyrosine kinase–1.[66]

Management

Because the cause of preeclampsia is not known, effective interventions have been elusive. The only definitive treatment is delivery of the fetus. Antihypertensive treatment can decrease the maternal risk of stroke but has not been shown to improve pregnancy outcome. Prophylactic treatment with intravenous magnesium sulfate decreases the risk of eclampsia. Preventive efforts to lower the risk for preeclampsia with aspirin or calcium supplementation have been unsuccessful. Close surveillance of both the mother and the fetus is essential and includes more frequent visits or inpatient observation with periodic evaluation of liver and renal function, as well as other blood markers of disease progression (e.g., platelet count), antenatal testing (e.g. nonstress testing, biophysical profile, or evaluation of amniotic fluid alone), and evaluation of fetal growth.

Complications

Complications of preeclampsia affect both the mother and the fetus. Maternal complications include stroke and intracerebral hemorrhage. The HELLP syndrome (hemolysis, elevated liver function, and low platelets) is a life-threatening maternal complication of preeclampsia.

Prognosis

Preeclampsia resolves with delivery or shortly thereafter. Women with a history of preeclampsia are at higher risk for the disorder in future pregnancies. In addition, these women may be at increased risk for the later development of essential hypertension and other cardiovascular disease.

GESTATIONAL DIABETES MELLITUS

Epidemiology

Gestational diabetes mellitus (GDM) affects about 7% of all pregnancies. The rate of GDM is higher in obese women and in women belonging to certain ethnic groups (e.g., Hispanics).

Pathogenesis

Insulin resistance increases in normal pregnancy. Women who cannot overcome this insulin resistance develop GDM.

Diagnosis

GDM is defined as carbohydrate intolerance diagnosed during pregnancy. However, no universal criteria exist for screening or diagnosis; these criteria differ within and between countries. The ADA recommends screening for GDM in all pregnant women with at least one of the following risk factors: age 25 years or older; ethnicity other than white; family history of DM in a first-degree relative; being overweight before pregnancy or experiencing greater than usual weight gain during pregnancy; or a personal history of either abnormal blood glucose levels or a previous obstetric complication. In the United States, screening is typically performed with a 1-hour glucose tolerance test (GTT) using a 50 g oral glucose load. For women with blood glucose values greater than 140 mg/dl, the next step is a fasting 3-hour 100 g GTT. The diagnosis of GDM is made when patients have two or more GTT values higher than those of either the National Diabetes Data Group or Carpenter-Coustan criteria [*see Table 3*].[67]

Management

The mainstay of treatment for GDM is diet. The therapeutic goals are fasting whole-blood glucose levels below 95 mg/dl and 1-hour postprandial glucose levels below 140 mg/dl.[67] Women with GDM are taught to perform home glucose monitoring.

If glucose levels remain elevated despite dietary intervention, insulin therapy should be initiated. Although this recommendation has been made routinely for some time, evidence supporting the benefit of treatment for pregnancy outcome was lacking until 2005, when a study demonstrated that perinatal complications were less frequent in newborns of women with GDM who were randomized to management with home glucose monitor-

Table 3 Venous Plasma Glucose Criteria for the Diagnosis of Gestational Diabetes after a 100 g Oral Glucose Tolerance Test*

Time	*NDDG Criteria (mg/dl)*	*Carpenter-Coustan Criteria (mg/dl)*
0 (fasting)	105	95
1 hour	190	180
2 hour	165	155
3 hour	145	140

*Gestational diabetes mellitus is diagnosed when two or more results exceed these values.[67]
NDDG—National Diabetes Data Group

ing, dietary therapy, and insulin, compared with the newborns of women who received routine care.[68] A 2004 study suggested that GDM may be effectively managed with oral glyburide rather than insulin,[69] but further studies are needed before this approach is advocated.

Women with GDM who have poor glycemic control or who require insulin or oral agents to regulate blood sugar may benefit from antenatal fetal testing. Clinical or sonographic evaluation for fetal macrosomia may lead physicians to recommend cesarean section rather than vaginal delivery.

Complications

Elevated fasting glucose levels have been associated with fetal demise. Macrosomia risk is also increased. As with preexisting DM, macrosomia increases the chance of shoulder dystocia during vaginal delivery and resultant cesarean section. Like pregestational DM, GDM may result in neonatal hypoglycemia.

Prognosis

GDM is an important risk factor for the future development of type 2 DM. As many as 50% of women who have had GDM will develop type 2 DM over the ensuing 10 years.[70] Obesity further increases this risk. Consequently, questions about GDM should be a standard part of the primary care evaluation in parous women. The ADA recommends yearly screening for DM in women with a history of GDM. Whether screening should entail measurement of a fasting glucose level or a postprandial glucose level has not been established. It seems prudent that women with a history of GDM be advised to reduce weight and to exercise, although studies supporting this recommendation are lacking. Some studies suggest that the use of insulin sensitizers may reduce the rate of conversion of GDM to type 2 DM[71]; these data need to be confirmed in large-scale trials, and cost-effectiveness must be taken into consideration before the use of these agents can be recommended.

X ENDOMETRIOSIS

Robert L. Barbieri, m.d

Definition and Pathophysiology

Endometriosis is a condition in which tissue resembling endometrial glands or stroma occurs outside the uterus. Endometriosis lesions are most often found in the pelvis. Common sites are the peritoneal surfaces posterior to the uterus; the ovary; the peritoneal surfaces anterior to the uterus; the bowel; the bladder; and the appendix. Rarely, endometriosis lesions occur at sites outside the pelvis, such as the respiratory diaphragm.

Endometriosis lesions are heterogeneous, ranging from 1 mm superficial peritoneal lesions to 4 cm deeply invasive lesions in the rectovaginal septum. Ovarian lesions of endometriosis can grow to 4 to 10 cm in size, necessitating surgical resection. Endometriosis lesions undergo cycles of growth and bleeding in tandem with the menstrual cycle. Intraperitoneal bleeding from the lesions elicits an inflammatory response in the pelvis that is associated with pain and infertility.

Epidemiology

Many authorities believe that approximately 5% of women between 15 and 45 years of age have endometriosis.[1] The precise incidence is difficult to determine because there is no inexpensive, highly reliable method for diagnosing endometriosis. The current gold standard for the diagnosis of endometriosis is surgical visualization of endometriosis lesions, usually by laparoscopy, and so (as with any disease that requires expensive and invasive procedures for diagnosis) a significant number of cases may be missed.[2] Collection of definitive data would require selecting a random sample of women and performing laparoscopy on them to determine whether they have endometriosis; understandably, no such study has been done.

Endometriosis is rare before menarche and after menopause, when estrogen production is low. Most cases of endometriosis are diagnosed in women in their 20s who have never had a child. Full-term pregnancy and delivery appear to markedly reduce the risk of developing endometriosis. Multiple full-term pregnancies further reduce the risk. Long periods of amenorrhea (for example, the amenorrhea of athletes) is associated with a reduced risk of endometriosis, as is aerobic exercise for more than 7 hours a week.

Pathogenesis

The pathogenesis of endometriosis lesions involves mechanical, hormonal, immunologic, and genetic factors. The prominence of particular factors may vary from case to case; indeed, it is possible that endometriosis comprises several different diseases with a common clinical outcome.

mechanical factors

In women with a normal uterus, 99.9% of menstrual blood flow occurs in an antegrade direction—that is, from the endometrium through the cervix and into the vagina. Numerous clinical observations as well as experiments in laboratory animals indicate that anatomic changes, such as cervical stenosis, that hinder antegrade flow are associated with an increased risk of endometriosis. In women with cervical stenosis, the relative obstruction at the level of the cervix causes blood to flow from the uterus back through the fallopian tubes and into the peritoneal cavity. This retrograde menstrual flow contains blood, growth factors, and viable bits of endometrial tissue. The greater the amount of retrograde blood flow, the higher the risk of endometriosis. For example, about 80% of women with congenital cervical stenosis and a functioning endometrium will develop endometriosis. Epidemiologic studies suggest that more prolonged menstrual flow (> 8 days) and more frequent menses (cycle length < 27 days) are also associated with an increased risk of endometriosis.[3]

hormonal factors

Steroid hormones control the growth and function of endometriosis lesions. Estradiol stimulates growth, and androgens cause atrophy of endometriosis lesions [*see Table 1*]. High doses of progestins induce terminal differentiation in endometriosis lesions, a process called pseudodecidualization. Once endometriosis tissue undergoes pseudodecidualization, it can no longer grow. The reason pregnancy reduces the risk of endometriosis is probably that the extremely high progesterone levels that occur in pregnancy cause pseudodecidualization of endometriosis lesions.

Organochlorine chemicals (e.g., dioxin) can disrupt steroid metabolism; exposure to these pollutants has been proposed as a factor in the development of endometriosis. In animal models, dioxin has been found to increase the incidence and severity of endometriosis,[4] possibly by interfering with the action of progesterone,[5] but the effect in humans has yet to be confirmed.

Table 1 Effects of Different Steroids on Endometrium and Endometriosis Lesions

Steroid	*Effect on Endometrium*	*Effect on Endometriosis Lesions*
Estrogen	Growth	Growth
Androgen	Atrophy	Atrophy
Progesterone at physiologic concentrations	Differentiation and secretory changes	No effect on lesions that have no progesterone receptors; differentiation and secretory changes in lesions with progesterone receptors
Progesterone at high concentrations	Decidualization	Pseudodecidualization (a terminal differentiation step)

immunologic factors

Numerous studies indicate that in women with endometriosis, the pelvic peritoneal environment is immunologically abnormal, with increased concentrations of white blood cells, cytokines, and growth factors. Indeed, elevated levels of cytokines—specifically, tumor necrosis factor–α in peritoneal fluid and interleukin-6 in serum—have been proposed as a potential diagnostic marker for endometriosis.[6] One group of researchers has found an increased incidence of autoimmune disease in women with endometriosis—a finding that supports the concept that immunologic abnormalities play a role in the development of endometriosis.[7]

Some authorities believe that in women with endometriosis, a primary immunologic abnormality prevents the clearance, from the peritoneal environment, of the endometrial tissue fragments deposited by retrograde menstruation.[8] This postulated primary alteration in the immune response allegedly contributes to the development of endometriosis. Other authorities believe that the observed peritoneal immunologic changes are not a cause of endometriosis but a consequence of it: the endometriosis lesions produce a chronic pelvic inflammation, which leads to an increase of immune cells in the peritoneal fluid. Interestingly, factors secreted by these immune cells appear to promote angiogenesis and cause endometriosis lesions to grow. It is likely that there is cross-talk between the immune system and endometriosis lesions: endometriosis lesions cause inflammation, inducing immune cells to enter the peritoneal environment; in turn, immune cells secrete factors that can stimulate the growth of endometriosis lesions.

genetic abnormalities

The risk of endometriosis is approximately doubled in first-degree relatives of women with endometriosis.[9] The heritable aspects of endometriosis may involve alterations in the immune response that predispose women to ectopic transplantation and survival of endometrial tissue.

Ovarian endometriosis cysts (endometriomas) are monoclonal and appear to arise from a somatic mutation in a precursor cell, although those mutations have not been characterized.[10] This finding suggests that a small number of genes play a central role in the pathogenesis of endometriosis.

endometriosis and infertility

An association between endometriosis and infertility in women has long been noted,[11] and many possible mechanisms for the infertility have been identified. Nevertheless, the hypothesis that endometriosis decreases fertility has not been definitively proved by consistent data from rigorous studies.

In advanced endometriosis, infertility can have an anatomic cause: adhesions interfere with the release of the ovum from the ovary and its uptake into the fallopian tube. Although women with early-stage endometriosis often have reduced fertility, a causal link between the endometriosis and the infertility is not clear.

Abnormalities in peritoneal, tubal, and endometrial function caused by endometriosis may inhibit fertility, especially in women with early-stage disease.[11] Numerous investigators have reported peritoneal abnormalities in women with endometriosis, including an increased volume of peritoneal fluid[12] and increased concentrations of activated macrophages,[13] prostaglandin, interleukin-1, tumor necrosis factor, and proteases.[14] Peritoneal fluid from women with advanced endometriosis appears to inhibit sperm function, thereby possibly reducing fertility.[15]

A few investigators have reported that women with endometriosis may have increased levels of antiendometrial antibodies, which may impair endometrial function.[16,17] Some women with early-stage endometriosis have luteal phase dysfunction,[18] abnormal follicle growth,[19] multiple premature luteinizing hormone surges,[20] and luteinized unruptured follicle syndrome.

Intrauterine endometrium may be abnormal in women with endometriosis, which suggests the possibility of a so-called field defect in the müllerian tract. Significant suppression of β_3 integrin has been reported in the endometrium of women with early-stage endometriosis.[21] This decrease in β_3 integrin expression may be associated with an impaired interaction of the embryo with the endometrium. In addition, elevated levels of the müllerian antigen CA-125 have been found on endometrial biopsies taken during the luteal phase of the menstrual cycle from women with advanced endometriosis[22] and in the menstrual discharge of women with endometriosis.[23]

Diagnosis

Although endometriosis is a common disorder, it remains remarkably difficult to diagnose. In one cohort study, women with endometriosis reported that, on average, 4 years elapsed between their first presentation with symptoms caused by endometriosis and their diagnosis.

clinical presentation

Women with endometriosis typically present because of chronic pelvic pain or infertility. Other possible symptoms include secondary dysmenorrhea, dyspareunia, pain with bowel movements (dyschezia), and pelvic pain not associated with menses. The rare cases of diaphragmatic endometriosis have been associated with chest pain at the onset of menstruation.[24]

physical examination

In most women with endometriosis, the physical examination is normal. However, certain findings on physical examination suggest the presence of endometriosis. These include tender, thickened, or nodular uterosacral ligaments and fixed adnexal masses. A retroverted, fixed uterus suggests involvement of the cul-de-sac with endometriosis.

The uterosacral ligaments connect the base of the uterus to the sacrum. Nodularity of the ligaments is evident on bimanual pelvic examination as pea-sized nodules palpable at 4 o'clock and 8 o'clock at the base of the cervix. These nodules most often are implants of endometriosis.

Two less common physical findings in endometriosis are cervical stenosis[25] and lateral displacement of the cervix. Lateral displacement of the cervix occurs when one uterosacral ligament becomes severely involved with endometriosis, shortens as a result of scarring, and pulls the cervix to the side.[26]

noninvasive laboratory tests

A complete blood count, urinalysis, and endocervical cultures for gonococci and *Chlamydia* should be performed to rule out infectious causes of pelvic pain in women. Results of all these tests will be normal in women with endometriosis. In most women with endometriosis, the pelvic sonogram is normal, but other conditions, such as uterine leiomyomas, will be evident on sonography. Although many conditions can cause

adnexal masses, including dermoids (mature teratomas), serous and mucinous cysts, and hemorrhagic corpora lutea, endometriomas have classic characteristics on ultrasound, which aids in their diagnosis.

surgical staging

The current gold standard for the diagnosis of endometriosis is the surgical visualization of lesions, usually by laparoscopy. The normal peritoneal surface is smooth and glistening, like the inner surface of the oral mucosa. Classic endometriosis lesions are often black, purple, or red and measure 1 to 5 mm in diameter; they stud the surface of the peritoneum. Atypical endometriosis lesions are often translucent or yellow, and they may take the form of either flat plaques or vesicles.

Unfortunately, surgeons vary considerably in their ability to detect endometriosis lesions reliably. One study reported pathologic confirmation rates of visually diagnosed endometriosis at 42%, 65%, and 76% for three different surgeons.[27]

Endometriosis is staged surgically using the American Society of Reproductive Medicine staging system. This system divides the disease into four stages: stage I, minimal; stage II, mild; stage III, moderate; and stage IV, severe. As with detection, however, staging is not always performed consistently. Studies of intersurgeon and intrasurgeon variability in the staging of endometriosis report low reproducibility and a kappa coefficient in the range of 0.28.[28]

histologic diagnosis

Biopsy and histologic analysis of lesions found on laparoscopy may enable more reliable diagnosis of endometriosis than does visual inspection alone. The criteria for histologic diagnosis of endometriosis include the presence of one of the following components: (1) both endometrial glands and stroma; (2) glandular epithelium with hemosiderin; or (3) endometrial stroma–like tissue with hemosiderin. One weakness of histologic diagnosis for endometriosis is that diagnostic criteria vary among pathologists.[29,30] Furthermore, no study has demonstrated high interobserver reproducibility in the histologic diagnosis of endometriosis.

clinical diagnosis

An innovative approach to the diagnosis of endometriosis is to use a combination of history, physical examination, and noninvasive laboratory testing.[31] This approach is called clinical diagnosis.

differential diagnosis

Pelvic Pain

Chronic pelvic pain, defined as the presence of pain below the umbilicus for more than 6 months, is a common gynecologic problem. In one study of primary care practices that included 284,162 women 12 to 70 years of age, the reported prevalence of chronic pelvic pain was 3.8%.[32] Along with endometriosis, other common gynecologic causes of chronic pelvic pain include chronic pelvic inflammatory disease, adenomyosis, and uterine leiomyomata. Nongynecologic diseases such as irritable bowel syndrome and fibromyalgia, as well as psychiatric diseases such as somatization, may also contribute to chronic pelvic pain. In populations in which the prevalence of sexually transmitted diseases is low, endometriosis is the most common cause of chronic pelvic pain. In three large studies, 70% to 80% of women with chronic pelvic pain had endometriosis as the cause.[31,33,34]

Infertility

Endometriosis is considered to be responsible for 8% of all cases of infertility. The most common causes of infertility, accounting for about 75% of cases, are ovulatory disorders, tubal disease, and semen abnormalities. Miscellaneous factors, such as cervical or immunologic abnormalities and uterine synechiae, cause 2% of cases; 15% are unexplained.[35-37]

Treatment of Pelvic Pain

Interventions that reduce estradiol production are the most reliable way to cause atrophy of endometriosis lesions and are the most effective in treating pain symptoms. A variety of hormonal and surgical interventions are available for this purpose. Most authorities recommend a stepwise approach to the use of these interventions [*see Table 2*].

Table 2 Stepwise Treatment of Pelvic Pain

Step	*Description*	*Recommendation*
1	Thorough history and physical examination	Detailed history and physical examination forms for evaluating pelvic pain are available on the Internet at www.pelvicpain.org
2	Noninvasive laboratory testing	Pelvic ultrasound, complete blood count, urinalysis, endocervical cultures for gonococci and *Chlamydia*
3	Empirical therapy	Oral contraceptive plus nonsteroidal anti-inflammatory medication
4	Surgical diagnostic procedure	Laparoscopy to determine the cause of pain if empirical therapy does not result in sufficient relief of pain
5	GnRH agonist therapy	For regimens, see Table 3
6	GnRH agonist therapy plus steroid add-back	Consider for reduction of GnRH agonist side effects; for regimens, see Table 4
7	Progestin-only treatment	If GnRH agonists cannot be tolerated because of side effects; for regimens, see Table 5

GnRH—gonadotropin-releasing hormone

hormonal treatment for relief of pain

Randomized clinical trials have demonstrated that combination estrogen-progestin oral contraceptives, gonadotropin-releasing hormone (GnRH) agonist analogues, danazol, and progestins are all effective in relieving pelvic pain caused by endometriosis. GnRH agonist analogues are the most effective; combination estrogen-progestin oral contraceptives are the least expensive.

Combination Estrogen-Progestin Oral Contraceptives

Oral contraceptives are sometimes effective in the treatment of pelvic pain caused by endometriosis because progestins can block the growth of endometrium and endometriosis lesions. Although estrogen stimulates the growth of endometriosis lesions, modern oral contraceptives are progestin dominant and contain low doses of estrogen.

In the United States, almost all women with chronic pelvic pain are initially treated empirically with a combination of cyclic oral contraceptives and nonsteroidal anti-inflammatory drugs (NSAIDS), such as ibuprofen. In contrast, in some European countries, the standard practice is to perform laparoscopy on women with chronic pelvic pain to determine the cause of the pain before starting hormonal treatment. In one randomized study, women with endometriosis who had not previously undergone hormonal treatment were randomized to receive treatment with either low-dose cyclic oral contraceptives or a GnRH agonist analogue. Both groups experienced significant improvement in pelvic pain and dysmenorrhea. However, the group treated with GnRH agonists had better relief of dyspareunia.[38]

Oral contraceptives can be used in monthly cycles or long-cycle regimens. If a regimen of oral contraceptives taken in monthly cycles does not relieve the pain, many physicians will try a regimen of long-cycle oral contraceptives. In long-cycle regimens, the active pills are taken for 42 to 105 days in a row; no pills are taken for a period of 1 week between cycles.

If oral contraceptives and NSAIDs fail to relieve chronic pelvic pain, most physicians recommend laparoscopy to definitively determine whether endometriosis is present.

GnRH Agonist Analogues

Several GnRH agonists have been approved for use in endometriosis [*see Table 3*]. These agents are analogues of the native decapeptide GnRH, with substitutions in amino acids 6 and 10. The introduction of D-amino acids at position 6 of native GnRH produces GnRH analogues that are resistant to degradation by endopeptidases and have long half-lives, high affinity for the GnRH receptor, and long receptor occupancy.

Paradoxically, initial treatment with a GnRH agonist analogue stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Prolonged treatment, however, suppresses gonadotropin secretion through the cellular processes of downregulation and desensitization. The suppression of secretion is greater for LH than for FSH. The suppression of pituitary gonadotropin secretion results in suppression of ovarian follicle growth and a 95% decrease in estrogen production. In women treated with many GnRH analogues, the circulating estradiol concentration is suppressed to about 15 pg/ml, which is in the range observed in menopausal women. In essence, this therapy constitutes a reversible medical oophorectomy.

Numerous clinical trials have demonstrated that approximately 85% of women with endometriosis and pelvic pain who are treated with GnRH agonist analogues experience relief of their pain. In one placebo-controlled trial, treatment with a GnRH agonist resulted in better relief of pelvic pain than the administration of placebo (85% and 30%, respectively).[39]

Table 3 GnRH Agonists Approved for the Treatment of Endometriosis*

GnRH Agonist	*Dose*
Leuprolide acetate depot	3.75 mg I.M. every 4 wk
Goserelin acetate	3.6 mg subcutaneous implant every 4 wk
Nafarelin acetate	200 µg twice daily as a nasal spray

*Note: In the United States, GnRH agonist therapy is approved for 6 mo as single-agent therapy and for 1 yr when used in combination with a steroid add-back.

GnRH Agonist Analogues plus Steroid Add-Back

GnRH agonist treatment is associated with hypoestrogenic side effects such as vasomotor symptoms (hot flashes), decreased libido, dry vagina, and decreased bone density. Recent trials have demonstrated that use of a steroid (either high-dose progestin or very low dose estrogen) in so-called add-back therapy can minimize these side effects. GnRH agonist treatment combined with low-dose steroid add-back causes atrophy of endometriosis lesions and improves pelvic pain while minimizing hypoestrogenic vasomotor symptoms and bone loss. In one clinical trial, women with endometriosis and chronic pelvic pain were randomized to four different hormone treatment groups: GnRH agonist alone, GnRH agonist plus progestin only (norethindrone, 5 mg daily), GnRH agonist plus low-dose estrogen-progestin (conjugated equine estrogen, 0.625 mg daily, plus norethindrone acetate, 5 mg daily), or GnRH agonist plus high-dose estrogen plus progestin (conjugated equine estrogen, 1.25 mg daily, plus norethindrone acetate, 5 mg daily). All women were treated with the GnRH agonist leuprolide acetate, given in a depot injection of 3.75 mg I.M. every 4 weeks for 1 year. The rate of treatment discontinuance because of continuing pain was significantly higher in the group that received the combination of GnRH agonist and high-dose estrogen than in any of the other treatment groups.[40] The high-dose estrogen probably stimulated continuing function of the endometriosis implants. Consequently, treatment with a combination of GnRH agonist and high-dose estrogen is not recommended for most women with endometriosis and pelvic pain. The women in the three other groups experienced similar decreases in their pelvic pain, suggesting that all three regimens are effective. Bone density de-

Table 4 Steroid Hormone Regimens for Pelvic Pain from Endometriosis

Regimen	*Comments*
Transdermal estradiol patch, 25 µg daily, plus medroxyprogesterone acetate, 2.5 mg daily[27]	Does not completely prevent bone loss; achieves estradiol concentration in the range of 30 pg/ml
Norethindrone acetate, 5 mg daily[26]	A high dose of progestin; may be associated with symptoms such as bloating and mood changes
Conjugated equine estrogen, 0.625 mg daily, plus norethindrone, 5 mg daily[26]	Preserves bone density and markedly reduces vasomotor symptoms

creased significantly in the women who received the GnRH agonist alone. Bone density was preserved in the groups that were treated with a combination of a GnRH agonist and steroid add-back therapy, and vasomotor symptoms were significantly reduced. This study and others suggest that an optimal treatment of pelvic pain from endometriosis may involve the use of GnRH agonists to suppress ovarian estrogen production, followed by add-back therapy with low doses of estrogen-progestin or progestin alone [*see Table 4*].

Endometriosis lesions grow when serum estradiol concentration is in the premenopausal range (30 to 300 pg / ml), and they regress when estradiol levels are in the menopausal range (< 20 pg / ml). An important clinical question is, What concentration of estradiol will minimize the growth of endometriosis implants but not cause severe hypoestrogenic side effects? Treatments that achieve estradiol levels in the range of 20 to 30 pg / ml are associated with amenorrhea and regression of endometriosis lesions. In addition, these treatments are associated with fewer side effects than treatments that target estradiol levels to less than 20 pg / ml.[41]

Danazol

The first hormonal treatment of endometriosis was the intramuscular administration of testosterone. High-dose parenteral testosterone therapy was demonstrated to cause regression in endometriosis lesions. Unfortunately, many women became virilized by this treatment. Androgen treatment of endometriosis was resurrected after the development of synthetic oral androgens, such as danazol, which had attenuated androgen properties.[42]

Randomized clinical trials that have directly compared danazol and the GnRH agonists have demonstrated that both treatments improve pelvic pain in approximately 85% of treated women.[43] The side effects of these two treatments are very different. The main side effects of the GnRH agonists are those associated with hypoestrogenism (see above). The main side effects of danazol are weight gain (on average, approximately 4 kg at doses of 800 mg / day), muscle cramps, decrease in breast size, oily skin, and hirsutism.[44] In the United States, these side effects have limited the use of danazol for the treatment of endometriosis.[45] Many of the side effects of danazol are dose dependent. Doses of 50, 100, and 200 mg daily can be effective in relieving pelvic pain caused by endometriosis and are associated with less severe side effects than daily doses of 400 or 800 mg. Doses of danazol of less than 400 mg / day do not reliably suppress ovulation. Danazol crosses the placenta and is a known teratogen, so patients who are taking low doses of danazol must use a reliable method of contraception.

Progestins

High-dose synthetic progestins have been demonstrated to be effective in the treatment of pelvic pain in women with endometriosis [*see Table 5*]. These agents have multiple mechanisms of action: (1) suppression of LH and FSH secretion, which suppresses estradiol production; (2) direct antiestrogenic effects on endometriosis lesions; and (3) induction of pseudodecidualization. A problem with progestin treatment is that many women gain weight or experience symptoms typical of the premenstrual period, such as mood changes and bloating.

Table 5 Progestins Effective for Single-Agent Treatment of Endometriosis

Progestin	*Dose*
Norethindrone acetate	5 mg p.o. daily
Medroxyprogesterone acetate	50 mg p.o. daily; 150 mg I.M. every 90 days
Norgestrel	0.075 mg p.o. daily

surgical treatment

Surgical treatment of endometriosis is termed either conservative or definitive. In conservative surgery, all the pelvic organs are preserved; in definitive surgery, both ovaries are removed.

Conservative Surgery

Conservative endometriosis surgery is best accomplished by laparoscopy because postoperative recovery is very rapid, with discharge usually occurring within 1 day. Most surgeons utilize sharp excision to remove endometriosis lesions, electrosurgery to ablate endometriosis lesions, or a combination of the two methods. In one clinical trial, women with pelvic pain caused by endometriosis were randomized to undergo diagnostic laparoscopy and aspiration of peritoneal fluid or to undergo conservative surgery with laparoscopy and resection or ablation of endometriosis lesions. Six months after surgery, 63% of the women treated with surgical resection of endometriosis lesions reported relief of pain, whereas 23% of those treated with diagnostic laparoscopy without surgical resection reported pain relief.[46]

Conservative surgery typically fails to provide permanent relief of endometriosis, however. Within 2 years after surgical treatment, pain recurs in most women with endometriosis.[47] Also, surgical treatment may result in pelvic adhesions, which can become a primary cause of continuing pelvic pain.

Definitive Surgery

Definitive surgery for endometriosis involves removal of both ovaries. Typically, the uterus is removed as well; indeed, in the United States, endometriosis is second only to uterine fibroids as a reason for performing hysterectomy. Many large cohort studies report that about 90% of women with endometriosis and pelvic pain experience long-term relief of their pain through bilateral oophorectomy.[48,49]

After bilateral oophorectomy for endometriosis, patients are typically started on low-dose estrogen replacement. Low-dose estrogen therapy prevents vasomotor symptoms and osteoporosis; pelvic pain usually does not recur.

surgical excision of ovarian masses

Endometriomas require surgical excision if they are causing pain or are enlarging. Large ovarian cysts may be the result of ovarian cancer. Surgical removal of the cyst allows a definitive diagnosis of the cause of the cyst to be made. A randomized clinical trial demonstrated that surgical removal of endometriomas resulted in better long-term results than simple aspiration and fenestration of the cyst.[50]

Treatment of Infertility

early-stage endometriosis and infertility

Women with minimal or mild (stage I or II) endometriosis and infertility have a baseline fecundity of approximately 0.03

Table 6 Stepwise Treatment of Infertility in Early-Stage Endometriosis

Step	*Description*	*Recommendation*
1	Identify and treat all reversible causes of infertility	Proper timing of coitus in relation to ovulation Optimal coital frequency Cessation of cigarette smoking Optimal body mass index Reduce consumption of alcohol and caffeine
2	Laparosocopic surgery to resect endometriosis and remove adhesions	Attempt to restore pelvic anatomy to normal
3	Ovarian stimulation with clomiphene plus intrauterine insemination	Insemination timed to the day before and day of ovulation
4	Ovarian stimulation with gonadotropin injections plus intrauterine insemination	Insemination timed to the day before and day of ovulation; because of increased risk of twin, triplet, and quadruplet pregnancy, some clinicians prefer to skip step 4 and move directly to step 5
5	In vitro fertilization and embryo transfer	—

(3% per cycle, compared with 20% to 36% in normal couples). Numerous randomized studies have demonstrated that a stepwise approach to treatment can increase pregnancy rates in women with early-stage endometriosis [*see Table 6*].

Treatment of Infertility from Other Causes

The first step in the management of early-stage endometriosis and infertility is to identify and treat all reversible causes of infertility in the couple. Many couples have multiple causes of their infertility (e.g., endometriosis in the female partner and a low sperm count in the male partner).

Laparoscopic Surgery

If other causes of infertility have been addressed but the woman is still unable to conceive, the next step is to consider a laparoscopic surgical procedure to ablate or excise endometriosis implants and adhesions and to attempt to restore the pelvis to normal. In one randomized, prospective trial, diagnostic laparoscopy alone was compared with diagnostic laparoscopy combined with surgical resection or ablation of endometriosis in 341 women with early-stage endometriosis. During 36 weeks of postoperative follow-up, fecundity was 0.024 in the diagnosis-only group and 0.047 in the surgically treated group; cumulative pregnancy rates during follow-up were 18% and 31%, respectively.[51]

Intrauterine Insemination

Women who fail to become pregnant after laparoscopic surgery can be treated with intrauterine insemination (IUI) in combination with either clomiphene or gonadotropin injections. Clomiphene is far less expensive than gonadotropins; therefore it is generally used first. These methods are designed to cause multifollicle development and multiple ovulation. In addition, IUI places a large number of motile sperm high in the reproductive tract. Thus, the spermatazoa do not have to travel through the vagina, cervix, and lower portion of the uterus. Both of these methods have been demonstrated to improve pregnancy rates in women with early-stage endometriosis. In one randomized study in 40 women with early-stage endometriosis, fecundity was 0.045 (4.5% per cycle pregnancy rate) in the group that received no treatment and 0.15 in the group treated with three cycles of gonadotropin injections in combination with IUI.[52] Similar findings have been reported by other groups.[53-56]

Table 7 Stepwise Treatment of Infertility in Advanced Endometriosis

Step	*Description*	*Recommendation*
1	Identify and treat all reversible causes of infertility	Proper timing of coitus in relation to ovulation Optimal coital frequency Cessation of cigarette smoking Optimal body mass index Reduce consumption of alcohol and caffeine
2	Surgery to resect endometriosis and remove adhesions	Attempt to restore pelvic anatomy to normal
3	Ovarian stimulation with clomiphene plus intrauterine insemination	Insemination timed to the day before and day of ovulation; limited to patients with patent fallopian tubes and no dense ovarian adhesions
4	Ovarian stimulation with gonadotropin injections plus intrauterine insemination	Insemination timed to the day before and day of ovulation; limited to patients with patent fallopian tubes and no dense ovarian adhesions; because of increased risk of twin, triplet, or quadruplet pregnancy, some clinicians prefer to skip step 4 and move directly to step 5
5	In vitro fertilization and embryo transfer	—

Many authorities believe that the per-cycle pregnancy rate drops significantly after three or four cycles of clomiphene or gonadotropin injections in combination with IUI. Consequently, after three cycles of such treatment, the clinician should review with the couple the advantages of proceeding to the next step, which is in vitro fertilization (IVF) with embryo transfer.[57]

In Vitro Fertilization

There are no prospective, large-scale, randomized trials that demonstrate the efficacy of IVF in the treatment of infertility caused by endometriosis. However, the use of IVF in women with endometriosis and infertility routinely results in treatment-cycle pregnancy rates of approximately 0.30, a 10-fold increase over the baseline fecundity seen in such women.[58-60] It should be noted, however, that the outcome of IVF is highly influenced by the woman's age: women younger than 37 years have much better success with IVF than do women older than 37 years.

advanced endometriosis and infertility

In women with moderate or severe endometriosis and infertility, a stepwise approach to treatment is warranted [*see Table 7*].

Treatment of Infertility from Other Causes

The first step is to identify and correct all other reversible causes of infertility (see above).

Surgical Treatment

The second step is to perform surgical resection for ovarian endometriosis, peritoneal endometriosis, and pelvic adhesions to restore pelvic anatomy and function. There are no randomized, prospective studies that demonstrate the efficacy of surgery in the treatment of advanced endometriosis. However, most authorities believe that surgery improves fertility in these women. One retrospective analysis reviewed the outcome in 130 infertile women with endometriosis who were treated with expectant management, conservative surgery, or expectant management followed by surgery. Although no significant difference was noted between expectant management and surgery in women with mild or moderate endometriosis, women with severe endometriosis appeared to benefit from surgery. Of the 32 women with advanced endometriosis who were observed over 231 months of cumulative follow-up, none became pregnant. Of the 34 women with advanced endometriosis who underwent conservative surgery, 10 became pregnant during 702 cumulative months of follow-up.[61] Similar results have been reported in a meta-analysis of the impact of surgery on fertility in women with endometriosis.[62] These studies suggest that expectant management is not warranted in the treatment of infertility associated with advanced endometriosis and that surgical treatment may improve fecundity.

Pregnancy rates are highest in the 6 to 18 months after the surgical procedure. Additional surgical procedures have not been shown to be effective in increasing fecundity[63]; therefore, if pregnancy does not occur after the first surgery, the clinician should usually move on to intrauterine insemination. Physicians should carefully weigh the limited benefits of second and third operative procedures to enhance fertility against the potential risks of major surgery.

Intrauterine Insemination

Clomiphene or gonadotropin injections in combination with IUI are used empirically in patients with advanced endometriosis and infertility. Most of the clinical trials that have tested these modalities have focused on women with early-stage endometriosis (see above). However, many authorities believe that the benefits of these measures probably extend to women with advanced disease. In patients with severe pelvic adhesions, clinicians may choose to move directly from surgery to in vitro fertilization. Clomiphene or gonadotropins in combination with IUI should not be recommended for women with tubal blockage or dense ovarian adhesions.

In Vitro Fertilization

There are no large, randomized, controlled clinical trials that definitively demonstrate that IVF increases pregnancy rates in women with advanced endometriosis. In one small study involving 21 women with endometriosis and infertility, none of the six women randomized to undergo expectant management became pregnant, whereas five of the 15 women who were treated with IVF became pregnant.[64] Because of the small sample size, however, this study did not have sufficient statistical power to detect true differences between the two groups. One analysis of various infertility treatments demonstrated that for infertile women with advanced endometriosis, rapid progression through the steps to IVF is the most cost-effective treatment approach.[65] In the United States, the median projected cost per IVF cycle in 2001 was $9,226.[66] The cost of having a child with IVF is within the range of the cost of adopting a child. Furthermore, over the past decade, IVF success rates have increased.[67]

IVF is less successful in women with advanced endometriosis who have previously undergone bilateral ovarian surgery; after unilateral oophorectomy and a contralateral ovarian cystectomy, ovarian stimulation is often ineffective, and the pregnancy rate is low. Reduced pregnancy rates for women with advanced endometriosis (compared with women who have early-stage endometriosis or tubal factor infertility) may be the result of a premature depletion of the ovarian follicle pool,[68] abnormal folliculogenesis,[69] or reduced fertilization potential of oocytes.[70]

XI MENOPAUSE

Susan D. Reed, m.d., m.p.h.
Eliza L. Sutton, m.d.

Definitions

The female reproductive system matures in a continuous, natural process from menarche to menopause, as the finite numbers of oocytes produced during fetal development are gradually lost to ovulation and senescence. Menopause is defined as the permanent cessation of menses[1]; by convention, the diagnosis of menopause is not made until the individual has had 12 months of amenorrhea. Menopause is thus characterized by the menstrual changes that reflect oocyte depletion and subsequent reduction in ovarian hormone production. However, the manifestations that occur around the time of menopause are caused by the underlying ovarian changes, rather than by the cessation of menstruation itself. Therefore, a woman who has undergone a hysterectomy but who retains her ovaries will experience normal menopausal symptoms as oocyte depletion leads to hypoestrogenism, even though cessation of menstruation occurred with surgery.

Natural menopause occurs at or after 40 years of age and has no underlying pathologic cause [*see* Natural Menopause, *below*]. Induced menopause may occur after chemotherapy, pelvic radiation, or, most commonly, bilateral oophorectomy. Menopause is considered premature when it occurs before 40 years of age but is otherwise natural [*see* Premature Ovarian Failure, *below*].

The climacteric, a term now used infrequently, refers to the time of waning ovarian function associated with menstrual irregularity and vasomotor symptoms. Perimenopause is the time between the onset of the climacteric and the year after the last menses. Menopausal transition is replacing perimenopause and climacteric as the preferred term to describe the time of physiologic change around the cessation of ovarian function [*see Figure 1*].[2] Premenopause is the entire reproductive span before onset of the menopausal transition, and postmenopause is the span of life after menopause.

In the past, natural menopause was considered to be an endocrinopathy, with the ovary depicted as a failing organ and estrogen considered the optimal therapy. Given that menopause is a normal transition in the lives of most women and that significant risks have been associated with postmenopausal hormone "replacement," the viewpoint of menopause as an endocrinopathy is no longer espoused.

Natural Menopause

EPIDEMIOLOGY

The menopausal transition, which precedes menopause, has an average duration of 4 years, with a range of 0 to 10 years.[3-5] The mean age at which menopause occurs in developed countries is 51 years[4,6,7] and may be increasing.[8] The standard deviation around this mean is about 2 years.[4,9] Approximately 95% of women experience menopause by 55 years of age.[4] Several factors appear to influence the age at which women experience menopausal symptoms and the final menstrual period; for example, menopause occurs approximately 1 year earlier in smokers[6,7,10] and nulliparous women.[6,7] Menopause may also occur earlier in women who have had ovarian cystectomies or unilateral oophorectomies.[11]

PHYSIOLOGY AND GENETICS OF REPRODUCTIVE AGING

Ovarian follicular depletion, by means of atresia, is the final common pathway in female reproductive aging. At 5 months of fetal age, the ovaries contain their peak number of primordial follicles, totaling approximately two million. At birth, girls have one million primordial follicles, approximately 25% of which remain at puberty. During the reproductive years, many follicles will begin to develop during each ovulatory cycle; all but one, the dominant follicle, become atretic. An estimated 1,000 follicles remain in the ovaries of a woman 51 years of

Stages of reproductive aging	Reproductive Years			Menopausal Transition			Postmenopause	
	Early	Peak	Late	Early	Late*		Early*	Late
				Perimenopause				
Duration of stage	Variable			Variable		1 yr	4 yr	Until demise
Menstrual cycles	Variable to regular	Regular		Variable cycle length (> *7 days different from normal*)	≥ 2 skipped cycles and an interval of amenorrhea (≥ *60 days*)	0	None	
Endocrine function (FSH levels)	Normal		Elevated or normal	Elevated or normal		↑	Elevated	

*Stages most likely to be characterized by vasomotor symptoms.

Final Menstrual Period

Figure 1 **The Stages of Reproductive Aging Workshop (STRAW) reproductive staging system showing the relationship of the final menstrual period with menstrual cycle changes and FSH serum concentrations.[2] (FSH—follicle-stimulating hormone, ↑—elevated)**

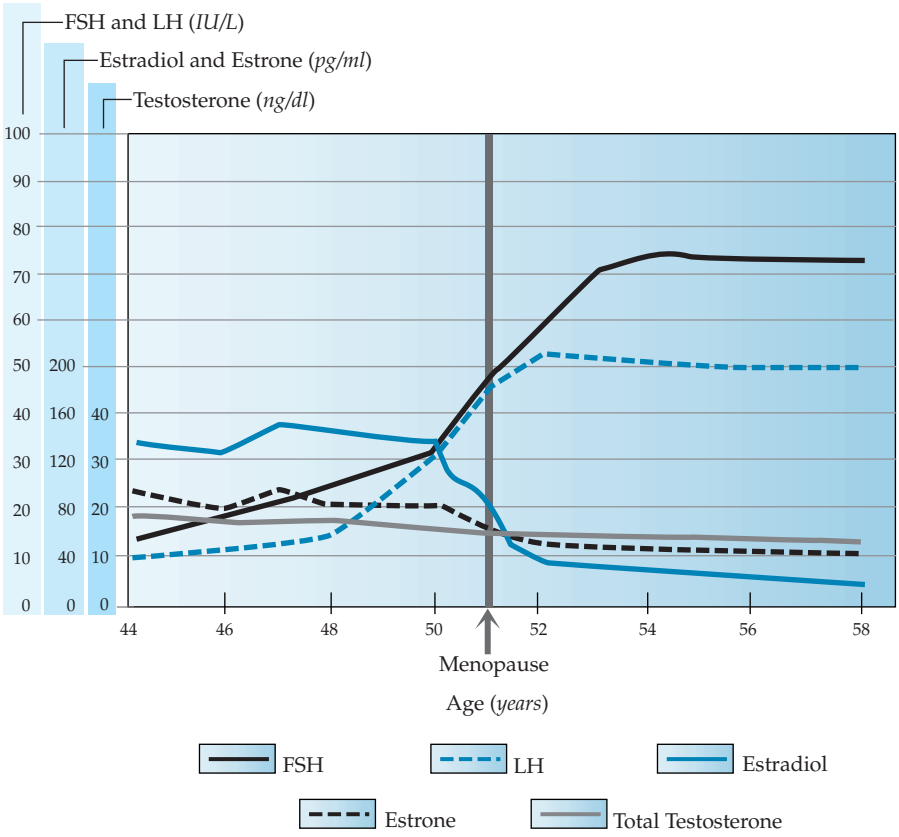

Figure 2 **Approximate average serum concentrations of estradiol, estrone, FSH, LH, and total testosterone during the menopausal transition and postmenopause. A subtle rise in FSH occurs first, followed by a rise in LH and a decline in estradiol and estrone. There are no abrupt changes in testosterone, but a gradual continuous decline occurs that begins before the menopausal transition.[130]**

age.[12] Some poorly responsive follicles persist for a few years after the menopause.[13] This progressive loss of follicles that accompanies aging is characteristic of all mammals studied to date; however, the controlling factors for this process have not been well defined.

Beginning as early as 10 to 15 years before menopause, the length of the menstrual cycle progressively decreases, owing to a shortening of the follicular phase of the cycle. The observed decrease in cycle length continues until the onset of the menopausal transition, when both the average cycle length and the standard deviation of cycle length begin to increase as follicles are depleted and ovulation occurs less frequently.[4,14] Insufficient follicular development results in inadequate estrogen production. With little estrogen available to stimulate the endometrium, amenorrhea results.

There is good evidence that the timing of natural menopause is genetically programmed,[15-17] but the specific genes involved are yet to be well defined. Common allelic variants of the estrogen receptor gene (estrogen receptor–α [*ER*-α] and *ER*-β) contribute to the variability in the timing of menopause.[18] In addition, all of the steroid receptors, as well as the proteins and enzymes involved in steroid biosynthesis and metabolism, are known to be coded by polymorphic sites (genetic changes found in at least 1% of the population). This genetic variability adds to the complexity of the actions and interactions of the reproductive steroids and to the timing and extent of menopausal symptoms.

PHYSIOLOGIC CHANGES IN MENOPAUSE

Hormonal Changes

A subtle rise in the concentration of follicle-stimulating hormone (FSH) is the earliest and most consistent clinically measurable hormonal change noted in studies of reproductive aging.[19,20] An FSH level measured during the early follicular stage of the menstrual cycle that is greater than two standard deviations above the mean level in women of reproductive age is a marker of impending menopausal transition.[2] Luteinizing hormone (LH) levels remain normal initially, but they eventually become elevated as ovarian steroid secretion falls and gonadotropin-releasing hormone (GnRH) increases [*see Figures 2 and 3*]. The early selective increase in FSH appears to be caused by decreased secretion of the hormone inhibin B by the ovarian granulosa cells and is a marker of follicular atresia. Inhibin A and B, hormones that are involved in directing follicular development and were first characterized in the 1990s, suppress pituitary FSH production.[21,22] As anovulation predominates, FSH and LH remain chronically elevated (i.e., there is a 10-fold to 20-fold increase in the FSH level and a threefold to fivefold increase in the LH level),[19,21,23] and estradiol levels fall below 50 pg/ml [*see Figure 2*].

The physiologic changes that are associated with menopause are predominantly reflected by changes in circulating levels of estrogens, androgens, and progesterone [*see Figures 2 and 3*]. The hormonal system is made more complex by fluctuations in steroid hormones that alternate between free and bound states. Sex hormone–binding globulin affects serum levels of all steroid

hormones, binding preferentially to testosterone, estrogen, and progesterone, in that order.

During the reproductive years, estradiol (E_2) is the principal estrogen, both in quantity and in potency; estrone (E_1) is present in a significant amount but is less potent than estradiol. Estriol (E_3), a weak estrogen, is a metabolite of estrone and estradiol. Despite diminished fertility and ongoing follicular atresia, the ovulatory cycles of women in the menopausal transition have normal to high concentrations of circulating estradiol and estrone. In fact, as women approach the menopausal transition, preovulatory estradiol levels can be higher than those seen in younger women.[24,25]

After menopause, estradiol production drops by 90%,[19,21] owing to follicular atresia [*see Figures 2 and 3a*]. What little estradiol is produced after menopause comes primarily from peripheral conversion of estrone. Estrone, the dominant estrogen after menopause, is produced through peripheral conversion of adrenal androstenedione by aromatase, primarily in adipose tissues [*see Figure 3d*]. Fatty breast tissue is a principal site of aromatase activity, but activity is also present in the brain, muscle, liver, and, minimally, the ovary of a postmenopausal woman.

As reproductive aging progresses, serum levels of androgens decrease but not to the extent that estrogen levels diminish. Androstenedione levels drop by approximately 50%,[26-28] ovarian

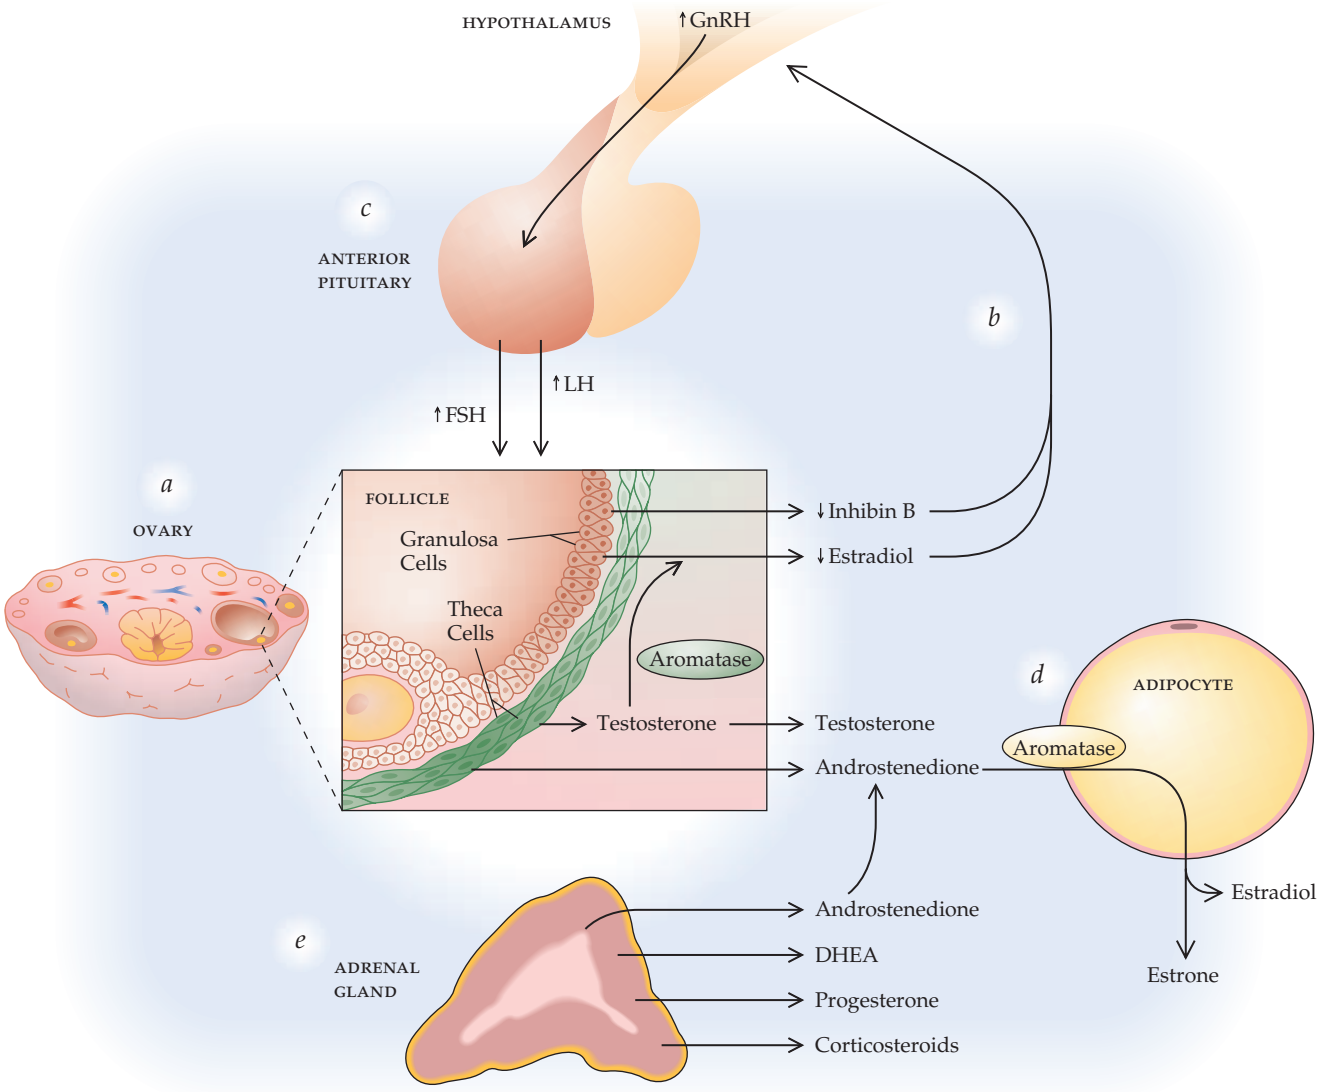

Figure 3 **Multiple hormonal changes are associated with reproductive aging. (*a*) Within the ovary, secretion of inhibin B by granulosa cells decreases when a woman is in her mid-30s, and follicular depletion results in increasing rates of anovulation and diminished ovulatory surges of estradiol and estrone by her early 40s. Ovarian testosterone secretion continues; some ovarian testosterone is converted to estradiol by the enzyme aromatase, and the remainder is secreted as testosterone or the androgen precursor androstenedione. (*b*) In the menopausal transition, decreased circulating levels of inhibin and, subsequently, decreasing estradiol concentrations result in stimulation of the hypothalamus to increase secretion of GnRH. (*c*) Elevated circulating GnRH levels stimulate the anterior pituitary to increase secretion of FSH, followed by an increase in LH. Eventually, attempts by the brain to drive the ovary to produce estrogen fail, but production of androstenedione and testosterone by the ovarian theca cells continues in early menopause. (*d*) With diminished serum estrogen levels, adipocytes are stimulated to convert androstenedione to estrone via the enzyme aromatase. (*e*) Hormonal synthesis by the adrenal gland remains fairly constant, undergoing changes associated with aging, not menopause per se.**

production declines [*see Figure 3a*], and adrenal output remains relatively constant [*see Figure 3e*]. Testosterone decreases by approximately 30% and continues to be secreted by the ovarian stroma, under the influence of LH [*see Figure 3a*].[26-28] Serum concentrations of the adrenal androgen precursor dehydroepiandrosterone (DHEA) decrease with biologic aging, beginning before the final menstrual period [*see Figure 3e*].[26]

During the reproductive years, the principal source of progesterone is the corpus luteum; small concentrations of progesterone continue to be produced by the adrenal gland after the menopause [*see Figure 3e*].

The overall changes in reproductive steroid hormones observed following menopause include the following:

- Negligible estradiol production by the ovary
- A shift from the ovary to the adrenal gland as the primary source of estrogen precursors
- Emergence of estrone as the dominant estrogen
- Continued testosterone production by the ovarian stroma
- An overall increase in the ratio of androgens to estrogens
- A decrease in progesterone levels resulting from anovulation

Target Tissues

During the past decade, remarkable advances in the understanding of steroid biosynthesis, metabolism, and receptor tissue specificity have occurred.[29] At least two estrogen receptors, ER-α and ER-β, and two progesterone receptors, PRA and PRB, have been identified. Estrogen receptors are found in the genitourinary, cardiovascular, and gastrointestinal tracts and in the brain, bone, and integument. Different tissues have a predominance of specific receptors, depending on the individual's endogenous hormonal profile. The complexity of the system leads to variations in the clinical manifestations of reproductive aging. Recent advances in the understanding of these complex physiologic processes have important implications for designing specific targeted therapies and have led to new classifications of pharmaceuticals: the selective estrogen receptor modulators (SERMs). Selective progesterone receptor modulators and selective androgen receptor modulators are also in development [*see* Preventive Health Care, *below*].

Endometrium During normal ovulatory cycles, progesterone, which is produced by the corpus luteum, causes the endometrium to mature to a secretory state. During the menopausal transition, endometrial shedding occurs less frequently because of anovulation, and oligomenorrhea results.[4] Bleeding may be quite heavy in anovulatory cycles because estrogen is still produced, although at diminished levels, and stimulates the endometrium unopposed by progesterone. Furthermore, with increasing anovulation, longer cycles predominate and result in a thicker endometrium. Eventually, as anovulation predominates and estradiol production by the ovary becomes negligible, amenorrhea results.

Genitourinary epithelium The vagina is a principal target tissue for estrogen. Estrogen matures the vaginal epithelium, making it thicker and rugated. The estrogen-stimulated epithelial cells produce more glycogen, which in turn changes the bacterial flora and increases vaginal acidity.[30] Hypoestrogenism results in thinning of the vaginal and vulvar epithelium. The base of the bladder is also derived from müllerian tissue and likewise is estrogen sensitive. Epithelial changes in the bladder are similar to those occurring in the vagina and vulva and result in thin, pale, friable tissues.

Central and sympathetic nervous systems Fluctuations in estrogen levels are associated with hot flushes.[31] Hot flushes are caused by thermoregulatory dysfunction that is most likely initiated by the hypothalamus in response to estrogen withdrawal. Small elevations in core body temperature are followed by peripheral vasodilation. This results in a sensation of warmth and perspiration, both of which occur at a core body temperature that is lower than normal.[32] To be susceptible to hot flushes, a woman needs to have been exposed to reproductive levels of estrogen and then experience estrogen withdrawal. For example, women with Turner syndrome, who never attain reproductive levels of estrogen, do not experience hot flushes.

Alterations in dopamine, norepinephrine, and serotonin pathways[33-35] associated with systemic estrogen fluctuations may contribute to the vasomotor symptoms experienced during the menopausal transition and postmenopause. In addition to hot flushes and diaphoresis, symptoms may include a sense of prickling of the skin, heart palpitations, and anxiety.

Sleep disruption from vasomotor instability can result in insomnia[36] and daytime fatigue, and it may also contribute to mood and other neuropsychiatric changes.[37] The prevalence of sleep-disordered breathing, including snoring and obstructive sleep apnea, increases after menopause,[38,39] most likely because of the estrogen responsiveness of the upper airway musculature.[40] Other pathophysiologic alterations resulting in changes in cognition, mood, and sleep are not as well studied.

Women may experience a decline in libido during the menopausal transition or after the menopause.[41] The contributing factors are complex and may include fatigue or stress (e.g., multiple responsibilities, including caretaking and employment), urogenital atrophy leading to dyspareunia, decreased testosterone levels [*see Figure 2*] (particularly in women who undergo surgical removal of both ovaries), sexual inactivity or dysfunction in a partner, and physical or emotional separation from a partner.

Bone Estrogen suppresses bone resorption. At the menopausal transition, bone resorption exceeds formation, and an accelerated loss in bone mass may occur.[42] Bone mass may be lost at an annual rate of 3% to 5% in the first few years after the final menstrual period, but eventually, this rate of loss slows and continues at 1% to 2% a year.[43] Trabecular bone, the predominant type of bone in the spine, hip, and distal radius, is affected first and to a greater degree than cortical bone [*see 3:VI Diseases of Calcium Metabolism and Metabolic Bone Disease*].

Cardiovascular system Cardiovascular risks[44] and events[45] increase after menopause. Among the factors that contribute to an increased risk of cardiovascular events are the levels of low-density lipoprotein (LDL) cholesterol and apolipoprotein B, which are higher after menopause.[46] Estrogen receptors have been found in the muscularis of arteries in cardiovascular tissue.[29] Estrogens appear to have a direct vasodilatory effect on the coronary artery, mediated by the formation and release of endothelium-derived relaxing factor, reduction of endothelin levels, and the promotion of prostacyclin production.[47]

Coagulation factors Menopause has been associated with increases in factor VII, factor VIII, plasminogen activator inhibitor–1 (PAI-1), and fibrinogen; all of these changes can lead to hypercoagulable states. Conversely, menopause has been associated with increased levels of antithrombin III and activated protein C, which may be beneficial in that these factors diminish

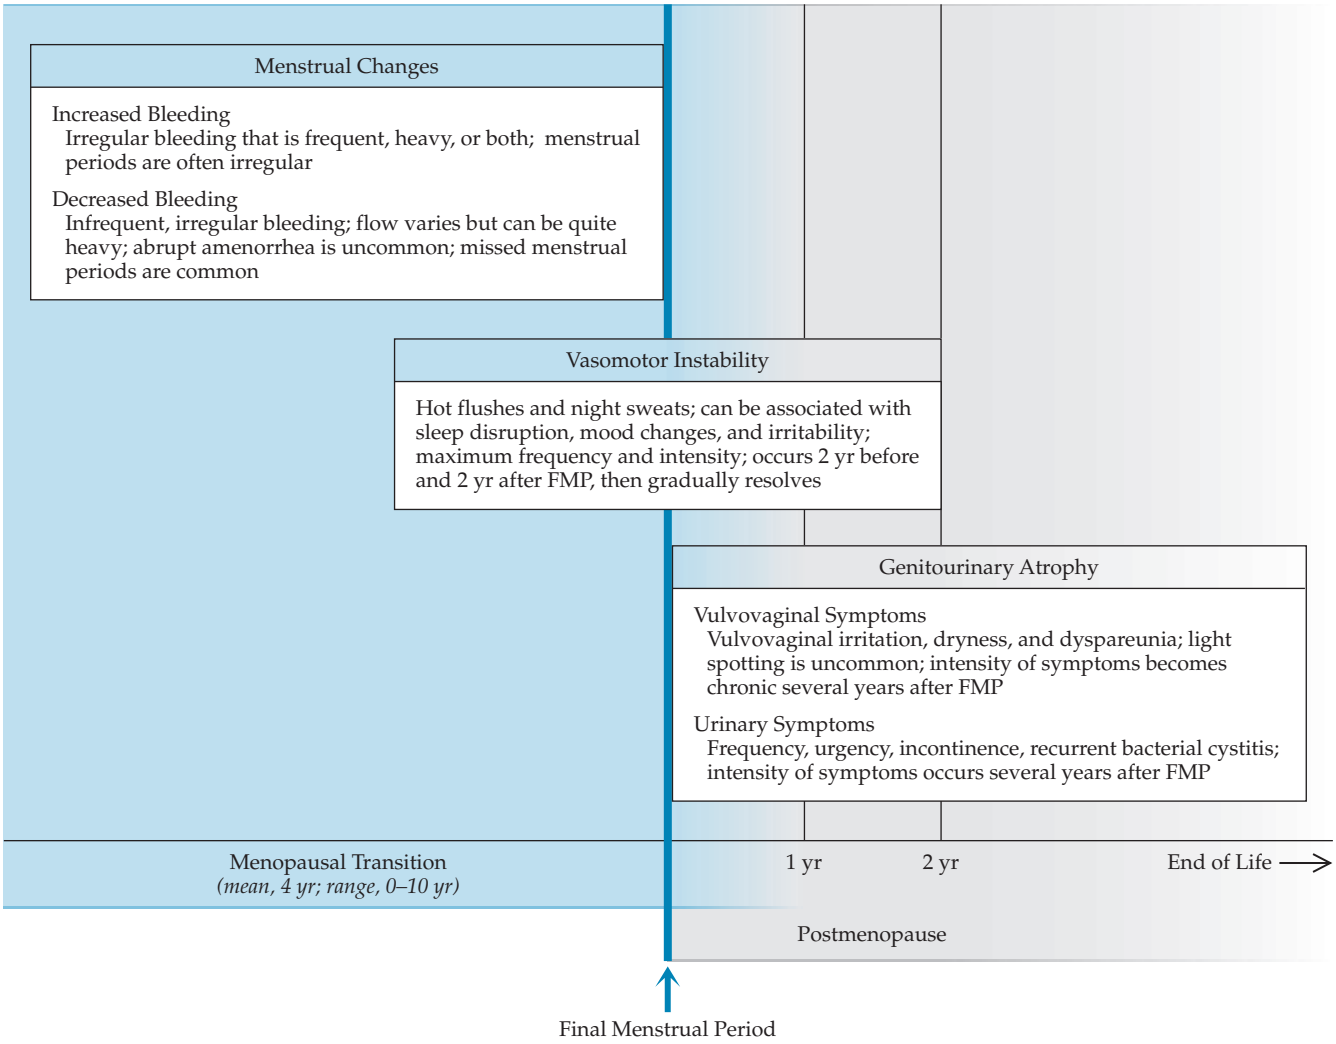

Figure 4 **Characteristic symptoms of the menopausal transition and menopause. Peak vasomotor symptoms occur around the time of the final menstrual period. Menstrual changes are common before the menopause; abrupt amenorrhea preceded by normal cycles is unusual. Genitourinary atrophy is most common in postmenopause.**

coagulation.[48] It is unknown whether these changes are caused by hypoestrogenism alone or by a combination of hormonal changes observed at the time of menopause.

Integument A decrease in the production of dermal collagen and a subsequent reduction in dermal thickness[49] result in significant changes in women's skin, including wrinkles and dryness. In addition, a reduced rate of cutaneous wound healing has been associated with diminished secretion of transforming growth factor–β1 (TGF-β1) by dermal fibroblasts.[50]

Target-sensitive tissues and neoplastic growth Changes in the balance of reproductive hormones at the time of menopause have been associated with increased neoplastic growth in specific tissues. Hormonally sensitive neoplasms of the breast, colon, ovary, endometrium, and myometrium (leiomyoma) are widely recognized. Leiomyomas commonly increase in size during the menopausal transition but diminish in the postmenopausal period, presumably as a result of low levels of estradiol and progesterone. Other less common neoplasms occur in the gastrointestinal tract (esophageal and gastric)[51]; blood vessels; adipose and angiolymphatic tissues (angiomyolipoma,[52] lymphangiomyomatosis)[53]; and the central nervous system (meningioma).[54] All of these neoplastic tissues have been found to have reproductive hormone receptors and appear to be sensitive to steroid hormones. Contrary to previous evidence, recent observations suggest that melanoma is not progesterone sensitive.[55]

DIAGNOSIS

The diagnosis of menopausal transition may be suspected on the basis of symptoms (e.g., menstrual irregularity and vasomotor symptoms) in a woman older than 40 years [*see Figure 4*] well before it can be proven by FSH testing [*see* Laboratory Tests, *below*]. The clinical diagnosis of natural menopause is made if a woman is of an appropriate age and has had 12 months of amenorrhea accompanied by symptoms suggestive of ovarian failure, at which point the FSH serum concentration is so certainly elevated that testing is usually not useful.

Clinical Manifestations

Reproductive system changes The most common changes in the bleeding pattern in the menopausal transition are shortened cycle length, heavier flow (menorrhagia), and irregular cycle length (metrorrhagia). Intermenstrual bleeding may also oc-

cur, but it warrants specific attention because of its association with endometrial neoplasia in women older than 40 years [*see* Laboratory Tests, Biopsy, *below*]. A woman with vasomotor symptoms who has completely missed a menses is likely to experience her final menstrual period within the next 1 to 2 years.[14] Menopause usually occurs several years after the onset of menstrual changes; however, about 10% of women experience abrupt onset of amenorrhea.[3,4] Infertility and the cessation of menses are the only universal manifestations of menopause.

Genitourinary atrophy Genitourinary atrophy is typically mild and asymptomatic during the menopausal transition, but it is progressive and can become quite severe in the postmenopausal years.[3,31] Atrophic vulvovaginitis can present as vaginal dryness, vulvovaginal pruritus, vaginal dyspareunia, or postcoital spotting. Atrophic urethritis and recurrent cystitis can manifest as dysuria, frequency, and incontinence.

Vasomotor symptoms Vasomotor symptoms (i.e., hot flushes and night sweats) are common manifestations of the menopausal transition; for example, 80% of white women experience vasomotor symptoms.[56] Women typically describe hot flushes as a strong sensation of warmth accompanied by flushing, a prickling sensation of the skin, and perspiration that seems to move from the trunk toward the head before it dissipates. These flushes are spontaneous, uncomfortable, and unpredictable, and they can occur any time of the day or night. Each episode is self-limited and typically lasts several minutes. A number of women describe feeling excessively warm in a more continuous pattern. The frequency of vasomotor symptoms may be represented by a bell-shaped curve that peaks around the time of the final menses.[3,37] The occurrence of vasomotor symptoms usually ceases within 4 to 5 years from first onset, although 10% of women may suffer symptoms for much longer (up to 10 years).[14,37]

Changes in libido, sleep, mood, and cognition Changes in mood, libido, and sleep may also occur but are variable in severity[37] and have a wider differential diagnosis. Snoring and daytime sleepiness suggest the possibility of obstructive sleep apnea. Women may complain of mildly diminished cognitive capacity, particularly during the menopausal transition; however, this has not been well studied.

Physical Examination

There are no pathognomonic physical findings in the menopausal transition. However, the physical examination may provide information that suggests the presenting symptoms are the result of an underlying pathologic condition and are not related to normal menopausal transition. Palpation of the thyroid gland and examination for physical signs of hypothyroidism or hyperthyroidism are warranted, particularly if menstrual irregularity, excessive diaphoresis, or neurocognitive changes are present. When intermenstrual bleeding is reported, speculum examination should be performed to rule out cervical or vaginal lesions, such as endocervical polyps. Bimanual pelvic examination is indicated when bleeding is heavy or frequent, to rule out the presence of adnexal masses and evaluate the uterus for fibroids; it is also indicated when pregnancy is possible. When the clinical presentation of oligomenorrhea or amenorrhea is not classic for the menopausal transition, prolactinoma may be suspected, in which case visual-field testing for bitemporal hemianopsia and breast examination for galactorrhea are appropriate. In addition, inspection of the skin for needle tracks from possible injection use of heroin and evaluation for low body weight or significant weight loss may be useful, because these findings suggest a hypothalamic cause for oligomenorrhea or amenorrhea.

After menopause, vulvovaginal atrophy typically occurs. The vulvovaginal skin may appear pale, thin, and friable and may exhibit a loss of rugae and possible fissuring and erythema. The uterus is smaller, measuring 5 to 6 cm in length, and the ovaries are usually nonpalpable. The cervix may become stenotic and flush with the vagina.

Laboratory Tests

Urine or serum β–human chorionic gonadotropin (β-hCG) testing is crucial in the evaluation of any woman suspected to be in menopausal transition but who has the potential for pregnancy and who presents with a missed period, oligomenorrhea, or irregular vaginal bleeding with or without pain. In addition, testing for high-sensitivity thyroid-stimulating hormone (TSH) should be considered when menorrhagia, excessive diaphoresis, or neurocognitive changes—all potentially associated with the menopausal transition—suggest thyroid dysfunction. If the clinical picture suggests hemorrhagic diathesis, it may be helpful to obtain a platelet count, prothrombin time, and partial thromboplastin time. Additional evaluation for coagulopathies, such as von Willebrand factor, should follow, if appropriate.

With the onset of menstrual irregularity, there are wide variations in the production of FSH, estradiol, and LH.[23] Because of these wide variations, measurement of serum concentrations of these hormones is generally not useful during the menopausal transition and is not indicated unless the clinical situation is atypical and suggests an underlying condition. An elevated follicular-stage FSH level demonstrates that ovarian function is declining, but the FSH level cannot predict when the final menstrual period will occur.[19,21,23] Once a woman has had 12 months without a menses, the FSH is reliably elevated at 25 IU/L, and the estradiol level is less than 50 pg/ml.

Oral contraceptive use during the menopausal transition will treat menopausal symptoms and mask menopause. Oral contraceptives suppress FSH; therefore, the FSH should be drawn on the seventh day of placebo pills or the seventh day of the pill-free week. If menopause has occurred, the serum FSH level will be greater than 25 IU/L when drawn on two separate occasions.

Measurement of FSH serum concentration can assist in the diagnosis of menopause in a woman with vasomotor symptoms who has had a hysterectomy without oophorectomy. FSH testing may also be appropriate in the evaluation of atypical clinical situations; for example, in a case of abrupt-onset amenorrhea in a 40-year-old woman with negative β-hCG testing, measurement of FSH, prolactin, and TSH concentrations should be performed to evaluate for premature ovarian failure, prolactinoma, or thyroid dysfunction [*see* Differential Diagnosis, *below*].

Tests of other body fluids Vaginal fluid pH is elevated after menopause, and vaginal cytology shows a decreased maturation index (increase in parabasal cells).[30] These tests are not typically performed, nor are they necessary, to establish the diagnosis of menopause. In evaluation of vaginal dyspareunia or vulvovaginal pruritus, vaginal fluid pH testing and microscopic examination of vaginal fluid (saline and 10% potassium hydroxide preparations) should be performed to rule out common vaginal infections such as candidiasis, trichomoniasis, or bacterial vaginosis. It should be noted that with genitourinary atro-

phy, the shift toward a more basic pH can precipitate bacterial overgrowth and concomitant infection.

Imaging Studies

No imaging study is useful in establishing the diagnosis of the menopausal transition or menopause, although pelvic ultrasound may be indicated in the diagnostic evaluation of women with abnormal vaginal bleeding before or after menopause. In women who present with metrorrhagia or menorrhagia during the menopausal transition, pelvic ultrasound can confirm a diagnosis of leiomyomas or endometrial polyps and can suggest a diagnosis of adenomyosis; however, ultrasound cannot rule out endometrial neoplasia in premenopausal women [*see* Biopsy, *below*]. In contrast, ultrasound can serve as a screening test for endometrial neoplasia in postmenopausal women who experience bleeding or spotting spontaneously or in conjunction with hormone therapy (HT). In a postmenopausal woman, a homogeneous endometrial thickness of 4 mm or less confers assurance that endometrial hyperplasia or cancer is not present in more than 96% of cases.[57-59]

Biopsy In the menopausal transition, endometrial biopsy should be performed in women who experience intermenstrual bleeding (i.e., bleeding at intervals of fewer than 21 days) or in obese women who present with menometrorrhagia. If the biopsy results are normal or if examination suggests leiomyoma or adenomyosis, ultrasonography should follow. Endometrial biopsy is also indicated in postmenopausal women at heightened risk for endometrial neoplasia (e.g., women with diabetes or obesity) who experience any bleeding after 12 months of amenorrhea or who have an ultrasound result that demonstrates an endometrium at least 4 mm in thickness.

DIFFERENTIAL DIAGNOSIS

Menstrual Changes

For women 45 to 55 years of age who are experiencing progressive oligomennorhea, the most likely diagnosis is the menopausal transition, especially if there are associated vasomotor symptoms. In this setting, a wider differential diagnosis rarely needs to be considered. In younger women who have no vasomotor symptoms or whose menstrual changes are abrupt, a wider differential should be considered [*see* Premature Ovarian Failure, *below*]. The differential diagnosis for oligomenorrhea and secondary amenorrhea should always include pregnancy, prolactinoma, thyroid dysfunction, and medication or supplement use.

For women with excessive or intermenstrual bleeding, the differential diagnosis includes hypothyroidism, hyperthyroidism, blood dyscrasias, leiomyoma, adenomyosis, endometrial polyps, endometriosis, endometrial or cervical neoplasia, and hormone-secreting neoplasms such as granulosa cell ovarian cancer. Increased menstrual bleeding induced by medication or supplement use should also be considered.

Genitourinary Atrophy

Multiple conditions can cause genitourinary symptoms similar to those associated with hypoestrogenism occurring in the menopausal transition and menopause. Vulvovaginal symptoms (e.g., vaginal dryness, pruritus, dyspareunia, and postcoital spotting) may be caused by trichomonas vaginitis, yeast vulvovaginitis, bacterial vaginosis, desquamative inflammatory vaginitis, vestibulitis, allergic vulvovaginitis, and vulvar dysplasia or cancer. Urinary symptoms (e.g., dysuria, urinary frequency, and incontinence) may be caused by dietary bladder irritants, detrusor instability, urinary tract infection, and interstitial cystitis. The presence of isolated microscopic hematuria on urinalysis should prompt evaluation for neoplasia of the urinary tract.

Hot Flushes and Night Sweats

Hot flushes and night sweats may be symptoms of a number of disease processes, including hyperthyroidism, pheochromocytoma, carcinoid, and occult infection or neoplasm (e.g., tuberculosis, HIV), and lymphoma with B symptoms. Nonvolitional weight loss or documented fevers suggest a possible underlying disease. On the other hand, weight gain or existing obesity, which provides insulation against loss of body heat, may explain easy perspiration and a sensation of excess warmth in some women.

Changes in Libido, Sleep, Mood, and Cognition

The changes in libido, sleep patterns, mood, and cognition associated with the menopausal transition and menopause may also be induced by mood or anxiety disorders, thyroid dysfunction, and stress. Medications or other substances may cause insomnia, anxiety, mood abnormalities, cognitive changes, and sexual dysfunction. Other symptoms, such as fatigue, may be the result of an unrecognized sleep disorder (e.g., obstructive sleep apnea and restless legs syndrome), an inflammatory or neoplastic process, or multiple sclerosis. New cognitive dysfunction may be the first manifestation of dementia.

MENOPAUSAL TRANSITION AND POSTMENOPAUSAL SYMPTOM MANAGEMENT

Management of women experiencing menopausal symptoms is best approached by (1) defining the reproductive phase[2] of the patient [*see Figure 1*]; (2) identifying the menopausal symptoms for which treatment is desired [*see Figure 4*]; and (3) identifying the medical conditions that might influence management options [*see Sidebar* Internet Resources for Information on Menopause].

The menopausal transition and menopause do not warrant management in and of themselves. However, women who experience bothersome symptoms may want to consider treatment. HT is effective in controlling symptoms of the menopausal transition and menopause, but it carries risks [*see* Hormone Therapy Risks and Benefits, *below*].

The Food and Drug Administration has recommended that HT be used only for women with symptoms severe enough to warrant its use and at the lowest dose and for the shortest duration required to ease the menopausal transition. The FDA further recommends that tissue-targeted therapies be used whenever possible.[60]

Because of the potential risks associated with HT, it is recommended that all women taking HT be evaluated on an annual basis. The woman who is taking HT should be instructed to refrain from taking HT 1 week before the annual assessment to allow the physician and patient to evaluate the current severity of symptoms. Women who choose to stop HT may require a slow taper, ranging from 3 to 6 months, for successful cessation. Women on HT are encouraged to attempt cessation after 5 years of use.

Uterine Bleeding

Vaginal bleeding during the menopausal transition is best managed (after appropriate evaluation) with low-dose, combi-

nation oral contraceptives (containing 20 µg ethinyl estradiol) or a progestin intrauterine device; both protect against pregnancy and reduce menstrual blood loss. The overall effect of ethinyl estradiol at 20 µg/day is estimated to be three to four times that of 0.625 mg/day of conjugated estrogen; head-to-head trials comparing the clinical effects of the two estrogens do not exist. Although the chance of pregnancy is low (< 1% after age 50),[61] pregnancy may occur during the menopausal transition. Women 40 to 49 years of age have a rate of unintended pregnancy that is now higher than that of any other age group, even teenagers[62]; thus, it is important to address the issue of contraception with every potentially fertile woman until she has experienced 12 months of amenorrhea. Oral contraceptives can be discontinued and symptoms reassessed at approximately age 50 [*see* Laboratory Testing, *above*]. Those with persistent and severe vasomotor symptoms and amenorrhea may be transitioned to postmenopausal HT.

Genitourinary Atrophy

Symptoms of genitourinary atrophy may be present during the menopausal transition but typically become more prominent after menopause. Symptoms of genitourinary atrophy usually improve within 2 weeks after initiation of estrogen therapy and should be controlled after 1 to 3 months of use.[63] Estrogen can be administered topically with excellent local effect. Vaginal estrogen creams result in little or no systemic absorption when used at extremely low doses of less than one-eighth applicator (< 0.15 mg conjugated estrogen cream) and one-sixteenth applicator (< 0.025 mg estradiol cream); a full applicator of vaginal estrogen cream can deliver a dose equivalent to that of an oral formulation, although the rate of absorption varies considerably. Initial therapy constitutes nightly application for 2 to 6 weeks; thereafter, maintenance doses can be applied one to three times a week, depending on the severity of symptoms. Use of low-dose vaginal creams does not necessitate the use of a progestin; however, cessation of therapy results in the return of genitourinary atrophy. Low-dose vaginal estrogen rings effectively treat genitourinary atrophy with little or no systemic absorption and no significant endometrial stimulation.

Nonhormonal alternatives include lubricants for use during intercourse and vaginal moisturizers.

Vasomotor Symptoms

Estrogen is highly effective for the treatment of vasomotor symptoms. For women in the menopausal transition who are at risk for pregnancy and who have heavy or frequent menses, treatment with low-dose oral contraceptives provides amelioration of vasomotor symptoms, control of bleeding, and contraception. Cyclical HT is preferable for women in the menopausal transition who are predominantly anovulatory and who do not need contraception, because it provides lower doses of hormones than oral contraceptives. Continuous HT, which is commonly used in women who are approximately 12 months from the final menstrual period, is often associated with bothersome bleeding patterns in women in earlier stages of the menopausal transition.

Low-dose oral contraceptives and HT result in prompt resolution of symptoms within 1 to 2 weeks in 80% of women; they should be titrated to the lowest dose possible to achieve acceptable symptom relief. Systemic administration of estrogen can be achieved orally, transdermally (in the form of a gel or patch), or transmucosally (at a higher dose via the use of a vaginal ring).

Some formulations include progestins. Implants and intramuscular injections are less preferable forms of delivery because they release extremely high levels of HT at the time of administration or placement. The lowest doses of estrogens found to be effective for vasomotor symptoms include oral conjugated estrogen 0.03 mg, oral estradiol 0.5 mg, and transdermal estradiol 0.025 mg.

Several nonhormonal alternatives for treatment of vasomotor symptoms may have some efficacy. These include venlafaxine,[64,65] selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine and paroxetine),[66-68] and gabapentin.[69] Less evidence supports the use of clonidine[70,71] and vitamin E[72] as being effective in the control of vasomotor symptoms. Results from controlled clinical trials evaluating the effectiveness of phytoestrogens (including dietary soy) for vasomotor symptoms vary, but most studies indicate that the use of phytoestrogens offers no significant improvement over placebo in reducing the frequency of hot flushes.[73] Black cohosh, a possible phytoestrogen, may be effective, but no large controlled trials have been conducted.[74] Progestin alone is effective[75,76] but is not recommended because of a potential increased risk of breast cancer.[77] Behavioral modification[78,79] and increased exercise[78,80] may diminish the severity of hot flushes. Red clover extract, dong quai, evening primrose oil, and Siberian ginseng have not been found to be effective in small randomized, controlled trials. Other botanicals purported to be effective, including valerian, motherwort, and chasteberry, have not been studied in clinical trials.[81]

Libido, Sleep, Mood, and Cognition

Treatment of sexual dysfunction depends on the underlying etiology. If the cause of decreased libido is not predominantly psychosocial, testosterone therapies have been shown, in some circumstances, to improve sexual function, interest and frequency of desire, and psychological well-being.[82,83] There are no FDA-approved products for diminished libido in women; however, esterified estrogen combined with methyltestosterone is commonly used. Vaginal estrogen therapy, if indicated, can play an important role in the treatment of diminished sexual function resulting from urogenital atrophy.[63]

Vasomotor instability may contribute to disruption of sleep;

thus, estrogen is effective for some women who begin to experience insomnia during the menopausal transition. Alternative therapies include short-term zolpidem and low-dose trazodone.

Estrogen may be beneficial in the treatment of depression in the menopausal transition.[84] Estrogen alone, without an antidepressant, does not appear to be sufficient to treat significant clinical depression in postmenopausal women.[85] However, some investigators support the use of estrogen as an adjunct to other therapies, such as SSRIs, particularly in older women.[86]

MANAGEMENT CONSIDERATIONS

Risks and Benefits of Hormone Therapy

Although the risks and benefits of using HT for the relief or prevention of symptoms in women in the menopausal transition have not been evaluated in clinical trials, information has been established on the risk-to-benefit profile of short-term and long-term use of HT for postmenopausal women 50 to 79 years of age. Historically, it was believed that the estrogen deprivation that accompanies menopause increases the risk of some chronic diseases—specifically, heart disease, osteoporosis, and dementia. On the basis of observational data, long-term postmenopausal HT was recommended during the 1980s and 1990s not only for symptom relief but also to reduce the risk of chronic disease and to prolong life. However, two large randomized, controlled trials (i.e., Heart and Estrogen/Progestin Replacement Study [HERS][87] and the Women's Health Initiative [WHI])[88,89] called this practice into question. HT is no longer recommended for primary or secondary prevention of these conditions in women older than 50 years.

HERS demonstrated no evidence to support the use of HT for the secondary prevention of heart disease[87]; more important, WHI found that HT use conferred an increased risk of cardiovascular disease,[90] stroke,[91] dementia,[92] thromboembolism,[88] and breast cancer[93] in women 50 to 79 years of age. Striking discrepancies in the findings of the randomized trials and the earlier nonrandomized (observational) studies can be explained by selection biases in participants in the observational studies. In the observational studies, women opting for HT therapy tended to be healthier and of higher socioeconomic status than non-HT users. In addition, these women were more likely to be carefully screened for chronic disease before starting HT and, therefore, had a lower risk of developing chronic disease than nonusers of HT.[94] The selection biases inherent in the observational studies were virtually eliminated in the randomized trials.

Counseling about the risks of postmenopausal HT use should now be based on the evidence provided by WHI.[88,89,91-100] The WHI postmenopausal estrogen and progestin therapy (EPT) and estrogen therapy (ET) trials are discussed in greater detail below.

Estrogen and progestin therapy The WHI prematurely halted its clinical trial of EPT in 2002; participants had been followed for an average of 5.2 years. The trial randomized over 16,000 postmenopausal women who were 50 to 79 years of age to take either conjugated equine estrogen (0.625 mg/day) plus medroxyprogesterone acetate (2.5 mg/day) or placebo. The study was halted because the rates of adverse events (i.e., cardiovascular events, stroke, thromboembolism, and breast cancer) were 1% higher in the intervention group and overshadowed the reduced risk of osteoporotic fractures and colon cancer.[88] There was no difference in overall or disease-specific mortality between the HT and placebo groups. The study reported the following risks: (1) thromboembolic events were highest in the first year and remained elevated over 5 years (absolute risk difference, 21/10,000/yr); (2) ischemic cardiac events were highest in the first year and remained elevated and statistically unchanged thereafter (absolute risk difference, 7/10,000/yr); (3) stroke risk was not elevated in the first year, rose slightly in the second year, and remained elevated through year 5 (absolute risk difference, 8/10,000/yr); and (4) breast cancer risk was not appreciably higher in years 1 to 3 but became elevated in year 4 (absolute risk difference, 8/10,000/yr), with the increased breast cancer risk being strongest in the approximately 25% of women who had taken HT before enrolling in the study [*see Table 1*]. The EPT portion of the WHI study showed a

Table 1 WHI Findings: Outcomes Associated with Use of Combined Estrogen and Progestin and Estrogen Alone in Healthy Postmenopausal Women

	*Combined Estrogen and Progestin**		*Estrogen Alone†*	
Outcomes	*Relative Risk (95% CI)*	*Absolute Risk Difference‡*	*Relative Risk 95% (CI)*	*Absolute Risk Difference‡*
Adverse/neutral				
Deep vein thrombosis[88,89]	2.07 (1.49–2.87)	13	1.47 (1.04–2.08)	6
Pulmonary embolism[88,89]	2.13 (1.39–3.25)	8	1.34 (0.87–2.06)	11

reduction in the risk of hip fractures (absolute risk difference, 6/10,000/yr)[96] and colorectal cancer (absolute risk difference, 6/10,000/yr).[100]

The Women's Health Initiative Memory Study (WHIMS), a substudy of the WHI continuous combined HT intervention trial, observed the effect of HT on memory and cognition in women 65 to 79 years of age (average age, 73 years).[92,95] A reduction in memory and thinking abilities (as measured by the Modified Mini-Mental State Examination)[95] and an increase in dementia of all types (absolute risk increase, 2/1,000/yr) were observed in women who took HT.[92]

Estrogen therapy The estrogen-only arm of WHI was halted prematurely in early 2004 because of increased risk of stroke; participants had been followed for an average of 6.8 years.[89] Over 10,000 women 50 to 79 years of age were randomized to receive 0.625 mg/day of conjugated equine estrogen or placebo. As in the EPT portion of WHI and HERS, the ET portion of the WHI trial found that estrogen use conveyed an increased risk of deep vein thrombosis (1.47 relative risk; 95% confidence interval [CI], 1.04 to 2.08) and stroke (1.39 relative risk; 95% CI, 1.10 to 1.77) [*see Table 1*]. Women taking ET had 12 more strokes and six more events of deep vein thrombosis a year than the women taking placebo. The study showed a reduction in the incidence of hip fractures (0.61 relative risk; 95% CI, 0.41 to 0.91) and an unanticipated, though not statistically significant, reduction in breast cancer incidence, a finding that requires further investigation. Observational studies support an increased risk of thromboembolism,[101-103] cholecystitis,[104] and breast cancer[77] in women taking ET.

In contrast to the EPT portion of the WHIMS study, women taking estrogen alone did not have a statistically increased risk of dementia.[98] For women taking ET, as compared with placebo, the risk of having a 10-unit decrease in the Modified Mini-Mental State examination scores (greater than two standard deviations) was 1.47 (95% CI, 1.04 to 2.07). The risk was greater in women with lower cognitive function at initiation of ET.[99]

Type, route of administration, and dose of HT Two observational studies[77,105] and a population-based study from Southern California[106] have increased current understanding of the type, route of administration, and dose of HT with associated breast cancer risk. The findings are as follows: (1) use of estrogen therapy confers greater risk than nonuse[77,107]; (2) use of estrogen plus progestin confers greater risk than use of estrogen alone[77,105,106]; (3) risk increases with duration of estrogen use[77,105,106]; (4) risk with estrogen use is increased in women with low or normal body mass index but not in overweight and obese women[105]; (5) increased risk of breast cancer is associated with any dose and type of commonly used estrogen (i.e., conjugated estrogen and estradiol) and progestin (i.e., medroxyprogesterone acetate, norethisterone, and levonorgestrel/norgestrel); and (6) transdermal formulations of estrogen also confer increased risk.[77] Surprisingly, the use of tibolone, a synthetic steroid with estrogenic, progestogenic, and androgenic properties that is marketed in Europe for its favorable effect on breast symptoms (e.g., tenderness and mastalgia), was also associated with a greater risk of breast cancer than nonuse of steroid hormones.[77] Current evidence indicates that all forms of HT are associated with an increased risk of breast cancer.

Transdermal delivery of estrogen may not be safer if administration is long term; however, transdermal patches and transmucosal delivery systems (including estrogen vaginal rings that provide systemic levels of estrogen for treatment of vasomotor symptoms) avoid the first-pass effect through the liver and may carry a lower risk of thromboembolism,[48,102,108,109] elevation of bile acids,[110] and hypertriglyceridemia[111] than oral estrogen. Studies of moderate- to high-dose regimens suggest that transdermal systems may have a more favorable effect on the coagulation pathway[112] and C-reactive protein[113] than oral products. Transdermal and transmucosal products have been shown to be effective as treatment for vasomotor symptoms[114] and maintenance of bone mineral density.[115]

Given the newly appreciated risks of oral progestins,[77,88] alternative approaches to progestin therapy are gaining popularity. There is a widely held belief that natural progesterone is better than synthetic progestins, but this hypothesis has never been studied. Lower-dose oral micronized progesterone formulations have been widely used in Canada and Europe and were evaluated in the Postmenopausal Estrogen/Progestin Intervention (PEPI) trial.[116] The PEPI study of 596 postmenopausal women found that micronized progesterone combined with estrogen sufficiently diminished the hyperplastic endometrial changes associated with estrogen-only therapy.[116] No other randomized clinical trials exist to better inform us about risks and safety of micronized progesterone, particularly with respect to breast cancer. Likewise, over-the-counter transdermal progesterone creams have not been studied in this regard.

In addition, attention has been directed at nonsystemic therapies. Off-label use of a progestin intrauterine system (IUS) (20 µg/day of levonorgestrel) in postmenopausal women taking estrogen provides low systemic levels of progestin and attenuation of endometrial stimulation by estrogen.[117] Intrauterine levonorgestrel at doses of 10 µg and 14 µg/day have been studied in Europe.[117,118] No increased risk of endometrial hyperplasia or cancer has been observed in women taking estrogen with a progestin IUS in place.[117] Vaginal application of progesterone creams result in local uterine and systemic effects.[119]

Preventive Health Care

The menopausal transition offers women and their health care providers the opportunity to review and focus on preventive health care measures, including basic health habits, such as regular exercise, good nutrition with calcium and vitamin D supplementation, and avoidance of smoking [*see Table 2*].

WHI demonstrated that HT is effective for the prevention of osteoporotic fractures and colorectal cancer in postmenopausal women, but the risks outweigh the benefits[88] [*see Table 1*]. The prevalence of certain medical conditions (e.g., dementia, coronary artery disease, breast cancer, colon cancer, and diabetes mellitus) increase with age, rising more steeply after loss of ovarian function. Recommended management for these conditions is almost always nonhormonal. HT is not indicated for primary prevention of disease, unless a woman at high risk for osteoporosis chooses HT over other options after consideration of the risks and benefits.[60] Two chronic disease processes associated with hypoestrogenism and aging greatly impact women's health in the postmenopausal years, namely cardiovascular disease and osteoporosis. Cardiovascular disease is the leading cause of death in women in the United States, and osteoporosis is a major cause of morbidity. The management of these diseases is discussed more fully elsewhere [*see 16:IX Cardiovascular Disease in Women and 3:VI Diseases of Calcium Metabolism and Metabolic Bone Disease*].

Table 2 Preventive and Screening Measures for Common Conditions in Postmenopausal Women

Condition	*Prevention*	*Early Detection*
Dementia	Participation in cognitive leisure activities Regular exercise Treatment of hypertension Statins and possibly other lipid-lowering agents Long-term NSAID use* Avoidance of HT initiation in postmenopause†	
CAD	Smoking cessation Regular exercise Diet high in nuts, whole-grains, and total fiber (especially water-soluble fiber), folate, and marine n-3 fatty acids Diet low in saturated fat, *trans* fatty acids, and glycemic load Daily, low-dose alcohol Prevention and treatment of hypertension, diabetes mellitus, and hypercholesterolemia Consideration of low-dose daily aspirin if risk of CAD events is ≥ 0.7%/yr Avoidance of HT initiation in postmenopause Statins, aspirin, and beta blockers for secondary prevention (underutilized)	
Breast cancer	Minimal exposure to HT (estrogen and/or progestin) Regular exercise Avoidance of increase in weight and waist circumference Weight loss if overweight/obese Reduction of alcohol intake to 0–20 g/day Raloxifene* if at average risk, or tamoxifen if risk ≥ 1.67%/yr	Screening mammography every 1–2 yr, with or without clinical breast exam regardless of age until clinically significant comorbid conditions
Osteoporosis	Adequate calcium and vitamin D intake Weight-bearing exercise Thiazide* diuretics Antiresorptive treatment before first osteoporotic fracture Antiresorptive treatment after osteoporotic fracture HT† if intolerant of or unresponsive to first-line agents	Screening DEXA at age 65 (earlier if risk factors)
Colon cancer	High-fiber diet for primary, but not secondary, prevention of polyps Aspirin* if personal history of adenoma or colon cancer Removal of adenomatous polyps HT* effective but not advised for this indication†	Periodic screening‡ by fecal occult blood testing or sigmoidoscopy
Diabetes mellitus	Regular exercise Weight loss if overweight/obese Metformin, acarbose, and possibly thiazolidinediones for those at high risk HT† effective but not advised for this indication	

*Off-label indication.

†Increased risk of adverse outcomes has been demonstrated for HT initiation in the postmenopausal years. HT is not advised for the primary prevention of disease, because associated risks outweigh benefits for most women; in limited cases, HT may be used for prevention of osteoporosis, after consideration of all other options. HT should be used only for severe and debilitating symptoms, in the lowest dose and most directed therapy possible, and for the shortest time necessary to accomplish symptom control.

‡The United States Preventive Services Task Force (USPSTF) recommends screening for colon cancer starting at age 50 using either annual fecal occult blood testing, sigmoidoscopy (periodicity unspecified), or both.

HT—hormone therapy CAD—coronary artery disease DEXA—dual x-ray absorptiometry NSAID—nonsteroidal anti-inflammatory drug

Premature Ovarian Failure

Premature ovarian failure (POF) is defined as menopause that occurs before 40 years of age that is not iatrogenically induced. The prevalence of POF is approximately 1%.[120] The Study of Women Across the Nation (SWAN) investigated risk factors associated with POF[121] and found that ethnicity influences risk: POF occurs in 1.1% of white women and 1.4% of African-American and Hispanic women, but it occurs in only 0.5% of Chinese-American women and 0.1% of Japanese-American women. Higher body mass index is associated with increased likelihood of POF, especially in African-American women. Disability and current smoking are associated with greater risk in white women.

ETIOLOGY

There is good evidence to suggest that the timing of the age of menopause is genetically programmed[15,16] and that genes play a significant role in the etiology of premature ovarian failure.[120] Rare genetic and chromosomal causes of premature ovarian failure include familial predisposition, FSH receptor mutations, galactosemia, 17α-hydroxylase deficiency, alterations in gonadotropin structure or function, and structural alterations of the X

chromosome (e.g., Turner syndrome mosaicism). A common genetic cause of POF is the fragile X premutation. Up to 3% to 5% of women with POF are carriers of the fragile X premutation, the most common cause of mental retardation in males.[122] Approximately 16% of women who are fragile X premutation heterozygotes have POF.[123]

Premature menopause may be immune-mediated in 30% to 50% of women with POF.[123] Family history is often positive for autoimmune conditions,[124] and other autoimmune diseases may be present in the patient herself,[124] including autoimmune thyroiditis, type 1 diabetes mellitus, autoimmune hemolytic anemia, Addison disease, hypoparathyroidism, idiopathic thrombocytopenic purpura, Crohn disease, myasthenia gravis, rheumatoid arthritis, systemic lupus erythematosus, vitiligo, and polyendocrine failure.

DIAGNOSIS

Clinical Manifestations

The presentation of premature ovarian failure is identical to that observed in natural menopause, with the exception that POF occurs before 40 years of age. It is more common, however, for women with POF to experience waxing and waning of symptoms over longer periods than it is for women who have natural menopause, and some women will ovulate several years after a diagnosis of POF is made.

Physical Examination

A targeted examination for women with oligomenorrhea or secondary amenorrhea is described elsewhere [*see* Natural Menopause, Physical Examination, *above*]. Less common etiologies of POF, such as Turner Syndrome (i.e., short stature, webbed neck, shield chest, small fourth metacarpal, and minimal breast development with normal hair distribution), can be detected with a specifically targeted physical examination. Findings of other autoimmune conditions often associated with POF [*see* Etiology, *above*] may be present in some women, including signs of thyroid disease (i.e., enlarged, asymmetrical, or nodular thyroid gland; dry skin; lateral eyebrow thinning; delayed relaxation phase on deep tendon reflexes; and myxedema), adrenal dysfunction (i.e., hyperpigmentation and orthostatic hypotension), and systemic lupus erythematosus (i.e., synovitis or malar rash). Galactorrhea suggests an elevated prolactin (PRL) prolactinoma [*see* Differential Diagnosis, *below*].

Laboratory Tests

Ovarian failure is most accurately confirmed by measurement of serum FSH. In women with incipient ovarian failure, FSH levels are often between 15 and 25 IU/L and can fluctuate. Complete ovarian failure is associated with repeated serum FSH levels greater than 25 IU/L. Therefore, FSH levels persistently greater than 25 IU/L (drawn on at least two separate occasions) can be useful in making the diagnosis of POF. Testing of urine or serum β-hCG, TSH, and prolactin concentrations should not be deferred if indicated in the evaluation of oligomenorrhea or secondary amenorrhea [*see* Natural Menopause, Laboratory Tests, *above*]. If a diagnosis of POF is made, consideration of genetic testing for a premutation allele of fragile X may be advisable, providing that this information would benefit family members and that the patient agrees to testing. If a woman younger than 30 years is diagnosed with POF, a karyotype test should be considered to rule out Turner syndrome mosaicism. When POF may be caused by autoimmunity, the complete blood count (CBC), erythrocyte sedimentation rate (ESR), rheumatoid factor (RF), antinuclear antibody (ANA), glucose, calcium, and phosphorus levels can point to associated autoimmune conditions that may not otherwise be clinically apparent.

DIFFERENTIAL DIAGNOSIS

Hypergonadotropic amenorrhea can be caused by thyroid dysfunction, hyperprolactinemia, heroin addiction, and the use of some antidepressant and antipsychotic medications.

MANAGEMENT

All women with POF should be treated with exogenous estrogen, either in the form of a low-dose estrogen-progestin combination contraceptive or a postmenopausal HT formulation to manage symptoms and decrease the risk of osteoporosis and osteopenia. Bone mineral density should be obtained at baseline and followed at intervals of 3 to 5 years. It is recommended that women continue estrogen replacement until at least age 50 (approximately the time of natural menopause). Progestin therapy is recommended for women who have a uterus. Women who are at risk for unintended pregnancy should receive exogenous estrogen and progestin in the form of a contraceptive. For those desiring pregnancy, artificial reproductive technology is available. In vitro fertilization utilizing donor eggs and hormonal manipulation to mature the endometrium result in successful pregnancy in women with POF as often as in women with infertility from other causes.[125]

Treatment with oral contraceptives in the general population is associated with an increased risk of thromboembolic disease, cardiovascular disease in smokers, and stroke in women with migraine headaches or hypertension.[126] The risks of using oral contraceptives and postmenopausal HT in women with POF has not been specifically studied.

COMPLICATIONS AND PROGNOSIS

The chance of spontaneous pregnancy in POF is estimated to be less than 10%.[127] Women with POF may be at higher risk for younger onset of cardiovascular disease.[128] It is estimated that women with POF who do not take estrogen have a lower background risk of breast cancer and thromboembolism than the general population.[129] New onset of autoimmune disorders is not uncommon after the diagnosis of POF has been made.

Early-age mortality may occur in women with POF because of autoimmune phenomena, cardiovascular disease, and osteoporosis. A few epidemiologic studies suggest that an earlier age at menopause is associated with substantially increased mortality[128,129]; thus, careful screening for and management of chronic disease processes associated with hypoestrogenism [*see Table 2*] may be important for sustaining long-term health and quality of life. In addition, careful management of any coexisting autoimmune disorder and reduction, when possible, of potential risks posed by medications used to treat such disorders (e.g., corticosteroids) may be crucial for the long-term health of affected women.

Susan D. Reed, M.D., is a research consultant for Pfizer Inc.

Eliza L. Sutton, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

The progestin intrauterine system and esterified estrogen combined with methyltestosterone have not been approved by the FDA for uses described in this chapter.

XII URINARY INCONTINENCE AND THE OVERACTIVE BLADDER

Robert L. Barbieri, m.d.

The involuntary loss of urine is an extremely common problem in women—more common than Alzheimer disease or osteoporosis. Urinary incontinence affects approximately 15% of women younger than 65 years, 25% of women older than 65 years, and 50% of women who are nursing home residents.[1,2] It is underdiagnosed and undertreated; patients may fail to report it, and physicians may fail to address it.[3]

Pathogenesis

The normal pattern of urinary voiding requires the interaction of the central nervous system, the sacral parasympathetic and thoracolumbar sympathetic systems, the bladder muscle (detrusor muscle), the urinary sphincter muscle, and the mechanical support of the pelvic fascia. In the resting state, urine collects in the bladder, the bladder muscle is quiescent, and the tone of the urinary sphincter muscle is high, ensuring that urine remains in the bladder. Urination is initiated when signals from the CNS induce the bladder muscle to contract and the urethral sphincter muscle to relax. At the completion of voiding, the bladder muscle relaxes and the urethral sphincter contracts. A key feature of the urinary system is that in the normal resting state, the urethral pressure is greater than the pressure in the bladder. Reversal of that differential—whether from a rise in bladder pressure, a decrease in urethral pressure, or both—will result in incontinence.

Urinary Incontinence in the Nongeriatric Population

In the nongeriatric population, the five main causes of urinary incontinence are (1) loss of fascial support of the urethra (stress incontinence), (2) an overactive bladder muscle (detrusor instability), (3) intrinsic sphincter deficiency, (4) neuropathies, and (5) urinary tract fistulas. Many women with incontinence have both stress incontinence and bladder muscle overactivity. In a study of 303 women with urinary incontinence, 43% were diagnosed as having stress incontinence, 21% as having bladder muscle overactivity, and 36% as having both disorders.[4] In some women, the stress incontinence is predominant, with bladder muscle overactivity playing less of a role; in other women, the bladder muscle overactivity is predominant, and there is less of a contribution from stress incontinence. Race may be a factor: African-American women have lower rates of stress incontinence than Hispanic and white women but have higher rates of detrusor instability.[5]

The initial approach to urinary incontinence should include a history; physical examination; and laboratory tests, including a urinalysis and urine culture. In the history, the patient should be asked to describe the episodes of incontinence. Women with stress incontinence typically report urinary leakage with events that increase intra-abdominal pressure—for example, coughing, laughing, sneezing, and the lifting of heavy weights. Women with detrusor instability often report a sudden and intense urge to void that occurs just before the loss of urine. Symptoms such as frequency, nocturia, hesitancy, and terminal dribbling are not specific to incontinence from any one cause.

A voiding diary is a reliable method to establish the severity of urinary incontinence. In the voiding diary, the patient reports the time of continent and incontinent voids, the volume of continent voids, and any events that precipitate incontinence. To facilitate measurement of continent voids, patients can be given a graduated plastic receptacle (a so-called hat) to place on their toilet seat at home.

In the history, the physician should assess for substances that may contribute to incontinence. Caffeine, which is both a diuretic and a bladder irritant, may worsen incontinence in some cases. Other possible dietary bladder irritants include alcohol, citrus or other highly acidic fruit, tomatoes, spicy foods, dairy products, and sugar. Alpha blockers and some muscle relaxants (e.g., dantrolene) can exacerbate incontinence by relaxing the urinary sphincter.

The assessment should include a complete review of the patient's obstetric history, including the number of deliveries, their route, and any complications. Details of any abdominal or pelvic surgery should also be obtained.

The physical examination should include inspection of the vagina for mucosal atrophy and herniation of the pelvic structures.

Urinalysis and culture are necessary to screen for urinary tract infection or glucosuria. If those conditions are found, they should be treated before one proceeds with further evaluation of urinary incontinence. Curing the urinary tract infection or controlling the diabetes may correct the urinary incontinence in such cases.

Additional initial tests for incontinence include a clinical stress test and measurement of postvoid residual urinary volume. One approach to these two tests is to ask the patient to void and then catheterize the bladder to determine the postvoid residual urinary volume. If the postvoid residual volume is more than 200 ml, the physician should assess for a neurogenic process or a bladder outflow obstruction. Using the same catheter, 300 ml of fluid (sterile water or sterile saline) at body temperature can be instilled into the bladder. The patient is then asked to cough while in the supine and upright positions. Immediate leakage of urine with the cough is diagnostic of stress incontinence.

urodynamic testing with multichannel equipment

Urodynamic testing with multichannel pressure recording devices is the gold standard for identifying both stress incontinence and bladder overactivity. In this procedure, the intravesical pressure is directly measured by means of a bladder catheter, and intra-abdominal pressure is measured by use of a vaginal or rectal probe. Subtracting intra-abdominal pressure from intravesical pressure yields the true detrusor pressure. A separate channel in the bladder catheter allows fluid to be instilled into the bladder [*see Figure 1*].

Urodynamic testing is not necessary for every incontinent patient. Although widely available, the testing is expensive and time consuming. Some clinicians prefer to forgo urody-

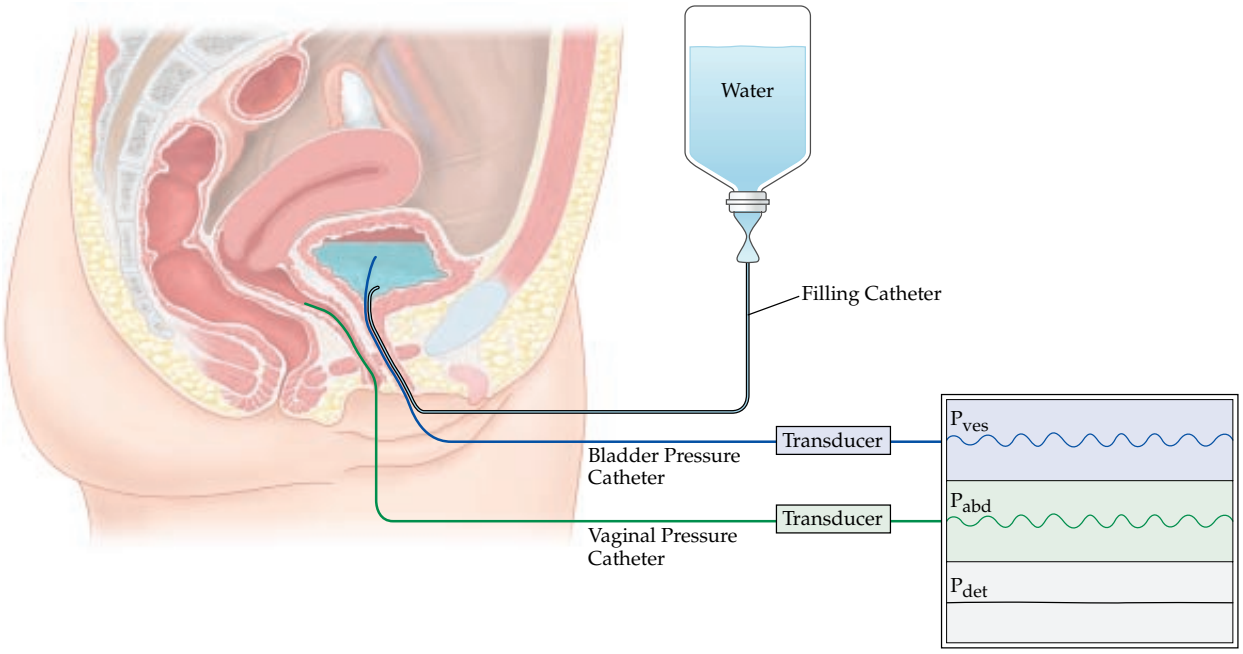

Figure 1 **Subtracted cystometry. Intra-abdominal pressure (Pabd) is measured with an intravaginal or intrarectal pressure catheter. Bladder pressure (Pves) is measured with an intravesical catheter. Subtraction of Pabd from Pves yields the true detrusor pressure (Pdet). Fluid can be instilled into the bladder through a separate channel in the intravesical channel. Bladder contractions that occur as the bladder is filling and that the patient is unable to completely suppress indicate detrusor instability.**

namic testing and treat on the basis of clinical diagnosis, whereas others (especially urogynecologists) use the testing routinely.

STRESS INCONTINENCE

Stress incontinence refers to a sudden involuntary loss of urine, usually secondary to a sudden increase in intra-abdominal pressure, in the absence of a bladder contraction. Intra-abdominal pressure can increase as a result of coughing, sneezing, running, climbing stairs, standing, or lifting heavy weights.

Normally, the pelvic fascia holds the urethral sphincter in an intra-abdominal position; consequently, any increase in intra-abdominal pressure is transmitted equally to the urethra and bladder, and the urethral sphincter remains closed. Damage to the pelvic fascia, laxity in the pelvic ligaments, and partial pelvic muscle tears and denervation—all common sequelae of childbirth—can cause the urethra to drop below the pelvic floor. If intra-abdominal pressure then increases suddenly, the pressure will be transmitted primarily to the bladder; bladder pressure will then exceed urethral pressure, the urethral sphincter will open involuntarily, and urine will spill.

Diagnosis

If the history suggests stress incontinence, the vaginal walls should be examined for laxity of the pelvic structures. Possible underlying abnormalities in stress incontinence include cystocele (a hernia of the bladder into the anterior vaginal wall), rectocele (a hernia of the rectum into the posterior vaginal wall), enterocele (a hernia of the small bowel into the posterior apex of the vaginal wall), and uterine prolapse (a hernia of the uterus into the lower portion of the vagina).

Treatment

If the physical examination reveals the cervix at the vaginal opening (uterine prolapse) or a cystocele, rectocele, or enterocele at the vaginal opening, the patient should be referred to a gynecologist or urogynecologist for surgical repair. If the physical examination reveals no significant herniations, a nonsurgical approach can be recommended.

Nonsurgical treatment The nonsurgical approach to the treatment of stress incontinence includes exercises to strengthen the pelvic floor musculature (Kegel exercises) and electrical stimulation of the pelvic muscles. The Kegel exercise is the voluntary contraction of the pubococcygeal muscles in sets of 10 contractions, five to 10 times daily. Contraction of the pubococcygeal muscle can be taught by asking the patient to stop her stream of urine while voiding. This requires contraction of pelvic muscles and relaxation of the abdominal muscles. Many patients have difficulty isolating the correct muscles and may benefit from instruction sheets on performing the exercises; one source for such instructional material is http://www.niddk.nih.gov/health/urolog/uibcw/exerc/exerc.htm.

Kegel exercises alleviate the symptoms in about 70% of women with stress incontinence.[6] Improvement in continence may not become apparent for 6 to 12 weeks, but once attained, the benefits may be maintained for years.[7]

Vaginal cones can also be used to teach women to contract pelvic floor muscles without contracting the abdominal muscles.[8] Vaginal cones come in sets of five cones, each of a different weight [*see Figure 2*]. Depending on the manufacturer, the cones may be all the same size or may decrease in diameter as they increase in weight. The patient inserts the lightest cone

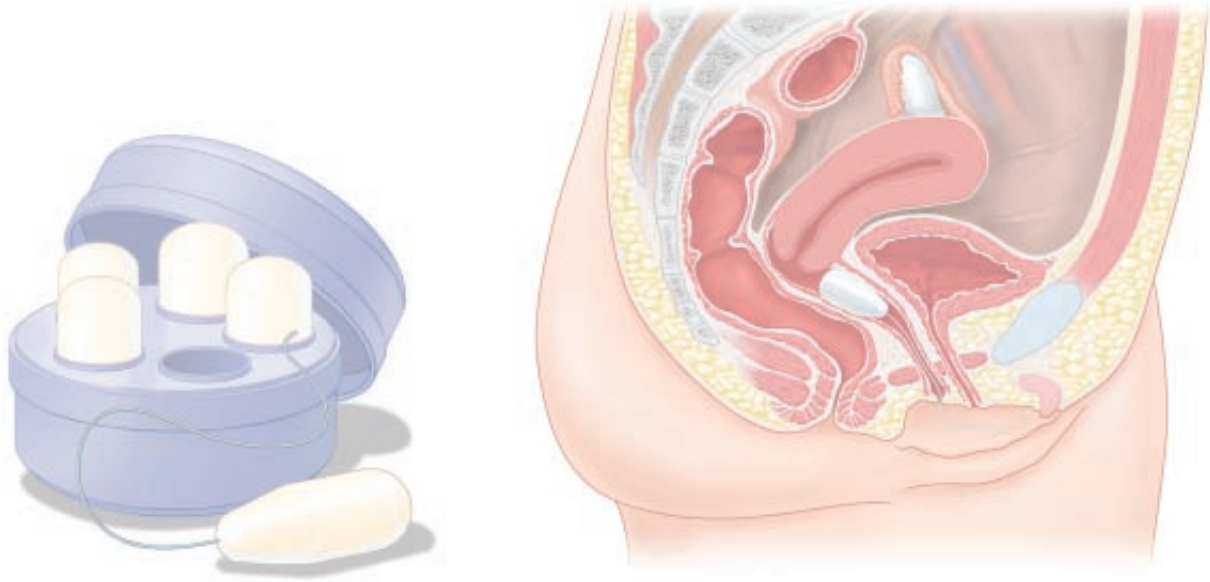

Figure 2 **Vaginal cones. Women with stress incontinence can use vaginal cones to learn how to contract their pelvic floor muscles. The cones come in sets of graduated weight and are shaped like a tampon, with a string to facilitate removal from the vagina (*a*). The patient inserts the cone (*b*) and keeps it in her vagina for 15 minutes. Successively heavier cones are used as the pelvic floor muscles increase in strength.**

into the vagina and uses the pelvic floor muscles to hold the cone in the vagina while walking. Once those muscles can hold the cone in place for at least 15 minutes, the patient progresses to the next heavier cone. For some women, the cones are superior to Kegel exercises for strengthening the pelvic floor musculature. As with the Kegel exercises, patients may not experience benefit for a number of weeks.

An alternative to Kegel exercises and vaginal cones is to electrically stimulate the paravaginal musculature. An approved device for strengthening the pelvic musculature consists of a probe that is placed in the vagina twice daily for 15 to 30 minutes. The probe stimulates the afferent fibers of the pudendal nerve, contracting the muscles of the pelvic floor and periurethral muscles. This stimulation strengthens the muscles that maintain the urethral pressure profile.

Estrogen therapy has been suggested for women with atrophic vaginitis and stress incontinence. Estrogen has not been documented to improve symptoms of stress incontinence,[9,10] but some researchers have speculated that topical estrogen may be effective even if oral estrogen is not[11]; and the combination of estrogen and pelvic floor exercises has been found to be more effective than exercises alone.[12] In one study, imipramine, 25 mg three times a day, produced significant improvement or cure in 60% of patients with stress incontinence.[13]

Surgical treatment If nonsurgical measures fail, the patient with stress incontinence should be referred to a urogynecologist for further evaluation. Incontinence surgery is very effective in the treatment of stress incontinence. In women older than 65 years, incontinence surgery has an overall mortality of less than 0.3%,[14] and surgery for stress incontinence has high cure rates.[15]

The current state-of-the art surgical procedure for stress incontinence is the tension-free vaginal tape procedure.[16] This procedure can be performed on an outpatient basis using local or regional anesthesia and conscious sedation. In this technique, a strip of polypropylene mesh (the tape) is used to create a urethral sling. The tape is inserted under the wall of the vagina, beneath the midurethra, and the ends of the tape are passed retropubically up to two small incisions on the lower abdomen near the superior border of the pubic hair. The tape is elevated just enough to eliminate urine leakage with coughing. It stays in place without sutures because of its Velcro-like surface, and it is further anchored by postoperative fibrosis. The tape allows increases in intra-abdominal pressure to be efficiently transmitted to the urethra, preventing loss of urine. In one study of women with stress incontinence, the tension-free vaginal tape procedure resulted in cure in about 85% of patients.[17] Other bladder neck suspension procedures for stress incontinence include the Burch colposuspension and the Raz needle vaginal suspension.

DETRUSOR INSTABILITY—OVERACTIVE BLADDER MUSCLE

Detrusor instability is defined as spontaneous or provoked bladder contractions during the filling phase of cystometry that cannot be completely suppressed by a neurologically normal patient.[18] A problem with this definition is that it requires an invasive test, cystometry, for the diagnosis. Some authorities prefer the term overactive bladder muscle to describe the condition. In the nonvoiding state, the bladder muscle should not contract spontaneously. Spontaneous contractions of the bladder muscle can raise the bladder pressure above that of the urethral sphincter, resulting in the involuntary loss of urine. Bladder muscle from women with detrusor instability is more sensitive to electrical and acetylcholine stimulation than is bladder muscle from healthy women.[19]

Detrusor hyperreflexia is defined as an overactive bladder muscle caused by a neurologic disorder, such as multiple scle-

rosis, Parkinson disease, cerebrovascular disease, or spinal cord injury. As many as 80% of women with multiple sclerosis have detrusor hyperreflexia.[20]

Diagnosis

Women with detrusor instability typically complain of urinary urgency (a desire to urinate immediately), urinary frequency (a need to urinate every half hour or hour), urge incontinence, and nocturia. A severe urge to void followed by incontinence at rest is common. Incontinent episodes typically involve the loss of large amounts of urine. Women who void 10 or more times a day often have detrusor instability. Physical examination discloses no specific findings in women with overactive bladder. However, because stress incontinence and overactive bladder can coexist, the physical findings associated with stress incontinence may be observed in women with overactive bladder muscle.

Treatment

Bladder retraining and acetylcholine blockade are the two most effective approaches to the treatment of overactive bladder. Surgery is not recommended for women with bladder overactivity.

Bladder retraining The goal of bladder retraining is to elicit behavioral changes that will lead to an increase in bladder capacity and will prolong the interval between episodes of voiding. At the beginning of bladder retraining, the patient is asked to urinate approximately once every hour. No nighttime schedule is recommended. As training progresses, the woman is asked to void once every 90 minutes, then once every 2 hours. Millard and Oldenburg reported that bladder retraining alleviated symptoms in as many as 75% of women with overactive bladder.[21] Biofeedback using a vaginal or anorectal probe may help some women better control urge incontinence.[22] Many physical therapy programs teach bladder retraining and biofeedback techniques.

Behavioral treatment may be as effective as drug treatment for many women with bladder overactivity. In one trial, behavioral therapy resulted in an 86% improvement in incontinent episodes, versus a 69% improvement with oxybutynin.[23]

Drug therapy Detrusor muscle stimulation is mediated by cholinergic fibers. Anticholinergic agents [*see Table 1*] can decrease detrusor muscle activity, reduce the urge to void, and result in improvement in women with urge incontinence. Traditional anticholinergic agents, such as oxybutynin, block detrusor muscle stimulation, but they also block cholinergic effects in the salivary glands, causing dry mouth. The typical dose of immediate-release oxybutynin is 2.5 or 5 mg three or four times a day. Contraindications to oxybutynin include narrow-angle glaucoma and cardiac arrhythmia. A new, extended-release formulation of oxybutynin (starting dose, 5 mg once daily, titrated to 20 to 30 mg once daily) appears to have fewer side effects, such as dry mouth, than the original rapid-acting formulation of the drug.[24] In a prospective, randomized, controlled trial, extended-release oxybutynin proved significantly more effective than tolterodine in improving incontinence and urinary frequency.[25]

Tolterodine, one of a new class of anticholinergic agents, has anticholinergic effects on the bladder but has little effect on the salivary glands. In one study, the mean number of incontinence episodes was reduced by 47% in women treated with tolterodine (2 mg twice daily), compared with 17% in women treated with placebo.[26] For young women, a dosage of 2 mg twice daily is usually effective in reducing the frequency of voiding. For older women, dosages of tolterodine as low as 1 mg daily may control the problem of frequent voiding.

Although alpha blockers are not often used for treating overactive bladder in women, these agents have a modulating effect on bladder smooth muscle. One prospective study found doxazosin [*see Table 1*], 2 mg at bedtime, to be effective in women with urinary frequency and urgency.[27]

INTRINSIC SPHINCTER DEFICIENCY

Intrinsic sphincter deficiency (ISD) is a form of urinary incontinence caused by the failure of the urethra to close completely. Urethral dysfunction in these patients results from mucosal and muscular atrophy and denervation. Postoperative scarring of the urethra can also cause ISD. Urinary leakage in ISD is often continual and can occur without an increase in intra-abdominal pressure. Surgical treatments for ISD include sling procedures, such as the tension-free vaginal tape procedure, or the periurethral injection of bulking agents, such as glutaraldehyde cross-linked bovine collagen (Contigen)[28] or carbon beads suspended in gel (Durasphere)[29] [*see Figure 3*]. Short-term success rates with injectable agents are very high, but long-term durability remains in question.[30]

Table 1 Drugs Used in the Treatment of Overactive Bladder

Class	*Agent (Brand Name)*	*Dosage*	*Cost*	*Comment*
Anticholinergic agents	Oxybutynin	2.5–5 mg, t.i.d.–q.i.d	5 mg t.i.d.: $10–19.99/mo	Dry mouth a common side effect
	Oxybutynin, extended release (Ditropan XL)	5–30 mg q.d.	5 mg: $100.99/mo 10 mg: $107.99/mo	Dry mouth a common side effect
	Tolterodine (Detrol)	1 mg q.d.–2 mg b.i.d.	2 mg b.i.d.: $70–79.99/mo	Lower dose often effective in older women
	Tolterodine, extended release (Detrol LA)	2–4 mg q.d.	2 mg: $100.99/mo	—
Alpha blocker	Doxazosin (Cardura)	2 mg h.s.	2 mg q.d.: $20—29.99/mo	—

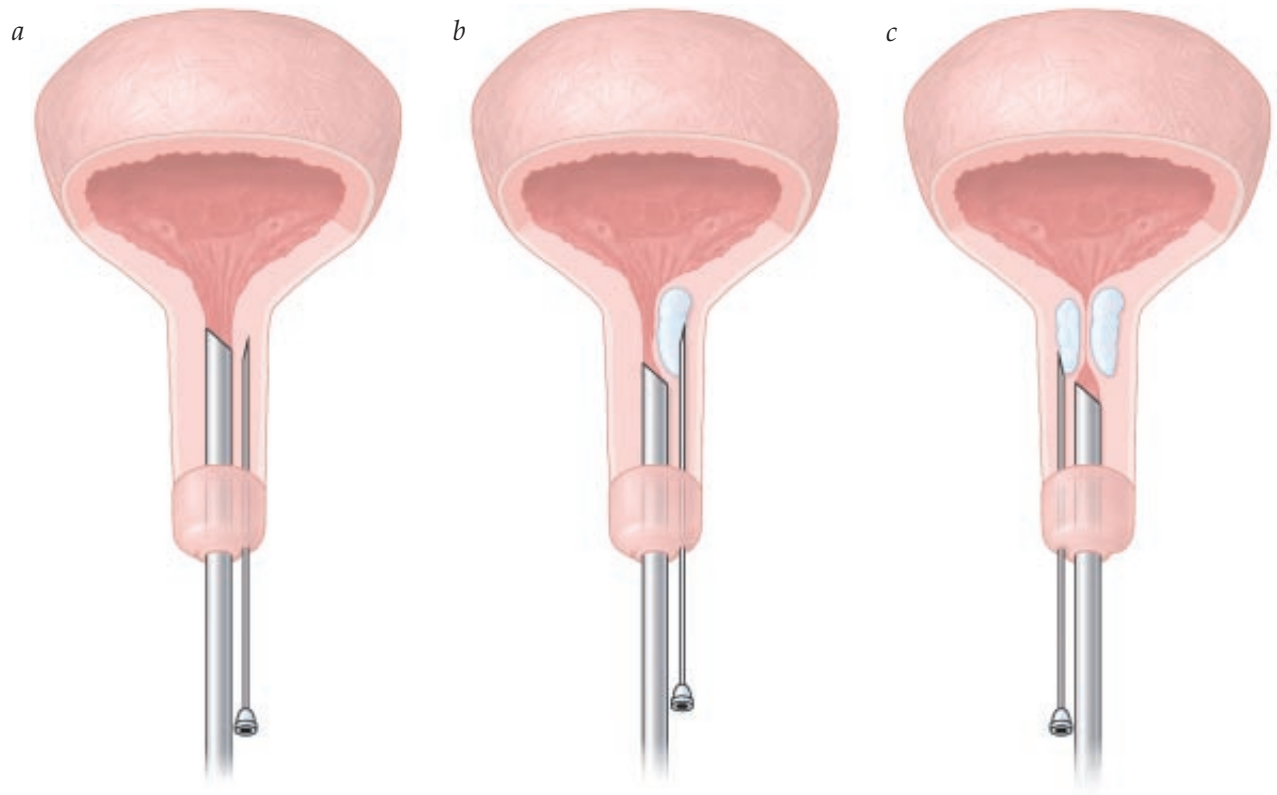

Figure 3 **Injection of bulking agents to treat intrinsic sphincter deficiency. The needle is advanced to the proximal urethra just below the bladder neck (*a*), and the bulking agent is then injected (*b*). Injection of the agent bilaterally closes off the proximal urethra (*c*).**

OVERFLOW INCONTINENCE

Rarely, neurologic problems that result in denervation of the detrusor muscle can lead to overfilling of the bladder and so-called overflow incontinence. Overdistention of the bladder can also be caused by outflow obstruction. Pharmacologic contributors to overflow incontinence include calcium channel blockers, which can relax the detrusor muscle, and alpha agonists, which can increase urethral resistance. Denervation of the detrusor muscle leading to overflow incontinence can result from cerebrovascular accidents, multiple sclerosis, spinal cord injury, cauda equina tumors, diabetes, and pelvic nerve damage during surgery.

A simple way to test the status of the sacral nerves is to look for the anal wink reflex. If the perianal region is lightly stroked with the wooden end of a cotton-tipped applicator, the anal sphincter should contract. Presence of this reflex suggests that the sacral dermatomes S2, S3, and S4 are intact. If an anal wink is not present, a complete neurologic evaluation is warranted.

URINARY TRACT FISTULAS

Fistulas between the bladder and vagina are a rare cause of incontinence. Most urinary tract fistulas occur after a pelvic surgical procedure, such as cesarean section, surgical vaginal delivery (e.g., involving repair of severe lacerations or forceps use), hysterectomy, or bladder surgery. Spontaneous fistulas are uncommon. Incontinence resulting from fistulas usually involves chronic, continuous leakage of urine.

In many cases, fistulas between the bladder and vagina can be observed on speculum examination of the vagina. Small fistulas can be detected by giving the patient a dose of oral pyridium and placing a tampon in the vagina. If the tampon turns orange after 2 hours, a fistula between the urinary tract and vagina is likely.

Urinary Incontinence in the Geriatric Population

As many as half of the women in nursing homes have urinary incontinence. Aging is associated with decreased urethral pressure and increased involuntary detrusor contractility, which increase the risk of symptomatic bladder overactivity. In addition, in the elderly, urine production increases during the night. Resnick has suggested the mnemonic DIAPPERS for the evaluation of incontinence in the geriatric population.[31] This mnemonic summarizes the most common causes of incontinence in the elderly: delirium, infection, atrophic urethritis, pharmaceuticals that interfere with bladder and urethral function, psychiatric causes (depression), excess urinary output, restricted mobility, and stool impaction. Treatment of these problems can often significantly alleviate the incontinence.

The incontinent woman with cognitive impairment often responds well to prompted voiding. One program of prompted voiding requires that the woman be asked every 2 hours if she would like to void. If she responds in the affirmative, she is escorted to the toilet.

XIV APPROACH TO THE PATIENT WITH A BREAST MASS

Valerie L. Staradub, m.d.
Monica Morrow, m.d.

More than half of the patients who present to a breast clinic have the chief complaint of a breast mass.[1] The identification of a breast mass causes a great deal of anxiety in women, although the majority of breast masses are benign. The most important task of the physician who is evaluating a breast mass is to exclude the presence of malignancy. Once malignancy is ruled out, the physician must provide an accurate diagnosis, suitable treatment, and reassurance to the patient.

Assessment of Normal Organ Function

The normal breast is a mixture of epithelial (glandular) elements, stromal tissue, and fat. This heterogeneity is responsible for the lumpiness that is characteristic of normal breasts, particularly in premenopausal women. The upper outer quadrant and the inframammary ridge are usually the most nodular areas of the normal breast. In women older than 40 years, small pealike nodules can often be felt beneath the areola. These nodules represent dilated ducts and are of no clinical concern. Most normal areas of nodularity can be readily identified by their presence in both breasts.

In premenopausal women, the normal hormonal fluctuations of the menstrual cycle often result in changes in breast nodularity that may be mistaken for disease processes. The progesterone surge at ovulation results in mammary duct differentiation and alveolar epithelial cell differentiation into secretory cells. Clinically, this translates to a greater degree of nodularity in the upper outer quadrants of the breasts and may also result in breast tenderness or discomfort. Cyclical nodularity generally decreases after the onset of menses, which is the rationale for the recommendation that a patient perform breast self-examination in the week after her period, when the breasts are the least nodular. These cyclical changes in breast nodularity are often erroneously termed fibrocystic disease, but they are in fact a component of normal physiology.[2] After menopause with its concomitant withdrawal of estradiol and progesterone, the epithelial elements of the breast atrophy, making the breasts softer, less nodular, and easier to examine.

History and Physical Examination of the Patient with a Breast Mass

The key to evaluating the patient who presents with a breast mass is to determine whether a dominant mass is present and to define the level of suspicion for malignancy associated with the mass, should one be detected. These determinations are initially made on the basis of a careful history and physical examination and will direct the approach to diagnosis and management for each patient.

HISTORY

The initial step in obtaining the pertinent history is to characterize the mass by determining the mass's duration, fluctuation with the menstrual cycle, associated tenderness, and whether it has changed in size since the patient first identified it. The patient should be asked whether she has a history of breast problems, including cyst aspirations and biopsies. A menstrual history is important, including the date of the last period, any recent menstrual irregularities, use of oral contraceptives or hormone replacement therapy, and recent changes in hormone preparation.

An assessment of the patient's level of risk for breast cancer is appropriate [*see Table 1*], although the characteristics of the breast mass rather than the patient's level of risk for cancer should be the primary determinant of the appropriate workup. The characteristics of the breast mass take precedence over the assessment of cancer risk because the majority of women with breast cancer lack identifiable risk factors.[3] When eliciting a family history, it is important to obtain information on both maternal and paternal relatives, because breast cancer on either side of the family is associated with an increased level of risk.

PHYSICAL EXAMINATION

Physical examination is important to confirm the presence of a mass. Often, a mass identified by a patient or a primary care physician is actually an area of normal glandular nodularity or normal breast tissue and underlying structures. In a study of 605 women younger than 40 years, Morrow and colleagues reported that referral by a primary care provider to a surgeon for the evaluation of a breast lump led to confirmation of the presence of a dominant mass in 29% of women, whereas patient-detected masses were confirmed by the surgeon in 36% (a difference that was not statistically significant).[4]

Examination should be carried out with the patient in both an upright sitting position and a supine position. The breasts should be evaluated for symmetry with the arms relaxed and with the arms raised over the head. The presence of skin or nipple retraction, edema, or erythema should be noted. In many women, the breasts are not precisely the same size, and in some women, there may be a significant difference in size. If a size discrepancy is noted, the patient should be questioned regarding its duration. Similarly, many women have bifid or chronically inverted nipples, the latter of which occur particularly after lactation; however, bifid nipples or chronically inverted nipples are of no concern, even if the chronically inverted nipples are present in a patient who has never lactated.

Table 1 Factors Used for Assessment of Breast Cancer Risk

- Patient age
- Patient race
- Age at menarche
- Age at first live birth
- Age at menopause
- History of postmenopausal hormone replacement therapy
- Number of relatives with breast and/or ovarian cancer
  - Relationship to patient
  - Age at diagnosis
- Number of previous breast biopsies
- Pathologic findings at biopsy

Palpation of both breasts, as well as the axilla, should follow. The axilla should be examined with the patient seated and the ipsilateral arm supported to relax the pectoral muscle. Small palpable nodes are not uncommon in slender women, and any palpable nodes must be assessed for worrisome characteristics such as fixation, large size, or hardness.

Breast palpation should be performed with the patient both in the upright position and in the supine position. In the supine position, the ipsilateral arm should be placed behind the head to spread the breast tissue across the chest wall. The pads, rather than the tips, of the first three fingers should be used for palpation, and pinching of the breast tissue between the fingers should be avoided. The goal of the examination is to determine if a dominant mass is present. Dominant masses are distinguished from nodular breast tissue by having three dimensions and a texture different from the adjacent normal breast. If a mass is identified, it should be measured with a ruler, the consistency should be noted (e.g., soft, rubbery, firm, hard), and the characteristics of its margins described (e.g., well circumscribed, poorly defined) [*see Table 2*]. Fixation of the mass within the breast or to the chest wall should also be noted. If there is uncertainty whether a finding represents a true dominant mass, comparison with the mirror-image location in the opposite breast is often helpful.

Once the examination is complete, regardless of whether a mass is identified, the patient should be asked to indicate the area that concerns her. This ensures that the area of concern to the patient is not overlooked by the physician. At the conclusion of the examination, the patient can be categorized according to four possible assessments: (1) no abnormal finding is appreciated; (2) a prominent nodularity is present, but it does not have the characteristics of a dominant mass; (3) a dominant mass with clinically benign characteristics is present; and (4) a dominant mass suspicious for cancer is present. The appropriate imaging and diagnostic workup is specific to the outcome of the physical examination.

Table 2 Physical Characteristics of Benign and Malignant Breast Masses

Characteristic	*Benign*	*Malignant*
Borders	Well circumscribed	Irregular
Texture	Firm or rubbery	Hard
Mobility	Mobile	Fixed to surrounding tissue
Skin changes	None	Dimpling, retraction
Nipple changes	None	Retraction, bloody discharge, scaling

Evaluation of a Breast Mass

NO ABNORMALITY DETECTED BY PHYSICIAN

If no abnormality is detected during a clinical breast examination, even after careful examination of the area of concern, the patient should be reassured of the absence of worrisome findings. Women 40 years of age and older who have not had a mammogram within the past year should receive a mammogram to screen for nonpalpable abnormalities. In younger patients, no imaging should be recommended unless their level of risk for malignancy indicates screening as a prudent measure. To ensure that no worrisome finding was overlooked, a follow-up examination 2 to 3 months after the patient's initial visit is appropriate for physicians who do not have extensive experience in evaluating breast masses. The follow-up visit is also a good time to review the woman's age and cancer risk to determine the appropriate type and frequency of screening tests.

NODULARITY

It can sometimes be difficult to confidently differentiate a nodularity from a dominant mass. In women between 35 and 40 years of age, mammography is usually not helpful in making this determination. Morrow and colleagues reported that in 197 women who were referred for evaluation of a lump but whose physical examinations were considered by the surgeon to be normal or characterized only by glandular nodularity, only three had a mass identified on mammography that resulted in a breast biopsy, and all three were benign.[4] More commonly, the imaging study led to a recommendation for a 6-month follow-up mammogram to monitor abnormalities that were classified as "probably benign" and were independent of the patient's reason for presentation. None of the abnormalities monitored by follow-up mammograms proved to be carcinoma. Similarly, Harris and Jackson reported that no malignant lesions were identified in their study of 625 women younger than 35 years when mammography was used to examine lumpy breasts and suspected fibrocystic disease.[5]

Directed ultrasound of the area in question is the initial study recommended in young women when there is uncertainty regarding the presence of a dominant mass. If no suspicious findings are revealed on ultrasound, a short-interval follow-up examination in 1 to 2 months is appropriate.

In women older than 40 years, a diagnostic imaging workup should be performed when a dominant mass is identified on physical examination. The mammogram should include placement of a skin marker over the area of interest and extra views of the indicated area, if these are determined to be appropriate by the radiologist. If no abnormality is seen on mammography, a directed ultrasound study should be performed to exclude the presence of mammographically occult carcinoma. If these imaging studies reveal no evidence of a breast mass, then a short-interval follow-up examination constitutes appropriate management.

Attempts at needle aspiration to reassure both the patient and her physician that no worrisome abnormalities are present are not usually helpful in the absence of a dominant mass. Normal breast tissue is significantly less cellular than dominant masses; thus, the rate of nondiagnostic aspirates is significantly higher in cases in which no discrete abnormality is detected than in cases in which a dominant mass is present.[4,6] An aspirate with insufficient material for diagnosis is generally considered an indication for surgical biopsy; therefore, the use of fine-needle aspiration (FNA) for vague areas of nodularity may lead to unnecessary biopsies.

In patients with nodularity on physical examination and a negative imaging workup, a follow-up examination should be performed in 1 to 3 months to ensure the stability and benign nature of the nodularity. If the finding persists, another examination after 6 months is appropriate to ensure that a discrete mass is not evolving [*see* Dominant Masses with Clinically Benign Features, *below*].

Imaging Evaluation

In the woman whose physical examination detected a dominant mass with benign clinical features, the initial step in evaluation is to determine whether the mass is cystic or solid. Cysts cannot be reliably diagnosed by physical examination alone, and thus, ultrasound or aspiration of fluid and subsequent resolution of the mass are required for diagnosis [*see Figure 1*].

Ultrasound In women younger than 35 years, ultrasound is often the only diagnostic study needed for the evaluation of a clinically benign breast mass. Mammography is recommended only if the mass is considered suspicious for malignancy, because cancer is rare in this group and mammograms are usually inconclusive because of breast density. Women older than 35 years who present with a breast mass should be evaluated by mammography and ultrasound.

Ultrasound, unlike mammography, has the capacity to differentiate solid masses from cystic masses. Simple cysts are seen on ultrasound as round or oval with sharply defined margins and posterior acoustic enhancement—that is, the tissue deep to the cyst appears brighter than other breast tissue found at the same level—and without any internal echoes. If a cyst is seen to have a solid component on ultrasound, further workup is warranted.

Aspiration Complex cysts are defined as those with septations or internal echoes and are traditionally managed by aspiration. However, in a study of 308 complex cysts, the incidence of malignancy was only 0.3%, suggesting that many complex cysts can be managed adequately by short-term follow-up.[7]

Biopsy Cystic lesions with thick and indistinct walls, thick septations, or any solid component should be biopsied, because some of these masses are malignant. In a study by Berg and colleagues, 18 out of 79 lesions with these characteristics proved to be malignant.[8]

It has been suggested that patients with a palpable breast mass exhibiting normal mammographic and ultrasound findings do not require tissue diagnosis[9]; however, evidence suggests that malignant masses may not be detected by mammography and ultrasonography. Edeiken reported that 22% of 499 women with a palpable breast cancer had a false negative mammogram,[10] and the majority of false negatives were observed in women younger than 50 years (a finding attributed primarily to the prevalence of breast density in young women). Ultrasound is an extremely operator-dependent technique. Although Dennis and colleagues[9] reported that ultrasound has a high sensitivity for the diagnosis of cancer, it is not clear that these results can be generalized to a variety of practice settings.

A patient with a palpable solid mass should be referred to a surgeon for a tissue diagnosis regardless of whether the mass is visualized by imaging studies. Solid masses may be diagnosed with FNA cytology, core-needle biopsy, or excisional biopsy [*see Figure 1*].

Triple Diagnosis Test

The triple diagnosis test uses a combination of physical examination, imaging studies, and FNA cytology as an alternative to surgical excision to establish that a breast mass is benign. The triple test is considered to identify the mass as benign if the physical examination, mammogram, and FNA all indicate a benign process. If the lesion cannot be visualized on mammogram or if the FNA contains insufficient cells for diagnosis, the triple test cannot be confirmatory for a benign lesion. In a study of 191 patients who had confirmatory surgical biopsy, Steinberg and

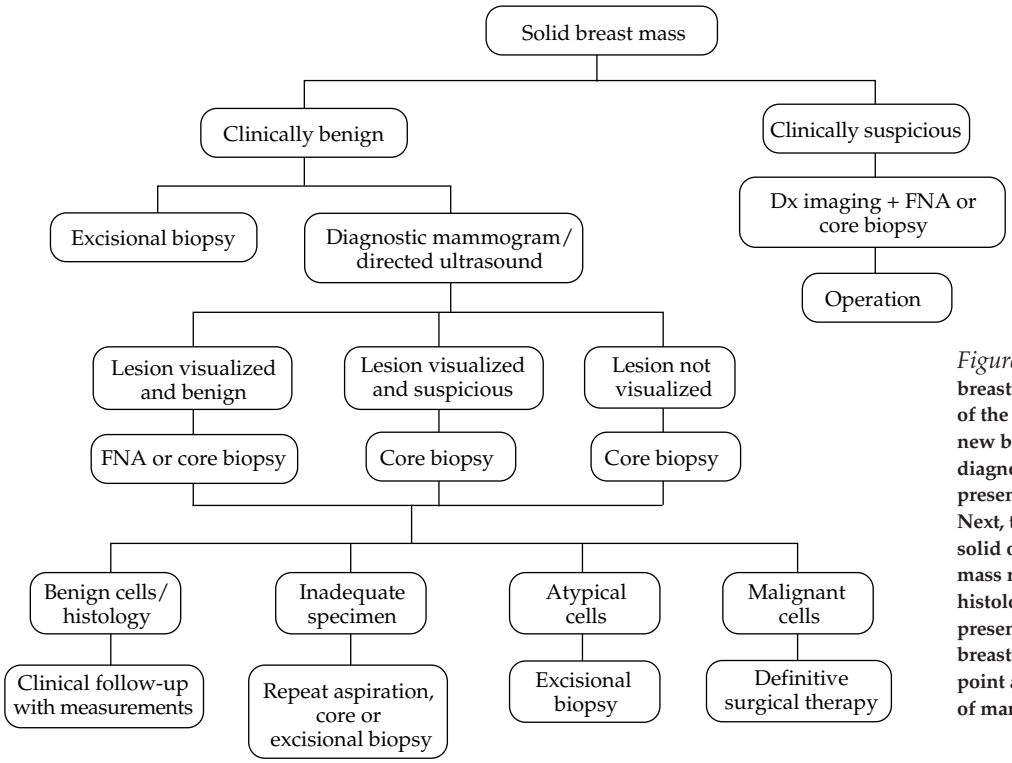

Figure 1 **Management of a solid breast mass. The most important facet of the evaluation and management of a new breast mass is the exclusion of a diagnosis of breast cancer. First, the presence of a mass must be confirmed. Next, the mass is classified as either solid or cystic [*see Figure 2*]. A solid mass requires either cytologic or histologic sampling to exclude the presence of malignancy. Referral to a breast specialist is indicated at any point at which the diagnosis or choice of management is in doubt.**

colleagues reported that the triple test had a sensitivity of 95.5% and a specificity of 100%.[11] Vetto and colleagues reported that the triple diagnosis test is accurate and results in a substantial reduction in the need for surgical excisional biopsies of benign lesions.[12] In their study of 46 breast lesions identified in 43 patients, the triple test produced concordant results in 21 lesions.[12] Twelve triple tests gave concordant benign results, and biopsy was confirmatory in all of these cases (negative predictive value of 100%). In nine cases, there were concordant malignant results, and final pathology on all of these confirmed malignancy (positive predictive value of 100%). There were 25 discordant triple test results (54%): in nine of these cases, the final pathology was benign, and the remaining 16 demonstrated malignancy (positive predictive value of 64%).

No single mode of evaluation used in the triple test is as accurate as the combination of the three.[12] Bicker and colleagues reported that only seven of 2,184 (0.32%) patients assessed as having benign disease by the triple test were subsequently found to have carcinoma, with five of the seven cancers diagnosed within the first year of observation.[13] Overall, FNA has been shown to be quite accurate in the evaluation of benign breast masses [*see Table 3*].[11,12,14-16] FNA cytology alone has a sensitivity ranging from 65% to 98% and a specificity of 34% to 100%. In a review of 29 studies, the likelihood of identifying malignant cytology in patients with breast cancer ranged from 35% to 92%.[17] Lower sensitivity is associated with smaller tumors and younger patient age; sensitivity is quite high when FNA is performed by trained personnel and interpreted by an experienced cytologist.[18]

Following a benign, concordant triple diagnosis test, an identified mass must be monitored for growth by serial examination and imaging studies, which are generally recommended to be performed every 6 months for 2 years, until stability is documented. Growth of the lesion should prompt surgical excision. Patients opting for observation should be counseled about the small possibility of a delay in the diagnosis of cancer. Particular caution should be used when taking a wait-and-see approach in women 50 years of age or older, because in this group benign breast masses are infrequent and carcinoma is more common.

Core-Needle Biopsy

An alternative approach to the diagnosis of a clinically and radiographically benign lesion is core-needle biopsy. This approach has two advantages: (1) it provides a histologic specimen that can be interpreted by a general pathologist, rather than requiring a specialized cytopathologist, and (2) it provides a specific histologic diagnosis rather than simply classifying the mass as benign. In one study, 286 breast lesions (232 of which were palpable) were evaluated both by FNA and core-needle biopsy, and the two tests were reported to have equal sensitivity, positive predictive value for malignancy, and equally low rates of samples inadequate for diagnosis.[15] Core biopsy is associated with slightly greater discomfort and higher costs than FNA. Because core biopsies may sample adjacent tissue, rather than the lesion itself, a follow-up evaluation is necessary, even if a benign result is obtained.

Before undertaking an extensive workup to establish with a high degree of certainty that a mass is benign, it is important to ascertain whether the patient will be comfortable with a palpable abnormality left in place in her breast. For the highly anxious patient, the patient in whom follow-up is difficult, or the unreliable patient, excisional biopsy may be the preferred diagnostic strategy, even for lesions felt to be clinically benign.

SUSPICIOUS DOMINANT BREAST MASSES

Imaging Evaluation

If a breast mass has characteristics suggestive of carcinoma, a diagnostic mammogram is the initial step in evaluation. The purpose of the mammogram is to define the absence or presence and extent of nonpalpable disease associated with the mass and to identify additional abnormalities in the ipsilateral or contralateral breast that may influence the choice of local therapy. The purpose of the mammogram is *not* to diagnose the palpable finding. Between 15% and 30% of palpable cancers are not seen on mammography[19]; therefore, a normal mammogram does not ensure the absence of cancer. However, the likelihood of a false negative result can be minimized through the use of a diagnostic mammogram, which may include multiple views in comparison with the two standard views used in screening mammography. In a diagnostic mammogram, a marker is placed on the palpable finding to ensure that the area of the breast containing the mass is included on the films. Failure to visualize lesions in the periphery of the breast is a well-documented cause of false negative mammograms. Extra views are obtained of the tumor site to define the extent of the primary tumor, and these views are critically important to the surgeon when assessing the local therapy options available to the patient. However, regardless of the findings of mammography, women with clinically suspicious breast masses require a histologic diagnosis to exclude the presence of cancer.

Histologic Diagnosis

Needle biopsy, either core biopsy or FNA, is the preferred technique for diagnosing clinically suspicious breast masses.

Table 3 Accuracy of Fine-Needle Aspiration

Study	*Number of Patients*	*Positive Predictive Value (%)*	*Negative Predictive Value (%)*	*Sensitivity (%)*	*Specificity (%)*
Morris[14]	261	100	95.5	96	100
Westenend[15]	286	100	—	92	82
Steinberg[11]	191	98	—	49	99.5
Vetto[12]	46	100	95.5	96	100
Patel[16]	731	99.4	85	91	56*

*Included specimens insufficient for diagnosis.

Needle biopsy is more cost-effective than primary surgical excision and does not involve incisions that may interfere with mastectomy incision placement or affect breast skin needed for breast reconstruction, should the patient choose such a treatment option.

False negative rates for core biopsy and FNA, as discussed previously, are similar. A small incidence of false positive findings with FNA has been reported. The likelihood of having a benign final diagnosis after a frankly malignant FNA result is between 0% and 0.2%. However, the likelihood of having a benign final diagnosis after an FNA result reported as suspicious for malignancy is as high as 6.2%; thus, a finding that is suspicious for malignancy on FNA should prompt a surgical excision for definitive diagnosis before proceeding to definitive cancer treatment.[17]

Core biopsy is preferred by many physicians because it provides information about tumor histology and reliably distinguishes invasive from intraductal carcinoma. If needle-biopsy techniques do not provide a definitive diagnosis of malignancy and the mass has suspicious characteristics on physical examination or mammogram, a surgical biopsy should be performed. When surgical excision is undertaken, the procedure should be performed as a lumpectomy that includes excision of some adjacent normal breast tissue and placement of orienting sutures for the pathologist. If the margins are free of cancer, the diagnostic procedure serves as the definitive breast procedure.

Differential Diagnosis and Management of Common Benign Breast Masses

CYSTS

Cysts are most frequent in the perimenopausal years, with 63% of cysts occurring in women between the ages of 40 and 49.[20] Cysts are less common in younger women, accounting for only 10% of breast masses in women younger than 40 years.[4] Cysts are also relatively uncommon in postmenopausal women, except in those receiving hormone replacement therapy. Multiple cysts in the same patient, whether synchronous or metachronous, are not uncommon.[21]

Cysts are usually round or oval and have smooth, well-demarcated borders. They may fluctuate with the menstrual cycle, and they may be tender, especially if they have filled rapidly. Cysts are indistinguishable from solid masses on physical examination and mammography, but they may be suspected because of a history of menstrual-cycle variation and the clinical finding of a well-circumscribed, firm mass. There are two methods to definitively characterize a mass as a cyst: aspiration and ultrasound [*see Figure 2*]. Aspiration is performed with a 20- to 22-gauge needle and is successful if fluid is obtained and the mass completely resolves. The fluid may be yellow, clear, or a murky greenish-brown. Bloody cyst fluid is an indication for excision, and if blood is identified in the aspirate, the procedure should be promptly halted in an attempt to preserve a part of the mass. Cyst aspiration fluid should not be sent for cytology, because dead epithelial cells are shed into a cyst and atypical findings are likely, despite the low likelihood of malignancy.[20] Additionally, once the cyst has been aspirated, there is no palpable target for the excision mandated by the finding of atypia. In a study of 6,747 cysts with nonbloody aspirates, no cancers were found.[20] If a mass is still present after aspiration, the mass should be evaluated as a dominant solid mass, and a histologic diagnosis should be obtained. If a cyst recurs rapidly (within 1 to 3 weeks) after aspiration, it should be reevaluated. Fewer than 20% of cysts will recur rapidly after aspiration,[22] and rapid refilling of the cyst raises the possibility of a mass resulting in ductal obstruction or a growth within the cyst wall. A second aspiration may be undertaken, but with multiple recurrences, surgical biopsy should be performed to ensure that a cancer with a cystic component is not overlooked.

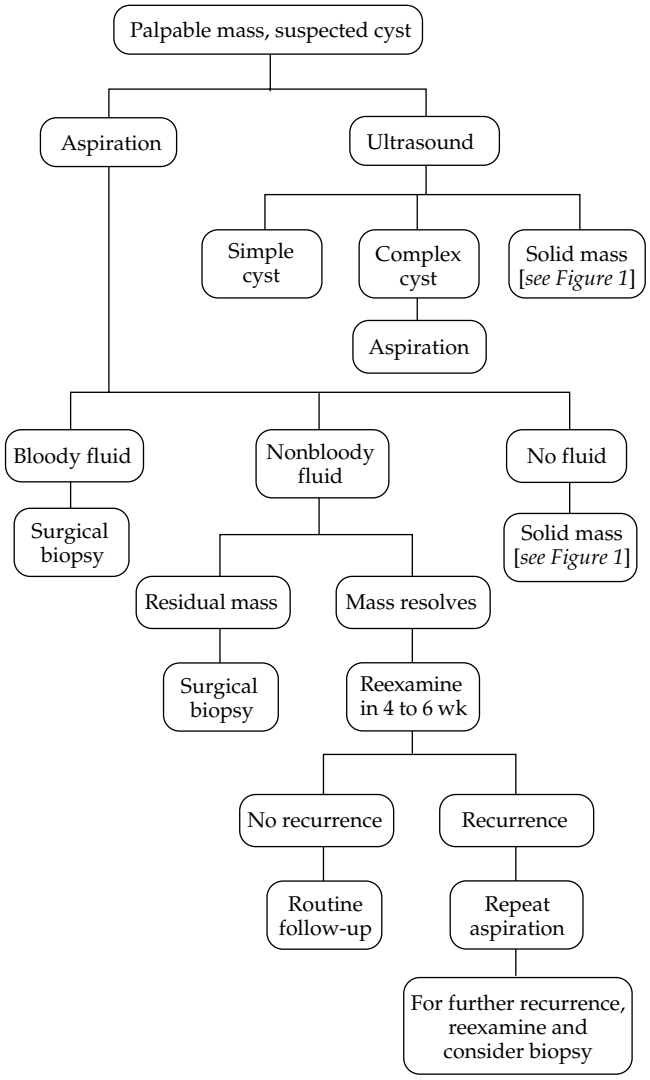

Figure 2 **Management of a breast cyst. Cysts can be identified either by aspiration of fluid or by ultrasound. Prompt diagnosis and management reduce the anxiety level of the patient.**

Patients who do not wish to undergo aspiration of the cyst may opt for targeted ultrasound of the mass. Ultrasound is 98% to 100% accurate in diagnosing simple cysts when careful criteria are used.[23] As previously stated, the criteria for identifying a simple cyst on ultrasound are its round or oval shape, sharply defined margins, posterior acoustic enhancement, and absence of internal echoes. Simple cysts positively identified on ultrasound do not require any treatment, although painful cysts may be aspirated for symptom relief.

Fibroadenomas

Fibroadenomas are a frequent cause of breast mass and occur most commonly in younger women. Fibroadenomas tend to occur at an earlier age in blacks than in whites.[24] A biphasic incidence is reported in white women, with peaks at 25 and 48 years of age[25]; in black women, the peak incidence is between 16 and 25 years of age.[25] Fibroadenoma cannot be definitively diagnosed by clinical examination alone.

Fibroadenomas in young women are usually firm; rubbery; well circumscribed; nontender; and very mobile, because they grow by displacing the surrounding breast tissue. Fibroadenomas can be diagnosed by core biopsy or excisional biopsy, or they may be observed after a benign and concordant triple diagnosis test, whichever is preferable to the patient. Excision is indicated if any aspect of the triple test is discordant or if the lesion enlarges after diagnosis.

Ultrasound is useful to document the stability of a lesion identified as a fibroadenoma that is being managed conservatively. Benign fibroadenomas can change in size. In a study of 1,070 cases diagnosed by FNA and followed for 3 years, a mean change in each of the three dimensions of 20% or less over a 6-month interval was not associated with malignancy.[26] A more significant change in size may be an indication of malignancy or phyllodes tumor.[27,28] Fibroadenomas may increase in size significantly during pregnancy, and younger women considering expectant management of a fibroadenoma should be educated regarding this possibility. Fibroadenomas can also regress entirely or become smaller over time. In a study of 92 fibroadenomas confirmed by FNA and followed for a mean of 47 weeks, 15 (16%) resolved and 30 (33%) enlarged throughout the study.[29] The remaining lesions either remained static or enlarged slightly and then remained unchanged. Tumor resolution is more likely to occur in fibroadenomas in very young women, in new-onset fibroadenomas, in small fibroadenomas, and in fibroadenomas occurring during pregnancy.

Although fibroadenomas themselves are benign, having a fibroadenoma may slightly increase the long-term risk for breast cancer development. For example, a retrospective cohort study showed a 2.17 relative risk for breast cancer in women with fibroadenomas, compared with the study's control subjects.[30] However, in the subset of patients without a family history of breast cancer and with a noncomplex fibroadenoma, no increase in risk was seen, whereas those with complex fibroadenomas had a relative risk between 2 and 4.

Complex fibroadenomas are characterized by epithelial calcification, apocrine metaplasia, and sclerosing adenosis and are larger than 3 mm.[30] Fibroadenomas rarely contain epithelial hyperplasia with atypia, with a frequency of 0.3%.[31] Furthermore, in one study, the presence of such atypia did not correlate with an additional increased risk of future breast carcinoma.[32] Fibroadenomas are regarded by the Cancer Committee of the College of American Pathologists as lesions that do not confer an increased risk for the development of breast cancer.[33]

Phyllodes Tumors

Phyllodes tumors are much less common than fibroadenomas. In one study of 515 benign masses, the ratio of fibroadenomas to phyllodes tumors was 29:1.[34] The majority of phyllodes tumors are benign, but they may grow to a very large size. A rapid change in the size of a mass thought to be a fibroadenoma is suggestive of a phyllodes tumor and is an indication for excision. Benign phyllodes tumors have a propensity to recur locally in about 20% of cases unless excised with a 1 to 2 cm margin of normal breast tissue.[35] For very large tumors, adequate resection may necessitate mastectomy.

Table 4 Benign Breast Lesions by Category

Nonproliferative lesions
Simple cysts
Mild hyperplasia of the usual type
Papillary apocrine change
Proliferative lesions without atypia
Fibroadenomas
Intraductal papillomas
Sclerosing adenosis
Moderate to florid hyperplasia
Proliferative lesions with atypia
Atypical ductal hyperplasia
Atypical lobular hyperplasia

Other Benign Masses

Hamartomas Hamartomas are uncommon benign breast masses that are usually well circumscribed and contain elements of fat, glandular tissue, and fibrous tissue.[36] Because they contain the same tissues as the normal breast, hamartomas are often difficult to feel and are more typically diagnosed by mammography. Hamartomas do not have specific diagnostic histologic features; thus, tissue diagnosis must be correlated to physical findings and mammographic imaging.[36] The cytologic findings overlap with findings in other benign masses, and they are unlikely to be confused with malignancy.[37] There are extremely rare reports of in situ or invasive carcinoma identified in a breast hamartoma, but for the most part, hamartomas are benign masses.

Fat necrosis Fat necrosis results from trauma to the breast, which can be secondary to operation, accident (e.g., seat-belt injury and falls), or radiation therapy. In up to 50% of cases, the patient cannot recall any antecedent trauma.[38]

Clinically, fat necrosis results in a firm irregular breast mass. Because fat necrosis often occurs superficially in the breast, it may result in skin retraction that mimicks carcinoma. There is a spectrum of imaging findings associated with fat necrosis, including radiolucent oil cysts (which are diagnostic of the condition), dystrophic calcifications, and spiculated masses mimicking carcinoma.[38] It can be difficult to differentiate fat necrosis from malignancy using clinical and radiographic features alone, and biopsy is usually required.

Benign Breast Lesions and Breast Cancer Risk

Much confusion has surrounded the relationship between benign breast disease and breast cancer risk. The seminal work in this area was by Dupont and Page, who reviewed over 10,500 women with benign breast biopsies and reported results based on 3,303 of these women, who were followed for a median of 17 years.[39] Benign disease was categorized into three groups: nonproliferative disease, proliferative disease without atypia, and proliferative disease with atypia [*see Table 4*].

Women with nonproliferative lesions were not found to be at increased risk for subsequent breast cancer, whereas women with proliferative lesions and no atypia had a relative risk for developing cancer of 1.9. Women with atypical ductal or lobular hyperplasia had a cancer risk 5.3 times that of women with nonproliferative lesions, and women with atypical hyperplasia and a family history of breast cancer had a relative risk for developing cancer of 11. These findings have been validated in a subsequent prospective, case-control study by London and colleagues, who evaluated 121 women with breast cancer who had a prior biopsy for benign breast disease and 448 control subjects (women without cancer matched for year of birth and year of benign biopsy).[40] This study reported a relative risk of 1.6 for patients with proliferative disease and no atypical hyperplasia and a relative risk of 3.7 for patients with proliferative disease and atypical hyperplasia. It is important to recognize that atypical hyperplasia is uncommon in clinically detected lesions, accounting for only 3.6% of patients in the study by Dupont and Page.[39] Although proliferative lesions increase the relative risk of breast cancer development by a factor of 1.5 to 2.0, the absolute risk of breast cancer remains low in the absence of other risk factors. Atypical hyperplasia is a significant risk factor, but the absolute risk of cancer will vary with the individual's age and other risk factors. The modified Gail model is a useful tool for evaluating a woman's overall level of risk after a diagnosis of atypical hyperplasia.[41]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XV APPROACH TO THE PATIENT WITH A PELVIC MASS

Joseph T. Chambers, m.d., ph.d.
Carolyn D. Runowicz, m.d.

The finding of a pelvic mass may occur in a female patient of any age; fortunately, most masses are associated with a benign neoplasm or process. Nevertheless, each year, between 5% and 10% of women in the United States undergo surgery for a suspected ovarian neoplasm; only 13% to 21% of these women prove to have a malignant ovarian neoplasm.[1]

A pelvic mass may be found on an abdominal or pelvic examination in an asymptomatic patient at a scheduled health maintenance assessment or on examination of a symptomatic patient who presents with a complaint. A mass may also be noted as an incidental finding on imaging studies, usually computed tomographic scans of the abdomen or pelvis or pelvic ultrasonography, obtained either for medical indications unrelated to a suspected pelvic disease or as a screening study for gynecologic malignancies. Increasingly, a pelvic mass is found on imaging studies obtained in the emergency department for the evaluation of vague abdominal pain or trauma.[2]

The differential diagnosis is extensive [*see Table 1*], because a pelvic mass may be of gynecologic or nongynecologic origin and may be associated with congenital, functional, neoplastic (either benign or malignant), obstructive, or inflammatory processes; a mass may also be associated with pregnancy. When a mass is of gynecologic origin, it may arise from the ovary, fallopian tube, broad ligament, round ligament, uterus, cervix, or uterosacral ligament. Adnexal masses arise from an area comprising the ovary, the fallopian tube, and the ligaments of the uterus. When the mass is of nongynecologic origin, it may arise from the urinary tract system, the gastrointestinal system, or the pelvic vessels or nerves. Rarely, a mass may arise directly from the peritoneum, the retroperitoneum, or the omentum.

The possible etiologies differ markedly, depending on the patient's age and symptoms. Consequently, the complete documentation of symptoms; the past medical, family, and surgical histories; the physical examination; and the initial imaging studies and laboratory tests will narrow the differential diagnosis and direct appropriate evaluation and referral. The overview of the diagnostic evaluation is presented [*see* Evaluation of the Patient with a Pelvic Mass, *below*], followed by a review of the distinctions in diagnostic workup required for patients of each age group [*see* Age-Specific Considerations in Patient Evaluation, *below*].

Evaluation of the Patient with a Pelvic Mass

MEDICAL HISTORY

The patient's medical history is essential in the evaluation of a pelvic mass; it includes a complete menstrual history, which establishes menarche and cyclicity of menses. Because ovulation generally occurs midcycle, a new pelvic mass found midcycle could be consistent with a functional cyst, whereas a mass identified later in the cycle would be more consistent with a corpus luteum cyst. A patient with a long history of irregular menses or even secondary amenorrhea with nontender bilateral adnexal masses may have polycystic ovaries. Pelvic inflammatory disease usually presents about a week after menstruation, and missed menses suggest a pregnancy. Therefore, an accurate menstrual history is useful in directing the patient evaluation.

Menstrual Bleeding

Increased menstrual bleeding often occurs with submucous leiomyomas. Postmenopausal bleeding may be caused by endometrial cancer or, rarely, by hormonally functioning ovarian or fallopian tube neoplasms. Irregular bleeding, pain, and missed menses suggest an ectopic pregnancy.

Although rare, estrogen-producing neoplasms may cause abnormal uterine bleeding, breast tenderness, or hirsutism. In children, precocious puberty may develop.

In women of reproductive age, the medical history must include questions about contraceptive practices, because a patient on oral contraceptive pills is less likely to develop physiologic and functional cysts (e.g., follicular and corpus luteum cysts). In addition, a patient with multiple sexual partners who does not use barrier contraception may develop pelvic inflammatory disease and a chronic tubo-ovarian abscess.

Abdominal Pain

Pain, if present, must be characterized. The onset, pattern of occurrence, and extent or severity of pain may give important indications of the etiology of the suspected pelvic mass. For example, new onset of midcycle pain in premenopausal women suggests the presence of a physiologic cyst. Pain following intercourse may be related to a ruptured cyst, whereas chronic pain during intercourse is suggestive of endometriosis.

Acute pain Acute severe abdominal or pelvic pain accompanies torsion of an adnexal structure or pedunculated leiomyoma (in which case the pain is usually intermittent); hemorrhage or rupture of an ovarian cyst; dilation of the fallopian tube in association with an ectopic pregnancy; or rupture of a pelvic abscess. In addition, a degenerating leiomyoma may also cause acute pain. The rapid stretching of the ovarian capsule by an expanding functional cyst or germ cell neoplasm may produce acute pain. Acute pain associated with nausea, vomiting, and fever suggests an inflammatory process, such as pelvic inflammatory disease, appendicitis, peritonitis from a perforation or infarction of bowel, or diverticulitis.

Chronic, cyclic pain More chronic, cyclic pain, particularly pain associated with dysmenorrhea, dyspareunia, and menorrhagia, suggests endometriosis. In addition, chronic pelvic or abdominal discomfort is often reported with long-standing tubo-ovarian abscesses or chronic hydrosalpinx. Chronic abdominal pain or vague abdominal discomfort accompanied by bloating suggests an ovarian neoplasm.

Changes in Bowel Habits

Changes in bowel habits and constitution, as well as changes in appetite, weight, and energy, may be more consistent with a benign colonic disease or with a cancer arising in any pelvic or-

gan. The medical history of gynecologic cancers or precancerous disease, breast cancer, melanoma, or any cancer may direct the workup. The family history is important, because hereditary cancers, such as those associated with a *BRCA1* or *BRCA2* mutation (e.g., breast, ovary, endometrial cancer), or nonpolyposis colon cancer may present as a pelvic mass.

PHYSICAL EXAMINATION

Before the pelvic examination, the patient should empty her bladder. There must be adequate light for a visual inspection of the external genitalia for signs of androgen excess. The vagina and cervix must be inspected for signs of infection and hormones. A Papanicolaou smear should be obtained if the patient's age and findings on physical examination indicate the need for it. The abdominovaginal examination gives information on the size, shape, consistency, location, mobility, laterality, and tenderness of the mass. This information must be confirmed by the rectovaginal examination, which also evaluates the uterosacral ligaments, the cul-de-sac, and the anorectal area. Physical examination may suggest whether the mass is benign or malignant [*see Table 2*]. When a pelvic mass is identified, a complete physical examination must be performed. Particular attention should be paid to the examination of the breasts, the respiratory system, the nodal areas, and the abdomen.

LABORATORY TESTS

In the evaluation of a pelvic mass, especially in women of reproductive age, a urinary or serum β-human chorionic gonadotropin (β-hCG) test is required. To determine pregnancy, the urinary test is adequate at the time of missed menses. This test, however, is qualitative in nature, and for the management of an ectopic pregnancy or molar pregnancy, a quantitative determination of the β-hCG serum concentration is necessary. In addition to being an indication for pregnancy, elevated levels of β-hCG may be associated with theca-lutein cysts, especially in women with choriocarcinoma, diabetes mellitus, and Rh sensitization; elevated levels of β-hCG are also associated with clomiphene use, human menopausal gonadotropin or human chorionic gonadotropin ovulation induction, and use of gonadotropin-releasing hormone analogues.[3]

A complete blood count will help in assessing anemia; an elevated white cell count suggests an infectious etiology. The erythrocyte sedimentation rate is nonspecific and does not narrow the differential diagnosis.

IMAGING STUDIES

The most important initial diagnostic tool in evaluating a pelvic mass is the pelvic ultrasound, which indicates whether the mass is more likely to be uterine, adnexal, or gastrointestinal in origin. A pelvic ultrasound scan also provides information on the size and consistency of the mass—characteristics that suggest whether the mass is malignant or benign.

Unilocular ovarian cysts are overwhelmingly benign and resolve spontaneously in 3 to 6 months; therefore, observation is the recommended approach to management. If malignancy is suspected on pelvic ultrasound, additional imaging studies such as abdominal pelvic computed tomography or magnetic resonance imaging may assist in confirming the diagnosis. The CT scan may further characterize the malignant potential of the mass and give information regarding evidence of metastatic spread to lymph nodes, the retroperitoneal space, or adjacent structures. If the origin of the pelvic mass is uncertain, an MRI may help clarify whether the mass arises from the uterus, adnexa, or another structure (e.g., muscles or nerves).

Table 1 Differential Diagnosis of Pelvic Mass

- Ovary
  - Functional cyst
  - Endometrioma
  - Benign neoplasm
  - Malignant neoplasm
- Fallopian tube
  - Tubo-ovarian abscess
  - Hydrosalpinx
  - Paratubal cyst
  - Ectopic pregnancy
  - Benign neoplasm
  - Malignant neoplasm
- Uterus
  - Fibroid (pedunculated or interligamentous)
  - Intrauterine pregnancy
  - Sarcoma
- Gastrointestinal tract
  - Bowel loops with feces
  - Diverticular disease
  - Inflammatory bowel disease
  - Appendicitis
  - Benign small bowel neoplasm
  - Colon cancer
- Urinary tract
  - Distended bladder
  - Pelvic kidney
  - Urachal cyst
- Retroperitoneum
  - Abdominal wall hematoma or abscess
  - Sarcoma, lymphoma, or teratoma
  - Benign neoplasm

Ultrasound

Transabdominal and transvaginal ultrasound Two methods of ultrasound provide extensive information about the characteristics of a pelvic mass. Transabdominal ultrasound is better tolerated by patients than is transvaginal ultrasound, and it gives more information about abdominal processes. Transvaginal ultrasound, however, provides better resolution and more precise information of the mass within the pelvic organ. The unique imaging patterns offered by each of these ultrasound modalities frequently help narrow the differential diagnosis.

Physiologic ovarian cysts are usually oval and filled with clear fluid. They may or may not have septations, and they have no echogenic or solid components, with the exception of the corpus luteum. Cystic teratomas are partially cystic and solid with echogenic foci of abnormal tissue from foreign tissues and hemorrhage. Endometriomas are simple cysts with echogenic elements secondary to old and new hemorrhage. Leiomyomas are solid or semisolid, well-circumscribed masses; they are similar in appearance to the myometrium but have no vascular vessels within the mass.

Several morphologic scoring systems have been introduced to predict whether a pelvic mass evaluated by ultrasound is benign or malignant. Most systems agree that the following characteristics are suggestive of malignancy: irregularity in the wall of the mass, the presence of thick septations within the mass, any papillary projection within or emerging from the mass, and a mass containing solid components. Size itself is an important characteristic; a mass larger than 8 cm in diameter raises concern. In general, the more of these characteristics that are present, the greater the chance that the mass is malignant.

Color Doppler ultrasound The use of color flow Doppler imaging may help in determining whether the adnexal mass is malignant or benign, because malignancies have an increased neovascularity and, thus, lower resistance and pulsatile indices. Currently, there is no agreement concerning pulsatile indices that indicate malignancy; nevertheless, specific indices may be

less important in suggesting malignancy than overall morphologic pattern, blood flow, and tumor location.

Taking into consideration the findings of regular and color flow ultrasound, the overall sensitivity, using morphologic criteria for malignant disease, ranges from 82% to 100%; specificity ranges from 60% to 95%. It is unclear, however, whether the addition of the color flow Doppler significantly improves these percentages. Two large studies reported that the combined approach (using regular and color flow ultrasound) has a sensitivity of 88% to 97%, a specificity of 97% to 100%, and an accuracy of 83% to 99%.[4]

Computed tomography CT is less frequently used in the initial evaluation of a pelvic mass than other imaging studies. However, the sensitivity, specificity, and accuracy of CT for determining whether the mass is benign or malignant is reported to be comparable to other modalities (i.e., sensitivity, 89%; specificity, 96% to 99%; accuracy, 92% to 94%).[4] CT is better than ultrasound in assessing the retroperitoneal spaces (i.e., nodal systems, pancreas, and spleen) and the omentum. CT is useful in establishing the extent of intra-abdominal and retroperitoneal disease in patients in whom an ovarian malignancy is highly suspected.

Magnetic Resonance Imaging

MRI may be used in the evaluation of a pelvic mass when findings from ultrasound studies are unclear or indeterminate. MRI is particularly useful in clarifying the origin of the mass as either uterine or ovarian. In addition, its accuracy in assessing fatty and hemorrhagic components of a mass can help in the diagnosis of dermoid cysts, hemorrhagic corpus luteum cysts, and endometriosis. This modality may be especially useful in the pregnant patient, if more information is needed than is provided by the pelvic ultrasound.[5]

Positron Emission Tomography

Positron emission tomography (PET) has limited application in the initial evaluation of pelvic masses. It is used primarily to detect recurrent pelvic malignancies.

SERUM TUMOR MARKERS

Serum tumor markers are not used for screening; they are used in the evaluation of patients with suspected malignant pelvic neoplasms. In deciding which serum markers to use, consideration must be given to the patient's age and medical history. For instance, in prepubertal girls and young women, germ cell tumors are the most frequent ovarian malignancy; appropriate serum markers for suspected germ cell tumors include α-fetoprotein (AFP), lactate dehydrogenase (LDH), and β-hCG. In older women with suspected malignancy, it is important to measure epithelial tumor markers, such as CA125. In patients with confirmed malignancy, a significant elevation in the level of a tumor marker may indicate malignant recurrence, whereas decreasing levels reflect response to treatment. Functional genomics and proteomics—the study of human gene sequences and protein sequences, respectively—show promise in identifying novel cellular targets that may be exploited in the future as screening tests for cancer.

Table 2 Physical Findings Associated with Pelvic Mass

Characteristic of Mass	*Suggestive of Benign Process*	*Suggestive of Malignant Process*
Unilateral	Yes	Occasionally
Bilateral	Occasionally	Yes
Cystic	Yes	No
Solid	No	Yes
Mobile	Yes	Occasionally
Fixed	Occasionally	Yes
Irregular contour	Occasionally	Yes
Smooth contour	Yes	No
Presence of ascites	No	Yes
Cul-de-sac nodules	Usually no	Yes
Rapid growth rate	No	Yes
Pain	Yes	Usually no
Size	< 5 cm	≥ 10 cm

Measurement of AFP, LDH, and β-hCG

Dysgerminomas are the most common germ cell tumors and can occur at any age; these malignancies are associated with elevations in AFP, LDH, and β-hCG. Placental alkaline phosphatase and LDH levels are sometimes elevated in patients with dysgerminomas. Endodermal sinus tumors can be monitored by measuring AFP levels, and choriocarcinomas can be monitored by measuring β-hCG levels. Embryonal carcinoma may secrete both AFP and β-hCG. Immature teratomas usually do not secrete any markers. Mixed germ cell tumors may secrete combinations of the above markers. Granulosa cell tumors are associated with elevated levels of inhibin and estradiol in prepubertal and postmenopausal women.

Measurement of CA125

CA125 is a glycoprotein expressed by fetal amniotic and coelomic epithelium and müllerian epithelium. Elevated levels of serum CA125 may suggest an increased risk of malignancy in certain patients; however, elevations of CA125 are also associated with normal and benign conditions. Therefore, CA125 measurement is not useful as a screening test for ovarian cancer. A CA125 serum concentration greater than 35 U/ml is found in 83% of patients with epithelial ovarian cancer, but it is reported to be elevated in only 50% of patients with stage I disease that is limited to the ovary.[6] In addition, CA125 is increased in patients with other malignancies; in those with benign gynecologic conditions; and in patients with diverticulitis and cirrhosis. It is also increased in normal conditions of pregnancy and menstruation [*see Table 3*].[7] Approximately 1% of healthy women have elevated CA125 serum levels.[8] In women with benign gynecologic conditions, the levels are usually less than 200 U/ml.

In postmenopausal women, CA125 measurement may have some application as a screening test for malignancy but is not a routine screening test. In a prospective Swedish study of 4,290 volunteer women who were at least 50 years of age, the specificity of CA125 measurement for ovarian cancer was reported to be 97% and the positive predictive value was 4.6%, using a CA125 level greater than 30 U/ml.[9] However, an elevated CA125 level in postmenopausal women with a pelvic mass suggests a malignancy. The positive predictive value for elevations of CA125 in this age group has been reported to be 97%.[10] In women of reproductive age, elevations of serum CA125 may raise the suspicion of malignancy when imaging findings (i.e., tumor location, morphologic pattern, and vascularity) are also consistent with malignancy.

Table 3 Conditions Associated with an Elevated Serum CA125 Level

Gynecologic malignancies	Epithelial ovarian cancers Germ cell cancers Sex chord stromal tumors Fallopian tube cancers Endometrial cancers Adenocarcinoma of the cervix
Benign gynecologic conditions	Adenomyosis Benign ovarian neoplasms Endometriosis Functional ovarian cysts Leiomyomas Meigs syndrome Menstruation Pregnancy Ovarian hyperstimulation Pelvic inflammation
Nongynecologic conditions	Liver disease and cirrhosis Colitis Congestive heart failure Diabetes Diverticulitis Lupus Mesothelioma Pericarditis Polyarteritis nodosa Surgery Previous irradiation Renal disease Sarcoidosis Tuberculosis
Nongynecologic cancers	Breast Colon Lung Pancreas Lymphoma

Measurement of Other Tumor Markers

CA19-9 and carcinoembryonic antigen (CEA) are commonly used to follow mucinous tumors. However, the sensitivity and specificity of these markers are lower than those found with CA125 measurement.

FINE-NEEDLE ASPIRATION

Fine-needle aspiration (FNA) is not routinely used in the evaluation of pelvic masses. Although it can easily be performed with ultrasound or CT guidance, FNA has limited diagnostic accuracy, especially in the evaluation of cystic structures. In a study of the use of FNA in 235 patients with cystic ovarian masses, 56% of the aspirates were devoid of diagnostic cells. The sensitivity for specific lesions ranged from 35% to 83%, and the specificity approached 100%.[11] Thus, FNA is not accurate, and should rupture of the cyst contents occur, dissemination of malignant cells may result.

BIOPSY

Rarely, a directed biopsy may be indicated in an individual whose imaging studies are consistent with advanced ovarian intra-abdominal disease and in whom surgery is contraindicated because of significant medical problems. A directed biopsy of a peritoneal tumor implant may be used to identify the histology of the tumor and thus assist in selecting appropriate nonsurgical management (e.g., initial or neoadjuvant chemotherapy) for ovarian cancer. Immunohistochemical staining profiles may provide additional information consistent with ovarian or peritoneal cancer.

Age-Specific Considerations in Patient Evaluation

PELVIC MASS IN PREPUBERTAL GIRLS

Ovarian cysts occur in 2% to 5% of prepubertal girls.[12] During the first months of life, ovarian cysts are generally functional cysts caused by maternal gonadotropin stimulation of the newborn ovary. Persistence of cysts or the finding of a solid or complex component (i.e., a component in which both cystic and solid elements are present) of the adnexal mass suggests other disorders, including Wilms tumors, neuroblastomas, or gastrointestinal tract abnormalities.

The older literature suggests a very high rate of malignancy for ovarian neoplasms in children, with germ cell tumors being the most frequent malignancy and dysgerminomas being the most common germ cell tumor.[13] More recently, it was reported that in girls younger than 10 years who undergo surgery for an adnexal mass, 60% of the masses were not neoplasms, and two thirds of the neoplasms were benign.[14] If there are signs of early sexual development, the child should be evaluated for precocious puberty or a hormonally functioning ovarian neoplasm.

If torsion of the adnexal mass is suspected, pelvic ultrasound may confirm this diagnosis. If a solid component of the adnexal mass is detected, the risk of a germ cell tumor must be considered and serum levels of appropriate tumor markers (i.e., AFP, LDH, and β-hCG) must be obtained.

Because of the rarity of gynecologic diseases in this age group, more common diagnoses, including acute appendicitis, intussusception of the bowel, gastroenteritis, genitourinary disorders, and chronic constipation, must be considered.

PELVIC MASS IN ADOLESCENTS

The differential diagnosis of a pelvic mass in an adolescent girl is broader than that for younger patients because adolescence is accompanied by functioning ovaries and the beginning of sexual activity. A pelvic mass may be caused by a benign neoplasm, a malignant neoplasm, an anatomic abnormality, or an ectopic pregnancy. Sexually transmitted disease (STD) and pelvic inflammatory disease (PID) must be included in the differential diagnosis.

The patient history should include questions about sexual activity, previous history of STD and PID, and use of contraception. Depending on the adolescent's sexual activity, a vaginal examination may also be appropriate. Adolescents deny sexual activity for multiple reasons, but studies show that 50% of adolescent girls have had sexual intercourse by 17 years of age.[15] In adolescents, a pelvic mass that is not associated with pregnancy may require further evaluation by abdominal CT or MRI. When anatomic abnormalities are suspected, the evaluation should include MRI. Genetic studies may also be indicated if a separate adnexal mass is found, because in 25% of the patients with a Y chromosome, dysgenetic gonads are malignant.[16]

Cystic Adnexal Masses

The majority of cystic adnexal masses are related to the normal physiologic ovary; such masses include follicular cysts, cor-

pus luteum cysts, and theca-lutein cysts. Usually unilocular and less than 8 to 10 cm in diameter, cystic adnexal masses commonly resolve within 6 to 8 weeks. Combination monophasic oral contraceptive pills with progestin, as well as estrogen at a dose higher than 50 μg, are reported to reduce the risk of further ovarian cysts. The use of lower-dose oral contraceptives may be less effective.[17,18]

Theca-lutein cysts that occur in pregnancy are usually bilateral, large, and multicystic. They are associated with high β-hCG levels.[3] Spontaneous resolution usually occurs post partum.

Cystic Teratoma

Overall, mature cystic teratomas (dermoid cysts) account for more than half of the ovarian neoplasms in children and adolescents younger than 20 years.[19] These neoplasms usually range from 5 to 10 cm in diameter; 15% are bilateral. Because they arise from pluripotential germ cell lines, they may contain hair, teeth, sebaceous material, neural elements, and other tissues not usually found in the ovary. Some of these elements show unique imaging patterns (e.g., calcified materials on plain radiograph and fat density on pelvic ultrasound).

Malignant Neoplasms

The risk of ovarian malignant neoplasms is lower in adolescents than in younger children.[14] In reports from referral centers, the rate of malignancy in ovarian neoplasms was 35% in prepubertal girls and adolescents; however, in community-hospital centers, the rate of malignancy was 10% in these patients.[20]

Germ cell tumors account for approximately 70% of the malignant ovarian tumors in girls younger than 15 years.[14] Dysgerminomas are the most common such tumors, followed by immature or malignant teratomas, endodermal sinus tumors, embryonal carcinomas, and choriocarcinomas. Stromal tumors and epithelial carcinomas each make up 15% of the ovarian tumors.[14]

Miscellaneous Masses

Pregnancy luteomas, sclerotic ovaries, and endometriotic cysts occur in adolescent girls. These may be incidental findings on physical examination, or they may be associated with symptoms of pain or irregular menses. Torsion, rupture, or leakage of the content of these cysts and subsequent peritoneal irritation may cause the pain. Laparoscopy may be required for full evaluation of the condition that causes the pain.

Anatomic Abnormalities

Around the time of expected menarche, anatomic abnormalities in the development of the müllerian system can cause obstruction of the uterovaginal outflow tract, resulting in a pelvic mass. The anomalies include imperforated hymen, transverse vaginal septa, vaginal agenesis with normal functional endometrium, vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns. If these anomalies cause a blockage of the vagina or the uterus, a mass may develop; such masses may result in cyclic pain, prompting these women to seek treatment.

Ectopic Pregnancy

In women younger than 17 years, approximately 82% of pregnancies are unintended; 75% of pregnancies are unintended in women 18 and 19 years of age.[21] Ectopic pregnancy is associated with pelvic pain, an adnexal mass, and missed or irregular menses. The risk of ectopic pregnancy is increased in women who have a history of STD or PID, as well as in women who fail to use contraception; oral contraceptives lower the risk.

Inflammatory Processes

The differential diagnosis of a pelvic mass in adolescents includes several infectious processes. When a patient presents with fever, an elevated white cell count, and a lower abdominal, pelvic, or adnexal tender mass that is associated with cervical motion tenderness and mucopurulent cervical discharge, a tuboovarian abscess or pyosalpinx must be considered. Often, a history of recent unprotected intercourse with a new partner will help establish the diagnosis. Appendicitis must also be considered in this setting. In the less acute setting, a patient with a pelvic mass and a history of STD should be evaluated for PID. Laparoscopy may be useful in confirming the diagnosis of PID; the clinical diagnosis of PID has been reported to be incorrect in up to one third of patients.[22]

PELVIC MASS IN WOMEN OF REPRODUCTIVE AGE

The detection of an asymptomatic pelvic mass is frequent during the reproductive years because women undergo annual examinations for family planning and gynecologic cancer screening. The differential diagnosis includes all the conditions that may cause a pelvic mass in adolescents (i.e., cystic adnexal masses, cystic teratomas, malignant neoplasms, and ectopic pregnancy), as well as leiomyomas, endometriomas, and metastatic neoplasms involving the ovary.

In a series of 100 women undergoing laparotomy for a pelvic mass, the most common diagnoses by age group were cancer, reported in 56% in women 50 years of age or older; endometriosis, reported in 27% of women 31 to 49 years of age; and cystic teratomas, reported in 33% of women younger than 30 years. In women younger than 30 years, only 10% had an ovarian malignancy, and most of these were tumors of low malignant potential. Thus, most pelvic masses that occur during reproductive years will be benign uterine neoplasms or benign ovarian neoplasms.[23]

A pregnancy test is required in all women of reproductive age who present with a suspected pelvic mass. In pregnant women, the use of abdominal and pelvic CT scans must be avoided. If ultrasound studies are inconclusive, an MRI may help identify the source of the mass.[5] If patient age, physical examination, and findings on ultrasound suggest malignancy, it is appropriate to measure epithelial serum tumor markers, such as CA125. However, elevated levels of CA125 may be associated with normal gynecologic conditions, as well as benign uterine and ovarian neoplasms. Risk of malignancy increases with patient age, positive family history, severity of symptoms, and number of imaging findings consistent with malignancy.

Uterine Neoplasms

Epidemiology Leiomyomas (fibroids) are the most common benign uterine neoplasm. They can also rarely arise from the ovary, the cervix, the pelvic ligaments, or other pelvic structures.

Leiomyomas are clinically apparent on examination in approximately 25% of women, but there is a marked difference in racial groups. In the United States, in women 25 to 44 years of age, the incidence rates of leiomyomas that were confirmed by ultrasound or hysterectomy were 8.9 for white women and 30.6 for black women per 1,000 women-years.[24] When uteri are surgically removed for treatment of noncancerous presentations, pathologic examination reveals leiomyomas in 89% of black

women and 59% of white women.[25] Similar results are obtained when screening women with ultrasonography: by 50 years of age, more than 80% of black women and 70% of white women will show fibroids.[26]

Leiomyomas are hormonally dependent; thus, these benign neoplasms usually shrink after menopause. They also frequently increase in size during pregnancy, as well as with the use of high-dose exogenous estrogens and, occasionally, with tamoxifen.

Sarcomatous degeneration of leiomyomas is rare. The incidence is reported to range from 0.4% to 1.4%. However, rapid increase in the size of a leiomyoma raises concern, although the definition of rapid growth has not been quantified. In fact, in a retrospective review of 371 patients operated on for rapidly growing leiomyomas, the incidence of leiomyosarcoma was 0.23%. When rapidly growing leiomyoma was defined as an increase of 6 weeks' gestational size over 1 year, none of 198 patients who satisfied this criterion were found to have a sarcoma.[27]

Clinical manifestations Most women with leiomyomas are asymptomatic, but symptoms may occur during the third and fourth decades. Leiomyomas, which are usually nontender, are most frequently found on clinical pelvic examination; but increasingly, they are identified by pelvic ultrasound during evaluation of nonspecific abdominal or pelvic symptoms.

Symptomatic patients may complain of pelvic discomfort, pressure, pain, menorrhagia, and dysmenorrhea. With degeneration or infarction, severe lower abdominal or pelvic pain develops. This may be associated with fever and an elevated white cell count. If the leiomyoma is pedunculated, torsion may cause severe pain, which may be intermittent. The pain may become part of a chronic pelvic pain pattern. Urinary symptoms include urinary frequency from extrinsic pressure on the bladder or, rarely, urinary retention secondary to urethral obstruction from a cervical or lower uterine leiomyoma. Depending on the location and the size of the leiomyoma, rectosigmoid compression and constipation may develop.

Leiomyomas coming through the cervical os can cause severe cramping; if necrotic, a foul vaginal discharge may develop. Abnormal uterine bleeding may be associated with a leiomyoma that disrupts the endometrial lining; the bleeding associated with a leiomyoma is cyclic, occurring in response to ovarian hormones.

Leiomyomas are usually discrete, firm, rounded, rubbery masses; they can vary in size from several millimeters to masses large enough to fill the abdominal pelvic cavity. They can be hard (if calcified) or soft (if cystic). Usually they cause an asymmetrical enlargement of the uterus, but multiple small leiomyomas cause a symmetrically enlarged uterus. Within the uterus, the leiomyoma may be located within the myometrium, beneath the endometrial lining, or on the surface of the uterus. When pedunculated or located posterior in the cul-de-sac, leiomyomas can give the clinical impression of a solid adnexal mass.

Ovarian Neoplasms

About two thirds of all ovarian neoplasms are discovered during the reproductive years; however, in women younger than 45 years, the chance that such neoplasms are malignant is 5% to 18%.[23,28,29] The most common ovarian neoplasms are endometriomas, cystic teratomas, and epithelial ovarian neoplasms. Most ovarian neoplasms produce few specific symptoms, the most common being vague abdominal pelvic pain or discomfort, abdominal distention, pelvic pressure, and urinary or gastrointestinal symptoms. Occasionally, in hormonally active neoplasms, irregular vaginal bleeding may occur.

Endometriomas Endometriomas are benign ovarian masses arising from ectopic endometrial tissue. Their incidence has not been determined. Frequently, endometriomas partially or almost completely replace normal ovarian tissue. Bilateral involvement of the ovaries has been reported in one third to one half of cases.[30] Endometriomas, which are usually less than 15 cm in diameter, may spontaneously rupture or resolve.

Patients who have an endometrioma usually complain of pelvic pain, dysmenorrhea, and dyspareunia; often, patients have an established history of endometriosis and infertility. On imaging evaluation, a mass 6 to 8 cm in diameter may be found. Endometriomas may by characterized by septations, debris, or solid components. These masses may not resolve over time. Endometriomas may be accompanied by an elevation in the CA125 serum level, which may cause concern regarding a malignancy; generally, however, CA125 serum levels associated with endometriomas are less than 200 U/ml.

Cystic teratomas Cystic teratomas, or dermoid cysts, are benign ovarian germ cell tumors. More than 80% of cystic teratomas are diagnosed during the reproductive years.[31] In a 10-year retrospective review, cystic teratomas constituted 62% of all ovarian neoplasms in women younger than 40 years.[29] The malignant transformation of these tumors is less than 2% and mostly occurs in women older than 40 years. There is a 15% risk of torsion and a 10% chance of bilateral presentation.

The risk of epithelial ovarian neoplasms increases with age. Bilateral ovarian neoplasms carry a 2.6-fold increased risk of malignancy, as compared with unilateral neoplasms.[29] Other causes of ovarian enlargement in this age group include metastatic cancer, especially from the breast or the gastrointestinal tract.

PELVIC MASS IN POSTMENOPAUSAL WOMEN

A pelvic mass in postmenopausal women may arise from the gynecologic organs, but increasingly in this age group, a mass may arise from nongynecologic organs. With decreasing ovarian hormone production, leiomyomas should undergo regression, and functional ovarian cysts are less likely. Endometriotic tumors are also not usually found in this age group. Thus, a newly found pelvic mass raises the suspicion of a malignancy.

Epidemiology The incidence of ovarian cancer increases with age, and 30% to 60% of ovarian masses in women older than 50 years are malignant.[23] The average age of a woman when diagnosed with ovarian cancer is 56 to 60 years. The majority of these tumors are epithelial malignancies. Fallopian tube cancer is rare. The differential diagnosis for a pelvic mass in postmenopausal women includes colon cancer, which is the third most common cancer in women.

Ovarian cysts have been reported in 3% to 17% of asymptomatic postmenopausal women undergoing pelvic ultrasound. In a study of 83 patients with thin-walled ovarian cysts less than 5 cm in diameter, 43 underwent surgery; no ovarian cancers were found in this group. In the remaining patients, 32 underwent serial ultrasound studies. In this group, 12 cysts resolved, seven decreased in size, four remained unchanged, and one increased slightly in size. The remaining eight patients underwent cyst aspirations; all the aspirated cysts were benign.[32]

Clinical manifestations The presentation of ovarian cancer is not specific. Patients may complain of vague gastrointestinal symptoms, including dyspepsia, early satiety, anorexia, bloating, and, occasionally, constipation. In a retrospective survey of 1,725 patients with ovarian cancer, 95% reported symptoms that were categorized as abdominal (77%), gastrointestinal (70%), pain (58%), constitutional (50%), urinary (34%), and pelvic (26%).[33] Fallopian tube cancer may present as uterine bleeding, pelvic pain, and an adnexal mass. Classically, profuse watery vaginal discharge is seen, although this finding is rare.

The findings on examination consistent with advanced disease include abdominal distention with ascites, an abdominal/pelvic mass, and nodularity in the cul-de-sac on rectovaginal examination. An ultrasound of the abdomen and pelvis may show ascites, bilateral complex adnexal masses, and omental implants. In addition, there may be a pleural effusion. Evaluation of these patients should include abdominal and pelvic CT scans and chest x-ray. Again, if imaging studies raise the suspicion of malignancy, it is important to measure serum levels of CA125. An elevated CA125 level in postmenopausal women with a pelvic mass suggests a malignancy, because the positive predictive value for elevated CA125 (i.e., > 65 U/ml) in this age group has been reported to be 97%.[10] Early referral to a gynecologic oncologist is appropriate for patients with a mass that raises suspicion of malignancy.

A pelvic ultrasound may also identify nonmalignant cysts. Studies have suggested that women with simple cysts that are less than 10 cm in diameter and that are without any excrescences, septations, or ascites should undergo serial ultrasound studies.[34,35]

A pelvic mass in a postmenopausal woman with a history of bowel symptoms may suggest colon cancer; the evaluation of the stool may be positive for occult or frank blood. Diverticular disease must also be considered.

Management

The management of a pelvic mass depends on the patient's age, history, tumor characteristics, and likelihood of malignancy. For all age groups, surgery is required for masses that are greater than 10 cm in diameter and for those that are solid, fixed, or bilateral. When these findings are accompanied by significantly elevated levels of tumor markers, the presence of ascites, or a finding on imaging or physical examination that suggests malignancy, the patient should be referred to a gynecologic oncologist.

INFANTS AND PREPUBESCENT GIRLS

Infants and prepubescent girls with suspected physiologic or functional cysts should undergo serial ultrasound studies approximately every 6 weeks. Aspiration of unilocular cysts in prepubescent girls, either with ultrasound guidance or laparoscopy, is associated with a 50% recurrence rate[3] and is usually not recommended. If the mass increases in size, persists after 6 months, or becomes complex, surgery via either laparotomy or laparoscopy is necessary. Conservative management is indicated if the malignancy is confined to one ovary. Consultation with a gynecologic oncologist is necessary.

ADOLESCENT GIRLS

The management of adnexal masses in adolescent girls should have as its aim the preservation of ovarian function. An asymptomatic simple cyst that measures less than 10 cm in diameter may be observed and followed with serial ultrasound studies. To prevent new formation of physiologic cysts, ovarian suppression with oral contraception should begin. If the cyst increases in size, becomes complex, or causes symptoms, then surgery should be performed.

For benign neoplasms, cystectomy is recommended. Because most malignant tumors are unilateral, only the ovary or adnexa need be removed. The contralateral ovary should be inspected. If the ovary appears grossly normal, biopsy need not be performed, nor should the ovary be bivalved (i.e., the surface of the ovary divided and the cortex inspected), because these procedures could lead to peritubal or periovarian adhesions. However, if suspicious areas are identified, biopsies must be performed and a frozen section ordered for histiologic analysis during surgery. Histiologic analysis will help determine malignancy and indicate the need for consultation with a gynecologic oncologist to establish surgical staging. If the frozen section does not clearly establish malignancy, a second surgery is preferable to performing unnecessary initial surgery. However, the choice of surgery should be undertaken cautiously, because any adnexal surgery may result in tubal adhesions, which could interfere with future fertility.

PID in adolescents should be managed medically. Surgical management of nonmalignant presentations is rarely indicated in adolescents. Surgery, however, may be required to treat a ruptured tubo-ovarian abscess; it may also be required if the disease fails to respond to broad-spectrum antibiotics. Ectopic pregnancy can be managed medically, providing the pregnancy is small and the patient is hemodynamically stable; surgical management is required if these conditions are not met. If surgery is indicated, the procedure should be conservative and aimed at preserving fertility.

WOMEN OF REPRODUCTIVE AGE

The management of a pelvic mass in women of reproductive age will depend on the malignant potential of the mass. Most often, the mass will be a benign uterine leiomyoma. The initial approach will depend on whether the patient is symptomatic and has completed childbearing.

Leiomyomas Asymptomatic leiomyomas should be followed with periodic pelvic examinations to ensure that there is not a rapid growth in size. The clinical records should document the location; a pelvic ultrasound can more accurately estimate the size. Rapid growth in the postmenopausal years may indicate transformation into a sarcoma. The risk, however, is reported to be less than 2 to 3 per 1,000.

In patients who will soon enter menopause or who are planning to undergo surgery for mildly symptomatic leiomyomas, hormonal therapy using gonadotropin-releasing hormone (GnRH) analogues results in a 40% to 60% decrease in uterine volume. GnRH treatment causes hypoestrogenic states that result in bone loss and hot flashes. Regrowth of the leiomyoma occurs within a few months of treatment cessation in one half of patients. Use of GnRH may be considered (1) as neoadjuvant therapy to shrink the size of the leiomyoma before surgery to permit a vaginal approach, (2) as treatment for anemia secondary to hemorrhage associated with leiomyomas, and (3) as treatment in perimenopausal women in an effort to avoid surgery.

Symptomatic leiomyomas require surgery. The usual indications include abnormal uterine bleeding with anemia that is unresponsive to hormone therapy; chronic pelvic pain with dysmenorrhea and dyspareunia; acute pelvic pain associated with

torsion of pedunculated leiomyoma; prolapsing leiomyoma; urinary frequency with hydronephrosis; and symptoms of pelvic or rectal pressure caused by a significantly enlarged leiomyoma. Rarely, infertility caused by a leiomyoma obstructing the fallopian tubes or loss of a pregnancy secondary to a leiomyoma may be an indication for myomectomy. The finding of a mass during pregnancy demands the same management approach as for a nonpregnant patient. If surgery is necessary during pregnancy, the second trimester is the safest period.

Once childbearing is complete, hysterectomy is traditionally the definitive management for symptomatic leiomyomas. However, other treatment options have become available, including laparoscopic myomectomy and hysteroscopic resection of submucosal leiomyoma. In addition, endometrial ablation (e.g., laser, thermal, or chemical ablation, as well as selective arterial embolization) can decrease the bleeding caused by intramural leiomyomas.[36]

Endometriomas Endometriomas that do not spontaneously resolve are managed with surgical excision.

Cystic teratomas In women younger than 45 years, the treatment for a cystic teratoma is ovarian cystectomy, which often can be performed laparoscopically, especially if the mass is less than 10 cm in diameter.

Epithelial ovarian neoplasms Surgical management of epithelial ovarian neoplasms includes removal of the adnexa and surgical staging. Whether the surgery can be conservative (i.e., a unilateral salpingo-oophorectomy) will depend on the extent of the disease and the degree of malignancy (i.e., invasive tumor versus tumor of low malignant potential). These decisions are made in consultation with a gynecologic oncologist.

POSTMENOPAUSAL WOMEN

The risk of a malignancy increases with age, and thus, the threshold for conservative management decreases in postmenopausal women. It has been reported that a suspicious mass seen on ultrasound combined with a CA125 level greater than 65 U/ml has a specificity of 96.1%, a sensitivity of 91.7%, and an accuracy of 94.3% for detecting an ovarian neoplasm in postmenopausal women.[37] On the other hand, a postmenopausal woman with an ovarian simple cyst that is less than 5 cm in diameter and a normal CA125 serum concentration has a 0% risk of malignancy. Thus, the former patient should be referred to a gynecologic oncologist for appropriate management, whereas the latter may be followed with serial ultrasound studies every 4 to 6 months for a year and, provided the tumor remains stable and the patient asymptomatic, annually thereafter.

XVI APPROACH TO THE PATIENT WITH AN ABNORMAL PAP SMEAR

Carolyn D. Runowicz, m.d.

Cervical cancer is the third most common gynecologic cancer in the United States. An estimated 10,370 new cases of invasive cervical cancer and 3,710 deaths occur annually, representing 1.4% of cancer deaths in women.[1] In the United States, the incidence of cervical cancer decreased by more than 70% between 1950 and 2000, largely as a result of screening[2]; more than half of the incident cases of invasive cancer are diagnosed in women who have not been adequately screened. Screening cytology methods, such as the Papanicolaou (Pap) smear, are excellent means of identifying preinvasive disease; however, false positive rates are relatively high. Each year, approximately 3.5 million cervical cytologic tests are interpreted as indicating an abnormality requiring additional follow-up or evaluation.[3]

Epidemiology and Risk Factors for Cervical Cancer

The occurrence of invasive cervical cancer is related to age. Premalignant cervical lesions are usually diagnosed in women younger than 40 years, which is 10 to 15 years earlier than in women diagnosed with invasive cervical cancer. This age gap suggests a long latency period for malignant transformation. For example, the diagnosis of cervical intraepithelial neoplasia (CIN) is usually made in women in their twenties, whereas the diagnosis of carcinoma in situ (CIS) is made in women 25 to 35 years of age, and invasive cancer is diagnosed in women older than 40 years.

Infection with high-risk strains of human papillomavirus (HPV) is the most important risk factor for cervical cancer.[4,5] HPV infection is usually transient[6,7]; however, persistent infection by high-risk HPV virus—most commonly, subtypes 16, 18, 31, and 45—is a prerequisite for the development of grade 1 and 2 CIN and invasive cervical cancer.[8]

HPV is usually acquired sexually; high-risk sexual behavior (e.g., having multiple sexual partners and promiscuous sexual partners) increases the risk for exposure to the virus.[9] HPV is a necessary precursor of CIN, but it does not act alone; host factors such as age, immune function,[10] a history of sexually transmitted disease (e.g., *Chlamydia trachomatis*),[11] and smoking[12] are surrogate markers for oncogenesis.

Natural History of Cervical Cancer

Early invasive cervical cancer is frequently asymptomatic, a fact that underscores the importance of routine screening. An abnormal Pap smear is frequently the first indication of a precancerous condition. The abnormalities observed on a cytologic smear or tissue biopsy of the cervix represent alterations in the degree of differentiation of cervical epithelial cells. An understanding of the natural history of low-grade and high-grade CIN lesions is central to the clinical management of patients who have abnormal cervical cytology.

CIN is a preinvasive pathologic intermediate of cervical cancer; it is slow to progress and can be easily detected and treated. The severity of CIN is designated by the extent to which the lesion involves the epithelial thickness. CIN 1 refers to intraepithelial neoplasia in which cellular changes are confined to the basal third of the epithelium; CIN 2 refers to intraepithelial neoplasia in which cellular changes are confined to the basal two thirds of the epithelium; and CIN 3 refers to cellular dysplasia encompassing more than two thirds of the epithelial thickness, including full-thickness lesions. CIS demonstrates full-thickness evidence of neoplasia without invasion of the basement membrane; CIN 3 and CIS may persist unchanged for 10 to 15 years, but eventually the lesion progresses to invasive carcinoma.

Low-grade lesions do not necessarily progress to high-grade lesions. A large cohort study indicated that CIN 1 lesions regressed to normal within 2 years in 44% of patients; they regressed to normal within 5 years in 74% of patients.[13] This series noted that the rates of progression of CIN 1 at 2 and 5 years were 2% and 6%, respectively; rates of progression of CIN 2 were 16% and 25%, respectively.

A primary goal of cervical cytologic screening is to identify women at risk for high-grade lesions; however, cytologic results are often equivocal. To improve the accuracy of cytologic interpretation, a standard system of terminology was adopted to distinguish findings most likely to be precancerous [*see* Test Interpretation—the Bethesda Reporting System, *below*]. Essentially, this reporting system classified a broad range of atypical findings into two categories: those findings that were more likely to represent high-risk lesions and those whose significance was undetermined.

Screening for Cervical Cancer

who should be screened?

Abundant evidence indicates that regular gynecologic examinations and cervical cytology decrease cervical cancer incidence and mortality. However, among policy-making organizations, there is some variation in the recommendations concerning the age at which screening should start, the interval of screening, and the age at which routine screening should stop.

Commencement of Screening

The United States Preventive Services Task Force (USPSTF) recommends beginning cytologic screening within 3 years of onset of sexual activity or by age 21, whichever comes first.[14] The recommendations of the American College of Obstetricians and Gynecologists (ACOG)[15] and the American Cancer Society (ACS)[16] are consistent with these guidelines. Other North American organizations, such as the Canadian Task Force on Preventive Health Care (CTFPHC), recommend that screening begin at onset of sexual activity or at 18 years of age.[17]

There is little value in screening women who have never been sexually active; however, many North American organizations recommend routine screening by age 18 or 21 on the basis of the generally high prevalence of sexual activity by that age and concerns that clinicans may not always obtain accurate sexual histories.

Table 1 The 2001 Bethesda System (Abridged)[29]

- Specimen adequacy
  - Satisfactory for evaluation *(note presence or absence of endocervical/transformation zone component)*
  - Unsatisfactory for evaluation *(specify reason)*
    - Specimen rejected/not processed *(specify reason)*
    - Specimen processed and examined but unsatisfactory for evaluation of epithelial abnormality because of *(specify reason)*
- General categorization (optional)
  - Negative for intraepithelial lesion or malignancy
  - Epithelial cell abnormality
  - Other
- Interpretation/result
  - Negative for intraepithelial lesion or malignancy
    - Organisms
      - *Trichomonas vaginalis*
      - Fungal organisms morphologically consistent with *Candida* species
      - Shift in flora suggestive of bacterial vaginosis
      - Bacteria morphologically consistent with *Actinomyces* species
      - Cellular changes consistent with herpes simplex virus
    - Other non-neoplastic findings (optional to report; list not comprehensive)
      - Reactive cellular changes associated with the following:
        - Inflammation (includes typical repair)
        - Radiation
        - Intrauterine contraceptive device
      - Glandular cells status post hysterectomy
      - Atrophy
  - Epithelial cell abnormalities
    - Squamous cell
      - Atypical squamous cells (ASC)
        - Of undetermined significance (ASC-US)
        - Cannot exclude HSIL (ASC-H)
      - Low-grade squamous intraepithelial lesion (LSIL) (cellular changes consistent with HPV, mild dysplasia, CIN 1)
      - High-grade squamous intraepithelial lesion (HSIL) (moderate to severe dysplasia, CIN 2, CIN 3, CIS) *(indicate if there are features suspicious of invasion)*
      - Squamous cell carcinoma
    - Glandular cell
      - Atypical glandular cells *(specify endocervical, endometrial, or not otherwise specified)*
      - Atypical glandular cells, favor neoplastic *(specify endocervicalor not otherwise specified)*
      - Endocervical adenocarcinoma in situ (AIS)
      - Adenocarcinoma
  - Other (list not comprehensive)
    - Endometrial cells in a women ≥ 40 years

CIN—cervical intraepithelial neoplasia CIS—carcinoma in situ

Screening Interval

Because cervical cancer is slow growing, considerable uncertainty surrounds the issue of the screening interval. The USPSTF found no direct evidence that annual screening achieves better outcomes than screening every 3 years. The most direct evidence on which to base a recommendation of a screening interval comes from a prospective cohort analysis of a randomized controlled trial.[18] Among 2,561 women (mean age, 66.7 years) with normal Pap tests at baseline, 110 had an abnormal Pap test within the next 2 years. No woman was found to have CIN 2, CIN 3, or invasive cancer; only one woman had CIN 1 or CIN 2. Thus, the positive predictive value of screening 1 year after a negative Pap test was 0%; after 2 years, the positive predictive value was 0.9%. The authors concluded that Pap tests should not be repeated within 2 years after a negative test. A large study of women younger than 65 years, which included data from the National Breast and Cervical Cancer Early Detection Program and which used a model to estimate the rate at which intraepithelial neoplasia progresses to cancer, found that little further mortality reduction from cervical cancer was achieved by screening every year as compared with every 3 years.[19]

On the basis of the limited evidence, the USPSTF recommends screening at least every 3 years. The ACS guidelines recommend waiting until age 30 before lengthening the screening interval from 1 to 3 years. The ACOG recommends initiating screening with annual smears for 2 or 3 years; if these are negative, intervals of up to 3 years may be appropriate.[20] The ACOG identifies additional risk factors that might justify annual screening, including a history of cervical neoplasia, infection with HPV or other sexually transmitted diseases, or high-risk sexual behavior; however, data by which to determine the benefits of these strategies are limited.[20]

Cessation of Screening

The USPSTF recommendations state that screening can be discontinued in women who have had a total hysterectomy for benign disease (i.e., disease in which there is no evidence of cervical neoplasia or cancer), given the low yield of screening and the potential harms from false positive results in this population.[18] In women with a cervix, the optimal age to discontinue screening is not clear, but the risk of cervical cancer and the yield of screening decline steadily through middle age. However, screening is recommended in older women who have not been previously screened or when information about previous screening is unavailable.[14]

The USPSTF recommends discontinuing routine screening for women older than 65 years who have had adequate recent screening with normal Pap smears and are not otherwise at high risk for cervical cancer.[18] The ACS guidelines recommend that screening can be safely stopped in older women who have had three or more documented, consecutive, technically satisfactory, normal cervical cytologic tests and who have had no abnormal cytologic tests within the past 10 years; routine screening may be discontinued at age 70.[16]

AVAILABLE TESTS

There are several methods for cervical cancer screening: the conventional cytologic Pap smear, the liquid-based Pap smear, and HPV DNA testing in combination with cervical cytology. The purpose of these tests is to screen for cellular abnormalities that are associated with an increased risk of the development of cervical cancer.

Conventional Cytology (Pap Smear)

The Pap smear is the standard screening test for genital tract neoplasia. The reported sensitivity of a single Pap smear varies widely, ranging from 32% to 92%.[21] This low sensitivity prompted the recommendation found in early guidelines that cytologic screening be made annually.[22] False negative rates have been at-

tributed to poor sample preparation, in which precursor cells were obscured by blood, pus, air-drying artifacts, and other cells.[23] A conventional Pap smear costs $25 to $40.

Liquid-Based Cervical Cytology

Liquid-based cytology offers higher sensitivity and comparable specificity to that of the conventional Pap smear.[24] The liquid-based test costs $45 to $60. If used at 3-year intervals, the liquid-based test is cost-effective.[25] Evidence-based reports show that both liquid-based and conventional cytology are acceptable screening tests.[26] One advantage of liquid-based cytology is that HPV testing can be performed on the same preparation (see below).

Cytology and HPV DNA Testing

HPV DNA testing in combination with conventional or liquid-based cytology has been approved by the Food and Drug Administration for primary screening for cervical cancer in women older than 30 years.[27] In this age group, the combination of cytology and HPV DNA testing has been reported to have a sensitivity approximately 10% to 20% greater than that of a single conventional cytologic smear; however, specificity is lower.[28] Because of the high negative predictive value of these combined tests, women who test negative on both the cytologic and HPV DNA testing can increase their screening interval to 3 years.[27]

TEST INTERPRETATION—THE BETHESDA REPORTING SYSTEM

The most common abnormal cervical cytologic result is one of uncertainty. Interpretation of equivocal cytologic findings is complicated by confusion among laboratories and clinicians concerning the use of multiple classification systems and inconsistently defined numerical grading conventions. The Bethesda System, which was introduced in 1988 and is periodically updated (most recently in 2001), was devised as a uniform system of terminology to guide the interpretation of cytologic findings. A significant contribution of the Bethesda System was the standardized laboratory report that includes a description of specimen adequacy (to improve the consistency and quality of reporting) and that uses simplified terminology for the interpretation of equivocal cytologic findings [*see Table 1*].

Specimen Adequacy

The 2001 update of the Bethesda System qualifies specimens as being either satisfactory or unsatisfactory for evaluation.[29] Minimal squamous cellularity varies with the specimen type: an estimated 8,000 to 12,000 well-visualized squamous cells are acceptable for conventional smears, and 5,000 squamous cells are acceptable for liquid-based preparations. Epithelial cells may be obscured by blood or inflammation and still be considered satisfactory; however, if more than 75% of epithelial cells are obscured, the specimen is unsatisfactory. For specimens containing adequate squamous cellularity, the cytologic report notes the presence or absence of an endocervical/transformation zone component. Adequate endocervical cellularity consists of at least 10 well-preserved endocervical or squamous metaplastic cells.

Interpretaton of Specimen

The Bethesda System stipulates that cervical cytology is primarily a screening test, and the interpretation of morphologic findings described by the cytologic report must be integrated into a clinical context to establish a diagnosis.

Specimens are broadly defined as negative for intraepithelial lesion or malignancy or positive for epithelial cell abnormality. Epithelial abnormalities include atypical squamous cells, low- and high-grade squamous intraepithelial lesions (LSIL and HSIL), and atypical glandular cells (AGC). A finding of atypical squamous cells that cannot be determined as precancerous is the most common result, and its correct interpretation poses a clinical challenge.

Atypical squamous cells The 2001 Bethesda System qualified a finding of atypical squamous cells (ASC) in two ways: (1) ASC of undetermined significance (ASC-US) and (2) ASC for which HSIL cannot be excluded (ASC-H) [*see Table 1*]. A finding of undetermined significance emphasizes that some cases of ASC-US are associated with underlying CIN 2,3. ASC-H is used when there are cytologic features suggestive of HSIL but definite evidence is lacking. The ASC-H category constitutes approximately 5% to 10% of all ASC, but it includes women at greatest risk for CIN 2,3.[30,31] HSIL is more often associated with viral persistence and higher risk of progression, whereas LSIL is generally the result of a transient infection of HPV.[32,33]

Squamous epithelial lesions The Bethesda System classifies squamous intraepithelial lesions as low-grade (LSIL) or high-grade (HSIL). Cellular changes consistent with HPV, mild dysplasia, and CIN 1 are combined within the category of LSIL. Moderate to severe dysplasia, CIN 2, CIN 3, and CIS are combined within the category of HSIL. In the Bethesda System, CIN and dysplasia terminology can be used either as substitute terms for squamous intraepithelial lesions or as additional descriptors of intraepithelial lesions.

Atypical glandular cells The Bethesda System classifies glandular cell abnormalities into three types: atypical endocervical cells, endometrial cells, and glandular cells. In the majority of cases, morphologic features permit differentiation between atypical endometrial and endocervical cells. The management of patients with glandular abnormalities may vary significantly, depending on cell type, and distinguishing between these cell types is justified, when possible. The Bethesda System distinguishes AGC (either endocervical, endometrial, or AGC that are not otherwise specified [AGC-NOS]) from AGC (either endocervical or AGC-NOS) that favor neoplasia, because these two categories are associated with different degrees of risk of significant disease. Biopsy-confirmed high-grade lesions, including CIN 2,3, adenocarcinoma in situ, and invasive cancer, have been found in 9% to 41% of women who have AGC-NOS, as compared with 27% to 96% of those who have AGC that favors neoplasia.[34-36]

Management of Cytologic Abnormalities

ATYPICAL SQUAMOUS CELLS

Each year, an estimated two to three million women are diagnosed as having cervical cytology containing ASC.[37,38] The majority of women with ASC do not have a clinically significant lesion. However, 5% to 17% of patients with atypical ASC cytology have CIN 2,3 confirmed by biopsy.[30,39,40] A large, prospective study of routinely screened women reported that 39% of cases of high-grade squamous lesions were detected in women with ASC cytology.[41]

Increased age and a history of treatment of CIN have been reported to increase the risk of CIN in patients with ASC cytology.[42] High viral levels of HPV types known to be associated

with cervical cancer have been found to be strongly predictive of high-grade CIN in patients with ASC Pap smears.[43] ASC findings suggestive of neoplastic processes carry a greater risk of high-grade lesions and carcinoma than ASC findings suggestive of reactive processes.

Management Options

The evaluation and management of women with ASC-US cytology is a topic of considerable controversy. The best approach to the management of abnormal cervical cytology is to use the fewest number of tests to resolve the clinical question posed by the presence of ASC. Management options include (1) repeat cytology at a designated interval, (2) high-risk HPV DNA testing, (3) immediate colposcopy, (4) a combination of repeat cervical cytology and HPV DNA testing, (5) direct visual inspection in combination with conventional cytology, (6) referral for colposcopy, and (7) a combination of these strategies.

Repeat cervical cytology A repeat cervical cytology obtained at a later date appeals to many health care providers, because most histologic abnormalities found with ASC-US will be low-grade cervical neoplasia that is likely to regress without definitive therapy. The repeat Pap smear should be obtained 4 to 6 months after the index cytology [*see Figure 1*]. This is considered the optimal interval; a repeat cytology obtained after less than 4 months is thought to be associated with decreased sensitivity,[40] and after 6 months, 7% of patients with ASC-US smears will have CIN 2,3.[44]

High-risk HPV DNA testing HPV DNA is associated with virtually all cervical cancers and high-grade precursor lesions; the identification of these types of HPV that are associated with a high risk of oncogenesis is useful in identifying patients with ASC-US who are at increased risk for neoplasia.[45]

The probability of HPV expression is influenced by several factors, including age, menstrual cycling, use of exogenous hormones, and immunocompetence.[10,46] The addition of HPV DNA testing to cervical cytologic screening for women with ASC-US may be most effective in women 30 to 35 years of age, who are past the peak of incidence of acute infections [*see Table 2*].[46] In women whose cytology was classified as ASC-US, those who were 30 years of age or older had a lower prevalence of HPV positivity and a lower referral to colposcopy than younger women (30% versus 65%); this improvement in specificity was not accompanied by a decrement in sensitivity. Establishing age- and population-specific analytic cutoff points for the detection of HPV may further enhance the specificity of HPV DNA testing. Other strategies for improving specificity without compromising sensitivity may include the use of serial HPV DNA testing or lengthening the interval between the index ASC-US cytology and HPV DNA testing.

Of the commercial HPV DNA detection kits, Hybrid Capture 2 (HC2) (Digene Diagnostics, Silver Spring, Maryland) has a higher sensitivity (94.8% versus 84.4% for high-grade precursor lesions) and detects a broader range of high-risk HPV types than other methods.[47] HC2 is a nonradioactive, rapid assay that can detect 18 HPV DNA types,[48] 13 of which convey high risk of oncogenesis. A retrospective study of 398 women showed the HC2 assay to be as sensitive and specific as a single repeat cytologic smear for the detection of CIN.[40] However, it has been argued by some that its use identifies large numbers of low-grade lesions (CIN 1) and transient HPV infections and may lead to overevaluation and overtreatment because of its low positive predictive value.[47]

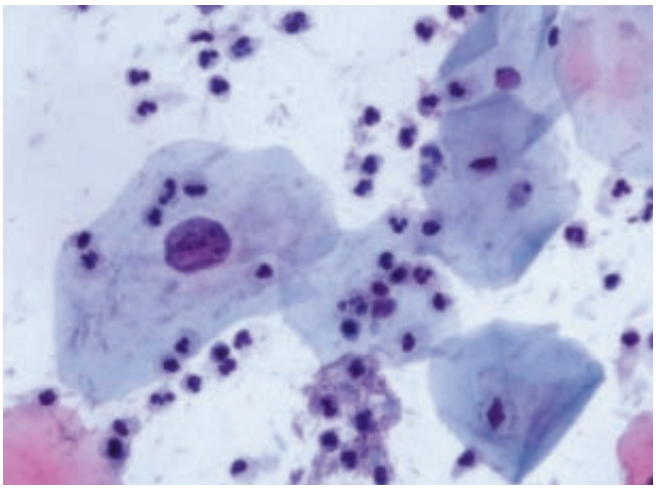

Figure 1 **A Pap smear showing atypical squamous cells of undetermined significance (ASC-US).**

Immediate colposcopy Colposcopy would be expected to detect almost all of the cases of high-grade CIN, but it has drawbacks, including expense and the risk of overevaluation and overtreatment in women who do not have CIN. Immediate colposcopy, however, may be indicated for women with a history of CIN, for poorly compliant women, and for women for whom waiting creates undue anxiety.

Studies of the natural history of HPV infection have demonstrated that most HPV infections produce only minor, transient infections.[10,11] A positive HPV DNA test in combination with an ASC-US cervical cytologic finding does not indicate high-grade disease or the presence of cancer, but it does indicate some increased risk of cancer now or in the future. Because of imperfect sensitivity, the initial colposcopy and directed biopsy will not detect about 10% of those women who will have histologically confirmed CIN 2,3 within 2 years of follow-up.[49]

Repeat cytology and direct visualization To compensate for the low sensitivity of a single repeat cervical cytology in women with atypical squamous cells, it has been suggested that repeat cytology be combined with a visual screening method. Direct visual screening methods include cervicoscopy (direct visual inspection of the cervix after an acetic acid wash), speculoscopy (direct visualization of the cervix under low magnification after application of an acetic acid wash), and cervicography (visual inspection of the cervix in which a static photographic image is used to document cervical abnormalities after an acetic acid wash).[50] Several studies that evaluated the combined use of cervicography and repeat cytology reported that this screening approach had a high sensitivity for the detection of CIN 2,3.[51,52] Because the data are limited, more studies are needed before recommending repeat cytology and direct visualization as a screening approach in patients with ASC-US.

Repeat cytology and HPV DNA testing Several studies have reported that the combination of HPV DNA testing and a repeat Pap smear has a sensitivity similar to that of colposcopy for the detection of high-grade CIN.[43,53-55] The negative predictive

value of DNA testing for high-risk types of HPV is generally reported to be 98% or greater.[40,56] However, other investigators question the cost-effectiveness of this combined screening strategy in women with ASC-US.[57,58] Use of liquid-based cytology permits the residual transport fluid to be used to test for HPV DNA (a technique referred to as reflex HPV DNA testing).[39] In a large study, Manos and colleagues evaluated HPV DNA testing of residual material from liquid-based cervical cytology using the HC2 assay. An overall sensitivity of 96.9% (95% confidence interval [CI], 88.3% to 99.5%) was achieved when colposcopy of HPV DNA–positive women was performed immediately after the reflex HPV DNA test. The authors concluded that reflex HPV DNA testing of cervical cytology aids in identifying those women at risk for high-grade lesions.[44]

The initial report of the ASC-US/LSIL Triage Study (ALTS) found that reflex HPV DNA testing was more sensitive than a single repeat cytologic smear in detecting CIN 3 in women with ASC-US cytology.[40] The sensitivity of HPV DNA testing for the detection of CIN of grade 3 or higher was 96.3% (95% CI, 91.6% to 98.8%); 56.1% (95% CI, 54.1% to 58.1%) of patients were referred for colposcopy. The sensitivity of a single repeat cytologic specimen for the detection of ASC-US or findings associated with higher risk was 85.3% (95% CI, 78.2% to 90.8%); 58.6% (95% CI, 56.5% to 60.6%) of patients were referred for colposcopy. However, the conventional clinical management strategy for cytologic follow-up is based on a series of repeat cytologic specimens, not on the sensitivity of a single cytologic sampling. A 2-year follow-up of the ALTS showed that a repeat cytologic specimen is as sensitive as HPV DNA testing at an ASC-US referral threshold, but this approach requires two follow-up visits and ultimately more colposcopic examinations than HPV triage (67.1% versus 53.1%).[59]

Reflex HPV DNA testing offers advantages over HPV DNA testing using conventional Pap smears: women do not need an additional clinical examination for specimen collection, and 40% to 60% of women with negative test results are spared a colposcopic examination. However, with this approach, the number of patients needing colposcopies remains high. The combination of HPV DNA testing and cervical cytology increases sensitivity at the expense of specificity, because even potentially oncogenic HPV-type infections are found in women without cervical neoplasia, particularly young, sexually active women. The positive predictive value of HPV DNA testing is similar to that of cytology (18% to 25%), but the negative predictive value is 99.8% to 100%.[60-62]

The drawbacks of reflex HPV DNA testing lie in its tendency to produce false negative and false positive results. A screening study of cervical cytology found a substantial degree of cross-reactivity (6.4%) between the reflex HPV DNA probe and the HPV types not included on the probe; this was detected by retesting all HPV DNA–positive samples with a polymerase chain reaction (PCR) assay. The PCR retest found a significant false positive rate of 3.6% and a false negative rate of 6.1% of all samples defined by the reflex HPV DNA test.[63] Thus, reflex HPV DNA testing has the potential for both overevaluation and underevaluation of high-risk HPV infections. However, the combination of a negative reflex HPV DNA test and a negative cytology indicated the absence of CIN 3 or cancer to a certainty of 100%, with a specificity, positive predictive value, and negative predictive value of 93.8%, 8.6%, and 100%, respectively.[63]

Table 2 Prevalence of High-Risk HPV Infections Stratified by Age of Women at the First Examination[61]

Age	*Women (%)*	*High-Risk HPV (%)*
< 20	418 (5.3)	84 (20.1)
21–30	1,843 (23.2)	435 (23.6)
31–40	2,076 (26.2)	289 (13.9)
41–50	1,925 (24.3)	235 (12.2)
51–60	1,014 (12.8)	110 (10.8)
> 60	656 (8.3)	61 (9.3)
Total	7,932	1,214 (15.3)

HPV—human papillomavirus

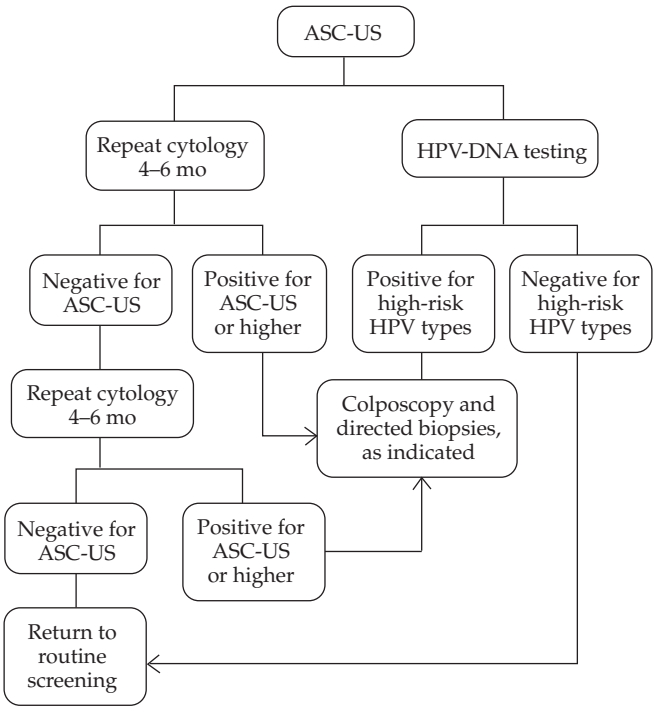

Figure 2 **Management scheme for atypical squamous cells of undetermined significance (ASC-US), based on the consensus guidelines developed by American Society for Colposcopy and Cervical Pathology.[64] (HPV—human papillomavirus)**

Recommended Management

Different policy-making organizations vary in their recommended approaches to the management of ASC. The American Society for Colposcopy and Cervical Pathology (ASCCP) established consensus guidelines for the management of ASC in 2001. The consensus guidelines classify ASC into two groups: ASC-US and ASC-H (see above).[64] For women with ASC-US cytology, a program of repeat cytologic testing, immediate colposcopy, or DNA testing for high-risk types of HPV are acceptable management options [*see Figure 2*].[64] When liquid-based cytologic is used or when cocollection for HPV DNA testing can be performed, reflex HPV DNA testing is the preferred approach. Women with ASC-US who test negative for high-risk HPV DNA should undergo repeat cytologic testing at 12 months. Women who are managed with immediate colposcopy and who are found not to have CIN should undergo repeat cytologic testing at 12 months.

When a program of repeat cervical cytologic testing is used, women with ASC-US should undergo repeat cytology (either conventional or liquid-based) at 4- to 6-month intervals until two consecutive results that are negative for intraepithelial lesion or malignancy are obtained. In most instances, women with ASC-H, LSIL, HSIL, and AGC should be referred for immediate colposcopic evaluation [*see* Squamous Epithelial Lesions, *below*].[64]

The National Comprehensive Cancer Network guidelines are consistent with the recommendation of the consensus guidelines.[65]

The Society of Obstetricians and Gynecologists of Canada (SOGC) guidelines recommend repeating the cytologic smear every 3 to 6 months until three consecutive negative smears are obtained, after which annual cytologic examinations can be resumed. If cytology continues to demonstrate ASC-US, colposcopy should be performed.[66]

Management of ASC-US in Special Circumstances

Immunosuppressed women with ASC-US are at increased risk for CIN 2,3; high-risk types of HPV are frequently detected in these women. Referral for colposcopy is recommended in all immunosuppressed women who have ASC-US.[64]

In postmenopausal women with ASC-US, the risk of CIN 2,3 is lower than in premenopausal women. Treatment with a course of intravaginal estrogen followed by a repeat cervical cytology 1 week after therapy is an acceptable option.[40] It is also acceptable to manage postmenopausal women who have ASC-US with immediate colposcopy or HPV DNA testing.

ASC-US AND ONCOGENIC HPV DNA

As demonstrated by ALTS and other studies, it is now possible to identify many women with ASC-US who do not need colposcopy. However, women who have oncogenic HPV DNA and ASC-US present a sizable management challenge. It is not known how to manage women with ASC-US who test positive for high-risk HPV DNA but who are not found to have CIN by colposcopy and biopsy. Expert opinion and review of the literature indicate that such women are at low risk for high-grade cervical neoplasia and that repeated colposcopy should not be performed in this setting. Instead, HPV DNA testing along with repeat cytology at 6 and 12 months is recommended.[27] The likelihood that these repeat tests will be negative and that patients will subsequently forgo further surveillance screening is not known.

SQUAMOUS EPITHELIAL LESIONS

For women with LSIL, colposcopy is the recommended management.[64] If the colposcopy results are negative for CIN and cancer, appropriate management entails either repeat cytology at 6 and 12 months or HPV DNA testing at 12 months; subsequent management entails (1) a repeat colposcopy if results are positive for ASC or HPV or (2) a return to routine screening if results are negative. If colposcopy reveals the presence of a lesion, the patient is managed in accordance with the guidelines recommended by the ASCCP.

For women with HSIL, colposcopy with endocervical assessment is the recommended management.[64] If colposcopy reveals no lesion or only biopsy-proven CIN 1, then cytology, colposcopy, and biopsy results should be reviewed; subsequent management depends on the final interpretation of tests. If colposcopy indicates the presence of a lesion, the patient is managed in accordance with the guidelines recommended by the ASCCP.

Management of LSIL and HSIL may vary if the patient is pregnant, postmenopausal, or an adolescent.

ATYPICAL GLANDULAR CELLS

The finding of AGC is significant because AGC is associated with a greater risk of high-grade lesions than the risk associated with ASC. On follow-up evaluation, high-grade lesions (either squamous or glandular) may be seen in 10% to 39% of patients with an AGC cytologic result[35,36]; in comparison, 5% to 17% of patients with atypical ASC cytology have CIN 2,3 confirmed by biopsy.[30,39,40]

Women with atypical endometrial cells should initially be evaluated with endometrial sampling.[64] If no neoplasia is identified, it is recommended that the patient undergo follow-up evaluation using a program of repeat cervical cytologic testing at 4- to 6-month intervals until four consecutive results that are negative for intraepithelial lesion or malignancy are obtained. If a result of ASC or LSIL is obtained on any of the follow-up smears, acceptable options include a repeat colposcopic examination.[64] Continued follow-up evaluation is needed.

XVIII HIRSUTISM

Robert L. Barbieri, m.d.

As an isolated clinical condition, excessive hair growth can significantly detract from a woman's quality of life. Hirsutism that occurs along with certain other clinical findings may also signal significant endocrine disease. For example, hirsutism in the presence of oligomenorrhea is often caused by polycystic ovary syndrome (PCOS) and may be associated with infertility, endometrial hyperplasia, and diabetes mellitus. Hirsutism in the presence of virilization may be caused by androgen secretion from an adrenal or ovarian tumor. Fortunately, almost all cases of hirsutism can be effectively treated with a combination of hormonal and nonhormonal therapies.

Definition

Hirsutism is the presence, in a woman, of coarse, dark terminal hair in a male pattern, often involving the upper lip, chin, sideburns, and chest. Terminal hairs are thick, stiff, and pigmented. In men, they are normally found on the face, chest, abdomen, and back. From a practice perspective, a woman who complains of hirsutism has hirsutism. Clinically, hirsutism is present if the patient's Ferriman-Gallwey score is greater than 8 [*see Figure 1*].[1,2]

Hirsutism must also be defined in the context of cultural, ethnic, and racial norms. Most Asian and Native American women have less body hair than white women; women from Mediterranean backgrounds have greater numbers of terminal hairs. In some southern European cultures, significant terminal hair on a woman's upper lip is considered normal. In other cultures, a similar amount of terminal hair might be viewed as abnormal.

Hirsutism must be distinguished from hypertrichosis, which is an increase in total body hair, including sites where terminal hair is not usually found, such as the forehead. Most cases of hypertrichosis are associated with the use of drugs such as phenytoin, penicillamine, diazoxide, minoxidil, and cyclosporine. Systemic diseases such as anorexia nervosa, malnutrition, porphyria, and hypothyroidism can also cause hypertrichosis. Treatment of hypertrichosis consists of discontinuance of the inciting drug or treatment of the systemic disease. If these approaches are not successful, treatment with an antiandrogen such as spironolactone (200 mg daily) has been reported to be moderately effective.[3]

Epidemiology

On the basis of a Ferriman-Gallwey score of more than 8, approximately 4% of women have hirsutism; only 1% of women have a Ferriman-Gallwey score above 10.[1,2] Approximately 10% of a population-based cohort of women in Finland self-reported having hirsutism.[4] In this study about 2.5 % of the women reported having both hirsutism and oligomenorrhea, indicating that in the general population, the prevalence of PCOS is lower than the prevalence of hirsutism. However, a greater proportion of women with PCOS seek medical care for their condition than women with hirsutism. Consequently, in a specialty endocrine practice, women with PCOS are overrepresented compared with women with self-reported hirsutism.

Pathogenesis

Hirsutism is caused by an excess of androgen production, androgen action, or both.[5,6] Androgen overproduction can take place in the ovary, the adrenal gland, or the skin itself (specifically, in the hair follicle). In many hirsute women, all three organs overproduce androgens.

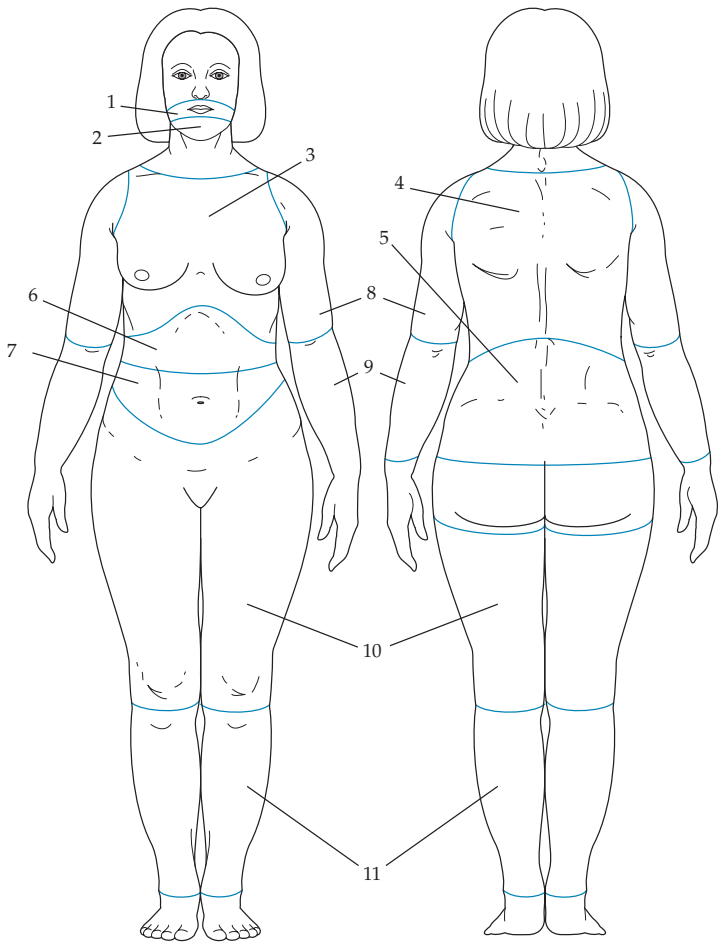
There are three types of hair: lanugo, vellus, and terminal. Lanugo is the soft, unmedullated hair seen in the fetus; it is shed in utero in the third trimester or shortly after birth. Vellus hairs are the thin, soft, unpigmented hairs that cover many areas of the body, such as the forehead. Terminal hairs are thick, coarse, and pigmented. Terminal hair is composed of an inner sheath of pigment with an outer sheath of keratin. Androgens stimulate the conversion of vellus hairs to terminal hairs in areas of the body sensitive to androgens, including the face and chest. Paradoxically, androgens cause the loss of terminal hairs in certain areas of the body, such as the frontal and parietal regions of the scalp.

The adrenal gland produces large quantities of the major androgens dehydroepiandrosterone sulfate (DHEAS), dehydroepiandrosterone (DHEA), and androstenedione. The ovary produces androstenedione and testosterone. In end organs, such as the pilosebaceous unit (hair follicle), androstenedione and testosterone can be converted to the potent androgen dihydrotestosterone (DHT) by the enzyme 5-α-reductase type 2. DHT and testosterone are the most potent androgens in humans; both bind with high affinity to the androgen receptor and initiate gene transcription that stimulates the growth of the pilosebaceous units on the face and chest and decreases the growth of pilosebaceous units on the frontal and parietal scalp. DHEA and DHEAS have no inherent androgen activity but can be metabolized to the active androgens testosterone and DHT. In research studies, nearly all hirsute women have been found to have increased production of testosterone, but standard clinical assays may not be sensitive enough to reliably detect the elevations in serum testosterone levels in these patients.[5,7]

Many women with hirsutism have several hormonal defects, including the following: (1) overproduction of adrenal androgens, (2) overproduction of ovarian androgens,[8] (3) increased conversion of androstenedione and testosterone to DHT in the hair follicle, and (4) increased sensitivity of the hair follicle to androgen action. Androgen overproduction in many hirsute women probably arises from multiple pathophysiologic defects, including (1) increased pituitary secretion of luteinizing hormone (LH), which stimulates ovarian production of testosterone and androstenedione; (2) elevated insulin levels, because of insulin resistance, which decrease the production of sex-hormone–binding globulin (SHBG) and thus increase free testosterone levels; (3) mild biochemical defects in the adrenal steroid enzymes that produce cortisol, which increase the ratio of androgen-to-cortisol secretion and result in adrenal androgen overproduction; and (4) increased activity of 5-α-reductase in the hair follicle, which increases the conversion of androgens to DHT in the follicle.

Etiology

The two most common causes of hirsutism are idiopathic hirsutism and PCOS. Idiopathic hirsutism is defined as hirsutism



Site	Grade	Definition
1. Upper Lip	1	Few hairs at outer margin
	2	Small mustache at outer margin
	3	Mustache extending halfway from outer margin
	4	Mustache extending to midline
2. Chin	1	Few scattered hairs
	2	Scattered hairs with small concentrations
	3 and 4	Complete cover, light and heavy
3. Chest	1	Circumareolar hairs
	2	With midline hair in addition
	3	Fusion of these areas, with three-quarters cover
	4	Complete cover
4. Upper Back	1	Few scattered hairs
	2	Rather more, still scattered
	3 and 4	Complete cover, light and heavy
5. Lower Back	1	Sacral tuft of hair
	2	With some lateral extension
	3	Three-quarters cover
	4	Complete cover
6. Upper Abdomen	1	Few midline hairs
	2	Rather more, still midline
	3 and 4	Half and full cover
7. Lower Abdomen	1	Few midline hairs
	2	Midline streak of hair
	3	Midline band of hair
	4	Inverted V-shaped growth
8. Arm	1	Sparse growth affecting not more than one quarter of limb surface
	2	More than this; cover still incomplete
	3 and 4	Complete cover, light and heavy
9. Forearm	1, 2, 3, and 4	Complete cover of dorsal surface; 2 grades of light and 2 of heavy growth
10. Thigh	1, 2, 3, and 4	As for arm
11. Leg	1, 2, 3, and 4	As for arm

Figure 1 **Ferriman-Gallwey system for clinical scoring of hirsutism.[1,58] Each of the 11 designated body areas is assigned a score of 0 (absence of coarse dark terminal hairs) to 4 (extensive terminal hair growth). A score higher than 8 indicates hirsutism. Hair scores over the forearms and lower leg do not contribute significantly to the distinction of hirsutism from nonhirsutism.**

(patient self-report or a Ferriman-Gallwey score above 8) in a woman with regular ovulatory menses. PCOS is the combination of oligomenorrhea (oligo-ovulation) and hyperandrogenism, as manifested by hirsutism or elevation in levels of a serum androgen such as androstenedione, testosterone, or DHEA. In many cases, idiopathic hirsutism may be a mild form of PCOS, in which androgen levels are elevated enough to cause hirsutism but not elevated enough to produce oligo-ovulation and oligomenorrhea.[9] In a very small number of women, hirsutism (usually severe hirsutism, the so-called bearded-lady phenomenon) is a manifestation of serious diseases such as adrenal or ovarian tumors. One study of 350 British women who presented with hirsutism or androgenic alopecia found that 68% had idiopathic hirsutism, 30% had PCOS, and 2% had serious underlying disease, including congenital adrenal hyperplasia, ovarian tumors, adrenal tumors, prolactinoma, and acromegaly.[10]

Controversy exists as to a possible relationship between hyperprolactinemia, excess production of adrenal androgens, and hirsutism. Several investigators have reported a relationship between hyperprolactinemia and excess production of DHEAS,[11] but others have not confirmed these observations.[12,13] In one of the most detailed studies, Schiebinger and colleagues[13] found that in women with hyperprolactinemia, successful treatment decreased the DHEAS production rate from 27 mg to 17 mg a day and increased the metabolic clearance rate from 16 L to 21 L a day. Along with these changes, serum DHEAS decreased from 2.5 μg/ml to 1.8 μg/ml. These results suggest that hyperprolactinemia may play a modest role in stimulating adrenal androgen production and may occasionally contribute to the development of hirsutism.

Diagnosis

The main goal in the evaluation of women with hirsutism is to determine whether idiopathic hirsutism or PCOS is present and to exclude rare, medically serious causes of hyperandrogenism, such as ovarian and adrenal tumors.[14] This can best be done on the basis of the history and physical examination, along with limited laboratory testing [*see Table 1*].

CLINICAL FEATURES

The differentiation between the two most common causes of hirsutism can be made by menstrual history. Women with idiopathic hirsutism have normal menstrual cycles lasting 23 to 35

Table 1 Differential Diagnosis of Hirsutism in Women of Reproductive Age

Associated Finding	*Most Likely Diagnosis*
Oligomenorrhea	Polycystic ovary syndrome (PCOS)
Regular ovulatory cycles	Idiopathic hirsutism
Fasting 17-hydroxyprogesterone level > 4 ng/ml	Nonclassic adrenal hyperplasia
Virilization	Ovarian or adrenal androgen-secreting tumor, or ovarian stromal hyperthecosis
Acanthosis nigricans	Severe insulin resistance syndrome, often associated with PCOS or ovarian stromal hyperthecosis
Galactorrhea and elevated serum prolactin level	Hyperprolactinemia

days. Women with PCOS have oligomenorrhea, with some menstrual cycles lasting longer than 35 days. Many women with PCOS have fewer than six spontaneous menstrual cycles a year.

Serious causes of hyperandrogenism (e.g., ovarian or adrenal tumors) typically manifest themselves clinically as virilization, with frontal balding, acne, clitoromegaly, increased upper body muscle mass, and deepening of the voice. Almost all women with signs of virilization are amenorrheic; none have regular ovulatory menstrual cycles. In addition, most women who present with virilization from an ovarian or adrenal tumor report recent onset (within the past year) of their hirsutism and rapid progression of their condition. In contrast, most women with idiopathic hirsutism or PCOS notice the onset of hirsutism many years before presenting for medical care, often during puberty.

When taking the history, the clinician should ask whether the patient has been using androgenic medications such as danazol or testosterone and its derivatives, which is a rare cause of hirsutism. Some female athletes may use anabolic steroids.

LABORATORY TESTING

Serum Androgen Assays

Patients with clinical evidence of hirsutism should undergo measurement of serum testosterone (total or free) and serum 17-hydroxyprogesterone levels. Unfortunately, most of the androgen assays available in clinical practice are designed to differentiate between levels found in normal women and men, and these assays are neither sensitive enough nor specific enough for detecting differences between normal and hirsute women. For example, the mean circulating total testosterone level is approximately 25 ng/dl in normal women, 50 ng/dl in hirsute women, and 600 ng/dl in men. Clinical assays are excellent at differentiating between 25 ng/dl and 600 ng/dl but are poor at differentiating between 25 ng/dl and 50 ng/dl.

Another problem with clinical assays is that testosterone circulates in both free and SHBG-bound forms. Testosterone bound to SHBG is not able to stimulate end organs, such as the pilosebaceous unit. The amount of free testosterone depends on both testosterone production rates and the concentration of SHBG. To complicate the situation, an increase in testosterone production causes a decrease in SHBG production, which results in a decrease in total testosterone (the form of testosterone that is most often measured in practice) and an increase in free testosterone (a form that is not typically measured in clinical practice).

In most clinical assays, the upper limit of normal for serum testosterone is 80 ng/dl. Almost all women with virilization have serum testosterone levels greater than 150 ng/dl.[15-17] It is probably wise for primary care physicians to seek the help of an endocrinologist if they identify a virilized woman or a woman with a serum testosterone concentration above 150 ng/dl.

Other Tests

In a hirsute woman who has amenorrhea, the serum prolactin level should be measured. Women with PCOS, especially those who are obese, should be screened for diabetes mellitus. This is particularly true of patients in whom physical examination reveals acanthosis nigricans, which suggests significant insulin resistance.

Between 1% and 5% of women who present with hirsutism and oligomenorrhea have nonclassic congenital adrenal hyperplasia (NCAH) from 21-hydroxylase deficiency that was too mild to be detected at birth.[18] All of these women have elevated levels of 17-hydroxyprogesterone (above 4 ng/ml) in the early morning (8 A.M.) during the follicular phase of the menstrual cycle. Consequently, measurement of a follicular-phase 8 A.M. 17-hydroxyprogesterone level can help rule out NCAH. It is not clear whether all women with hirsutism and oligomenorrhea should be screened for NCAH, because the disorder has a low prevalence in many populations. In addition, many women with NCAH respond well to the standard treatments for PCOS. Screening might be warranted in women of ethnic groups that have an increased prevalence of NCAH (e.g., Ashkenazi Jews, Inuits). One middle-of-the-road approach is to screen women for NCAH only if their serum testosterone concentration is above a clearly elevated level, such as 100 ng/dl or 150 ng/dl. This approach will detect the most clinically significant cases of NCAH.

Treatment

The goals of treatment of hirsutism include the following: (1) rule out a serious underlying medical condition such as a virilizing tumor of the adrenal or ovary, (2) slow or stop new hair growth, (3) remove or hide existing hair, (4) evaluate and treat associated hormonal problems such as oligomenorrhea, and (5) anticipate long-term health conditions that can occur in women with hyperandrogenism, such as an increased risk of diabetes.

Hormonal treatment of hirsutism typically does not result in normalization of the Ferriman-Gallwey score (i.e., to below 8). In many studies, patients' Ferriman-Gallwey scores are in the range of 20 to 25 at the initiation of treatment. After 12 months of treatment, the Ferriman-Gallwey scores are in the range of 10 to 15. On the basis of these general observations, clinicians can assure women that treatment is effective but should warn them that treatment is unlikely to reduce facial hair to a level similar to that in nonhirsute women. In addition, clinicians should advise women that it will take at least 6 months for treatment to reach near maximal effects. Finally, most patients report that if they discontinue hormone treatment, the hirsutism recurs over the next 3 to 9 months.

Treatment of hirsutism should be multimodal [*see Table 2*]. It should include hormonal suppression of androgen production

or action, along with a nonhormonal method of controlling hair growth. A common strategy is to combine an estrogen-progestin contraceptive formulation with an antiandrogen and to use electrolysis or shaving as a nonhormonal adjuvant. An alternative hormonal approach is treatment with an antiandrogen alone. Alternative nonhormonal treatments include the use of a facial antihair cream or laser destruction of hair follicles [*see* Nonhormonal Approaches, *below*].

WEIGHT LOSS

Body mass index (BMI) is a major determinant of insulin resistance and hyperinsulinemia. Women with a BMI greater than 27 kg/m^2 are often insulin resistant.[19] Women with a BMI under 25 kg/m^2 are seldom insulin resistant, unless they have a relatively rare genetic cause of insulin resistance, such as lipodystrophy. Hyperinsulinemia causes hyperandrogenism through several mechanisms. In combination with LH, elevated insulin levels cause the ovarian theca and stroma to produce excess quantities of androstenedione and testosterone.[20] In addition, hyperinsulinemia suppresses hepatic production of SHBG, which causes an increase in free androgens. Excess ovarian production of androgens and decreased SHBG work synergistically to increase the risk of development of hirsutism.

Numerous studies have demonstrated the benefits of weight loss in hyperandrogenic, insulin-resistant women.[21-25] In these studies, mean weight loss ranging from about 10 to 20 kg has been associated with decreases in insulin levels and testosterone concentration and with ovulation and pregnancy in many women.

Weight loss is difficult to achieve. A structured program that includes consultation with a nutritionist, encouragement by the physician, a low-calorie diet, and initiation of an exercise program may be the most effective nonsurgical approach in these patients. Surgical methods of weight reduction can be very effective, especially in women whose BMI is greater than 40 [*see 3:X Obesity*].

ESTROGEN-PROGESTIN CONTRACEPTIVES

Combination estrogen-progestin formulations at doses used for contraception (in the form of pills, transdermal patches, or vaginal rings) suppress LH secretion, which in turn suppresses ovarian androgen production.[26,27] In addition, the estrogen in estrogen-progestin combinations increases liver production of SHBG, which binds testosterone and decreases circulating bioavailable testosterone, reducing androgen stimulation of the pilosebaceous units.[28] A further advantage for women with PCOS is that estrogen-progestin combinations, when given cyclically, induce regular withdrawal bleeding.

In a study that examined the effects of 5 years of estrogen-progestin contraceptive treatment for hirsutism, the investigators reported that hirsutism continued to improve through all 5 years of the treatment. Acne improved significantly by 2 years of treatment, but minimal further improvement occurred between 2 and 5 years. Within 6 months of discontinuance of treatment, hirsutism and acne reappeared.[29]

The effectiveness of estrogen-progestin contraceptives may be influenced by body mass. In heavier women, it may be best to select a medication with 35 μg of ethinyl estradiol.

Some estrogen-progestin contraceptive formulations may differ with regard to their effect on hepatic production of SHBG. Norgestrel is an androgenic progestin (derived from 19-nortestosterone) that partially blocks estrogen-induced SHBG production. Contraceptives that contain androgenic progestins, such as norgestrel, do not result in as great an increase in SHBG production as contraceptives that contain less androgenic progestins, such as drospirenone, desogestrel, ethynodiol diacetate, and norgestimate [*see Table 3*]. However, for the treatment of hirsutism, any estrogen-progestin contraceptive is superior to no estrogen-progestin contraceptive.

Table 2 Treatment of Hirsutism

Category	*Treatment*	*Potential Toxic Effects*
Hormonal	Combination estrogen-progestin contraceptive	Deep vein thrombosis
	Spironolactone, 50–200 mg daily; typical dosage, 100 mg daily	Hyperkalemia in patients with renal disease
	Combination estrogen-progestin contraceptive plus spironolactone, 100 mg daily	—
	Flutamide, 62.5–500 mg daily; typical dosage, 125 mg daily	Liver toxicity
	Finasteride, 2.5–5 mg daily; typical dosage, 5 mg daily	Teratogenicity in male fetuses
	Metformin, 1,500–2,250 mg daily; typical dosage, 2,000 mg daily	Nausea, vomiting; fatal lactic acidosis in patients with renal disease, heart failure, or liver disease
	Gonadotropin-releasing hormone analogue	Hypoestrogenism, including vasomotor symptoms and bone loss, when used as a single agent
Nonhormonal	Shaving; depilatories; bleaching; laser photothermolysis; nonlaser, rapid pulse, intense light therapy; eflornithine cream; electrolysis	—

Note: treatment is best accomplished with the combination of a hormonal treatment and a nonhormonal treatment.

ANTIANDROGENS

Antiandrogens are a cornerstone of therapy for hirsutism. Used alone, antiandrogens appear to be as effective as oral-contraceptive treatment.[30] As with estrogen-progestin treatment, cessation of antiandrogen therapy is followed by recurrence of hirsutism within 1 year in the majority of women.[31]

The antiandrogens with demonstrated efficacy against hirsutism include spironolactone, finasteride, flutamide, and ketoconazole [*see Table 2*].[32-38] In one high-quality clinical trial, 40 hirsute women were randomized to receive spironolactone (100 mg daily), flutamide (250 mg daily), finasteride (5 mg daily), or placebo. Placebo did not produce a decrease in hirsutism, but all three active treatments were associated with a significant reduction in hirsutism scores. The reductions in the Ferriman-Gallwey score observed after 6 months of treatment were 41% with spironolactone, 39% with flutamide, and 32% with finasteride.[39] Similarly, in a placebo-controlled trial of finasteride (5 mg daily), flutamide (500 mg daily), and estrogen-progestin, the three active treatments resulted in similar decreases in Ferriman-Gallwey scores.[40] A randomized trial that compared flu-

tamide (250 mg daily), finasteride (5 mg daily), ketoconazole (300 mg daily), and estrogen-progestin in 66 hirsute women found that after 1 year of treatment, all three agents significantly decreased the Ferriman-Gallwey score. The magnitude of the reduction in the Ferriman-Gallwey score was 55% with flutamide, 44% with finasteride, 53% with ketoconazole, and 60% with estrogen-progestin; the differences between the agents were not statistically significant.[41]

Individual Antiandrogens

Spironolactone The most widely used antiandrogen for the treatment of hirsutism, spironolactone inhibits the binding of testosterone and DHT to the androgen receptor. Because spironolactone and its active metabolites have very long half-lives, the entire dose can be given once daily. The usual dosage of spironolactone is between 50 and 200 mg daily. Many authorities recommend a dosage of 100 mg daily because it is near the top of the dose-response curve and is associated with fewer side effects than 200 mg daily. Approximately 70% of women treated with spironolactone have reported improvement. In one study of spironolactone (200 mg daily) for the treatment of moderate to severe hirsutism, 19 of 20 women reported improvement, with beneficial effects noticeable within 2 months, peaking at 6 months, and maintained through 12 months of therapy.[42] Because spironolactone may be a teratogen, sexually active patients who are not taking spironolactone along with an estrogen-progestin contraceptive should use barrier contraception.

Finasteride Finasteride inhibits type 1 (skin) and type 2 (prostate) 5-α-reductase, the enzyme that transforms testosterone to the most potent androgen, DHT. The Food and Drug Administration has placed a so-called black-box warning on finasteride, advising that no woman of childbearing age should take the medication or touch a broken pill because of the potential teratogenic effects of an antiandrogen on a male fetus. Consequently, a physician who prescribes finasteride to a hirsute woman may find that the pharmacist refuses to dispense the medication or that the patient's insurance company urges the patient to stop taking the medicine. These practical considerations argue against prescribing finasteride for the treatment of hirsutism.

Table 3 Androgenicity of Progestins Used in Oral Contraceptives

Level of Androgenicity	*Progestin*	*Brand Name of Products*
High	Norgestrel	LoOvral
	Levonorgestrel	Alesse, Levlite, Nordette, Trilevlen, Tri-Phasil
Moderate	Norethindrone	Genora 1/35, Norinyl 1/35, OrthoNovum 1/35, Ovcon 35
	Norethindrone acetate	Loestrin 1/20 Loestrin 1.5/35
Low	Ethynodiol diacetate	Demulen 1/35
	Norgestimate	Ortho-TriCyclen Ortho-TriCyclen Lo
	Desogestrel	Desogen Ortho-Cept
	Drosperinone	Yasmin

Flutamide An androgen receptor antagonist, flutamide is widely used in Europe for the treatment of hirsutism. It is effective at dosages ranging from 67.5 to 500 mg daily. Flutamide is probably a more potent antiandrogen than spironolactone. However, flutamide is much more expensive than spironolactone and can be associated with fatal hepatotoxicity.[43]

Ketoconazole Ketoconazole is an antifungal agent that inhibits cytochrome P-450 enzymes, which are involved in the synthesis of androgens. Treatment with ketoconazole (300 mg daily) inhibits androgen production and is as effective as finasteride, spironolactone, and flutamide in the treatment of hirsutism. However, ketoconazole has more side effects than the other antiandrogens that are commonly used to treat hirsutism.[41] The most commonly reported side effects are nausea, alopecia, headache, and elevated liver enzyme levels. For that reason, I do not recommend the use of ketoconazole to treat hirsutism.

ESTROGEN-PROGESTIN PLUS AN ANTIANDROGEN

The combination of an oral contraceptive and an antiandrogen may be somewhat more effective against hirsutism than either agent used alone. One trial studied the use of an oral contraceptive plus either finasteride (5 mg daily) or placebo for the treatment of hirsutism. After 1 year of treatment, the women who received combination therapy had greater reductions in their Ferriman-Gallwey score than women who received the oral contraceptive alone (48% versus 38%, respectively; $P < 0.05$).[44] On the other hand, a trial comparing an oral contraceptive plus flutamide (250 mg daily) with flutamide alone found the two treatments to be equally effective.[45]

One disadvantage of combined therapy is that it is more expensive than single-agent therapy. Also, the side effects may be additive.

GONADOTROPIN-RELEASING HORMONE ANALOGUES

Long-term administration of a gonadotropin-releasing hormone (GnRH) agonist analogue suppresses pituitary secretion of LH and ovarian secretion of testosterone. Treatment with a GnRH analogue has been demonstrated to reduce Ferriman-Gallwey scores. In head-to-head studies, however, antiandrogens have produced greater reductions in Ferriman-Gallwey scores than GnRH agonist treatment.[46] GnRH agonists are also generally more expensive than antiandrogens, limiting the clinical utility of GnRH agonists as first-line agents in the treatment of hirsutism.

METFORMIN

Many women with hirsutism have insulin resistance, and abnormally elevated concentrations of circulating insulin appear to stimulate ovarian androgen production. Metformin improves insulin dynamics, decreases circulating insulin levels, reduces serum testosterone levels, and reduces the rate of abnormal terminal hair growth. Clinical trials suggest that metformin at a dosage of 1,500 mg daily is effective in the treatment of hirsutism. For example, one randomized study that compared metformin with a cyclic oral contraceptive in 52 women with PCOS and hirsutism found that Ferriman-Gallwey scores after 12 months of treatment were significantly re-

duced in patients taking metformin (25% decrease; $P < 0.01$) but not in those taking oral contraceptives (5% decrease; P = not significant).[47] Mean hair diameter was significantly reduced with both treatments. Similar results have been reported by other investigators.[48]

THIAZOLIDINEDIONES

Like metformin, the thiazolidinediones increase insulin sensitivity. Neither pioglitazone nor rosiglitazone has been extensively studied for its efficacy against hirsutism, however. Before being withdrawn from the market because of hepatic toxicity, troglitazone was demonstrated to be effective in the treatment of hyperandrogenism and hirsutism.[49]

GLUCOCORTICOIDS

Suppression of adrenal gland androgen production with glucocorticoids is effective in the treatment of hirsutism, but long-term glucocorticoid treatment can lead to such serious side effects as weight gain, osteopenia, impaired glucose metabolism, and suppression of adrenal function. Consequently, most endocrinologists do not recommend the long-term use of glucocorticoids for the treatment of hirsutism.

NONHORMONAL APPROACHES

Eflornithine Cream

Topical eflornithine (α-difluoromethylornithine) retards hair growth through mechanisms that are not fully characterized. Eflornithine inhibits ornithine decarboxylase and is active as an anthelmintic agent. Eflornithine is not a depilatory agent; rather, it retards hair growth. The FDA has approved eflornithine for the treatment of hirsutism, and it is available as a 13.9% cream. The standard treatment regimen is application of a thin film to the upper lip and other affected areas of the face twice daily. The applications should be at least 8 hours apart. Patients should not wash the treated areas for 4 hours. To minimize inflammatory side effects, eflornithine should not be applied until at least 5 minutes after plucking, tweezing, cutting, or shaving of hair. In one study, after 24 weeks, approximately 32% of women treated with eflornithine reported marked improvement in facial hirsutism, compared with 8% of women treated with a placebo cream.[50] Improvement is seen within 4 to 8 weeks after starting treatment. Hirsutism may return to pretreatment levels 12 weeks after discontinuing the medication.

The major side effects of eflornithine are stinging and burning at the site of application and inflammation, with reddening of the irritated skin. Less than 1% of the applied dose is absorbed through the skin.

Laser Treatment

Laser therapy can induce selective photothermolysis of the pilosebaceous unit. A brief laser pulse at a wavelength that will be absorbed by the melanin in darkly pigmented hair, but not by lightly pigmented skin, is used to selectively heat the pilosebaceous unit. The use of brief pulses of laser energy minimizes the lateral diffusion of the thermal effect, resulting in maximal delivery of energy to the target and minimal effects in the adjacent skin. Three to six treatments performed every 8 weeks are necessary to control hair growth. Laser hair removal is most successful in patients with lighter skin color and dark hairs. Lasers with ruby and alexandrite generators appear to be most widely utilized.[51] Patients who have undergone laser treatment of hirsutism report a high degree of satisfaction with the therapy and its results, although many women have recurrence of hirsutism 6 to 12 months after the treatment.[52]

Intense Pulsed Light

An alternative to laser treatment for hirsutism is the use of intense pulsed light that is not coherent (nonlaser). In one form of this treatment, thermal energy is created in hair follicles through the use of broad-spectrum noncoherent radiation with wavelengths from 550 to 1,200 nm administered in macropulses divided into three minipulses. The thermal energy destroys the epithelial cells in the hair follicle and thereby reduces hair growth.[53] In another form of this treatment, nonlaser light with wavelengths of approximately 550 to 585 nm is delivered in energy pulses of 38.7 joules/cm.[54] In small series, many of which had no control group, intense pulsed light has been demonstrated to be effective in reducing facial hirsutism.[55]

Hair Removal and Lightening

Shaving is a safe and useful method for hair removal but may need to be done multiple times each week; depilatory agents and wax can remove hair; and bleaches can lighten hair. These treatments, however, can cause skin irritation and erythema, which is especially troublesome when it occurs on the face. Electrolysis, which destroys the pilosebaceous unit with electrical energy one hair follicle at a time, is effective but labor intensive and expensive. In contrast, laser therapy removes hundreds of hairs simultaneously.

EXPERIMENTAL TREATMENT

Finasteride cream, 0.25%, applied to facial areas has been found superior to placebo in hirsute women. In a small study, administration of finasteride cream for 6 months reduced hair counts by approximately 40%, whereas placebo had no beneficial effects.[56] The FDA has not approved finasteride cream; a compounding pharmacy would need to prepare the medication.

Prognosis

Women with hirsutism should be warned not to expect significant improvement for at least 3 to 6 months after starting hormone therapy. Hair follicles have a life cycle of up to 6 months, and the actively growing hair must reach the end of its life cycle before it will cease to grow. The first response that a patient may observe is that hair is thinner (has a smaller diameter) and lighter in color. This occurs because the pigmented core of the hair shrinks in diameter before the linear growth rate of the hair slows.

Therapy for hirsutism is usually continued indefinitely because increased androgen production or sensitivity may persist for decades. In one study, hormone therapy for 2 years led to a marked decrease in hirsutism, but 80% of patients noted recurrence of hirsutism within 6 months after discontinuing therapy.[57] In most women, excess androgen production begins to decline in the late portion of the fourth decade of life.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

None of the oral contraceptives or hormonal agents discussed in this chapter has been approved by the FDA for the specific treatment of hirsutism.

XIX CARDIOVASCULAR DISEASE IN WOMEN

JoAnne Micale Foody, m.d.

Heart disease is the leading cause of death in women in the United States: in 2002, almost half a million women died of heart disease, which is more than 10 times as many as died of breast cancer.[1] Indeed, almost one out of every two women in the United States will die of some cardiovascular event—most likely, myocardial infarction (MI), hypertensive heart disease, or stroke.[1] In addition, heart failure is a growing epidemic in women, particularly older women.

Despite the importance of cardiovascular disease in women, it has been viewed as a disease of middle-aged men, and most knowledge of it comes from studies in middle-aged men.[2] Yet there is increasing evidence that significant gender differences do exist in cardiovascular risk factors and in their modification in women. The clinical presentation of heart disease,[2,3] the impact of individual cardiovascular risk factors,[1,4-7] and the results of risk-factor interventions differ dramatically by gender.[8-17] Moreover, although the mortality associated with coronary artery disease (CAD) in men has shown major improvements, mortality in women continues to increase [*see Figure 1*]. This chapter reviews those uniquely female attributes that are associated with differences in cardiovascular disease presentation and discusses ways to reduce risk and improve clinical outcomes.

Coronary Artery Disease

EPIDEMIOLOGY

Coronary artery disease is the leading cause of mortality in women in the United States. One third of women develop CAD, and one in three die of the disease—in 2002, a toll of almost 242,000 deaths.[1,18] CAD is not limited to older women; a significant number of younger women also develop CAD.[19,20]

RISK FACTORS

The increasing rates of CAD are not surprising, in view of the fact that coronary risk factors are highly prevalent and are increasing in women in the United States. Of women 20 to 74 years of age, a third have hypertension, more than 25% have hyperlipidemia, more than 25% smoke cigarettes, more than 25% are overweight, and more than 25% report having sedentary lifestyles.[1] These risk factors are more prevalent in men than in women, but as women grow older, their risk-factor profile approaches, and, in some instances, surpasses that of their male counterparts.

Although multiple clinical trials have identified important risk factors and effective therapies for CAD, few of these studies have included sufficient numbers of women to draw meaningful conclusions.[21] Thus, much of the evidence that supports contemporary recommendations for testing, prevention, and treatment of CAD in women is extrapolated from studies conducted predominantly in middle-aged men. Applying the findings of studies in men to management of CAD in women may not be appropriate, because the symptoms of CAD, its natural history, and the response to therapy may differ in men and women.

Dyslipidemia

It is well established that the higher the level of serum cholesterol, the higher the risk of CAD in both men and women.[22,23] In women, however, lipid and lipoprotein concentrations vary with ovarian function; consequently, CAD risk varies as ovarian function changes.

After 20 years of age, the plasma total cholesterol level increases progressively in both sexes; however, until the sixth decade, the rate of increase is slower in women. After the sixth decade, women's total-cholesterol levels generally increase faster, exceeding those of men of similar age. Although elevations in total cholesterol are significantly associated with CAD in women, women have lower absolute rates of disease than men for any given cholesterol level. For example, the Framingham investigators found that with total-cholesterol levels above 295 mg/dl, the rate of MI in women was 60% that in men.[5]

Similarly, high-density lipoprotein (HDL) cholesterol levels are different between men and women. Until puberty, HDL levels are slightly higher in boys than in girls, but as girls pass through puberty, HDL levels do not fall as they do in boys of the same age. After puberty, HDL levels in women increase slowly until before menopause, whereas they remain constant in men. Thus, average HDL values in women are approximately 20% higher than those in men.[24] HDL levels decline by approximately 3.5 mg/dl after menopause, but they generally remain higher in women than men throughout life.[25]

Elevated HDL levels protect both men and women against the development of CAD, but the protective effect appears to be more powerful in women. In the Framingham Study, every 10 mg/dl increase in HDL was associated with a 40% to 50% reduction in coronary risk; the Framingham investigators suggest that the protective effect of HDL in women is approximately twice the atherogenic effect of low-density lipoprotein (LDL).[26-29] Both the Framingham Study and the Donolo–Tel Aviv Study have documented increased CAD incidence and mortality in women whose HDL levels are greater than 35 mg/dl but less than 50 mg/dl.[30,31]

LDL levels are lower in women than in men throughout the

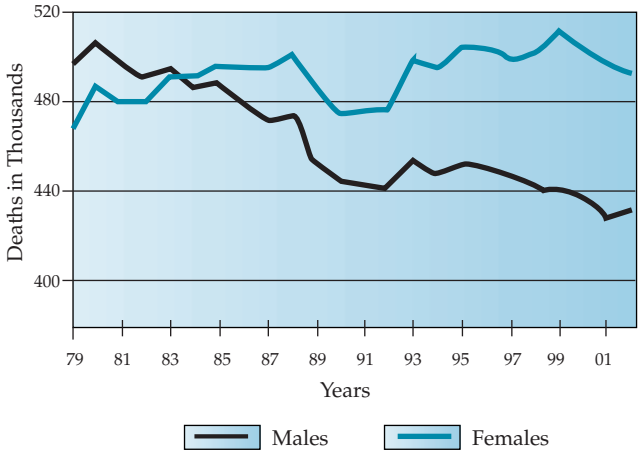

Figure 1 **Cardiovascular disease mortality trends for males and females, United States 1979–2002.[111]**

first two thirds of the life span. After the middle of the fifth decade, as a result of menopause, LDL levels in women rise abruptly, whereas LDL levels in men remain stable. In the last third of life, women generally have higher LDL levels.[5] Although an LDL level of 130 mg/dl or higher is considered a risk factor for CAD in both men and women, independent of the HDL level, the role of LDL as a risk factor in women is somewhat controversial. Few prospective studies have examined LDL and CAD risk in women. Very high LDL concentrations carry the same poor prognosis in both sexes, but mild elevations of LDL are not associated with the same risk burden in women as in men, perhaps because of women's generally higher levels of HDL.

Little difference in triglyceride concentrations is noted between sexes until puberty. Then, triglyceride concentrations increase in both sexes with increasing age, albeit at a much slower rate in women. Triglyceride levels in men actually decrease in middle age, whereas they continue to increase gradually in women. By the age of 70 years, mean levels in women equal those of men.

Triglyceride levels appear to be statistically independent predictors of CAD risk even after adjustment for multiple risk factors, including total-cholesterol levels. Elevated triglyceride levels are common in older postmenopausal women, in whom they may be markers for the presence of metabolic syndrome, insulin resistance, and associated atherogenic lipoproteins.

Diabetes Mellitus

Diabetes mellitus is one of the most important risk factors for CAD in women, regardless of age. The risk of MI is twice as high in women with diabetes as in nondiabetic women of the same age. The incidence of CAD in diabetic women is almost three times that of nondiabetic women, whereas the incidence is doubled in diabetic men. The presence of diabetes tends to attenuate any gender-related differences in cardiovascular morbidity and mortality. In fact, the risk of cardiovascular events in diabetic women is higher than that of both diabetic men and nondiabetic women, even after adjustment has been made for age and other cardiovascular risk factors.

The higher risk in diabetic women may be partially explained by the clustering of multiple risk factors, such as hypertension, smoking, and obesity. Aside from diabetes or high blood glucose levels, diabetic women have significantly greater degrees of four cardiovascular risk factors: low HDL levels, high triglyceride levels, high systolic blood pressure, and high body mass index (BMI). Differences in lipoprotein levels between diabetic and nondiabetic patients are much more dramatic in women than in men.[32] Whether the increased risk associated with diabetes in women results from the clustering of other risk factors or from diabetes itself remains to be fully explored.

Hypertension

Premenopausal women are less likely than men to have hypertension. Nevertheless, one in four white women 20 years of age or older have hypertension. The tendency of women to have lower blood pressure than men early in life is counterbalanced by the fact that blood pressure increases more steeply with aging in women than it does in men. Before menopause, the predominant risk factors for hypertension in women are gender specific: contraceptive use and pregnancy. With menopause, many women—African-American women in particular—develop hypertension. By age 65, more than half of all women are hypertensive, and about 80% are hypertensive by age 75.

Obesity

Obesity has been shown to be an independent risk factor for the development of CAD in women. In a 26-year follow-up of participants in the Framingham Study, relative weight in women was positively and independently associated with cardiovascular events. It is estimated that 30% to 40% of CAD cases in obese women can be attributed to the excess weight alone, and even mild to moderate overweight increases the risk of CAD in middle-aged women.[33] In the Nurses' Health Study, women with a BMI of 25 to 29 kg/m^2 had an age-adjusted relative risk for CAD of 1.8, compared with the leanest women, and obese women (i.e., those with a BMI greater than 29) had a relative risk for CAD of 3.3.[34,35] Approximately 25% of women in the United States between 35 and 64 years of age have BMIs of 29 or higher, and in this group, the relative risks of nonfatal MI and fatal CAD are 3.2 and 3.5, respectively.

The distribution of body fat may be more important than absolute weight in determining cardiovascular risk. Fat distribution, as assessed by the waist-to-hip ratio, is significantly related to coronary atherosclerosis in both women and men, and the waist-to-hip ratio is significantly greater in women with CAD. Truncal obesity (also known as android or male-pattern obesity), manifested as a high waist-to-hip ratio, correlates with higher LDL and lower HDL levels.

Smoking

Whereas diabetes is the most gender-differentiated biologic risk factor for CAD in women, cigarette smoking may be the most psychologically and sociologically distinctive behavioral risk factor. Although the prevalence of smoking has always been lower in women than in men, smoking prevalence has declined more rapidly in men than in women, and young women are now smoking at greater rates than young men. This narrowing of the gender gap in smoking prevalence is likely to contribute to a substantially greater burden of cardiovascular disease in women.

Physical Activity

Sedentary lifestyle is now recognized as a major risk factor for CAD.[36-38] Even moderately fit women demonstrate significantly lower blood glucose levels, blood pressures, and weight, in addition to better lipid profiles, than women in the lowest-fitness category. Consequently, exercise is a key component of any prevention program.[39-41]

PREVENTION

The American Heart Association (AHA) has released evidence-based guidelines for the prevention of cardiovascular disease in women, which are available on the Internet (http://circ.ahajournals.org/cgi/content/full/109/5/672).[42] To provide interventions tailored to individual patient risk, the guidelines provide a scoring sheet for calculating a woman's 10-year risk of having a coronary event, on the basis of the Framingham Risk Calculator [*see Table 1*]. The Framingham Risk Calculator can be used to assess a patient's 10-year absolute risk of CAD and, on that basis, to categorize her as being at high, intermediate, low, or optimal risk.

Once a patient's risk factors have been assessed and her risk level stratified, interventions can be tailored accordingly. Interventions can be directed toward lifestyle, major risk factors, cardiovascular preventive therapies, or measures to counter atrial fibrillation and prevent stroke, according to the patient's risk level [*see Tables 2 through 4*]

Hormone Replacement Therapy

Much controversy surrounds the role of hormone replacement therapy (HRT) in cardiovascular disease prevention. Although pathophysiologic and epidemiologic data suggest that estrogen replacement has beneficial cardiovascular effects, other data from large, randomized, controlled trials have demonstrated no benefit as well as potential harm from HRT when it is used for the prevention of CAD.[43-54] One arm of the Women's Health Initiative (WHI), a randomized, controlled trial of combined estrogen and progesterone replacement in 16,608 healthy postmenopausal women, was halted early because of an increased risk of breast cancer (hazard ratio [HR], 1.26); cardiovascular events were also increased (HR, 1.29), as was the risk of stroke (HR, 1.41) and pulmonary embolism (HR, 2.13).[43,44] In a meta-analysis of 22 small randomized trials of HRT encompassing 4,124 women, the calculated odds ratio for cardiovascular events in women assigned to hormones versus those not assigned to hormones was 1.39 (95% confidence interval [CI], 0.48–3.95).[45]

The first large-scale clinical trial to examine the cardioprotective effect of estrogen in postmenopausal women with CAD was the Heart and Estrogen/progestin Replacement Study (HERS), a multicenter, randomized, double-blind, placebo-controlled trial in 2,763 postmenopausal women.[46] Over the first year of the study, there was a statistically significant 52% excess risk of CAD events in the HRT group; an additional 6.8 years of follow-up also failed to show any evidence of long-term cardiovascular benefit.[47,48]

In the Estrogen in the Prevention of Reinfarction Trial (ESPRIT), a randomized , controlled trial in 1,017 postmenopausal women with prior MI, 2 years of estrogen treatment did not lower the frequency of reinfarction or cardiac death or reduce all-cause mortality.[49] Similarly, the Estrogen Replacement and Atherosclerosis (ERA) trial, a randomized, controlled trial in 309 postmenopausal women, found that after an average follow-up of 3.2 years, women assigned to HRT showed no significant difference in mean minimal coronary artery diameters, despite significant reductions in LDL levels and increases in HDL levels.[50,51] Finally, in the Women's Angiographic Vitamin and Estrogen (WAVE) trial, a randomized trial in 423 postmenopausal women that assessed estrogen and progesterone with or without vitamins E and C, there was greater progression of coronary atherosclerosis in the treatment groups.[52] Studies investigating the role of estrogen in the secondary prevention of cerebrovascular disease, including the Women's Estrogen for Stroke Trial (WEST), have failed to show benefit.[53]

Because of these trial results, long-term HRT is not recommended for either primary or secondary prevention of CAD. The AHA advises that there are insufficient data to support starting HRT in women who do not have CAD for the sole purpose of preventing CAD; the decision to initiate HRT—or to continue it, if the patient is already receiving it—should be made on the basis of non-CAD benefits and risks, possible CAD benefits and risks, and patient preference.[54,55] Women with CAD should not be started on HRT for the secondary prevention of CAD; if they are already receiving long-term HRT, the decision to continue or stop it should be made on the basis of established non-CAD benefits and risks and patient preference.

DIAGNOSIS OF CAD

The approaches to the diagnosis of CAD are similar in men and women [*see 1:I Approach to the Cardiovascular Patient and 1:IX Chronic Stable Angina*]. Regardless of the patient's gender, diagnosis encompasses a detailed history, a complete physical exami-

Table 2 Lifestyle Interventions for Cardiovascular Disease in Women[42]

Intervention	*Comment*	*Evidence Rating*
Tobacco avoidance	Consistently encourage smoking cessation; encourage nonsmokers not to smoke and to avoid environmental tobacco smoke	Class I, level B
Physical activity	Cumulative ≥ 30 min moderate-intensity physical activity (e.g., brisk walking) on most, and preferably all, days of the week	Class I, level B
Cardiac rehabilitation	Women with a recent acute coronary syndrome or coronary intervention, new-onset or chronic angina should participate in a comprehensive physician-guided or community-based risk-reduction regimen	Class I, level B
Heart-healthy diet	Eat a variety of fruits, vegetables, grains, low-fat or nonfat dairy products, fish, legumes, and sources of protein low in saturated fat (e.g., poultry, lean meats, plant sources); limit saturated fat intake to 10% of calories; limit cholesterol intake to < 300 mg/day; limit intake of *trans*–fatty acids	Class I, level B
Weight maintenance/ reduction	Use appropriate balance of physical activity, caloric intake, and formal behavioral programs when indicated to maintain or achieve a BMI of 18.5–24.9 kg/m^2 and waist circumference < 35 in	Class I, level B
Psychosocial factors	Evaluate women with cardiovascular disease for depression; refer or treat when indicated	Class IIa, level B
Omega-3 fatty acids	Consider dietary supplementation with omega-3 fatty acids in high-risk women	Class IIb, level B
Folic acid	Consider dietary supplementation with folic acid in high-risk women (except after revascularization procedure) who have elevated homocysteine levels	Class IIb, level B

BMI—body mass index

nation, and an electrocardiogram. Once the initial evaluation is performed, laboratory blood tests, stress testing, and cardiac catheterization may be necessary to obtain further diagnostic insight. General recommendations have been published by the American College of Cardiology (ACC), the AHA, and the American College of Physicians (ACP); these are available on the Internet (http://www.annals.org/cgi/content/abstract/141/7/562).[56] An essential point is that because of a lower pretest probability of CAD at any age, tests have lower sensitivity in women.

Clinical Manifestations

Whereas MI and sudden cardiac death are the more common presentations in men with CAD, angina pectoris is the main initial and subsequent presenting symptom of CAD in women. Compared with men, women with angina are more likely to be older and to have hypertension, diabetes, and heart failure. They are less likely than men to have a history of either MI or percutaneous coronary intervention.[57-59]

When women present with symptoms of CAD, they are less likely to have typical or classic symptoms of heart disease and more likely to have atypical symptoms, particularly abdominal, neck, and shoulder pain. Older and diabetic women have a higher frequency of dyspnea and fatigue. Other ischemic symptoms in women are sleep disturbance, indigestion, and anxiety.

Laboratory Testing

Because women at all ages are less likely to have obstructive CAD, the pretest probability of CAD is lower in women with

Table 3 Major Risk Factor Interventions for Cardiovascular Disease in Women[42]

Intervention	*Comment (Evidence Rating)*
Blood pressure normalization	Lifestyle: encourage optimal BP of < 120/80 mm Hg (class I, level B) Drugs: treat when BP ≥ 140/90 mm Hg, or lower in patients with target-organ damage or diabetes; thiazide diuretics should be part of initial regimen in most patients unless contraindicated (class I, level A)
Lipid normalization—nonpharmacologic	Encourage lifestyle approaches to maintain optimal levels: LDL < 100 mg/dl, HDL > 50 mg/dl, triglycerides < 150 mg/dl, non–HDL cholesterol < 130 mg/dl (class I, level B) Diet: in woman at high risk or with elevated LDL, reduce saturated fat intake to < 7% of calories, cholesterol to < 200 mg/day; reduce *trans*-fatty acid intake (class I, level B)
Lipid normalization—pharmacologic	High-risk patients: LDL-lowering therapy—preferably a statin—plus lifestyle therapy in women with LDL ≥ 100 mg/dl (class I, level A); statin therapy in women with LDL < 100 mg/dl, unless contraindicated (class I, level B); niacin or fibrate therapy for women with low HDL or elevated non-HDL (class I, level B) Intermediate-risk patients : LDL-lowering therapy (preferably a statin) if LDL ≥ 130 mg/dl despite lifestyle therapy (class I, level A); niacin or fibrate therapy for women with low HDL or elevated non-HDL after LDL goal reached (class IIa, level B) Low-risk patients: consider LDL-lowering therapy in women with one or no risk factors when LDL ≥ 190 mg/dl or in women with multiple risk factors when LDL ≥ 160 mg/dl (class IIa, level B); consider niacin or fibrate therapy in women with low HDL or elevated non-HDL after LDL goal reached (class IIa, level B)
Diabetes treatment	Use lifestyle and pharmacotherapy to achieve glycosylated hemoglobin < 7% (class I, level B)

BP—blood pressure HDL—high-density lipoprotein cholesterol LDL—low-density lipoprotein cholesterol

Table 4 Preventive Drug Interventions for Cardiovascular Disease in Women[42]

Drug	*Comment (Evidence Rating)*
Aspirin	High-risk patients: 75–162 mg/day, unless contraindicated; clopidogrel in aspirin-intolerant patients (class I, level A) Intermediate-risk patients: consider 75–162 mg/day, if blood pressure is controlled and benefit is likely to outweigh risk of GI side effects (class IIa, level B) Low-risk patients: Routine aspirin use not recommended (class III, level B) Patients with chronic or paroxysmal atrial fibrillation: 325 mg/day, for stroke prevention when warfarin is contraindicated or stroke risk is low (< 1%/yr) (class I, level A)
Beta blockers	Unless contraindicated, should be used indefinitely in all women who have had an MI or who have ischemic syndromes (class I, level A)
ACE inhibitors	Unless contraindicated, should be used in women at high risk (class I, level A)
ARBs	In high-risk women with clinical evidence of heart failure or an LVEF < 40% who are intolerant to ACE inhibitors (class I, level B)
Warfarin	Treatment to INR of 2.0–3.0; for stroke prevention in women with chronic or paroxysmal atrial fibrillation, unless they are considered at low risk for stroke (< 1%/yr) or at high risk for bleeding (class I, level A)

ACE—angiotensin-converting enzyme ARBs—angiotensin receptor blockers GI—gastrointestinal INR—international normalized ratio LVEF—left ventricular ejection fraction MI—myocardial infarction

chest pain presenting for a diagnostic evaluation. Therefore, false positive results with exercise ECGs are more common in women than in men[60-62]; this also means that a negative result on exercise ECG in a woman has high predictive accuracy for the absence of clinically significant CAD.

The use of exercise echocardiography and single-photon emission computed tomography (SPECT) imaging has been promoted in women, but data on the utility of these tests in this setting are limited. In a cross-sectional study of the accuracy of exercise SPECT imaging with thallium-201, the sensitivity of exercise thallium SPECT imaging was lower in women than in men. Specificities were similar in men and women. A systematic review of SPECT versus exercise echocardiography showed that although the sensitivity of exercise SPECT was high (87%), its specificity was low (64%), resulting in a low likelihood ratio (1.9) for both men and women.[63]

Myocardial perfusion imaging improves the diagnostic accuracy of exercise testing; technetium-99m sestamibi SPECT imaging offers particular benefit. Stress echocardiography in women with adequate echocardiographic images displays sensitivity and specificity comparable to those in men. The most cost-effective diagnostic strategy is a sequential approach to testing tailored to patient risk and symptoms.

The most cost-effective diagnostic strategy is a sequential approach to exercise testing that is tailored to the patient's coronary risk factors and symptoms. According to the ACC/AHA practice guidelines for exercise testing, a woman's pretest likelihood for CAD may be crudely defined on the basis of age and the presence and characteristics of symptoms [*see Table 5*]; testing has the largest potential effect on diagnostic outcome in women at intermediate risk.[64] In addition, symptomatic women who have diabetes mellitus or multiple risk factors (i.e., the metabolic syndrome) are at increased risk for CAD and should be considered for testing.

Acute Coronary Syndromes

Although women with acute coronary syndromes (i.e., unstable angina, non–ST segment elevation MI, and ST elevation MI) are more likely to present with nausea and vomiting and indigestion than men, typical symptoms are the strongest predictors of acute coronary syndromes in women [*see I:X Unstable Angina and Non–ST Segment Elevation Myocardial Infarction*]. In the Myocardial Infarction Triage and Intervention Registry, the clinical presentation of MI was indistinguishable by sex, with comparable numbers of women and men having typical and atypical pain presentations.[65] However, in the Worcester Heart Study, more women than men had a history of angina pectoris before their initial MI.[66-70] In addition, women with acute coronary syndromes are more likely to have a higher Killip class, tachycardia, atrioventricular block, and pulmonary rales on presentation; complications such as shock, heart failure, recurrent chest pain, cardiac rupture, and stroke are more common in women.

Time to presentation may differ between men and women. In the first Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Arteries (GUSTO-I) trial, median time from onset of chest pain to admission was longer for women than for men.[71] Initial studies suggested that women were more likely to have unstable angina than to have documented acute MI.[72,73] Women with MI are less likely than men to have ST segment elevation MI. Compared with men with MI, women with MI tend to be older; are more likely to have diabetes and hypertension and to have had heart failure; and are less likely to have had an MI.

TREATMENT

There is currently no evidence that acute coronary syndromes should be treated differently in women than in men, and current therapeutic guidelines do not make recommendations based on gender. A number of randomized, controlled clinical trials of MI therapies—including antiplatelet drugs, beta blockers, calcium channel blockers, fibrinolytic drugs, and ACE inhibitors—confirm comparable reductions in mortality for women and men. Unfortunately, the use of these therapies after acute coronary syndromes is less common in women than in men. For example, in the GUSTO-I study, median time from onset of chest pain to thrombolysis was longer for women than for men. In addition, women are less likely than men to be treated aggressively. They are half as likely to be considered for acute catheterization, angioplasty, thrombolysis, or coronary artery bypass grafting.[71] Women are also less likely to be referred for cardiac rehabilitation after a cardiovascular event. The inequitable application of treatment guidelines may result in poorer outcomes for women.

Table 5 Pretest Probability of Coronary Artery Disease in Women[64]

Age	*Typical or Definite Angina Pectoris*	*Atypical or Probable Angina Pectoris*	*Nonanginal Chest Pain*	*Asymptomatic*
30–39	Intermediate	Very low	Very low	Very low
40–49	Intermediate	Low	Very low	Very low
50–59	Intermediate	Intermediate	Low	Very low
60–69	High	Intermediate	Intermediate	Low
≥ 70	High	Intermediate	Intermediate	Low

PROGNOSIS

Women with ST segment elevation MI have a higher mortality than men of the same age, whereas women with non–ST segment elevation MI have outcomes similar to those of men. Some of the differences in outcome may be explained by differences in disease burden or severity of MI on presentation.

In the second National Registry of Myocardial Infarction (NRMI-2), younger women with MI (< 70 years) had higher death rates during hospitalization than their male counterparts.[13] Only at older age was there gender parity, and in the very oldest age group (over 80 years), women had better outcomes. Whether these mortality differences reflect the contribution of gender per se or of residual confounders and treatment differences remains to be determined.[13,74-77] Certainly, increasing the use of proven standard therapies offers significant potential to improve clinical outcomes and increase survival in women with suspected acute MI.

Race also affects prognosis: African-American women have a higher mortality from CAD than white women. In the United States, the age-adjusted CAD mortality is 25% to 50% higher for African-American women than for white women; in particular, the mortality from MI is twice as high in African-American women.[78]

Heart Failure in Women

EPIDEMIOLOGY

Each year, more than one million women have heart failure in the United States and approximately 100,000 die of this disease. Men and women differ with respect to the risk, causes, and prognosis of heart failure.[79-81] The majority of deaths attributable to heart failure occur in women, even though women with heart failure have a lower risk of death than men.[82]

RISK FACTORS

Risk factors for development of heart failure differ by sex. Hypertension and diabetes mellitus have a greater role in women, with diabetes disproportionately increasing the risk of heart failure in women.[5,83-86] Women may also be more likely to develop heart failure after MI.[84] An excess number of cases of heart failure and pulmonary edema in women after revascularization was reported both in the Coronary Artery Surgery Study (CASS) and in the Bypass Angioplasty Revascularization Investigation (BARI), despite left ventricular ejection fractions (LVEFs) that were equivalent to those or better than those in men.[87,88]

PATHOPHYSIOLOGY

Although chronic heart failure from left ventricular systolic impairment is well characterized, less is known regarding heart failure with preserved left ventricular systolic function. From 30% to 50% of all patients with chronic heart failure have preserved left ventricular systolic function, and most of these patients are women, are elderly, and have hypertension. Patients with chronic heart failure and preserved left ventricular systolic function appear to have pathophysiologic derangements that are similar to, but less severe than, those with impaired systolic function.[89-92]

DIAGNOSIS

Irrespective of gender, heart failure has a wide spectrum of potential clinical presentations. The majority of patients have signs and symptoms of pulmonary congestion, including dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Others do not have congestive symptoms but instead have manifestations of low cardiac output, including fatigue, effort intolerance, cachexia, and renal hypoperfusion. Clinically, the New York Heart Association (NYHA) functional classification can be utilized to assess the severity of functional limitations and correlates well with prognosis in both men and women [*see Table 6*]. In addition, the ACC/AHA have issued guidelines to promote earlier identification of heart failure in patients at risk [*see I:II Heart Failure*].

Clinical Manifestations

Women with heart failure have more symptoms than men with similar LVEFs, are older, and are more likely to have hypertension, diabetes mellitus, and preserved systolic function.[79] Patients with heart failure and intact ventricular systolic function, predominantly women, experience dyspnea and fatigue, exercise intolerance, and resultant impaired life quality.

Laboratory Testing

In general, the evaluation of new-onset heart failure in women is similar to that in men [*see 1:II Heart Failure*].

TREATMENT

Pharmacologic Therapy

Although a significant body of evidence supports the use of angiotensin-converting enzyme (ACE) inhibitors, diuretics, and beta blockers in patients with reduced systolic function, few women were included in these studies, and data regarding the benefits of these therapies in women remain conflicting.

ACE inhibitors Afterload reduction and neurohormonal modulation with ACE inhibitors lower mortality; improve heart failure symptoms, exercise tolerance, and LVEF; and reduce emergency room visits and hospitalizations. In a meta-analysis of gender-stratified data for all seven major studies that assessed the impact of ACE inhibitors on mortality, however, the authors conclude that women with symptomatic left ventricular systolic dysfunction probably benefit from ACE inhibitors but that treatment with ACE

Table 6 New York Heart Association Classification of Heart Failure

NYHA Class	*Comment (Evidence Rating)*
I	No symptom limitation with ordinary physical activity
II	Ordinary physical activity somewhat limited by dyspnea (e.g., long-distance walking, climbing two flights of stairs)
III	Exercise limited by dyspnea at mild work loads (e.g., short-distance walking, climbing one flight of stairs)
IV	Dyspnea at rest or with very little exertion

inhibitors may not reduce mortality in women with asymptomatic left ventricular systolic dysfunction (pooled relative risk, 0.96; 95% confidence interval [CI], 0.75 to 1.22) [*see Figure 2*].[93]

Angiotensin receptor blockers Gender-specific analyses of angiotensin receptor blockers (ARBs) in heart failure have not been performed. In clinical trials, ARBs were superior to placebo but not better than ACE inhibitors in improving mortality. ARBs improve morbidity when given along with ACE inhibitors; they are recommended as second-line therapy in patients who cannot tolerant ACE inhibitors because of cough or angioedema.[94] They should not be substituted for ACE inhibitors in cases of hyperkalemia or renal dysfunction. ARBs may be useful for the treatment of diastolic heart failure.

Beta blockers Three beta blockers—carvedilol, metoprolol succinate, and bisoprolol—have been shown to increase survival in patients with heart failure.[95-99] Metoprolol tartrate has not been approved by the Food and Drug Administration for heart failure and was less effective than carvedilol in preventing sudden death in the Carvedilol Or Metoprolol European Trial.[100]

Although the addition of beta blockers to a treatment regimen of diuretics, ACE inhibitors, and digoxin has been recommended to improve clinical outcomes and decrease mortality and hospitalizations, questions have arisen regarding the benefit in women. However, a meta-analysis of the five major mortality studies of beta-blocker treatment in heart failure showed lower mortality in women (risk ratio in women, 0.63 [95% CI, 0.44 to 0.91]; risk ratio in men, 0.66 [95% CI, 0.59 to 0.75]; HR in women, 0.75 [95% CI, 0.51 to 1.09]; and HR in men, 0.68 [95% CI, 0.51 to 0.89].[93]

Despite gender-related differences in outcomes, current guidelines from the Heart Failure Society of America (HFSA) and the ACC/AHA recommend the use of beta blockers for NYHA classes I through III heart failure, irrespective of gender. Beta blockers are also indicated in NYHA class IV patients who are euvolemic—again, irrespective of gender.

Digoxin HFSA and ACC/AHA guidelines recommend digoxin for patients with left ventricular systolic dysfunction who remain symptomatic despite standard medical therapy, particularly if they are in atrial fibrillation. No distinctions are made for gender. Significant gender differences have been reported in response to digoxin for the management of heart failure, however. In the 6,800-patient Digitalis Investigation Group study, for example, women who were randomized to digoxin had a higher rate of death (33.1%) than women who were randomized to placebo (28.9%). In contrast, men who received digoxin or placebo had similar death rates. In the multivariable analysis, digoxin was associated with significantly higher risk of mortality in women (HR, 1.23; 95% CI, 1.02 to 1.47), but it had no significant effect on mortality in men (P = 0.014; HR, 0.93; 95% CI, 0.85 to 1.02).[101] This study suggests that digoxin therapy is associated with an increased risk of death from any cause in women with heart failure and depressed left ventricular systolic function.

Diuretics and aldosterone antagonists Diuretics and aldosterone antagonists (e.g., spironolactone) in the treatment of heart failure are used similarly in men and women [*see 1:II Heart Failure*].

Heart Failure with Preserved Ventricular Systolic Function

Most large clinical trials of heart failure management strategies have involved patients with a decreased LVEF. Older patients with heart failure, among whom women predominate, are more likely to have preserved ventricular systolic function, a problem not addressed in these major treatment trials.[11,102-104] The few heart failure trials in patients with preserved ventricular systolic function have failed to produce conclusive evidence for optimal pharmacologic management. Because no clinical trial evidence is consistent, the ACC/AHA guidelines recommend a pathophysiologic approach to treatment that consists of measures to control blood pressure and tachycardia, to decrease cen-

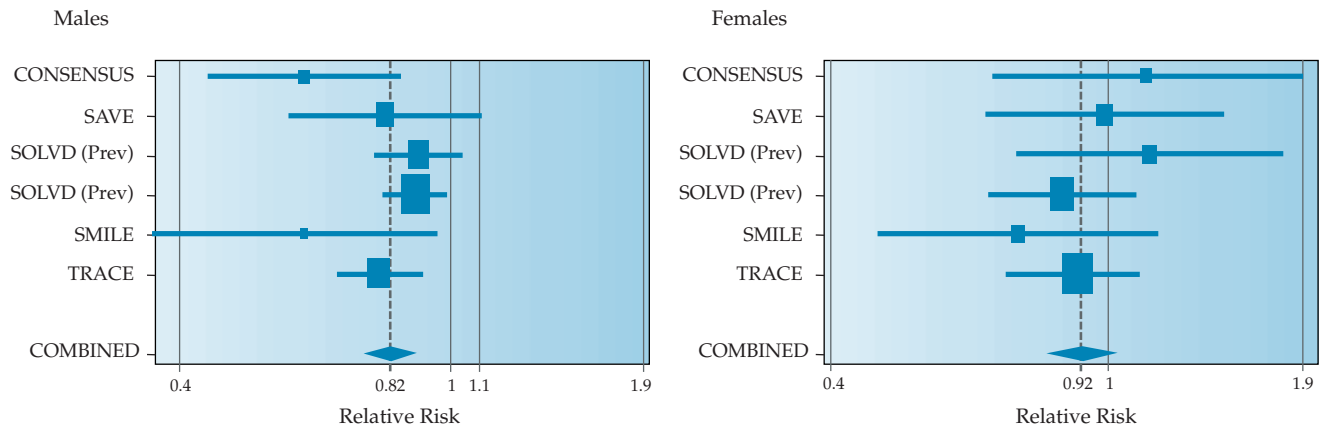

Figure 2 **Efficacy of angiotensin-converting enzyme inhibitors in the management of left ventricular systolic dysfunction according to sex.**[93]

tral blood volume, and to alleviate myocardial ischemia.

PROGNOSIS

Research on gender and heart failure prognosis has shown inconsistent results.[105-109] Epidemiologic data from the Framingham cohort suggest that the prognosis in women is better than that in men.[83] In contrast, Bourassa and colleagues demonstrated a poor prognosis in older women with heart failure.[82]

Differences in survival may reflect differences in etiology.[105,110] An Italian study found that women were more likely than men to have a nonischemic cause of their heart failure, and LVEF was higher in nonischemic women than nonischemic men; the survival advantage in women was in part attributed to better left ventricular function and in part to the primary etiology of heart failure.[111] In a United States study, survival was significantly better in women than in men when heart failure was from nonischemic causes; but when the principal etiology was ischemic heart disease, men and women had similar survival rates.[105]

Pathophysiology also affects prognosis in heart failure. Although mortality is significantly greater in patients with chronic heart failure who have impaired left ventricular systolic function than in those with preserved systolic function, even patients with preserved systolic function—most of whom are women—have a 25% 5-year mortality.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXI MUSCULOSKELETAL PROBLEMS IN THE FEMALE ATHLETE

Carol C. Teitz, m.d.

Musculoskeletal injuries in the female athlete are for the most part similar to those in the male athlete. However, there are differences in the incidence of these injuries and in the sports in which they tend to occur.[1] Stress fractures are more common in the female athlete because of the higher prevalence of eating disorders and subsequent osteopenia in females. In addition, for reasons that are not completely elucidated, the female athlete has a higher rate of noncontact anterior cruciate ligament (ACL) injuries than the male athlete. Finally, as a function of greater participation by females in certain sports, such as dance and gymnastics, injuries specific to those sports are more common in females. This chapter addresses the injuries that are seen commonly in the female athlete.

Stress Fractures

Stress fractures result from an imbalance between bone resorption and formation secondary to repetitive submaximal loads. Extrinsic mechanical causes that can induce this imbalance include duration, frequency, and intensity of load; muscle fatigue; and the shock-absorbing capacity of sports equipment. Intrinsic causes for abnormalities in bone remodeling include the nutritional and hormonal milieu, as well as endocrine disorders that are beyond the scope of this chapter. Disordered eating, amenorrhea, and low bone mineral density—the so-called female athlete triad—can result in osteoporosis in young women.[1] Insufficient caloric intake for the expenditure required for sports is thought to lead to changes in the pulsatile secretion of gonadotropin-releasing hormone and abnormalities in luteinizing hormone, which in turn produce the menstrual irregularities found in some female athletes.[2]

Amenorrhea and oligomenorrhea may cause loss of 2% of bone mass a year, especially when these conditions occur during late adolescence and early adulthood—periods during which peak bone mass is acquired.[3] When amenorrhea is present for more than 3 years, treatment with calcium and estrogen will not reverse this bone loss; nor is there evidence that treatment with oral contraceptives prevents stress fractures.[4] Many studies report increased stress fracture rates in athletes with menstrual irregularities, even when dual-energy x-ray absorptiometry indicates that their bone density lies within the normal range.[4] Epidemiologic studies of stress fractures in athletes and military recruits have shown that these injuries are 1.5 to 4 times more common in females than in males.[5-7] This differential between male and female athletes is especially notable for stress fractures in the pelvis, femoral neck, and metatarsals.

General Treatment Guidelines

Recommending that the patient rest the affected body part—the standard treatment for stress fractures—is insufficient for female athletes. Instead, the physician needs to address any features of the athlete's training habits, nutritional and menstrual status, or equipment that may have contributed to the stress fracture. This will ensure that once the fracture heals, the patient will not be exposed to the same factors that led to the fracture.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are contraindicated in the treatment of pain related to stress fractures, because there is evidence that NSAIDs may interfere with fracture healing.[8,9] When pharmacologic pain control is needed, acetaminophen usually suffices.

A stress fracture is healed when the involved bone is no longer tender to palpation and the patient is able to tolerate either impact on the bone or the use of muscles that place stress on the bone. Progressive return to the desired activity level ensues. For lower-limb fractures, the patient can begin a so-called amphibious rehabilitation program when she can walk without discomfort. In this program, patients begin by jogging in water that is chest high and gradually progress to waist-high water. They then move out of the water and onto land. The decrease in buoyancy provides a gradually increasing load to the bone, giving it a chance to adapt. The next step is sport-specific rehabilitation: the athlete resumes her former training regimen for her sport but starts with a time or distance that is about a third of that at the time of fracture. The mileage or time is then increased at a rate of 10% to 15% a week.

Pubic Ramus Stress Fractures

Pelvic stress fractures make up only 1% to 5% of all stress fractures in all runners, but they are significantly more common in female runners. The most common site is the inferior pubic ramus. In a military population, Hill and colleagues found that 11 of 12 pubic ramus fractures were in female recruits.[10]

Pathophysiology

A crossover running style and overstriding may contribute to the higher incidence of pubic ramus stress fractures in female athletes. The term crossover running refers to adduction of the lower extremity across the line of gait progression. This may occur more commonly in women because of their wider pelves. Overstriding refers to excessive flexion of the lower extremity; it is usually done either to gain speed or to keep up with a taller running partner. Both crossover running and overstriding create repetitive pull by the adductor musculature at its origin on the pubic ramus. Sometimes this pull results in adductor tendinitis; at other times, it results in inferior pubic ramus stress fractures.

Diagnosis

The patient complains of groin or medial thigh pain that increases with activity, especially impact, and is relieved by rest. The physician should ask whether the patient runs with a taller partner. The differential diagnoses of adductor tendinitis, osteitis pubis, and pain originating in the hip joint can be sorted out through careful physical examination and imaging studies.

Physical examination findings Painless range of motion of the hip essentially rules out the hip as the origin of the pain. The key physical findings in pelvic stress fracture include tenderness to palpation of the pubic ramus and difficulty standing on one

leg. Pain with resisted use of the adductor muscles is common but is not helpful for sorting out the other possible diagnoses. Pain during passive adductor stretch is more consistent with tendinitis.

Imaging studies Unless the fracture is very recent, it will appear on an anteroposterior radiograph of the pelvis as a lucent line in the pubic ramus, often surrounded by callus [*see Figure 1*]. When the radiograph is unremarkable but a stress fracture seems likely, the physician should obtain either a bone scan or a magnetic resonance imaging scan. Bone scans are very sensitive, although not specific, and usually suffice to make the diagnosis. MRI can reveal a stress fracture; alternatively, it may show fluid in the adductor tendons or edema on both sides of the symphysis pubis in patients with tendinitis or osteitis pubis, respectively.

Treatment

The patient should stop impact activity, as well as other activities that cause pain. If walking is painful, then crutches should be prescribed for a few weeks, or until the patient can walk without pain. Swimming is often well tolerated as long as the patient avoids the whip kick, which uses the adductor muscles. Bicycling may not be tolerated, because despite the lack of impact, the bicycle seat often presses right on the area of the fracture, creating discomfort.

Pubic ramus stress fractures may take from 2 to 5 months to heal. Surgical treatment is not indicated.

FEMORAL NECK STRESS FRACTURES

Femoral neck stress fracture is relatively uncommon, accounting for less than 10% of all stress fractures,[7] but it is two to four times more common in women than in men.[6,11] Moreover, this fracture typically does not occur in the recreational or novice athlete but rather in athletes who participate in high-level training six or more times a week and who have been involved in regular training for more than 2 years.[6] If the diagnosis is missed, a femoral neck stress fracture may progress to complete fracture, with potentially devastating consequences.

Pathophysiology

In epidemiologic studies, femoral neck stress fractures have been associated with overuse and with demineralization. Weak hip musculature and a discrepancy in leg length of greater than 0.5 in. may contribute as well.

Diagnosis

Patients with a femoral neck stress fracture complain of groin or thigh pain, often referred to the medial knee (via the obturator nerve). The pain increases with weight bearing or impact activity.

Physical examination findings Tenderness to palpation of the femoral neck is rare because of the thickness of the soft tissues in this area. Passive log-rolling of the lower limb may produce pain. If not, active straight-leg raising and passive movement of the hip to its maximal range of motion should be performed; these maneuvers will produce pain in patients with a femoral neck stress fracture. Standing on only the affected limb often produces pain. The Trendelenburg sign is sometimes positive. When none of these findings are present, the examiner should check patellar tendon reflexes, quadriceps muscle strength, and ankle dorsiflexion strength to assess L3 and L4 nerve root function. Strength testing of the hip flexor muscles can yield confusing results in this setting because weakness may be from inhibition by pain rather than a neurologic deficit.

Imaging studies In two thirds of the cases of femoral neck stress fractures, the fracture does not appear on radiographs.[12] Bone scans are so sensitive (93% to 100%) that increased uptake is commonly seen in military recruits whose fractures are asymptomatic. MRI is accurate (100% with MRI, as compared with 68% with bone scan), sensitive, and specific.[12] If an intrapelvic lesion seems possible, the radiologist can be asked to include the pelvis in the hip MRI, or vice versa.

Differential Diagnosis

The differential diagnosis for groin or anterior thigh pain includes adductor tendinitis, osteitis pubis, and pubic ramus stress fracture (see above). In addition, pressure on either the obturator nerve or the femoral nerve from an intrapelvic mass, as well as disk disease at the L2-L4 levels, can produce pain in the same distribution.

Treatment

The treatment depends on the location of the stress fracture in the femoral neck. The superolateral aspect of the neck is under tension; consequently, patients with fractures at this site are at increased risk for complete fracture and displacement. The inferomedial aspect of the neck is under compression; for that reason, complete fracture is less likely. Therefore, medial femoral neck stress fractures are usually treated by the avoidance of weight bearing on the involved limb until the patient is pain free. This may take months. Follow-up radiographs should be obtained monthly, or sooner if symptoms change. Swimming and cycling are not allowed because of the forces across the hip joint induced by the musculature. Patients with medial femoral neck stress fractures should be referred to an orthopedic surgeon if they show no improvement in symptoms after

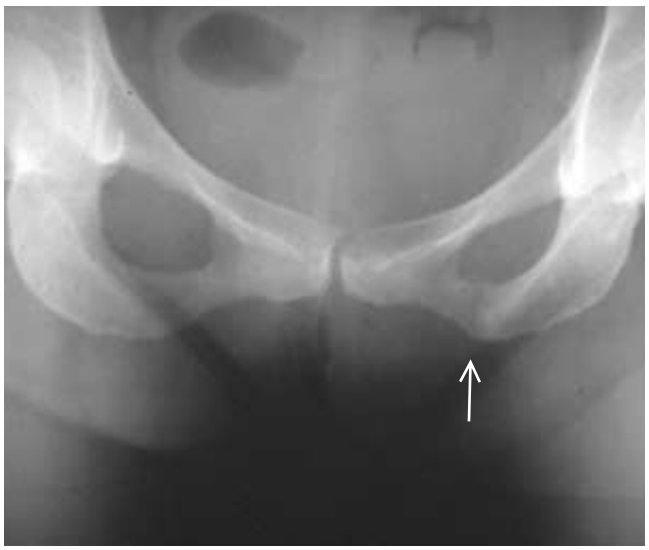

Figure 1 **In a patient with a stress fracture of the inferior pubic ramus, the fracture will appear on an anteroposterior radiograph of the pelvis as a lucent line in the pubic ramus (arrow), often surrounded by callus.**

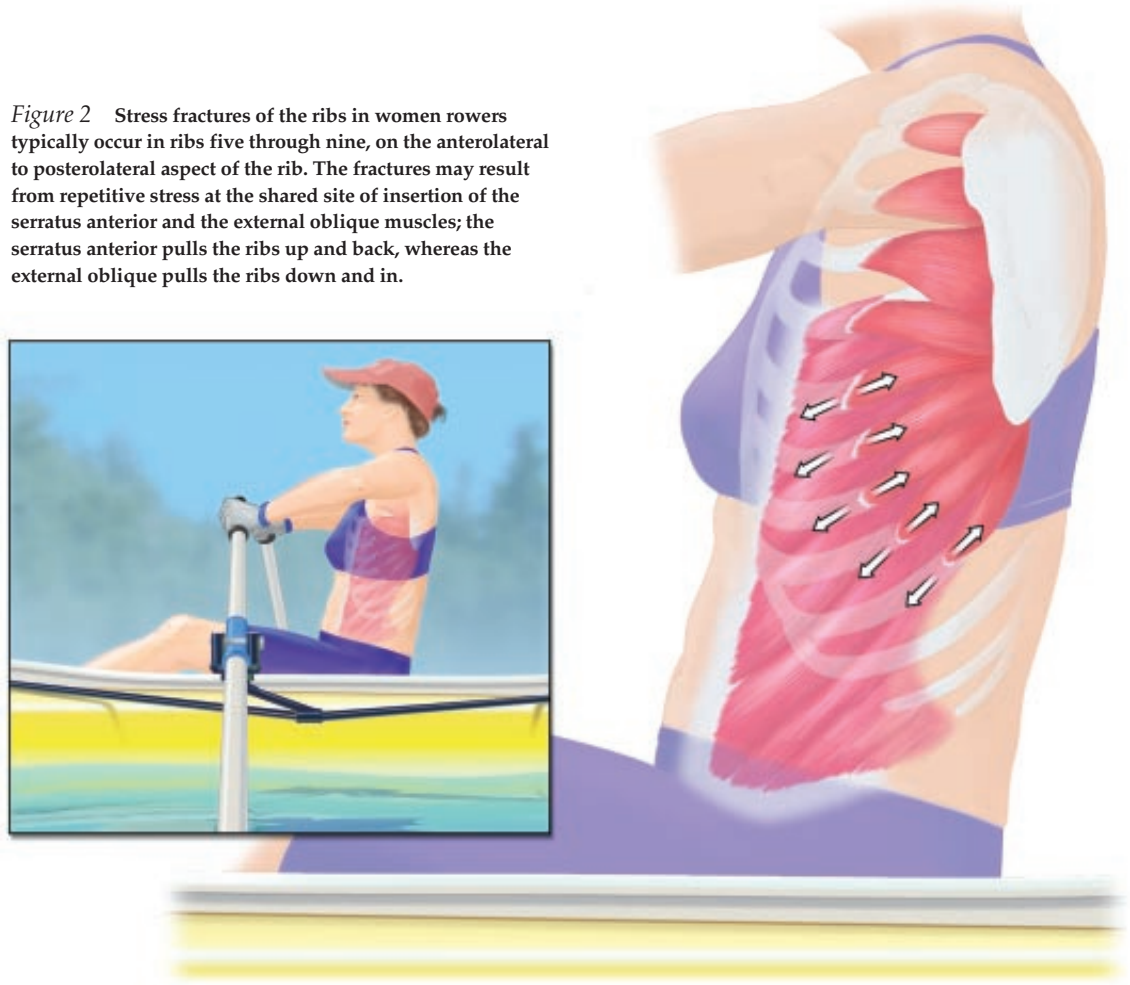

Figure 2 **Stress fractures of the ribs in women rowers typically occur in ribs five through nine, on the anterolateral to posterolateral aspect of the rib. The fractures may result from repetitive stress at the shared site of insertion of the serratus anterior and the external oblique muscles; the serratus anterior pulls the ribs up and back, whereas the external oblique pulls the ribs down and in.**

3 months or if follow-up radiographs show propagation of a fracture line.

Lateral femoral neck stress fractures are usually treated with internal fixation and thus require immediate referral to an orthopedic surgeon. Although internal fixation is debated, no prospective studies have compared operative and nonoperative treatment of the lateral femoral neck stress fracture because of the fear that nonoperative care will result in complete fracture, with its risk of subsequent avascular necrosis, malunion, or nonunion.[12]

RIB STRESS FRACTURES IN ROWERS

Rib stress fractures account for 7.4% of all injuries in the female rower. These fractures typically occur in ribs five through nine, on the anterolateral to posterolateral aspect of the rib.[13]

Pathophysiology

Ribs five through nine share the insertion of the serratus anterior and the external oblique muscles; the serratus anterior pulls the ribs up and back, whereas the external oblique pulls the ribs down and in [*see Figure 2*]. Holden and Jackson attribute these fractures to repetitive stress on the ribs from the pull of these muscles.[14]

Diagnosis

Clinical manifestations Rowers with rib stress fractures present with chest or thoracic back pain that increases during rowing or weight lifting. Coughing also produces pain.

Physical examination findings Patients have tenderness to palpation on the affected rib, usually between the anterior and posterior axillary lines. Compression of the rib cage in an anterior to posterior direction and from side to side increases pain in patients with rib fractures, because these maneuvers produce bending stress on the rib cage. This finding holds even when the compression is applied away from the tender rib. When the problem is muscular, rib-cage compression does not usually produce pain. Muscle and rib injures cannot be differentiated on the basis of resisted muscle use.

Imaging studies The diagnosis of rib stress fractures is confirmed by bone scan.

Differential Diagnosis

The differential diagnosis of rib stress fracture includes muscle strain involving the serratus anterior, pectoralis, or inferior trapezius. Pulmonary or cardiac problems must also be excluded.

Treatment

The athlete should stop rowing. If coughing produces significant pain, a rib belt can be prescribed. While waiting for the fracture to heal, the athlete may do core strengthening and scapular stabilization exercises, omitting the serratus anterior. Once the rib is nontender, serratus strengthening exercises should be

added, with gradual return to rowing. Surgical treatment is not indicated for this fracture.

Multidirectional Shoulder Instability

Shoulder problems are especially prevalent in athletes who engage in swimming, racquet sports, and softball. These sports involve frequent overhead use of the arm, which, in the presence of instability, can cause secondary impingement under the acromion. Shoulder problems are also common in gymnasts, who use the shoulder as a weight-bearing joint.[15] Acquired laxity has been noted in gymnasts, weight lifters, and swimmers who use the butterfly stroke or the backstroke. Laxity, however, is not synonymous with instability; the term instability refers to symptomatic laxity.[16]

Shoulder instability can result from acute trauma or repetitive microtrauma; it may also be atraumatic and multidirectional. Traumatic shoulder instability is more common in males, whereas multidirectional instability is believed to be more common in females, although the literature in this regard is controversial.[16] Generalized ligamentous laxity, which may play a role in shoulder instability, has been noted in numerous studies of multidirectional instability. McFarland and colleagues observed that in 178 asymptomatic high school and college athletes, the shoulder could be subluxated posteriorly in 65% of females compared with 51% of males; generalized laxity was also significantly more common in the female athletes.[17]

PATHOPHYSIOLOGY

Shoulders with multidirectional instability have large inferior capsular pouches that extend both anteriorly and posteriorly. Often, the tissue in the rotator interval between the supraspinatus and subscapularis tendons is attenuated.[15] Some authors have theorized that proprioception is abnormal in these patients, or that weak rotator cuff muscles fail to generate an adequate compressive force against an intact labrum. This type of muscular force is especially important for stabilizing a lax shoulder.[15]

DIAGNOSIS

Clinical Manifestations

Patients with multidirectional shoulder instability often present with pain rather than dislocations. The pain occurs during activities of daily living while the shoulder is in the middle of its range of motion, rather than in the extreme ranges normally associated with traumatic dislocations. The pain is aggravated by overhead use of the arm. Subluxations and dislocations may occur during low-demand activities such as carrying objects with the arm at the side. In extreme cases, the patient is able to voluntarily subluxate or dislocate the glenohumeral joint, as well as reduce it spontaneously.

When a patient presents with pain rather than instability, the differential diagnosis is broad and can include stress fractures, rotator cuff injuries, and tumors, in addition to referred pain from the cervical nerve roots or heart.

Physical Examination Findings

Diagnostic criteria for multidirectional shoulder instability include the demonstration of subluxation in multiple directions in a patient with a history of midrange symptoms.[15] Frequently, the contralateral shoulder is also lax but not symptomatic. The examination should start with an evaluation of the entire kinetic chain, looking for spinal postural abnormalities, hip weakness, and scapular dyskinesia. The one-legged–instability screening test can be informative.[18]

Figure 3 **In a patient with multidirectional shoulder instability, pulling down on the arm at the side may produce inferior translation of the humeral head, as demonstrated by an indentation or dimple beneath the acromion (sulcus sign).**

On examination of the shoulder girdle, the distance between the scapula and the thoracic spine should be symmetrical bilaterally. During range of motion of the arm, the scapula should rotate laterally as the arm elevates. The scapula should not wing away from the thorax. The rotator cuff muscles should be tested with and without scapular retraction. If muscle strength improves with scapular retraction, the functional weakness is more likely from poor scapular stabilization, rather than cuff weakness per se.

Pulling down on the arm at the side may produce inferior translation of the humeral head, as demonstrated by an indentation or dimple beneath the acromion (sulcus sign) [*see Figure 3*]. This test is positive when the inferior translation exceeds 1 to 2 cm; it reflects insufficiency of the superior glenohumeral ligament and capsular rotator interval. The same finding when the arm is tested while abducted 90° reflects attenuation in the inferior capsule.

The degree of instability can be further assessed with the so-called load-and-shift test. With the patient in the supine or lateral decubitus position, the examiner uses one hand to apply an axial load, pushing upward on the arm to force it into the socket, and uses the other hand to shift the patient's arm posteriorly or anteriorly.[15] The glenohumeral joint may dislocate or subluxate in more than one direction (e.g., inferiorly, posteriorly, or anteriorly), with the patient experiencing symptoms in one or more directions.

Imaging Studies

Shoulder radiographs are normal in patients with multidirectional instability. Nevertheless, radiographs are recommended because they may demonstrate Bankart or Hill-Sachs lesions and glenoid dysplasia, which can also cause shoulder instability.

TREATMENT

Operative treatment is not as successful for atraumatic shoulder instability (with or without impingement) as it is for trau-

matic instability. Consequently, surgery should not be the first choice of treatment. Burkhead and Rockwood found that 88% of patients with multidirectional shoulder instability had good or excellent results when treated with specific exercises to increase muscle strength and neuromotor coordination; these exercises are designed to stabilize the scapula and the humeral head in the glenoid fossa.[19] Overhead activities are restricted in the initial phases of rehabilitation. Rotator cuff strengthening alone is not sufficient to stabilize the humeral head. If the scapula fails to rotate normally during arm motion, then the glenohumeral relationship is disturbed and the humeral head is more likely to slide off the glenoid. The hip and trunk often begin the kinetic chain of many upper limb activities and also bear the proximal attachment of many shoulder muscles (e.g., the latissimus dorsi and pectoral muscles). Therefore, strengthening starts with the core muscles, followed by the scapular-stabilizing muscles, and finally the rotator cuff muscles. The scapular stabilizers include the serratus anterior, the latissimus dorsi, the lower trapezius, and the rhomboids. Kibler and Livingston recommend that these exercises first be done in closed kinetic chain fashion (i.e., with the distal limb fixed, or at least touching something; for example, closed kinetic chain exercises of the upper limb are typically done with the hands against a wall).[18] Ultimately, athletic activities require a combination of open and closed kinetic chain muscle function, and both should be addressed in the rehabilitation program. A patient who has failed to recover after 6 months of a good, supervised exercise program should be referred to an orthopedic surgeon for consideration of operative treatment.

Low Back Pain

When evaluating a female athlete with low back pain, the physician should not forget that pain in this area can be referred from the uterus. In addition, the female athlete, particularly in adolescence, has a higher prevalence of spondylolysis, a stress fracture through the pars interarticularis of the posterior elements of a vertebral body. This fracture occurs developmentally in 4% to 5% of the white population and has a familial association. Its prevalence, however, is significantly higher in athletes who hyperextend their spines, such as gymnasts (32%), dancers (12% to 15%), divers (63%), and football linemen.[20] Unlike stress fractures, spondylolysis has not been associated with bone mineral density abnormalities.

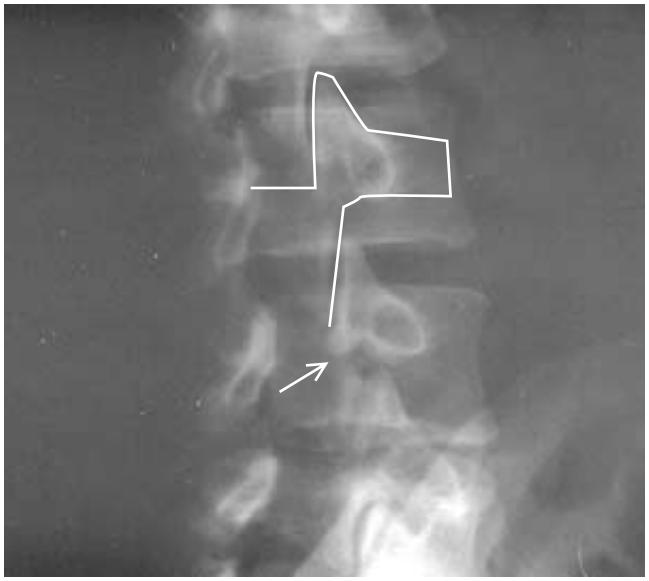

Figure 4 **Spondylolysis may be evident on radiographs, particularly oblique views of the lumbar spine, as the so-called Scottie dog sign. In this radiograph, the Scottie dog is outlined on the normal vertebra above the affected one. Spondylolysis produces the appearance of a collar on the dog (arrow).**

DIAGNOSIS

Clinical Manifestations

The patient presents with low back pain that is made worse by extension or hyperextension of the spine. Sciatica, weakness, and numbness are rare, although the athlete may note decreasing hamstring flexibility. The pain is not exacerbated by Valsalva maneuvers.

Physical Examination Findings

Excessive lumbar lordosis is common. The examiner may find spinal muscle spasm and tenderness to palpation just lateral to the midline of L4, L5, or S1. Pain increases with hyperextension of the spine or leg (i.e., the arabesque position in ballet). When the athlete is asked to stand on one leg and lean back, pain may be produced on the affected side. The straight-leg raising maneuver does not produce pain. Spondylolysis can be differentiated from a spinous process fracture by the fact that in the latter injury, the tenderness will be in the midline on the involved bone rather than lateral.

Imaging Studies

Radiographs, particularly oblique views of the lumbar spine, may show a spondylolysis as the so-called Scottie dog sign [*see Figure 4*]. However, radiographs are often unremarkable in patients with new stress fractures, and these views involve a relatively high dose of radiation. Therefore, bone scans, single-photon emission computed tomographic scans, or MRI scans are recommended.[20] CT can be used later to demonstrate healing. Associated findings in familial spondylolysis include scoliosis, spina bifida occulta, and transitional vertebrae.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for low back pain that is exacerbated by extension includes injuries or arthritis of the facet joints, fracture of a spinous process, or erector spinae muscle strain.

TREATMENT

Although there is controversy regarding whether spondylolysis can heal, Micheli has demonstrated that antilordotic bracing is effective in the nonfamilial type seen in athletes—especially when the fracture is acute, is "hot" on bone scan, or shows edema and stress reaction on MRI.[20] All athletes with nonfamilial spondylolysis are advised to temporarily refrain from hyperextension activities and to participate in core strengthening exercises. When the spondylolysis is visible radiographically as a fracture line and bracing is used, the athlete probably should not return to activities that involve hyperextension until the fracture line has healed. When a scan shows that the fracture is inactive (i.e., chronic), the athlete may return to full activity when the pain has resolved. Surgery is recommended only when bilateral spondylolysis is present and has progressed to significant spondylolisthesis.[20] Surgical referral is indicated when symptoms have not improved after 6 to 8 weeks of treatment, when

any neurologic abnormalities are noted, or when spondylolisthesis is seen on radiographs.

Anterior Cruciate Ligament Tears

Noncontact ACL tears are two to eight times more common in females than in males. Since 1995, when this increased prevalence was first noted, research has focused on possible etiologic contributing factors and the effectiveness of prevention programs.[21]

PATHOPHYSIOLOGY

Investigators agree that there is no one identifiable cause of the increased incidence of ACL injuries in female athletes and that hormonal, anatomic, and proprioceptive factors may play a role. Studies on hormonal influences are inconclusive. Investigators have found estrogen receptors in the ACL and have reviewed ligamentous laxity, collagen synthesis, and ACL injuries in varying phases of the menstrual cycle. Human studies of the role of hormones in ACL injuries in female athletes have been limited by a failure to determine serum hormone levels in the athletes. Menstrual diaries, urinary hormone levels, and serum estrogen levels alone have been used as markers of the menstrual cycle phase. In addition, the variability in menstrual cycle characteristics makes correlation with injury difficult. A significant limitation of animal models is the difference between estrous and menstrual cycles. Finally, ligamentous laxity may not be directly related to injury risk. Moreover, if hormones do play a role in ACL injury, it may be primary or secondary: hormones could have a direct effect on collagenous tissue, or they could cause neuromuscular changes that in turn affect proprioception, balance, or agility.

Studies of anatomic factors that compared the size of the ACL and the size of the femoral intercondylar notch (home of the ACL) in males and females have yielded inconclusive results. However, a study at West Point found that a combination of increased body mass, generalized joint laxity, and decreased intercondylar notch width significantly increased the risk of ACL injury.[21]

Proprioceptive factors have garnered significant attention, in part because they are the most easily modified etiologic factors. A number of multicenter analyses of athletes videotaped while tearing their ACLs noted that the "position of no return" included apparent knee valgus, tibial rotation, and a relatively straight knee and hip.[22] Laboratory studies have shown that compared with males, females have less knee and hip flexion, increased knee valgus and internal rotation of the hip, and higher quadriceps muscle activity while cutting, pivoting, or landing after jumps.[23]

DIAGNOSIS

Clinical Manifestations

Athletes usually sustain a noncontact ACL injury while in the process of sudden deceleration or directional change. The athlete often feels or hears a pop, falls, and is unable to continue playing. Although athletes often sense that their knee was hyperextended at the time of injury, this has not been documented on video. The knee swells within the first 12 hours after injury, because of hemarthrosis; swelling that develops after that time is likely a synovial effusion. Two large studies have shown that when a knee hemarthrosis is present, even in the absence of demonstrable instability on physical examination, 72% to 80% of patients will have a torn ACL.[24,25]

Physical Examination Findings

In a patient with a torn ACL, the knee is swollen, the range of motion is limited, and motion is painful. Aspiration of the knee joint yields gross blood. An ACL tear that occurs without rupture of the surrounding synovial membrane can present without a hemarthrosis, but this injury is uncommon. The Lachmann test is usually, but not invariably, positive. Joint-line tenderness suggests meniscal tears or bone bruises, which are commonly found in association with ACL tears. Tenderness along the medial retinaculum and apprehension when the examiner pushes the patella laterally suggest a patellar dislocation rather than an ACL tear.

Imaging Studies

MRI is usually definitive in the diagnosis of ACL tears. Although tears most commonly occur "midsubstance," the ACL can avulse from the femoral origin; in children, the ACL can avulse off the tibial insertion. MRI will demonstrate any associated injuries. Finally, MRI will detect other conditions in the differential diagnosis of ACL tears, which includes patellar dislocation and intra-articular fractures.

Treatment

A patient with an ACL tear should be referred to an orthopedic surgeon to discuss therapeutic options. The treatment goal is to provide a stable knee and prevent episodes of instability that are likely to result in a tear of the meniscus or lead to osteoarthritis (OA). ACL reconstruction is recommended, especially in athletes younger than 50 years. Previous studies suggested that patients who experience instability only while engaging in pivoting sports could get by with a brace. However, more patients have opted for reconstruction since ACL reconstruction became an outpatient arthroscopic procedure. Subsequent studies have found that the incidence of OA does not seem to have changed despite reconstruction and early motion postoperatively.[26] Therefore, current avenues of inquiry are whether the OA in these patients results from articular damage at the time of ACL tears, the biochemical environment, or continued athletic activities.[26,27]

PREVENTION

Current prevention programs are resulting in a decreased incidence of ACL injuries.[22] However, these programs are still being studied to determine which components are the most important, the best time to institute such a program, how long the program should last, and which athletes are at risk and thus would benefit the most from such training.

Neuromuscular training is the mainstay of these prevention programs and includes one or more of the following: stretching and strengthening exercises; aerobic, agility, kinesthetic, and plyometric exercises; and risk-awareness education. Strength training and endurance training focus on hip abductor and external rotator muscles. Agility and skill drills emphasize rapid directional changes and therefore stimulate maximum cocontractions of agonist-antagonist muscle pairs to increase stiffness and reduce the number of unanticipated joint movements. Agility drills also improve reflex and cortical response time. Kinesthetic training emphasizes keeping the center of gravity forward and the athlete on her toes. Plyometric training decreases the time to peak torque and increases dynamic joint stability by decreasing landing forces and varus/valgus moments through increased muscle activation.[22]

Patellofemoral Pain

The term patellofemoral pain is used synonymously with anterior knee pain. It has replaced the term chondromalacia patellae because arthroscopic surgery in patients with anterior knee pain has shown no consistent correlation of articular cartilage damage with symptoms.[28]

Patellofemoral pain in the absence of trauma is quite common in women and occurs independently of pain from patellar instability, dislocation, or subluxation—all of which may well be associated with actual morphologic changes in the patellar articular cartilage. The differential diagnosis of anterior knee pain in the absence of trauma includes quadriceps or patellar tendinitis and, rarely, patellar stress fracture. Anterior knee pain can also be a manifestation of chronic regional pain syndrome, which is beyond the scope of this chapter.

PATHOPHYSIOLOGY

Although the pathophysiology of atraumatic patellofemoral pain remains incompletely defined, many factors have been shown to be associated with this type of knee pain. Modification of these factors leads to resolution or lessening of the symptom complex. Theories have centered around subtle abnormalities of patellar tracking related to misalignment of bone, the transmission of aberrant forces from the foot, or imbalance of the musculature controlling knee motion. Because bony alignment is not easily changed, this chapter focuses on soft-tissue factors that may contribute to the clinical problem and that are modifiable.

The lower limb kinetic chain includes the hip, the knee, and the ankle/foot. Aberrations in one area can affect normal mobility and function in another. The patella lies within the quadriceps muscle-tendon complex. Because of the way in which the patellar tendon attaches to the tibial tubercle, as well as the way in which the tibia rotates in response to pronation or supination of the foot, some theorize that excessive subtalar joint motion can produce abnormal patellar angular or rotational movement. At the other end of the kinetic chain, chronic excessive lumbar lordosis can result in a tightening of the hip flexor muscles, including the rectus femoris component of the quadriceps. This tightness, in turn, creates greater compressive patellofemoral forces. Hip stability may also influence the stability of the patella. When hip abductors and external rotator muscles are weak, the knee is more likely to go into a valgus position during weight bearing.[22] A valgus knee tends to cause the patella to move laterally in the trochlea. Finally, muscle balance also influences the movement of the patella in the trochlea. The retinacular attachments to the medial patella of the vastus medialis obliquus component of the quadriceps tendon can be thought of as resisting the pull of the iliotibial band fibers that attach to the lateral aspect of the patella.

DIAGNOSIS

Clinical Manifestations

The patient with patellofemoral pain complains of diffuse pain in the anterior knee. The pain is worse when the patient spends much of the day standing; goes up, and especially down, stairs; walks or hikes down hills; or has to sit with her knees flexed at an angle of 90° or greater (the so-called theater sign). Not uncommonly, when these patients go to the movies, they choose seats at the end of a row so that they can extend the affected leg into the aisle. There may or may not be a history of the knee swelling, clicking, catching, or popping, especially during the performance of deep knee bends. Tendinitis is not usually aggravated by standing or sitting but is made worse by jumping, kicking, or, in adolescents, rapid growth spurts.

Physical Examination Findings

Although the history of a patient with patellofemoral pain should raise the prospect of this diagnosis and therefore focus the physical examination, screening the patient for signs of meniscal and ligament problems of the knee is worthwhile. Any condition causing knee pain or effusion can lead to reflex quadriceps muscle inhibition and atrophy, with resulting changes in patellofemoral mechanics. Therefore, patellofemoral pain can be secondary, in which case the primary problem should be addressed first.

Assessment of the biomechanical factors associated with patellofemoral pain is as follows:

- With the patient standing, the examiner looks for signs of hip flexor tightness, such as increased lordosis or forward-leaning trunk. The orientation of the patellae is observed to determine whether they are facing straight ahead or appear "cross-eyed" (femoral anteversion) or "wall-eyed" (femoral retroversion). The structure of the foot is observed for high arch or flat foot. Finally, the patient attempts a minisquat (i.e., a squat to 20° of knee flexion) on one leg. Angular or rotational movement of the knee or shifting of the trunk during the single-legged minisquat implies weakness of the hip abductor and external rotator muscles.
- With the patient seated, the examiner observes patellar tracking during active knee extension. The patella usually moves laterally just as the knee "screws home" to a fully extended position. If the patella moves medially or the lateral motion begins earlier, abnormal kinetics are present. The knee is palpated for crepitus during active flexion and extension. Coarse crepitus does not correlate with anatomic findings unless the clunking or clicking sensation is persistent and is present at a specific point in the range of motion, in which case it may represent a horizontal plica in the knee or an articular surface irregularity on the back of the patella or on the trochlea. More often, however, the clicks will come and go. Fine crepitus (like sand in the joint) usually implies synovitis. Tenderness to palpation of the patellar or quadriceps tendon is more consistent with tendinitis. Pain produced when the patient extends her knee against the examiner's manual resistance is not useful as a differential finding. However, the absence of this pain is inconsistent with tendinitis.
- With the patient supine, the examiner looks for effusions about the knee. Effusions are uncommon, and their presence implies arthritis or meniscal damage. The patella should be passively mobile—laterally and medially as well as proximally and distally. In the absence of arthritis, restricted motion implies tightness of the retinacular tissues attached to the patella.
- With the patient prone, the examiner measures the range of motion of the hips in internal and external rotation. The range differs between the prone and supine positions because hip flexion and abduction are eliminated when the patient is prone. When internal rotation exceeds external rotation by more than 15°, the patient has femoral anteversion. The converse holds for femoral retroversion. The thigh-foot axis is then measured to assess tibial torsion. Tightness of the quadriceps muscle is checked by gently flexing the knee

to the point of resistance and measuring the distance between the heel and the buttock. This should be no greater than 2 inches. If the buttocks lift, a flexion contracture of the hip is present. If this maneuver produces pain, tendinitis is likely.

- With the patient lying on the unaffected side, the examiner performs an Ober test: The unaffected hip and knee are flexed sufficiently to eliminate lumbar lordosis, and the examiner holds the affected extremity with the knee flexed. The examiner's other hand stabilizes the patient's pelvis. The affected limb is then flexed, abducted, hyperextended, and finally adducted at the hip. If the iliotibial band is tight, the limb cannot be adducted back down to the examining table or opposite limb but will remain passively abducted; in such patients, typically, the distance from the underside of the knee to the surface of the examination table will exceed 2 inches.

Finally, examination of a runner's shoes may reveal abnormal wear, reflecting abnormal dynamic biomechanics that are not apparent during static examination.

Imaging Studies

Imaging studies are not necessary initially in a patient with atraumatic patellofemoral pain. However, if initial treatment is not successful, obtaining radiographic Merchant views (also known as sunrise, sunset, and axial views) of the patellofemoral joint may demonstrate gross misalignment of the patellae in the trochlear groove; narrowing of the patellofemoral joint space; or osteophytes, reflecting patellofemoral arthritis.

TREATMENT

Treatment of patellofemoral pain is tailored to the physical examination findings. A patient who is unstable in the single-legged squat position should undertake exercises to strengthen the hip abductors and external rotators. Patients with excessive lumbar lordosis are given pelvic tilt, core, and gluteal muscle strengthening exercises, as well as hip flexor stretching exercises. Patients with abnormal patellar tracking, a tight iliotibial band, or tight quadriceps muscles should be prescribed stretching exercises. Myofascial release by a physical therapist also may be of use. When excessive pronation or supination is present (either statically or dynamically), orthotic arch supports (over-the-counter or custom) may be beneficial. Bracing, straps, and patellar taping also change patellofemoral compression forces and may relieve pain.[29] Quadriceps muscle strengthening specifically directed at the vastus medialis obliquus is useful and is best done in a closed kinetic chain fashion.[30] Patients should avoid full arc extension exercises and deep squats, both of which markedly increase patellofemoral forces. Finally, if the patient is unable to do quadriceps muscle strengthening exercises because of pain, treatment can start with electrical muscle stimulation.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXII FEMALE SEXUALITY: ASSESSING SATISFACTION AND ADDRESSING PROBLEMS

Jennifer Potter, m.d.

Historically, little attention has been devoted to studying female sexual function and dysfunction. A number of factors have contributed to this neglect. Gender bias remains strong.[1] Cultural proscriptions, such as those regarding premarital intercourse, tend to be much more stringent for women. Women's sexual pleasure is often valued less (exemplified in the common statement, "My husband's needs come first") or not at all (demonstrated in its most extreme form by female circumcision, in which sensitive vulvar structures are surgically removed).[2] Evaluation of sexual difficulties in women emphasized psychological origins, whereas biologic factors were relatively ignored.

Scientific investigation of female sexuality has been hampered by numerous methodological challenges. Arriving at a precise definition of female sexual dysfunction, for example, has proved difficult because sexual difficulties reported by women are not discrete, tending to occur together. Specific diagnostic criteria, such as duration of symptoms and degree of distress, continue to be debated. Sexual response is more difficult to evaluate objectively in women than in men, and until recently, few reliable animal models existed.

For all of these reasons, funding to support research on female sexuality has been suboptimal. Nevertheless, knowledge about female sexuality has expanded rapidly during the past decade. Although further study is needed to throroughly address remaining questions and controversies, there are now sufficient data to guide rational evaluation of women who present with sexual concerns.

As in men, sexual problems in women impact quality of life, general functioning, and adaptation to illness. Levels of distress associated with sexual dysfunction range from mild unhappiness, frustration, or a sense of sexual inadequacy to a more pervasive loss of self-esteem that can have profound effects on intimate relationships, as well as functioning in other social and occupational realms.[3] Sexual complaints can be important clues to the presence of an underlying illness, such as depression. Sexual side effects of medications are common and may result in lack of compliance if they are not adequately addressed. For these reasons, it is imperative for clinicians to become adept at addressing patients' sexual concerns. However, many practitioners lack formal training in this area and thus are unsure of what questions to ask and what to do when a sexual problem is identified. This chapter provides a practical approach to the evaluation and management of sexual dysfunction in women.

Epidemiology

In the Pfizer Global Study of Sexual Attitudes and Behaviors, a survey of over 27,500 persons in 29 countries, 63% of women (and 83% of men) 40 to 80 years of age described sex as extremely, very, or moderately important.[4] It is reasonable to assume that younger men and women find sex to be equally if not more important.

Large population-based studies in several countries have examined the prevalence of sexual difficulties in women and men. In all of the studies, a higher percentage of female respondents than male respondents reported experiencing sexual difficulties: 43% versus 31% in the United States,[5] 54% versus 35% in the United Kingdom,[6] 30% versus 27% in Sweden,[7] and 71% versus 46% in Australia.[8] The wide variation in these numbers may reflect differences in the specific questions that were asked, the time intervals that were studied, the demographics of the study populations, and whether or not unpartnered persons were included. The numbers may be inflated in that not all persons who report having sexual difficulties consider themselves to have a sexual dysfunction: only one third to one half of women who report having decreased sexual desire or response believe they have a problem or feel distress for which they would like help.[9] However, even when personal distress and the desire for intervention are factored in, the prevalence of sexual problems in women remains high (10% to 35% of women in these studies).

Some, but not all, studies of sexual function report an association between older age and lower desire; however, when the relationship between low interest and distress over sexual difficulties is taken into account, the age factor largely disappears.[9] Although menopause can be associated with decreased lubrication, vaginal dryness, and discomfort during sexual penetration, pain during sex seems to be significantly more common in younger women than in older ones.[5] In a large random telephone survey done in Australia, which included 8,282 women and 8,510 men 16 to 59 years of age, the most common problem cited by both women and men was lack of sexual interest.[8] Women and men felt equally anxious about their ability to perform. Women were more likely than men to report being unable to achieve orgasm, not finding sex pleasurable, experiencing physical pain during intercourse, and worrying during sex that their body looked unattractive. Few studies have examined the effect of factors such as ethnicity and sexual orientation on rates of sexual satisfaction and sexual difficulties in women.

Female Sexual Function

Female sexual function is far more than a simple biologic response to a stimulus. When a woman experiences sexual difficulty, there is almost never just one cause; a multifactorial etiology is the rule. Similarly, there is usually no quick fix. This may help explain why medications such as sildenafil and other phosphodiesterase (PDE5) inhibitors, which rapidly restore sexual function in many impotent men, are not particularly useful in most women.[10,11] To fully understand the nuances in each case, it is crucial to identify and address all of the factors that contribute to the patient's lack of satisfaction with her sex life. These factors can be readily enumerated if the clinician examines each case in two ways: first, from the perspective of a biopsychosocial model of sexual function and, second, by examining which functional domains (i.e., desire, arousal, orgasm, satisfaction, absence of pain) are affected.

Biopsychosocial model of female sexual function

Normal female sexual function involves successful integration of key factors in psychological, interpersonal, and biologic realms [*see Figure 1*]. For example, women raised in societies in

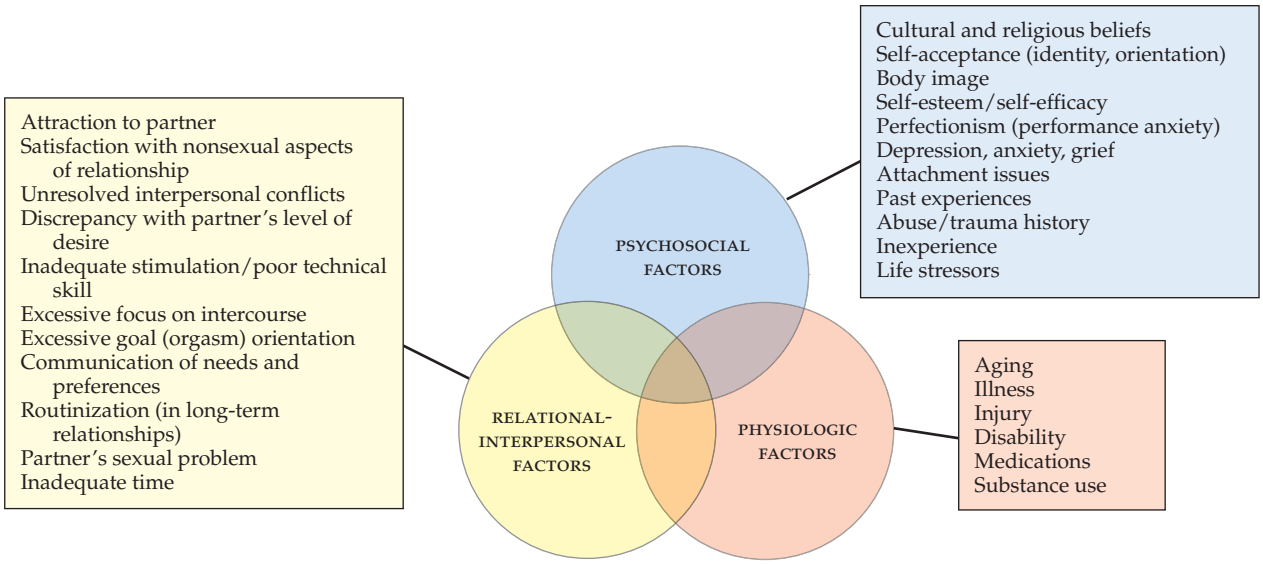

Figure 1 **The biopsychosocial model posits that overlapping physiologic, psychosocial, and relational factors influence sexuality.**

which discussion of sex is taboo are often ignorant about genital anatomy, sexual needs, and techniques. Young women whose families have strong expectations regarding sexual orientation and virginity may feel anxiety, confusion, or shame if their evolving sense of self turns out to be discordant with the values of their families. Finally, gender roles shape power dynamics in relationships and likely affect the degree to which different societies tolerate sexual coercion and violence. A pattern of sexual inhibition and avoidance often follows sexual trauma; disempowered women typically find it difficult to communicate sexual needs to their partner or to advocate for safer sex.

In addition to culture and contextual background, studies show considerable variation with respect to how women rate the importance of sex, the specific sexual practices they choose to participate in, the frequency of sexual activity they feel is optimal, and the intensity and duration of stimulation they need to achieve arousal and orgasm.[12] What would be a satisfying sex life for one woman might seem woefully inadequate to another. Clearly, the only person who can decide she has a sexual problem is the patient herself. Diagnosis of a sexual dysfunction should never be made unless a problem is persistent and causes distress and unless the patient articulates a desire for further evaluation.[13]

MODELS OF HUMAN SEXUAL RESPONSE

Traditional models of male and female sexual response were initially described by Masters and Johnson in the 1960s and embellished later by Helen Kaplan [*see Figure 2*].[14,15] In these linear models, events proceed in an orderly, stepwise manner; desire is a necessary first step; and orgasm is the explicit goal, although it may not always be attained. An important difference between the sexes is that orgasm in the male is followed by a longer refractory period; multiple sequential orgasms are more readily achieved in women.

Basson and colleagues developed a new model of sexual response in an attempt to convey more aptly the complexity of female sexual function.[16] This model is circular and contains multiple feedback loops through which sexual desire and arousal may be intensified or inhibited [*see Figure 3*]. Spontaneous desire is not a necessary factor to enter the cycle; simply feeling emotionally close and engaging in intimate touching can lead to arousal. This more realistic model acknowledges the fact that subjective response (emotional closeness to one's partner during

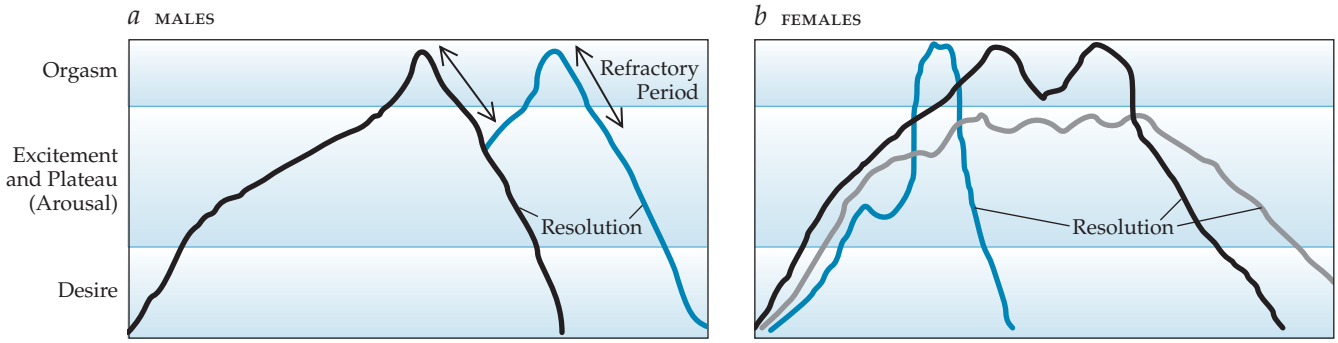

Figure 2 **Traditional models of human sexual response are linear.[14,15] In males (*a*), orgasm is followed by a short refractory period, after which further stimulation (blue line) can again lead to arousal and a second orgasm. Females (*b*) may experience a single-orgasm event (blue line), multiple orgasms (black line), or a plateau without orgasm (gray line).**

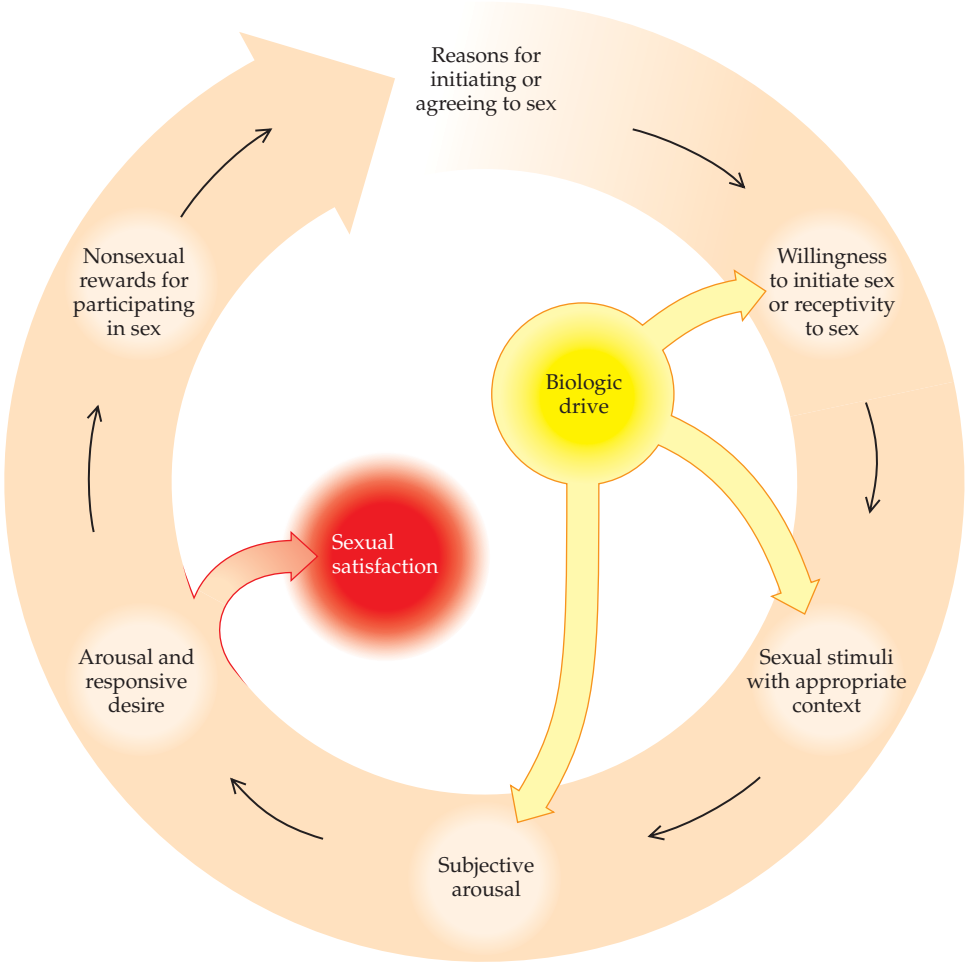

Figure 3 **Female sexual response is most accurately described by a circular model containing multiple feedback loops.[139] At several points in the cycle, sexual response can be either inhibited or stimulated by cognitive influences (e.g., negative thoughts can interrupt the response; erotica or fantasy can enhance the response). Sexual satisfaction can occur with or without orgasm. Nonsexual rewards may include emotional intimacy, feelings of well-being, or avoiding negative consequences for not participating in sex.**

sexual activity) can be as important for some women as physical response (attainment of orgasm).

STRUCTURE AND EROGENICITY OF THE FEMALE GENITALIA

Erogenous external genital structures in women include the clitoris, labia majora and minora, vaginal introitus, and anus. Of these, the densely innervated and highly sensitive clitoris is exceedingly important: arousal proceeds most readily and orgasms are strongest when the clitoris is stimulated.[17] Indeed, an excessive focus on penile-vaginal intercourse without clitoral stimulation is a chief cause of anorgasmia in women.

Internal genital structures involved in female sexual response include the vagina, cervix, and uterus. Of these, stimulation of the anterior vagina seems to be most pleasurable. Popular literature describes a so-called G-spot, or Grafenberg spot, an allegedly highly erogenous area located along the lower third of the anterior vaginal wall.[18] Although few studies provide objective evidence supporting the existence of the G-spot, stimulation of this area is purported to result in a kidney bean–size area of swelling and to be associated with high levels of arousal and powerful orgasms. Similarly, the existence of female ejaculation has been postulated because of the observation that fluid is released during orgasm in some women. Whether this fluid is simply urine or might represent a true ejaculate, such as emission of secretions from female paraurethral glands (analogous to the male prostate), is not clear from available data.[18]

Despite its proximity to the major pelvic or paracervical ganglion, the cervix itself is a relatively insensitive structure.[19] There are numerous theoretical reasons why removal of the uterus might be expected to interfere with sexual response, including anatomic changes (shortening of the vaginal vault and scar formation in the vaginal cuff), surgical damage to pelvic nerves and blood vessels, secondary hormonal changes,[20] and the possibility that uterine contraction itself contributes substantively to orgasmic pleasure. Although studies of sexual function after hysterectomy are fraught with methodological problems, the preponderance of evidence suggests that detrimental effects of either total or supracervical hysterectomy are rare and that preoperative sexual function is the most important predictor of postoperative sexual satisfaction.[21]

BIOCHEMISTRY AND METABOLISM OF SEX STEROIDS

Sex steroids and their receptors play a key role in the maturation, maintenance, and function of the tissues that are involved in female sexual response. The modulating effects of estrogen and androgen help explain the changes in sexual function that

are associated with changes in the levels of these hormones, whether the hormones are endogenous (as with changes that occur during puberty, within each menstrual cycle, during pregnancy and post partum, during lactation and after weaning, and with surgical or natural menopause) or exogenous (i.e., given as contraceptives or fertility drugs or for hormone replacement). Other hormones, including progesterone, oxytocin, and prolactin, probably also have important effects.

Synthesis of both estrogen and androgen takes place in the ovaries, adrenal glands, and peripheral tissues. Estradiol predominates before menopause. After menopause, estrogen is made extragonadally via aromatization of ovarian and adrenal androgens, and estrone predominates. The ovaries produce androstenedione, testosterone, and a small amount of dehydroepiandrosterone (DHEA). The adrenals produce androstenedione and DHEA sulfate (DHEAS). Both DHEA and DHEAS are converted in brain, bone, and adipose tissue to androstenedione or testosterone, which can then be either converted by 5-reductase to dihydrotestosterone (DHT) or aromatized to estrone or estradiol. Only free testosterone and DHT can bind to receptors and are therefore biologically active.

Before menopause, 25% of a woman's testosterone is produced in the ovaries, 25% in the adrenals, and the remaining 50% in peripheral tissues. Circulating androgen levels peak during the third decade of life, then decrease slowly with age because of reduced adrenal synthesis.[22] Diurnal and menstrual cycle–linked changes in testosterone and androstenedione also occur, with levels highest in the morning before 10 A.M. and during the middle third of the menstrual cycle.[22] Stromal cells of the ovary continue to make androgen precursors and testosterone after natural menopause; the amount of bioavailable testosterone may actually rise slightly during the first few years of the menopausal transition because of lower serum estrogen and, therefore, lower sex hormone–binding globulin (SHBG) levels.[23] Surgical menopause presents a dramatically different situation: bilateral salpingo-oophorectomy can lead to a sudden 50% decline in circulating levels of androstenedione and testosterone, with the effect being most pronounced in younger women.[24] Compromised ovarian function from premature ovarian failure, chemotherapy, pelvic radiotherapy, or administration of gonadotropin-releasing hormone agonists is also associated with low circulating androgen levels, as are adrenal insufficiency or adrenalectomy, glucocorticoid treatment (which suppresses pituitary adrenocorticotropic hormone secretion), and administration of exogenous estrogen (which increases SHBG levels and suppresses pituitary luteinizing hormone secretion).[25]

NEUROBIOLOGY OF FEMALE SEXUAL RESPONSE

Studies of the anatomy, physiology, and pathophysiology of female sexual function and dysfunction are limited. Much of what is known, or inferred, is extrapolated from animal studies, primarily in rodents, and drawn by analogy from studies in men.[19]

Normal female sexual function involves intact neural, vascular, and muscular circuitry; complex interactions between multiple neurotransmitter systems; and critical modulating influences from the endocrine system. Numerous neurotransmitters, bioactive substances, and sex steroids appear to be involved. These include, but are probably not limited to, dopamine, norepinephrine, serotonin, acetylcholine, nitric oxide, vasoactive intestinal peptide (VIP), prostaglandin E_1 (PGE_1), estrogen, testosterone, progesterone, oxytocin, and prolactin. Emerging evidence suggests that α-melanocortin–stimulating hormone (α-MSH) may also play an important role.[26] Some of these substances act centrally, in the brain and spinal cord, whereas others have peripheral sites of action (e.g., arteries, peripheral nerves, and the pubococcygeal muscles) [*see Figure 4*]. Some neurotransmitters have effects at both central and peripheral locations, but the nature of these effects (i.e., excitatory versus inhibitory) is not always the same at these two locations. For example, central norepinephrine activity appears to have stimulatory effects on female sexual response, whereas peripheral effects tend to be largely inhibitory. This has important implications for the design of pharmacologic therapies for female sexual problems. Because peripheral responses (e.g., vasocongestion) and observable behaviors (e.g., lordosis as a measure of proceptivity and receptivity in female rats) are easier to measure than central events, research to date has concentrated more on peripheral mechanisms than on central ones. The neurophysiology of each phase of the female sexual-response cycle—desire, arousal, and orgasm—can be considered separately.

Neurobiology of Desire (Libido)

Desire can be defined as a mental state created by external and internal stimuli that induce an urge to participate in sexual activity.[19] Manifestations of increased desire include sexual thoughts or fantasies and the motivation to initiate, or the willingness to be receptive to, sexual activity. It is useful to consider three non–mutually exclusive aspects of sexual desire: drive, motivation, and beliefs/values.

Sex drive has biologic roots and appears to be mediated by the excitatory action of dopamine and modulating effects of sex steroids in the mesolimbic system of the brain.[27] Higher-order cortical processes likely provide excitatory and inhibitory influences on lower cortical centers. Dopamine enhances sex drive and the wish to continue sexual activity once sexual stimulation has been initiated; these effects are inhibited by serotonin. Estrogen seems to have a small permissive effect, whereas testosterone and progesterone appear to influence initiation of sexual activity and receptivity to partner approach, respectively.[27] Serum prolactin concentrations increase after orgasm in men and women, and chronic hyperprolactinemia is associated with reduced libido in both sexes.[28] These observations suggest that prolactin may be a regulatory factor that signals central nervous system centers involved in the initiation or control of sexual behavior. Although sexual pathways in female humans need to be further elucidated, α-MSH agonists have been found to selectively stimulate solicitational behaviors in female rats and enhance desire and stimulate erection in men with psychogenic erectile dysfunction.[26]

Sexual motivation is fueled by anticipation of a risk or reward associated with initiation of or participation in sexual activity. Incentives are diverse and may include the following: feeling close to one's partner, giving or experiencing sexual pleasure, relieving tension, becoming pregnant, or exchanging sexual favors for tangible and intangible gifts. Conversely, the expectation, based on negative past experiences, of pain or injury resulting from sexual activity serves as a major disincentive.

Beliefs/values include unique personality and cultural factors that exert either excitatory or inhibitory influences on the wish to engage in sexual activity. Motivation and beliefs/values probably affect libido via excitatory and inhibitory cortical influences on lower cortical structures; further study is needed to elucidate specific pathways.

Knowledge of the basic neurophysiology of libido helps predict the effects of various exogenous substances. As expected, libido seems to be increased by dopamine enhancers, such as am-

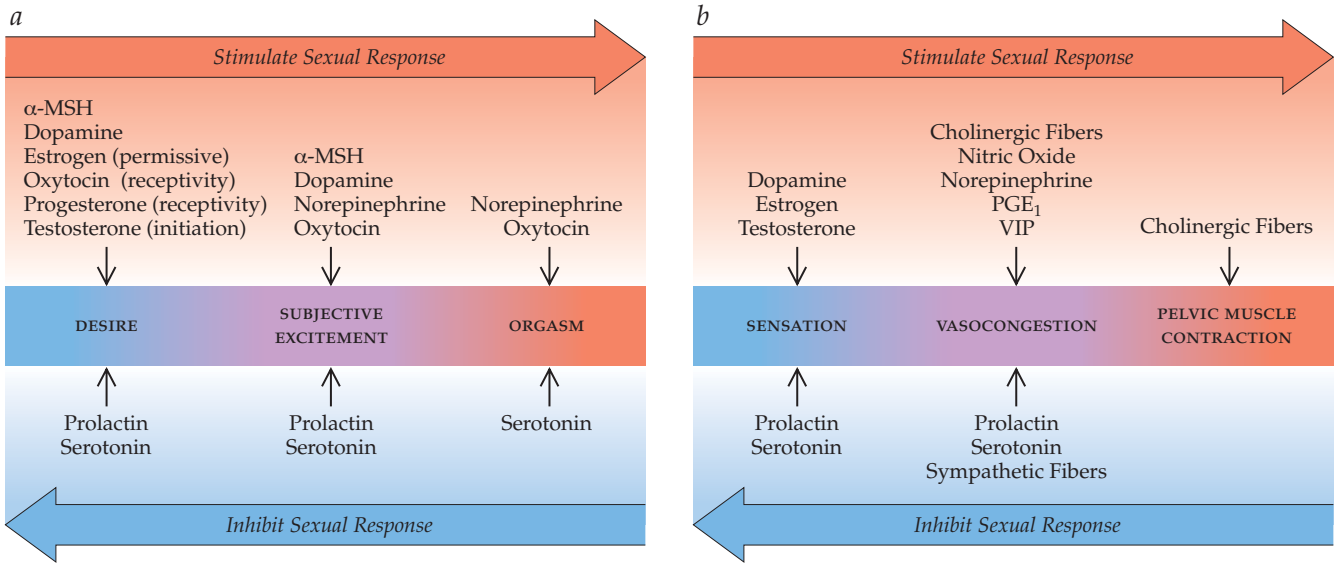

Figure 4 **The neurobiology of female sexual response includes both central and peripheral events.[27] Although these may be visualized as occurring sequentially, in reality, the physiologic and biochemical components of arousal may occur simultaneously and to some extent independently. Whether sexual desire, arousal, and orgasm are enhanced or inhibited depends on the coordinated activity of numerous bioactive substances, as well as the presence or absence of key environmental influences.**

(*a*) Central events are critical in the emergence of sexual desire and subjective excitement (arousal) and play an important role in orgasm. Increased levels of serotonin can result in inhibition of this response through reduction of dopamine and norepinephrine levels in the brain.

(*b*) Peripheral events include genital sensation, vasocongestion, and muscle contraction. The baseline state of the genital vasculature is tonic vasoconstriction, which is maintained by outflow from sympathetic fibers. In response to stimulation, release of vascular mediators (e.g., nitric oxide, prostaglandin E_1 [PGE_1], and vasoactive intestinal peptide [VIP]) promotes dilation of vessels and tissue vasocongestion. Both vasocongestion and pelvic muscle contractions are mediated by the release of acetylcholine from cholinergic fibers. Increasing feedback along afferent pathways to the spinal cord culminates in a spinal reflex arc that produces pelvic muscle contractions; transmission of these impulses cephalad to pleasure centers in the brain produces the sensation of orgasm.

phetamines and norepinephrine-dopamine reuptake inhibitors (NDRIs) (e.g., bupropion). Conversely, substances that reduce dopamine activity diminish libido: examples include D_2 dopamine receptor blockers and selective serotonin reuptake inhibitors (SSRIs). Hyperprolactinemia (caused by pituitary macroadenomas, lactation, or use of so-called typical antipsychotic drugs), intoxication with CNS depressants such as alcohol, and use of antiandrogens also reduce libido.

Fortunately, decreased libido does not have to relegate a woman to an unsatisfactory sex life. Many women whose spontaneous level of desire is reduced or absent retain the capacity for arousal and even orgasm by strong cognitive motivation to engage in sexual activity and skillful sexual-stimulation technique.

Neurobiology of Arousal

Sexual arousal includes both subjective excitement (i.e., awareness of, comfort with, and appreciation of erogenous stimulation) and objectively measurable signs (both nongenital and genital) of physiologic arousal.[27] It is important to distinguish between subjective and objective arousal, because studies show that women often experience measurable physiologic arousal in the absence of a subjective sense of excitement or pleasure.[13] Indeed, the feeling of sexual arousal in women seems to be heavily dependent on cognitive processing of stimulus meaning and content,[29] as opposed to being related purely to peripheral vasocongestive and neuromuscular events.

Subjective arousal is a central event that appears to be mediated by excitatory effects of both dopamine and norepinephrine; oxytocin, which is elevated throughout the follicular phase of the menstrual cycle, may also play a stimulatory role.[30,31] The effects of dopamine and norepinephrine are inhibited by serotonin; prolactin also has a negative effect on subjective excitement.

Genital sexual arousal appears to be mediated by spinal reflexes.[31] One such spinal reflex is the bulbocavernosus reflex, in which stimulation of light-touch pudendal sensory fibers activates pudendal motor neurons, resulting in contraction of striated perineal muscles. Activation of this reflex contributes to development of the orgasmic platform and strengthens urinary continence during arousal. The bulbocavernosus reflex can be evaluated during physical examination to check both sensory and motor function of the pudendal nerve. Another spinal reflex involves vaginal and clitoral cavernosal autonomic nerve stimulation, which results in clitoral, labial, and vaginal engorgement.[19] The efferent and afferent arms of these spinal reflexes have been relatively well defined in men; pathways in women are probably similar. Efferent facilitatory parasympathetic output arises in the sacral parasympathetic nucleus and is conveyed to the vagina and clitoris by the pelvic nerve. Efferent inhibitory sympathetic output arises in the dorsal gray commissure and the intermediolateral cell column at the thoracolumbar level and travels to the genitalia via the hypogastric nerve and the paravertebral sympathetic chain. The activity of the spinal nuclei is controlled both by descending projections from multiple supraspinal sites and by sensory afferents from the genitalia that are conveyed by the pudendal, hypogastric, pelvic, and vagus nerves. Serotoninergic projections from the brain to the spinal cord ap-

pear to inhibit the induction of genital arousal by afferent peripheral stimulation; noradrenergic projections also exist, but their functional significance is not fully understood.[31]

In the basal state, clitoral corporal and vaginal smooth muscles maintain contractile tone under noradrenergic mediation.[19] During sexual stimulation, neurogenic and endothelial release of nitric oxide, produced by the action of nitric oxide synthase on L-arginine, triggers a rise in cyclic guanosine monophosphate (cGMP) in postjunctional cells, causing calcium influx to vascular smooth muscle in the clitoris and vagina, vasodilatation, and tissue engorgement.[19] The result is extrusion of the glans and enhanced sensitivity. The vaginal epithelium continuously reabsorbs sodium from submucosal capillary plasma transudate. During sexual stimulation, release of nitric oxide and VIP induce increased capillary inflow; sodium reabsorption becomes overwhelmed; and 3 to 5 ml of vaginal transudate is produced, enhancing lubrication during sexual activity.[19] In addition to nitric oxide and VIP, a number of other vasoactive substances, including PGE_1, have been found in the clitoris and vagina; all deserve further study.[32] Cholinergic fibers innervate vascular smooth muscle in the vagina and may help mediate vaginal engorgement during arousal; however, the chief role of acetylcholine in the periphery is to increase pelvic striated muscle contractility.[33] Estrogen plays a critical role in maintaining vaginal tissue integrity and has local regulatory effects on nerve transmission (thereby increasing genital sensation) and mediators of vasocongestion (thereby enhancing genital blood flow and lubrication).[34] Preliminary evidence suggests that androgens may also affect genital sensation, genital hemodynamics, and mucin production (a minor component of sexual lubrication).[34] Peripherally, serotonin acts via 5-hydroxytryptamine-2A ($5\text{-}HT_{2A}$) receptors to reduce genital sensation and to inhibit nitric oxide synthase.[35] Exogenous substances that increase genital arousal include estrogens; pPDE5 inhibitors; PGE_1 agonists; and alpha blockers. PDE5 inhibitors potentiate the effects of the nitric oxide pathway by blocking the degradation of cGMP.[36] Substances that reduce genital arousal include antiestrogens, SSRIs, and anticholinergic medications.

Neurobiology of Orgasm

Arousal and orgasm can be viewed on a continuum. Arousal is necessary for buildup of the orgasmic platform; there can be no orgasm if there is no arousal. The experience of orgasm comprises both central events (experience of pleasure) and peripheral events (measurable pelvic muscle contraction). The central control of orgasm is poorly understood, but it is postulated that norepinephrine has stimulatory effects (via $alpha_1$- and $alpha_2$-adrenergic receptors) and that serotonin and prolactin have inhibitory effects, as they do on the production of subjective excitement.

Genital events that take place during orgasm are likely the result of a spinal reflex, as is the ejaculatory response in men. When afferent impulses from the genitals to the spinal centers reach threshold, efferent impulses result in stereotyped contractions (typically, five to 12 in number) of the vagina, uterus, and pelvic floor muscles at 0.8-second intervals; simultaneous messages are sent to cortical pleasure centers. Acetylcholine is the primary mediator of pelvic floor muscle contraction. Oxytocin may also play a role peripherally, in that plasma oxytocin levels rise substantially during orgasm and are correlated with the intensity of orgasmic contractions. Serotonin has an inhibitory effect on orgasm in the periphery, via stimulation of $5\text{-}HT_{2A}$ receptors. No definitive role for either estrogen or testosterone in orgasm has been established.

The neurobiology of orgasm helps explain the differential effects of several antidepressants [*see Table 1*]. Orgasm is inhibited by substances that reduce central levels of norepinephrine or increase levels of serotonin (e.g., SSRIs); anticholinergic medications also have negative effects. However, antidepressants that enhance the central effects of norepinephrine and dopamine, including NDRIs such as bupropion, as well as compounds that block $5\text{-}HT_{2A}$ receptors, seem to be less likely to affect sexual function adversely. Antidepressants that block $5\text{-}HT_{2A}$ receptors include mirtazapine, trazodone, and nefazodone. Mirtazapine is a noradrenergic and specific serotoninergic antidepressant with postsynaptic $alpha_2$-antagonist, $5\text{-}HT_{2A}$, $5\text{-}HT_{2C}$, and $5\text{-}HT_3$ receptor antagonism; trazodone and nefazodone are serotonin antagonist/reuptake inhibitors, which act by potent blockade of $5\text{-}HT_{2A}$ receptors combined with less potent inhibition of 5-HT reuptake. Some agents have different effects at different doses. For example, venlafaxine inhibits sexual function at low doses because of 5-HT inhibition; has less of an effect on sexual function at moderate to high doses because of norepinephrine reuptake inhibition; and has the least effect on sexual function at highest doses, at which it inhibits dopamine reuptake.

Sexual Behavior

Adolescence and young adulthood are periods of intense exploration of sexual identity and orientation and of experimentation with sexual behavior. According to the 2003 National Youth Behavior Risk Survey, 45% of young women have had penile-vaginal intercourse by the end of high school, and 4% have had intercourse before the age of 13.[37] The prevalence of other sexual behaviors, including mutual masturbation, oral sex, and anal sex, is also high. Of sexually active young women, 14% have had four or more sexual partners by age 19.

Sexual health is not a given during this time of self-discovery. Shame, depression, and increased rates of substance use are common in some groups of teens, particularly sexual-minority women (i.e., those who are lesbian, bisexual, or transgender), whose sense of self may conflict strongly with societal and family expectations. The majority of sexually active young women do not consistently engage in safe sexual practices. Only 63% of sexually active young women report using condoms, and only 17% report having been on birth control pills during their last sexual intercourse.[37] Moreover, 25% of teens report having been under the influence of alcohol or drugs at the time of intercourse.[37] Although the incidence of prostitution is difficult to determine, up to 2% of women report a history of engaging in oral, anal, or vaginal sex in exchange for money or drugs.[38] Moreover, young women are the most frequent targets for rape, whether by an acquaintance or a stranger. Not surprisingly, therefore, rates of unintended pregnancy and sexually transmitted infection (STI) remain high. The pregnancy rate in young women 15 to 19 years of age is 84 cases per 1,000[39]; each year, one in four teenagers in the United States contracts an STI,[40] and over their lifetime, half of all persons will contract an STI.[41] It is important to address these issues, because poor self-esteem, substance use, and depression have profound effects on sexual satisfaction and overall health, as do events such as unplanned pregnancy, abortion, development of STIs, and sexual trauma. Misconceptions and concerns must be addressed, or patients may be reluctant to use contraceptives and

safer-sex methods. Examples of common beliefs and misconceptions include the following: "I can't get an STI because I'm on the pill;" "If someone I am dating has an STI, I would know it;" and "If I ask my partner to use a condom, he will be suspicious or worried about my sexual history."

Misconceptions on the part of the clinician may interfere with the assessment of sexual risk. For example, it is unwise to assume that a particular patient is not sexually active (e.g., because she is too young, too old, or too ill); that the patient (or her partner) is exclusively heterosexual or participates solely in penile-vaginal intercourse; or that a person (or her partner) who is in a committed relationship is consistently monogamous. Same-sex sexual activity is quite common: in the 2002 National Survey of Family Growth (NSFG),[42] 7% of men and 11% of women 25 to 44 years of age reported same-sex activity at some point in their lives. Sexual activity does not always correlate with sexual orientation: in the Minnesota Adolescent Health Survey, self-identified bisexual or lesbian teens 12 to 19 years of age were as likely as their heterosexual peers to have had penile-vaginal intercourse and reported twice as high a prevalence of pregnancy.[43] Men and women engage frequently in sexual activities other than penile-vaginal intercourse: in the NSFG, 90% of male and 88% of female participants reported a history of oral sex with the opposite sex, and 40% of men and 35% of women reported a history of anal sex with the opposite sex.[42] Sexual activity is common outside the context of committed relationships. For example, 21% of men and 13% of women report having had sex with someone other than their spouse while married.[38] Clinicians who wish to provide pertinent risk-reduction counseling must consider all of these facts and remember that sexual behavior is fluid. It is crucial to ask all patients about their sexual behaviors and to ask repeatedly over time, because behaviors may change.

Many men and women are sexually active from extreme youth through old age, so both sexes stand to benefit from repeated risk-assessment and risk-reduction counseling throughout their lives. It may, in fact, be especially important to discuss sexual health with older people, who, because of the loss of a long-term partner, may be reentering the dating world after many years in a monogamous relationship. Many of these individuals have little knowledge of safer-sex methods and minimal or no experience having frank discussions about sexual safety with prospective partners. As a result of societal restrictions, women often feel particularly uncomfortable initiating these kinds of conversations.

Sexual pleasure tends to be enhanced during young to middle adulthood, as a result of experience, greater confidence, and, in many cases, greater intimacy in the context of committed relationships. However, women in this phase of life may develop sexual concerns related to pregnancy, lactation, parenting, infertility, and pregnancy loss.[44] Sexual function during pregnancy is affected by a woman's (and her partner's) emotional reactions to the pregnancy, body image/physical comfort, and hormonal changes. Women who feel excited about their pregnancy, close to their partner, and happy about being able to dispense with contraception often experience enhanced enjoyment. Conversely, women who feel anxious or who experience nausea and fatigue during the first trimester may be more inhibited. Desire and responsiveness tend to be enhanced during the second

trimester, though weight gain, body-image issues, or withdrawal of a woman's sexual partner can have detrimental effects. Some women find that desire and ease of orgasm increase during the last trimester, whereas others avoid sex because of physical discomfort or concerns about injuring the fetus or causing preterm labor.

In the absence of pregnancy complications, women and their partners should be reassured that sexual activity is safe throughout pregnancy. Creative positioning can be suggested to maximize comfort.

After the birth of a child, many couples experience changes in their sex life. A combination of factors, including initial perineal/pelvic discomfort, disrupted sleep and exhaustion, anxiety about being a new parent, hyperprolactinemia associated with breast-feeding, feelings of unattractiveness, fear of becoming pregnant again, or postpartum depression, can all have inhibiting effects. Over the short term, a period of reduced sexual activity post partum is beneficial, in that it allows healing of delivery trauma and adjustment to parenthood; after a few months, most couples establish a new sexual equilibrium. If sexual intimacy is not eventually restored and if the couple is distressed by the loss, it is appropriate to pursue an evaluation.

Infertility and pregnancy loss can also have profound effects on a couple's sex life, through the combination of hormonal influences and intense feelings (e.g., anger, grief, guilt) about the situation. Provision of emotional support, referral for counseling, and psychopharmacologic intervention, as appropriate, are critical.

Sexual function remains a critical ingredient of a satisfying life in older women. In the Modern Maturity Sexuality Study of 1,384 persons performed by the American Association of Retired Persons (AARP), a satisfying sexual relationship was reported as being important to the quality of life of 66% of women 45 to 59 years of age, 48% of those 60 to 74 years of age, and 44% of those 75 years of age or older.[45] In a study of 1,292 men and women 60 years of age or older that was performed by the National Council on Aging, 51% of women in their 60s, 30% of those in their 70s, and 18% of those 80 years of age or older had engaged in sexual activity at least once a month during the past year.[45] For heterosexual women, some of the reduction in sexual activity with age is related to the availability of a male partner; in the AARP study, only 21% of women 75 years of age or older had a current partner, compared with 78% of women 45 to 59 years of age and 53% of women 60 to 74 years of age.

With age, sexual desire normally shows a gradual decline. Contrary to popular belief, menopause, in and of itself, is not necessarily associated with a precipitous drop in libido. In the Harris Interactive Study, which surveyed 580 menopausal women, 45% of the women reported a decrease in sexual desire after menopause, whereas 37% reported no change and 10% actually noted an increase.[45] On the other hand, menopause results in clear changes in arousal: genital blood flow, vaginal lubrication, and genital sensation all decrease. Orgasmic capacity is maintained as women age, although typically, clitoral stimulation needs to be more direct, more intense, and of longer duration. Decreased muscle tension in the pelvic floor and decreased uterine contractions during climax may diminish the intensity of orgasm. Despite these changes, satisfaction tends to be preserved. In the Association of Reproductive Health Professionals Sexual Activity Survey of 1,000 persons in the United States, 52% of women 50 to 59 years of age, 42% of women 60 to 69 years of age, and 49% of women 70 years of age or older were as satisfied or more satisfied with their current sex life as compared with their sex life when they were younger.[45] There seems to be a difference between the so-called genital prime and the sexual prime. The former represents biologic responsiveness; the latter reflects positive effects of the intimacy that develops in many long-term relationships, the knowledge about one's body that accrues with experience, and the greater ability to ask for and accept pleasure that often accompanies maturity.

Importantly, some women do experience a distressing diminution in sexual satisfaction associated with aging, menopause, or both. Hormonal factors are only one aspect of this decline. Other contributing factors include poor body image and self-esteem; unrealistic expectations; relationship difficulties; lifestyle issues and stress; the onset of acute or chronic illnesses; use of medications with sexual side effects; having a partner with sexual dysfunction; or, often, the absence of a partner. Negative feelings about growing older, including lack of acceptance of physical changes, lead some women to worry that their partner will no longer find them attractive. Some older women may feel that sex is only for the young—that they shouldn't want to have sex any longer. Other women may expect sex to be just as it was during their 20s and 30s and may therefore have difficulty accepting and adapting to the changes associated with growing older. Although long-term relationships often result in increased trust, respect, and sexual satisfaction, some couples find that over time, sex becomes predictable and even boring.

Events that disrupt the equilibrium that has been reached in a long-term relationship, such as a man's increased interest in intercourse after beginning a PDE5 inhibitor, can be challenging for a female partner if she was happy with the status quo. Lifestyle changes that occur during midlife and beyond can upset decades-long patterns in a couple's life. Examples include children leaving home, retirement, financial stresses, aging parents, and concern about one's own or one's partner's health. Fortunately, sexual satisfaction can be maintained and even enhanced in older couples with attention to communication, making time for intimacy, and using a broad range of sexual techniques. In acute illness, a reduction in sexual function can be adaptive, allowing a woman to focus her energy on healing and survival. Chronic illness and disabilities are often associated with changes in sexual function. However, sexual activity continues to be very important to many affected women. A period of adjustment may be needed to allow her and her partner to adjust to a changed body that responds differently. Subsequently, a satisfying sex life can be achieved in many circumstances with adaptations such as timing sexual activity when the energy level is high, using creative positioning to maximize comfort, and learning creative ways of providing pleasurable stimulation.

Classification of Sexual Disorders

Classification of female sexual disorders is important for guiding research, for legitimizing clinical discussion of this topic, and for facilitating the development of diagnosis codes so that clinicians are more likely to be paid for managing these disorders. However, because female sexual function is nonlinear, multifaceted, and subject to individual interpretation, delineating a reliable classification of female sexual problems has proved difficult. Two classification schemes are in common clinical use: those found in the American Psychiatric Association's *Diagnostic and Statistical Manual, Fourth Edition, Text Revision* (DSM-IV-TR)[46]

and the International Statistical Classification of Disease and Related Health Problems, 10th Revision (ICD-10).[47] Both have been criticized because they are based on the sexual response cycle of men and are overly focused on penile-vaginal intercourse; they ignore the fact that changes in sexual function can be adaptive or normative at certain junctures in a woman's life; they overemphasize the medical aspects of the problem by downplaying psychological and relational factors; they categorize problems narrowly, whereas multifactorial etiologies are actually the rule; and they ignore the enormous variation that exists between individual women.[13]

The American Foundation for Urologic Disease (AFUD) convened a multidisciplinary group of experts to review and revise definitions of female sexual problems in 1998; initial recommendations were published in 2000,[48] and the definitions continue to be debated and updated. Overall, the AFUD classification contains more appropriate diagnostic descriptors for women because it attends to context and the presence of distress, is less focused on physical symptoms and intercourse, and distinguishes between subjective and objective events. The AFUD classification divides female sexual problems into the following major categories: sexual interest and desire disorder, sexual-aversion disorder, sexual-arousal disorders, orgasmic disorders, and sexual-pain disorders [*see Table 2*].[13] Unfortunately, the less appropriate DSM-IV and ICD-10 diagnostic codes are still needed to bill for clinical work with patients.

Diagnosis

SEXUAL AND RELATIONSHIP HISTORY

A general sexual assessment can be accomplished relatively quickly. Initial questions should be open-ended and nonjudgmental and should convey a willingness to discuss sexual issues [*see Table 3*]. Follow-up questions should address specific sexual activities and the risk of unintended pregnancy, STIs, and sexual abuse [*see Table 3*].

When a woman articulates concerns about her sex life, further questioning is appropriate. Useful questions include the following:

1. Do you notice a change in your interest in sex?
2. Do you have trouble becoming aroused or sufficiently lubricated?
3. Are you able to reach orgasm?
4. Do you experience pain or discomfort during sex?

If a problem is identified, further questions should be asked about its severity (global versus situational) and chronicity (primary versus secondary), as well as about the context in which it has developed (e.g., relating to psychiatric or medical illness, substance use, relationship problems, life stressors, or medication use) and the extent to which it causes the patient distress. When the woman has a partner, specific questions should be asked about communication, technical skill, and sexual repertoire. Both individuals in the relationship should be included in the evaluation whenever possible.

The History in Women with Sexual-Desire Problems

When decreased desire is primary and generalized, the problem often traces back to a highly sex-negative upbringing or an early traumatic sexual event; when the decreased desire is acquired or situational, it is more likely to be caused by relationship problems, stress, poor physical health, hormonal changes, and exogenous substances. Questions to ask women with low sexual desire include the following:

1. When did you notice a change in your level of desire?
2. What do you think is responsible for the change?
3. Do you ever feel motivated to have sex? If so, what motivates you?
4. Do you experience spontaneous sexual thoughts or fantasies?

Table 2 Classification of Female Sexual Dysfunction[13]

Desire Disorders

Sexual interest and desire disorder

Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies, and a lack of responsive desire. Motivations (defined as reasons/incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is considered to be beyond a normative lessening with life cycle and relationship duration

Sexual-aversion disorder

Extreme anxiety, disgust, or both at the anticipation of having, or the attempt to have, any sexual activity

Arousal Disorders

Subjective sexual-arousal disorder

Absent or markedly diminished feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation, although vaginal lubrication or other signs of physical response still occur

Genital sexual-arousal disorder

Absent or impaired genital sexual arousal; self-report may include minimal vulvar swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia; subjective sexual excitement still occurs from nongenital sexual stimuli

Combined subjective and genital sexual-arousal disorder

Absence of, or markedly diminished feelings of, sexual arousal (sexual excitement and sexual pleasure) from any type of sexual stimulation, as well as complaints of absent or impaired genital sexual arousal (vulvar swelling, reduced lubrication)

Persistent sexual-arousal disorder

Spontaneous, intrusive, and unwanted genital arousal (e.g., tingling, throbbing, pulsating) in the absence of sexual interest and desire; any awareness of subjective arousal is typically but not invariably unpleasant; the arousal is unrelieved by one or more orgasms and the feelings of arousal persist for hours or days

Orgasmic Disorder

Self-report of high sexual arousal or excitement but lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any type of stimulation

Sexual-Pain Disorders

Dyspareunia

Persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse

Vaginismus

Persistent difficulties in allowing vaginal entry of a penis, finger, or any object, despite the woman's expressed wish to do so; there is variable involuntary pelvic muscle contraction, (phobic) avoidance, and anticipation/fear/experience of pain; structural or other physical abnormalities must be ruled out or addressed

Noncoital sexual-pain disorder

Recurrent or persistent genital pain induced by noncoital sexual stimulation

Table 3 Helpful Questions to Ask for the Sexual History

Initial Questions

- Are you currently involved in a sexual relationship? Have you ever been?
- How old were you when you first had sex?
- How many partners have you had in the past month? Six months? Over your lifetime?
- Have your partners been men, women, or both?
- How are things going in your relationship(s)?
- How satisfied are you with the sexual aspect of your relationship(s)?
- Is there anything about your (or your partner's) sexual activity that you would like to change?

Follow-up Questions

- How often do you have sex?
- What types of sexual activity do you engage in (e.g., hand on genital, mouth on genital, penis in vagina, penis in anus, use of sex toys)?
- Do you think any of your sexual activities put you at risk? Do you take any precautions to reduce your risk?
- Do you feel comfortable discussing safer sex with your partner or partners?
- Has anyone ever coerced you or forced you to have sex against your will?
- Are you currently in a relationship where you feel physically, sexually, or emotionally threatened?

5. Are you "turned on" by erotic descriptions in books or sex scenes in movies?
6. How do you feel about your body?
7. Do you ever masturbate?
8. Are you attracted to your partner (or partners)?
9. Do you find other men or women attractive?

When the decrease in desire seems to stem from low self-esteem, interpersonal issues, or cultural prohibitions, it is appropriate to ask additional questions, such as the following:

1. What are your beliefs and values about sex in general?
2. (For women who are heterosexual) Were you raised with strong beliefs about premarital sex and virginity?
3. Were you raised with strong negative beliefs about specific sexual activities, such as oral sex, self- and partner masturbation, vaginal penetrative sex, and anal sex?
4. (For women who are not exclusively heterosexual or who may be questioning their sexual orientation) Were you raised with strong beliefs about same-sex attraction and same-sex relationships?
5. Do you feel comfortable with your gender identity and sexual orientation?
6. Has anything ever happened that made you feel guilty or bad about sex?

Questions should also be asked about life stressors, as well as about medical conditions, medications, and other substances that are known to be associated with diminished libido. A history of medical conditions (e.g., thromboembolism, active liver disease, hormone-responsive cancers, eating disorders, and seizures) that might contraindicate potential treatment options (e.g., estrogen, testosterone, and bupropion) should also be sought.

Sexual-aversion disorder is usually associated with low sexual desire and sometimes with vaginismus or dyspareunia. A history of sexual trauma is common, and patients with such a history often have extensive negative, unexpressed feelings about their relationships. Questions should therefore focus on psychological and relationship issues; ascertaining a history of abuse; and ruling out coexistent mental health conditions, including anxiety and obsessive-compulsive disorders. It can be helpful to find out whether a woman's aversion is generalized or specific. Generalized aversion refers to all partners or any type of sexual activity, whereas specific aversion refers to only certain partners or to anticipating or attempting a particular sexual act.

The History in Women with Sexual-Arousal Problems

Absent or impaired sexual arousal The etiology of decreased sexual arousal includes either a decrease in central excitatory activity or an increase in central inhibitory activity, as well as medical conditions that compromise genital blood flow and pelvic innervation. Diabetes mellitus is associated with decreased genital vasocongestion and arousal in women[49]; atherosclerosis caused by other risk factors should also be considered. Multiple sclerosis and other neurologic conditions can be associated with neurogenic impairment.[50] Obstetric trauma, including episiotomy, traumatic delivery, and cesarean section, is associated with sexual dysfunction, though painful sex is usually more common than reduced arousal. Decreased arousal and pain also occur frequently in women who have had pelvic surgery (e.g., hysterectomy, with or without oophorectomy, and procedures to correct urinary incontinence or pelvic organ prolapse) and women who have sustained pelvic trauma.[51] The incidence and severity of sexual problems after hysterectomy depend on preoperative sexual function and psychosocial state, the degree to which the surgery alleviates the symptoms for which it was performed, and the extent of the surgical procedure.[52] Surgical technique (i.e., whether blood vessels and nerves are spared) is probably a key factor. Clinical experience suggests that women who undergo pelvic evisceration for treatment of malignancy, whether gynecologic or nongynecologic, frequently develop arousal problems. Contrary to popular opinion, there is little sexual advantage to performing a supracervical rather than a total hysterectomy.[53] Persistent perineal pressure (e.g., from prolonged bicycle riding) may cause injury in women.

Questions to ask patients with reduced arousal include the following:

1. Do you feel aroused by sexual thoughts, fantasies, reading a sexy passage in a book, or seeing a sexy scene in a movie?
2. Do you feel aroused by having different parts of your body touched (by yourself or your partner)?
3. What parts of your body do you most like having touched?
4. What kinds of stimulation (hand-genital, mouth-genital, genital-genital, sex toy–genital) are most pleasurable?
5. Do you feel comfortable talking with your partner about what you like?
6. Do you lubricate enough to make sex comfortable? Have you tried using lubricants, and if so, which ones? Do you think they are effective?
7. Has there been a change in your level of arousal? If so, when did things change, and why do you think they changed?

The history should also include questions about menopausal status, medical illnesses, medications, obstetric injury, pelvic surgery, and pelvic trauma.

Persistent sexual-arousal disorder The etiology of persistent sexual-arousal disorder is unknown, because the entity is rarely seen and little studied. Anecdotal reports have described patients with both vascular (aneurysmal dilatation of genital blood vessels) and neurologic (persistent clitoral paresthesias from bicycle-seat trauma) abnormalities. Therefore, it is probably useful to ask questions about the onset and duration of the condition, as well as the presence of medical conditions, injuries, or surgeries that might have triggered a neuropathic response.

The History in Women with Orgasm Problems

The etiology of orgasm problems varies according to whether the lack of orgasm is lifelong and generalized or is situational and intermittent. Primary (lifelong, generalized) orgasmic disorder rarely has a physical cause; it is usually the result of a highly sex-negative upbringing, unpleasant or abusive sexual experiences, and ineffective sexual technique on the part of either the patient during self-masturbation or her partner during sex. One of the most common causes of failure to achieve orgasm is ignorance about the need for clitoral stimulation and an excessive focus on penile-vaginal intercourse as an optimal technique.

Secondary (situational/intermittent) orgasmic disorder can be caused by any inhibiting influence that dampens sexual arousal on a temporary basis. Common causes include psychological issues, relationship problems, an unskilled sexual partner, stress, illness, and medications. It is important to address the issue of expectations relating to orgasm, because women sometimes express satisfaction with a sexual encounter that does not include orgasm. On the other hand, it is quite common for a woman's partner to feel inadequate if she does not have an orgasm. Secondary orgasmic disorder can be permanent if severe illness or injury significantly impairs the neural circuitry necessary for normal arousal and orgasm.

Questions for women with primary orgasmic disorder should focus on beliefs and values; prior sexual experiences; and knowledge about female sexual anatomy, function, and technique. Women with secondary orgasmic disorder should be queried about self- and relational issues, partner skill, physical problems that interfere with sexual arousal, and medications that interfere with arousal and orgasm. In addition, all women presenting with sexual problems should be asked about urinary incontinence.

Sexual complaints are common in women with urinary incontinence and pelvic organ prolapse.[54,55] The prevalence of urinary incontinence that occurs during sexual activity (i.e., sexual incontinence) ranges from 2% in randomly selected population samples to as high as 56% in women in clinical samples.[56] Understandably, sexual incontinence can be associated with avoidance of sexual activity and sexual dissatisfaction; research using standard definitions and measures is needed to determine the frequency of sexual problems in this context. Limited data suggest that stress incontinence is most often associated with urinary leakage at the time of vaginal penetration, whereas women with urge incontinence are more likely to experience leakage during orgasm.[57]

The History in Women with Sexual-Pain Disorders

Traditional definitions of sexual-pain disorders (i.e., dyspareunia, vaginismus) focused on vaginal pain caused by insertion of a penis—that is, pain during penile-vaginal intercourse. Dyspareunia is a general term that does not specify etiology, whereas vaginismus refers to pain on insertion that is caused by involuntary spasm of the perineal and levator muscles. Revisions have broadened these descriptions to include vaginal pain on insertion of other objects; in addition, a new category, noncoital sexual-pain disorder, has been added [*see Table 2*]. This expanded view is appropriate, in that it embraces the existence of noncoital sexual activities and recognizes that sexual stimulation of external genital structures can also trigger a painful response rather than a pleasurable one.

The chief causes of noncoital sexual pain are vulvodynia and vestibulitis. The International Society for the Study of Vulvovaginal Disease has defined vulvodynia as vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder.[58] Vulvodynia is further characterized by whether the pain is generalized or localized and whether it occurs with or without provocation, or both. Vestibulitis is a term used to describe vulvodynia that is localized to the region of the vestibule. Vestibulitis may involve sexual pain associated with light touch around the vestibule, as well as pain on attempted penetration.

It is important to note that different pain disorders can coexist and that, at times, one may trigger another. For example, chronic yeast infection may trigger vestibulitis, which, in turn, may lead to avoidance of penetrative activity because of anticipated pain, with secondary vaginismus.

The history should include assessment of the onset, character, intensity (graded on a scale of 1 through 10), location, and duration of the pain. Clues to etiology can also be obtained by asking about apparent triggers of the pain (including timing during the menstrual cycle), as well as ameliorating factors (e.g., position changes, lubricants, analgesics, and pain-modulating agents). The clinician should ask whether the pain is present invariably (i.e., during each sexual encounter with every partner) or only intermittently. A primary, lifelong pain that is complete and generalized during penile-vaginal intercourse is usually the result of congenital anomalies, psychosocial issues, or vulvodynia/vestibulitis, whereas secondary, situational pain is more likely to have an acquired physical cause. It is important to ask about a history of sexual trauma, which is commonly associated with pain during sexual activity, especially vaginismus. Evaluation should always assess the impact of the problem on the patient and her relationship with her partner, as well as the willingness of both parties to participate in counseling, as appropriate.

The location of the pain (i.e., superficial, present on penetration, or deep within the pelvis) is the best clue to its etiology.[59] Superficial pain is associated with light touch around the clitoris, labia, and vestibule, and it tends to be caused by anatomic abnormalities, dermatitis, dermatosis, infection, and vulvodynia/vestibulitis. Pain on penetration occurs with entry of any object (finger, sex toy, penis, and, in premenopausal women, tampons) into the vagina, and it is usually the result of a structural abnormality (e.g., episiotomy scar, hymenal ring, vaginal stenosis, or vaginal septation/duplication), vaginitis (e.g., bacterial vaginosis, candidiasis, trichomoniasis, or chemical induced), vaginal atrophy, or vaginismus. Other causes of vaginal pain include inadequate lubrication associated with inhibited arousal caused by psychological or relationship factors, lack of estrogen, medications (e.g., antihistamines or anticholinergics), and diseases that cause dryness (e.g., Sjögren syndrome); urinary tract

problems (e.g., urethritis and interstitial cystitis); and vaginal shortening (congenital or postsurgical). Pain associated with deep penetration or thrusting is sometimes seen in women with retroverted uteri; position changes are typically helpful. Other causes of deep pain include pelvic adhesions; infections (e.g., chronic pelvic inflammatory disease); endometriosis; benign pelvic processes (e.g., ovarian cyst, uterine enlargement from adenomyosis or fibroids, interstitial cystitis, irritable bowel disease, and inflammatory bowel disease); pelvic organ prolapse; malignancy in the pelvis (e.g., cervical, ovarian, endometrial, urinary tract, or gastrointestinal tract); and a history of pelvic surgery for either benign or malignant conditions.

The timing of the pain is also informative. For example, pelvic pain during orgasm may be related to uterine contractions, whereas pain after sexual activity may be from pelvic congestion. Vulvovaginal itching, swelling, and erythema after intercourse may be caused by seminal plasma hypersensitivity; this diagnosis can be made by absence of symptoms with condom use and by positive skin testing with a pooled sample of seminal fluid.[59]

Sexual Questionnaires

Having patients complete a written questionnaire can sometimes help define key issues. Several multidimensional self-report instruments on female sexual dysfunction have been developed.[60] These include the 25-item Derogatis Interview for Sexual Functioning (DISF/DISF-SR),[61] the 22-item Brief Index of Sexual Functioning for Women (BSFI-W),[62] and the 19-item Female Sexual Function Index (FSFI).[63] The FSFI, which is the most commonly used of these questionnaires, is available free of charge on the Internet (http://www.FSFIquestionnaire.com). Each of these questionnaires is well standardized, relatively unobtrusive, and inexpensive and takes 15 to 20 minutes to administer and score; moreover, normative values for both clinical and nonclinical populations are available. There is reason to believe that use of questionnaires may result in a more accurate history, because women may be more willing to answer sensitive questions privately than during a face-to-face conversation.

PHYSICAL EXAMINATION AND LABORATORY TESTING

If a woman wishes to pursue an evaluation, the clinician should perform a comprehensive but pertinent physical examination, which should be adapted to her specific presenting complaints as well as to anticipated treatments. It is reasonable to palpate the thyroid in all women, because both hypothyroidism and hyperthyroidism can affect sexual function adversely. The breasts and liver should be examined when hormonal, especially systemic hormonal, treatments are a consideration, because of known toxicities. A detailed genital exam should be performed in all women, especially in those with decreased arousal, anorgasmia, or sexual pain [*see Table 4*]. The pelvic exam can be especially challenging in some women, especially those with a history of abuse or a negative experience during a past clinical encounter. Simple measures can help reduce anxiety and discomfort and maximize a woman's sense of control, including the presence of a support person or chaperone; a contract to stop the exam if requested by the patient; the use of a small speculum; and adequate lubrication.[59] In severe cases, administration of a short-acting benzodiazepine before the exam may also be useful.

The integrity of pelvic blood vessels and nerves should be assessed in women with arousal problems. Blood pressure and peripheral pulses provide an assessment of overall cardiovascular function. Several methods have been devised to measure pelvic blood flow objectively, including vaginal photoplethysmography,[64] Doppler ultrasound,[65] application of oxygen electrodes to measure oxygen tension,[66] and magnetic resonance imaging[67]; however, this equipment is costly and useful primarily in research. Sensation can be evaluated by light touch with a cotton-tipped applicator.[59] In this test, the patient is asked to report whether or not she is able to ascertain light touch of the swab to the labia majora and minora, clitoris, and clock-face locations around the vestibule. This test is also useful in determining the location and intensity of pain (graded from 1 through 10) in women with suspected vulvodynia/vestibulitis.

The biothesiometer, a device originally developed to test sensation in the feet of diabetic patients with peripheral neuropathy, can also be used to test sensation in the labia and around or on the clitoris. A vibrating probe is first applied to a neutral region of the body (e.g., the patient's finger), and the degree of vibration is carefully adjusted to determine the lowest level of stimulation that can be appreciated by the patient. Subsequent measurements of labial and clitoral sensation can then be obtained. Biothesiometry is a relatively inexpensive way to confirm the presence of reduced genital sensitivity, establish the degree of neurologic impairment, and provide objective measurements that can be tracked during treatment; devices are available that cost approximately $500.

Pelvic floor muscle tone can be assessed by grading the degree of vaginal and anal sphincter contraction that can be generated by a patient during digital vaginal and rectal examination (i.e., absent, mild, moderate, or strong) or by using a peritoneometer. The peritoneometer is a handheld device with a vaginal probe that measures vaginal muscle contraction. Rarely, pelvic ultrasonography and laparoscopy are necessary in the investigation of deep pelvic pain.

Laboratory testing should be tailored to individual circumstances, with careful consideration given to cost and evidence of clinical usefulness. Assessment of cardiovascular risk factors (e.g., elevated lipid or glucose levels) are useful when hemodynamic compromise is suspected. Measurement of pituitary hormone levels (i.e., follicle-stimulating hormone, thyroid-stimulating hormone, and prolactin) may be helpful when evaluating postpartum, lactating, and perimenopausal women and when manifestations of thyroid disease are present. Measurement of baseline lipid levels, liver function tests, and a complete blood count may be performed in women for whom androgen supplementation is anticipated, because excess androgen replacement can be associated with adverse changes in the lipid profile, abnormal liver function, and polycythemia. An appropriate evaluation should be performed when vulvar or vaginal lesions, vaginal discharge, or cervicitis is discovered, including a biopsy of suspicious lesions, vaginal pH testing, a wet mount, a potassium hydroxide preparation, and selected tests for STIs. Routine vaginal cultures are not useful.

Recommendations regarding serum androgen levels are more difficult to make, because there are no precise definitions of androgen deficiency, normal serum androgen levels for women of different ages are poorly characterized, the accuracy of available testosterone assays in women is questionable,[68] and not all studies show a correlation between low serum testosterone levels and low sexual desire.[69] One large study, however, has demonstrated a significant association between self-reported low sexual function and a low serum DHEAS level (below 10th percentile for age).[69] Further studies are needed to determine

Table 4 The Genital Examination in Women with Sexual Difficulties

Anatomic Feature or Examination Maneuver	*Possible Sources of Sexual Difficulty*
Clitoris	Phimosis, adhesions, female genital circumcision
Urethra	Erythema, carbuncle, prolapse
Labia majora and minora	Atrophy, lesions
Introitus	Erythema, scarring, stricture
Vagina	Atrophy, erythema, discharge
Valsalva maneuver	Uterine prolapse, urinary incontinence
Bimanual examination	Masses, pain
Vaginal and rectal sphincter contraction	Poor tone, prolapse
Bulbocavernosus reflex	Pudendal neuropathy

whether serum DHEAS measurement has any utility in identifying a subgroup of women with low desire who are most likely to benefit from treatment. Part of the difficulty is that circulating androgen levels are not good indicators of intracellular androgen activity, because extensive intracellular metabolism of androgens occurs without the release of active metabolites into the pericellular compartment.[70] Moreover, studies of the efficacy of androgen supplementation show inconsistent results. Some of this inconsistency may be explained by differences in the responsiveness of individual women to androgen supplementation as a result of variations in the amount or activity of 5-reductase and aromatase, as well as differences in the androgen receptor response.[71] At present, the major reasons to check serum androgen levels are to exclude women with generous levels from treatment and to monitor serum levels during treatment to prevent overreplacement. Routine screening with a clinical breast examination, mammography, and Papanicolaou (Pap) testing should follow usual guidelines.

Management

GENERAL TREATMENT RECOMMENDATIONS

Effective treatment for women with sexual problems must address each area of distress (i.e., psychological, relational, and physiologic) and must intervene in each affected domain (i.e., desire, arousal, orgasm, overall satisfaction, and comfort or absence of pain). The goal of treatment is to increase pleasure and satisfaction, rather than to achieve a perfect genital response. Certain interventions are useful in the treatment of all female sexual difficulties; these include basic education and information about lifestyle measures that enhance sexual satisfaction and, in many circumstances, referral for counseling.

Education and Counseling

As expected from the substantial placebo effects observed during trials of various interventions for female sexual problems, simply inviting women to talk about their sexual concerns can be extraordinarily therapeutic. Discussion should include basic education about normal female sexual anatomy and function, and permission should be given to explore self-pleasuring. Many women have unrealistic expectations about sex and feel that they should be immediately and reliably aroused and responsive, despite normal distractions or age-related changes. Education alone can be extremely beneficial. For example, a woman who has lost some of her sex drive but remains motivated to be close to her partner can be reassured that willingness to participate in intimate touching and skillful sexual technique can still lead to arousal and orgasm. Similarly, women with arousal problems often benefit from the knowledge that increased intensity and duration of stimulation, such as that which can be provided by a vibrator, can restore their ability to experience pleasurable genital sensations. Finally, because an emphasis on intercourse and ignorance regarding the importance of clitoral stimulation are common in women with primary anorgasmia, many of these patients are able to achieve their first climax after learning about anatomy and practicing appropriate sexual technique.

Simple lifestyle measures can go a long way toward enhancing interest and ensuring comfort. For example, in one study of the effects of free testosterone levels and other psychosocial variables on sexual function in women undergoing natural menopause, the only variable significantly associated with satisfaction was exercise.[72] Couples can be encouraged to maximize opportunities for closeness and intimacy by setting aside specific times for this purpose (i.e., making "dates"). Thought should be given toward creating environments conducive to intimacy; considerations include time of day, music, lighting, and temperature and children being away or asleep. If a woman and her partner are open-minded, the use of diversified sexual techniques, as well as experimentation with different sex positions, venues, sex toys, fantasy, and erotica, can be suggested as means to enhance excitement and eliminate routine. Strategies that maximize comfort can also be recommended, including relaxing in a warm bath before sex (for women with vaginismus), using effective lubricants (for women with atrophy or dryness), trying position changes (for women with pelvic discomfort from fibroids or organ prolapse), and strategic dosing of mild analgesics before engaging in sexual activity (for women with arthritis). Many different lubricants are available, including water-, oil-, and silicone-based products. Selection should be based on the need for safer sex protection, palatability, and glide. Oil-based and silicone-based lubricants last longest and produce the best glide during penetrative sex. Vegetable oils are inexpensive, reasonably physiologic, and taste good—an important consideration when oral sex is part of the sexual repertoire. However, oil-based products degrade latex; only water-based lubricants should be used with latex male condoms. The manufacturer's recommendations should be closely reviewed when choosing lubricants for use with sex toys. Many books and Internet resources now exist that provide high-quality information about sex [*see Sidebar,* Selected Resources for Female Sexuality].

Referral for individual, couples, or sex therapy can be beneficial when psychological problems or couples issues are present.[73] The purpose of sex therapy is to help women identify thoughts or behaviors that interfere with sexual enjoyment, become more aware of and comfortable with sexual feelings, learn what kind of stimulation is most pleasurable, and increase communication of sexual needs to their partners. Various techniques may be used, including sexual fantasy and skills training, masturbation exercises, the use of erotica and vibrators, and practicing communication using role playing. Cognitive restructuring techniques can be useful for women who experience distracting thoughts that inhibit arousal. Women who have experienced

sexual trauma may be helped by a combination of cognitive-behavioral techniques, eye-movement desensitization and reprocessing (EMDR), and insight-oriented psychotherapy. For women whose instinct is to avoid sexual activities because of either prior abuse or pain, the use of nondemand, sensual touching exercises (so-called sensate focus), which focus on the pleasurable sensations associated with nongenital touch, can be extremely helpful. Typically, these exercises begin with the least threatening kinds of touch, such as back rubs or foot massage, and progress over time to nude, full-body caressing, including the genitals. Sexual-aversion disorder is best approached using gradual exposure and habituation exercises, which are also effective in the man-

agement of other phobias. A useful resource for sex therapists is the American Association of Sexuality Educators, Counselors, and Therapists (www.aasect.org). It should be noted that the use of surrogate partners, a practice that was utilized in the past, is fraught with ethical and legal issues and is no longer an accepted sex-therapy modality.

INDIVIDUALIZED EVALUATION AND MANAGEMENT

In addition to education, lifestyle changes, and referral for counseling, a number of individualized treatment options can be considered for selected women who present with specific symptoms and findings. Therapeutic measures in these patients are tailored to the domain of sexual response affected—desire, arousal, or orgasm, alone or in combination—and the particular cause.

Sexual-Desire Disorders

Postmenopausal women Reduced sexual desire after menopause—especially surgical menopause—may result from estrogen and androgen deficiency. Medical and psychiatric illnesses that could be contributing to the low libido should be ruled out. If any medications need to be prescribed for contributing illnesses, agents that do not themselves have a negative impact on desire should be selected, if possible. For some women with low sex drive, cognitive motivation to engage in sex, coupled with skillful technique, can compensate for their lowered libido. For women who are not satisfied with this strategy, it is reasonable to consider additional management options, including supplemental estrogen or androgen or both. Laboratory evaluation might include checking thyroid-stimulating hormone and baseline serum androgen levels, which, if androgen supplementation is elected, can subsequently be followed to avoid excessive dosing.

Most studies of systemic estrogen replacement in postmenopausal women demonstrate an improvement in sexual function in all phases of the sexual-response cycle.[74] It is not clear to what extent the effect on desire is mediated indirectly through amelioration of vaginal discomfort caused by atrophic changes or through alleviation of sleep deprivation caused by vasomotor symptoms. Lubricants and local application of topical estrogen[75] can help counteract atrophy. Systemic estrogen replacement may be indicated for vasomotor symptoms, in the absence of contraindications; however, it should be remembered that oral estrogen increases SHBG levels and, thus, may theoretically reduce rather than increase desire. Therefore, the optimal vehicle for systemic estrogen replacement may be a transdermal preparation, which avoids the hepatic first-pass effect. In patients with only minor vasomotor symptoms, topical estrogen applied to the genitalia might be a safer long-term strategy.

Studies of testosterone therapy in the form of oral preparations,[76,77] intramuscular injections,[78,79] and subcutaneous implants[80-82] have demonstrated significant improvement in sexual desire in postmenopausal women, and there is increasing use of testosterone for this purpose. Many of these studies, however, included small sample sizes, were of short duration, achieved supraphysiologic levels of serum testosterone (at which risks are more likely to outweigh benefits), or exclusively enrolled surgically menopausal women, in whom the dramatic decline in postoperative androgen levels is commonly associated with a significant loss of sexual desire. In general, it has been more difficult to demonstrate efficacy of androgen replacement in naturally menopausal women or to show a benefit in either surgically or naturally menopausal women with restoration of testosterone levels within the physiologic range—perhaps because of the large placebo effect seen in these trials, which could obscure the beneficial effects of testosterone. Two trials have demonstrated benefits of testosterone replacement to physiologic levels in surgically menopausal women using a 300 g transdermal patch.[83,84] A trial in naturally menopausal women has shown similar benefits.[85]

It has been suggested that the beneficial effect of testosterone results from an increase in bioavailable estrogen. Studies of hormone replacement therapy, however, show that the combination of estrogen and testosterone improves sexual function to a greater degree than estrogen alone,[86,87] and trials have not documented an increase in serum estrogen levels after the addition of testosterone.[83,84] Whether coadministration of estrogen is necessary for testosterone to achieve its beneficial effect is unknown, because all studies in postmenopausal women to date have included systemic estrogen replacement.

The steroidal agent tibolone appears to have beneficial effects on sexual function in postmenopausal women.[88-90] Tibolone is not available in the United States, however, and the efficacy and safety of this agent in the management of sexual problems in postmenopausal women need to be assessed in randomized, placebo-controlled trials.

It is important to identify women in whom low desire is the result of androgen deficiency and who are therefore most likely to benefit from androgen replacement. Consideration of androgen replacement is most appropriate for symptomatic, surgically menopausal women, especially those who underwent bilateral salpingo-oophorectomy at a young age. Clinicians should be circumspect about prescribing androgens, however, for a number of reasons. First, numerous factors impact sexual desire, and androgen deficiency probably plays a significant role in only a minority of women with low libido. This is consistent with the finding that most women with low self-reported sexual desire and sexual satisfaction do not have correspondingly low serum levels of total or free testosterone, androstenedione, or DHEAS.[91] Second, it is not clear that the benefits of androgen replacement outweigh the risks. The benefits found with replacement of androgen to physiologic levels appear to be quite modest. For example, Buster and colleagues found that surgically menopausal women receiving the testosterone patch engaged in one additional sexual episode per 2.5 weeks, compared with one additional episode per 5.5 weeks in those who received placebo.[84] Short-term adverse events associated with use of the 300 g patch include application-site reactions (usually mild) and a nonsignificant increase in androgenic side effects (e.g., acne, alopecia, facial hair growth, voice deepening).[84] Excessive androgen replacement can be associated with significant adverse effects, such as hyperlipidemia and hepatotoxicity. No meaningful changes in lipid profiles, carbohydrate metabolism, liver function tests, hematology parameters, or clotting measures were seen in recent studies, but the duration of these studies was only 24 weeks; concerns remain regarding the possibility of longer-term adverse effects, including possible increases in the incidence of atherogenesis and breast cancer.

Androgen therapy is contraindicated in women with a history of breast cancer, severe liver disease, or deep vein thrombosis. In general, androgen supplementation should be avoided in premenopausal women (see below), because there is little evidence of their efficacy, and adverse effects can be especially severe.

Because of the lack of long-term data regarding efficacy and safety, few countries have approved the use of androgen re-

placement for the treatment of sexual dysfunction in women. Consequently, the majority of available androgen preparations are formulated for use in men. A variety of androgen preparations are used for off-label treatment of low libido in women. Oral formulations include 1.25 mg of esterified estrogens plus 2.5 mg methyltestosterone (Estratest), 0.625 mg esterified estrogens plus 1.25 mg methyltestosterone (Estratest HS), and DHEA. The two Estratest preparations are approved by the Food and Drug Administration for the management of hot flashes. Nevertheless, these preparations, which were formulated before the publication of the Women's Health Initiative trials, contain estrogen doses that are higher than optimal; in addition, periodic progestin withdrawal in women who have not had hysterectomies is indicated to prevent endometrial hyperplasia.

DHEA is available as a nonregulated, over-the-counter dietary supplement. A double-blind, placebo-controlled, randomized crossover trial in 24 women with adrenal insufficiency showed that DHEA at a dosage of 50 mg/day for 4 months significantly increased sexual interest and the level of satisfaction with sex, as well as overall well-being and mood.[92] In women without adrenal insufficiency, however, the value of DHEA for treating low sexual desire remains questionable.[93,94] Clinical reports describe using a starting dose of 25 to 50 mg/day of DHEA and titrating the dose upward in 25 mg increments until a maximum dose of 100 mg is achieved.[95]

Topical androgen is commercially available as a 1% testosterone gel, which comes in a packet or a pump dispenser. Doses for men (one 5 g packet or four pumps) are excessive for women, who should start at approximately one tenth the male dose. Daily topical application of a pea-sized dollop to nongenital skin seems to be a reasonable starting point. Testosterone can also be formulated in a 1% or 2% ointment or cream by compounding pharmacies. Because of its central permissive effect on libido, systemic estrogen along with androgen may be needed to achieve an improvement in libido, although studies have not yet confirmed this need.

The optimal follow-up schedule, laboratory monitoring, and duration for androgen therapy have not been defined. Because of concerns about supraphysiologic dosing and long-term safety, however, it is advisable to monitor women at regular intervals. In trials of the 300 g testosterone patch, free, total, and bioavailable testosterone levels; free and total estradiol levels; estrone levels; and SHBG levels were measured at baseline, 12 weeks, and 24 weeks.[83,84] Androgen levels rose at 12 weeks and remained fairly stable over the remainder of the study period. Estrogen levels did not rise appreciably in either study. Maximal effects on sexual-function end points were seen at 8 to 12 weeks[84]; therefore, it is reasonable to see women at 8- to 12-week intervals initially. Monitoring should include an assessment of clinical efficacy (i.e., symptom reduction) and potential side effects (e.g., acne and hirsutism), as well as laboratory assessment of free and total testosterone levels. Androgen doses can be titrated up or down to achieve symptom reduction in the absence of side effects without allowing serum testosterone levels to exceed the top of the normal range. Periodic monitoring of serum lipid levels and liver function is also reasonable. Until data are available that demonstrate long-term safety, it is advisable to utilize systemic androgen supplements in short-term management only. Extrapolation from safety data regarding systemic estrogen use (which may or may not be germane to systemic androgen use) suggests that short-term management translates into 5 years or less of continuous treatment.

Premenopausal women In the postpartum period, common contributing factors to low sexual desire include fatigue and adjustment to life as a new parent. Hypothyroidism and hyperprolactinemia must be ruled out.

Use of oral contraceptives results in low libido in 5% to 13% of patients.[96] It is not helpful to check serum hormone levels in the setting of oral contraceptive administration. When decreased desire occurs in this context, four management options are available: (1) switching to a nonhormonal contraceptive (which may lead to a higher rate of unintended pregnancy), (2) reducing the estrogen dose (which will lower SHBG levels and result in increased free testosterone levels), (3) changing to a transdermal preparation (which eliminates the hepatic first pass and thereby also lowers SHBG levels), and (4) switching to a preparation with a more androgenic progesterone. Available progestins, listed in order of decreasing androgenicity, include levonorgestrel, desogestrel, norgestimate, norethindrone acetate, norethindrone, and ethynodiol diacetate.[97]

In general, when a woman develops sexual side effects related to a medication, management options include discontinuing the medication, substituting an alternative agent that is less likely to cause the problem, and adding an antidote. Antidotes are indicated when it is medically inadvisable to change the offending medication or when the addition of a second agent is likely to have benefits beyond those of reducing the side effect caused by the first drug. The best example of this is the addition of bupropion to SSRI treatment in the management of depression [*see* Orgasm Problems, *below*].

Whether bupropion is useful as a sexual stimulant for women with low libido who are not taking SSRIs remains to be determined. One study evaluated the use of sustained-release bupropion (300 mg a day for 112 days) in nondepressed, premenopausal women with hypoactive-sexual-desire disorder; significant increases were seen in sexual arousal, orgasm completion, and sexual satisfaction but not in sexual desire.[98] Larger trials are needed to elucidate these findings and to determine which specific sexual-function domains are impacted. It should be noted that the use of bupropion requires careful assessment for possible medication interactions, as well as precautions regarding seizures, particularly in young women who may have eating disorders. Adverse effects, particularly seizures, may be more frequent with immediate-release bupropion than with the sustained-release preparation.

There is little evidence regarding the efficacy of androgen supplementation in premenopausal women (see above).[99] Testosterone is a known teratogen, which can cause virilization of a female fetus. Therefore, most clinicians rarely prescribe androgens to premenopausal women, and in cases in which they are prescribed, they are used only in patients with excellent long-term contraception, such as tubal ligation or an intrauterine device.[100]

Arousal Problems

Subjective arousal problems Useful management strategies for women with subjective sexual-arousal difficulty include permission to use fantasy and erotica to enhance excitatory cognitive stimulation; referral for individual, couples, or sex therapy to address inhibitory cognitive influences; and cautious review and adjustment of any medications that might be interfering with central arousal. Such medications typically include agents that reduce central dopamine and norepinephrine concentrations, those that increase serotonin

levels [*see* Orgasm Problems, *below*], and those that increase prolactin levels.

Objective arousal problems General treatment strategies that are useful in women with genital-arousal problems include the use of lubricants during sexual activity, treatment with estrogen when genital-tissue atrophy is present, and the use of more direct and intense stimulation for longer periods. Additional interventions can be considered in certain circumstances, including PDE5 inhibitors or a clitoral pump (see below) to increase genital blood flow and strategies to combat sexual side effects caused by medications [*see* Orgasm Problems, *below*].

Prescription of an appropriate estrogen regimen requires careful consideration. Systemic estrogen has well-known adverse side effects. Oral estrogen increases levels of SHBG, resulting in lower serum testosterone levels, which may have negative effects on libido. Except in women who have undergone a hysterectomy, estrogen must be given with progesterone to prevent endometrial hyperplasia; however, progesterone downregulates estrogen receptors, which diminishes the benefits of estrogen. Local treatment with small doses of estrogen applied to the genitalia avoids systemic side effects and the need for progesterone. Vaginal suppositories and the estrogen-impregnated silicone ring are good options to relieve vaginal atrophy with minimal systemic absorption. The ring is inserted intravaginally every 12 weeks. Silicone lubricants should be avoided because they may degrade the matrix. The use of suppositories for restoration of vaginal mucosal integrity generally requires daily application for several weeks; frequency of use should then be reduced to the lowest exposure needed to maintain beneficial effects. Long-term intravaginal use of estrogen cream should generally be avoided because it results in significant systemic absorption, but a thin film of estrogen cream applied to the perineum helps restore external-tissue integrity and is probably safe. When systemic estrogen treatment is desired for the management of vasomotor symptoms, parenteral delivery with the transdermal patch is recommended, because this method avoids the hepatic first-pass effect. Direct application of androgen gels or creams (available at compounding pharmacies) to the genitalia is touted to increase sensation; this approach is supported by current data on the role of androgens in female genital response, but it has not yet been proved to be effective in clinical studies.

When decreased sexual arousal is postulated or shown to be vasculogenic, strategies that increase genital blood flow can be considered. Current options include PDE5 inhibitors and clitoral vacuum pumps. PDE5 inhibitors (i.e., sildenafil, tadalafil, and vardenafil) have been shown to be generally effective for men with erectile dysfunction, although the degree of efficacy varies according to the etiology and severity of the disorder.[101] Adverse effects, which include headache, flushing, rhinitis, nausea, and visual symptoms, are usually minor, although sudden cardiac death and stroke have been reported in high-risk patients. Two large studies have assessed the efficacy and safety of sildenafil in women receiving or not receiving estrogen therapy who have genital or subjective sexual-arousal problems.[10,102] In both studies, 50 mg of sildenafil was shown to increase genital blood flow, but subjective arousal did not improve significantly. There was a large placebo response (30% to 40%); no serious adverse events were reported. A smaller study of sildenafil in women receiving estrogen therapy who have clear-cut genital-arousal disorder stratified study patients according to degree of arousal deficit by using vaginal photoplethysmography.[11] In this study, sildenafil increased perception of genital arousal, improved subjective arousal, and reduced the latency to orgasm but only in patients with a low vaginal pulse amplitude response. This finding suggests that sildenafil may be useful in selected women with pure genital-arousal problems. Studies have examined the effects of PDE5 inhibitors in women with multiple sclerosis,[103] spinal cord injury,[104] and sexual dysfunction induced by SSRIs,[105] but numbers are too small to permit firm conclusions. PDE5 inhibitors should be used with caution in patients with recent myocardial infarction or stroke and in those with active coronary ischemia and episodes of heart failure. These agents are contraindicated in women who are taking nitrates.[106]

A large number of other pharmacologic agents have been demonstrated to increase genital blood flow in response to erotic stimuli. These include ephedrine,[107] phentolamine,[108,109] topical alprostadil (a PGE_1 that increases cyclic adenosine monophosphate),[110-112] and a combination of yohimbine (an $alpha_2$ antagonist derived from the bark of the African yohimbe tree) and L-arginine (a nitric oxide precursor).[113] To date, no large-scale, randomized, controlled trials of these agents have shown efficacy in the treatment of female sexual dysfunction; as with sildenafil, changes in genital blood flow have not correlated with changes in subjective arousal in most studies.

Numerous plant-derived remedies are purported to treat sexual problems.[114] Of these, both ginseng and ginkgo biloba have been shown to increase genital blood flow, but neither has yet been shown to benefit women with sexual-arousal disorders. However, a small study of ArginMax, a nutritional supplement containing ginseng, ginkgo, L-arginine, damiana, vitamins, and minerals, did demonstrate improvements in sexual desire, vaginal dryness, clitoral sensation, and frequency of sexual activity in normal female volunteers.[115]

Other options that can be used to treat women with genital-arousal problems are mechanical devices that work either through vibratory stimulation or by causing clitoral vascular engorgement using a vacuum system.[116] Vibrators supply stimulation that is high in intensity, can be delivered directly to the genital sites that have greatest sensitivity, and have the advantage that, unlike a human partner, they do not become fatigued with prolonged duration of use. These characteristics make vibrators invaluable tools for women who require high-intensity, direct clitoral stimulation for prolonged periods to overcome the effects of vascular or neurologic compromise.

The Eros–Clitoral Therapy Device is a small, handheld, battery-powered vacuum pump that can be used to increase blood flow to and around the clitoris during foreplay and self-stimulation. The device received FDA approval on the basis of a small study that showed that application for 3 to 5 minutes, three times a week, for a total of 6 weeks resulted in significant improvement in sensation, vaginal lubrication, ability to achieve orgasm, and greater overall sexual satisfaction in women with and without sexual-arousal disorder.[117] The device costs approximately $400; less expensive knockoffs, some of which also vibrate, can be obtained from sex boutiques.

Persistent sexual-arousal disorder Because persistent sexual-arousal disorder is rare, there are no studies to guide the management of women with the condition. A vigorous attempt should be made to determine the etiology in each case, utilizing specialized testing of genital sensation and blood flow, and treatment should be targeted accordingly. Anecdotal treatments that

have been tried include the following: cognitive reframing of the arousal as a healthy response; discontinuance of potentially offending medications such as trazodone (which causes a similar syndrome in men); administration of SSRIs (because of their dampening effects on arousal); genital application of topical anesthetic agents; administration of antiandrogens; and pelvic embolization (for a pelvic arteriovenous malformation with branches to the clitoris).

Orgasm Problems

Primary orgasmic disorder Classically, women with primary anorgasmia have been raised in a sexually repressive culture, feel guilt or shame about sexual urges, may have negative attitudes toward masturbation, and are relatively unassertive in their relationships. Both the woman and her partner typically are not very knowledgeable about female anatomy or sexual function.

Available data suggest that women with primary orgasm problems respond well to education (of both the patient and her partner) and directed masturbation.[118] Directed masturbation training involves self-stimulation in which the woman becomes aware of the type of stimulation she needs to increase her arousal and pleasure; this knowledge can subsequently be generalized to sexual encounters with a partner.[119-121] A wide variety of self-help books are available to help guide this activity. It may be necessary to address negative attitudes toward the use of erotica and vibrators before introducing these aids. The use of sensate focus exercises in combination with a temporary refrain from intercourse can be recommended as a nonthreatening way for both partners to explore each other's bodies. Counseling can be helpful to improve both sexual and nonsexual communication. Unfortunately, the few studies that have examined the effectiveness of these modalities suffer from numerous methodological deficiencies, including inadequate definitions of dysfunction and treatment success, failure to control for therapist or expectancy factors, failure to isolate specific effects of different treatments, small numbers of study patients, and an absence of control or comparison groups.

Secondary orgasmic disorder Acquired orgasmic dysfunction is a common side effect of medications, particularly antidepressants. In particular, sexual dysfunction is reported by as many as 30% to 60% of patients taking SSRIs.[122] Although these drugs can adversely affect any sexual-function domain, orgasm delay is the problem most frequently cited. It is imperative to address sexual side effects during SSRI treatment, because consequent nonadherence or premature treatment discontinuance can place patients at risk for recurrent depression, relapse, chronicity, and, in extreme cases, suicide.

When discontinuance of antidepressants is not an option, several other strategies can be considered. These include dose reduction or drug holiday, adding a second medicine as an antidote, or switching to an alternative agent with less sex-negative effects.[123] Sexual side effects appear to be dose related and may be reduced by lowering the daily dose. Similarly, drug holidays (stopping the drug for 48 hours before anticipated sexual activity, such as 2 days before a weekend) may reduce sexual side effects in women who are taking agents that have a short half-life. Such strategies, however, carry the risk of decreasing the antidepressant dose to subtherapeutic levels and should therefore be used with caution. Antidotes are especially appealing when the agent added not only helps to treat sexual side effects but also has additional benefits, such as augmenting antidepressant efficacy.

Two small, randomized, placebo-controlled trials have examined the effectiveness of adding sustained-release bupropion to SSRI treatment in euthymic men and women who had developed sexual side effects related to SSRI use. One trial did not demonstrate efficacy, but the dosage of bupropion was low (150 mg a day) and the duration of the trial was short (3 weeks).[124] In the second trial, patients receiving bupropion did demonstrate an increase in both the desire to engage in sexual activity and the frequency of sexual activity.[125] The bupropion dosage used in this trial was 300 mg a day, and the duration of the study was 4 weeks. Anecdotal reports suggest that a 75 mg dose of immediate-release bupropion taken several hours before anticipated sexual activity also helps improve libido, lubrication, orgasm delay, and orgasm quality in women taking SSRIs.[126] Larger trials are needed to further investigate these findings and to determine the optimal bupropion preparation and treatment dose.

Because the sexual side effects of SSRIs appear to be mediated in part through the nitric oxide pathway, PDE5 inhibitors are of theoretical benefit. Small studies suggest that sildenafil may be beneficial in women with SSRI-induced sexual dysfunction.[105] Case reports also suggest efficacy with the addition of methylphenidate and dextroamphetamine at dosages of 5 mg/day.[123]

Substitution therapy is sometimes a viable option. Both bupropion and nefazodone are less likely than SSRIs to cause sexual dysfunction; 10% or less of patients taking these drugs experience this side effect. Mirtazapine may also be associated with a lower rate of sexual side effects.

Anecdotal experience suggests that the use of pelvic floor exercises to increase pelvic floor muscle tension enhances sexual arousal and orgasmic pleasure in some women, including women who experience sexual incontinence. Unfortunately, studies have been small, have lacked appropriate controls, and have had inconsistent outcome measures. In one small, randomized trial, Bo and colleagues demonstrated a 50% improvement in sexual incontinence in women who performed pelvic-strengthening exercises, versus 10% in the control group.[127] Pelvic floor exercises are easily taught, pose little potential for harm, and have minimal cost; they are therefore a reasonable first-line treatment for women with stress incontinence. Effectiveness can be augmented by using biofeedback techniques, including self-use of a handheld peritoneometer, or by using vaginal weights.[128] Estrogen, either systemic or topical, has not been found to be effective for the management of stress incontinence.[129] Alpha-adrenergic agonists and tricyclic antidepressants may be helpful for the incontinence, but their use for this purpose is not FDA approved, and they may have sexual side effects.[130] Surgical treatment can be a double-edged sword: although it often restores continence, it sometimes reduces sensation and blood flow, resulting in impaired sexual arousal and orgasm.[131] In addition, some procedures performed to correct incontinence or prolapse are associated with an increase in dyspareunia.[132]

Women with acquired orgasmic dysfunction are often less satisfied with their overall relationship and are more distressed. Therefore, counseling is frequently a requisite aspect of treatment.[133]

Pain during Sexual Activity

Treatment for women who experience pain during sexual activity should be directed at the underlying etiology. A multidisciplinary approach, including involvement of a medical

provider, psychotherapist or sex therapist, and a specially trained physical therapist, is often very useful. It may not be possible to eliminate the pain completely. More realistic goals are to help the patient develop better coping strategies and gradually achieve or regain satisfactory sexual function. When the pain is the result of inadequate lubrication, causes to consider include inadequate foreplay before intercourse and vulvovaginal atrophy. Lubricants can be very useful in such patients; topical estrogen should also be considered in postmenopausal women, especially if atrophic changes are evident. Medications that cause vaginal dryness should be avoided or discontinued, if possible. Infections, dermatitis, dermatosis, correctable anatomic abnormalities, and conditions associated with deep pelvic pain must each be addressed appropriately. Women who have experienced pain during sexual activity often feel anxious that the pain will recur and frequently avoid subsequent sexual contact. Over time, this fear and withdrawal can become as problematic as the pain itself. By working with a sex therapist, affected women and their partners can learn to focus on activities that are pleasurable. The use of sensate focus exercises, which direct attention to activities and part of the body that do not provoke anxiety or cause pain, may be particularly helpful.

Vulvodynia and vestibulitis The causes of vulvodynia and vestibulitis are not known. Proposed etiologies include increased urinary oxalates, genetic or immune factors, hormonal factors, inflammation, infection, and neuropathic changes.[134] Treatments that have been tried include vulvar care measures; topical measures (e.g., local anesthetics, capsaicin, amitriptyline, nitroglycerin, and baclofen); oral medications (e.g., tricyclic antidepressants and anticonvulsants); injectable medications (e.g., interferon, steroids, local anesthetics, and botulinum toxin); pelvic floor muscle rehabilitation; low-oxalate diet and calcium citrate supplementation; acupuncture; hypnotherapy; and surgery (e.g., vestibulectomy, perineoplasty, and pudendal nerve decompression).[135] Of these, several are of little harm and fall within the purview of the general internist.

Vulvar care measures consist of wearing cotton underwear, avoiding exposure to irritants, gentle cleansing with water, patting dry (no rubbing or use of hair dryers), application of soothing emollients (e.g., vegetable oils and petrolatum) that do not contain preservatives, and use of ice or gel packs for discomfort. Referral to a physical therapist with expertise in vulvar pain management may be worthwhile, especially for patients with concomitant vaginismus. Topical products, such as 5% lidocaine ointment applied to painful areas 10 minutes before sexual activity, can be helpful. Topical preparations should be formulated as ointments, because creams contain more preservatives and can cause stinging or burning. Oral agents such as tricyclic antidepressants and gabapentin may also be tried; however, vaginal dryness can be a side effect. Finally, referral to a specialist with expertise in the management of vulvodynia and vestibulitis is warranted when simple measures do not provide relief.

Vaginismus Psychological issues, such as ambivalence about sex from a strict upbringing or avoidance because of past trauma, are common in women with vaginismus. Secondary vaginismus is a common conditioned response in women who have experienced genital pain (e.g., from urinary tract procedures performed during childhood). Vaginismus is characterized by pelvic floor hypertonicity or spasm and impaired ability to both contract and relax the pelvic floor musculature. The most effective treatment for women with vaginismus consists of a combination of psychotherapy to address personal issues, cognitive-behavioral therapy to break the pain-spasm-pain cycle, sphincter muscle exercises to achieve pelvic muscle relaxation,[135] and gradual desensitization using vaginal self-dilation with fingers or vaginal dilator insertion.[15] The use of functional electrical stimulation biofeedback to teach pelvic muscle relaxation improves the efficiency and success rate of treatment.[136] Injection of botulinum toxin may be useful in refractory cases.[137,138]

NORMAL LABORATORY VALUES

Chemistry

Analyte	*Specimen*	*Conventional Units*	*SI Units*	*Method or Instrument*	*Factor for Conversion to SI Units*
Adrenocorticotropin (ACTH)	P	6.0–76.0 pg/ml	1.3–16.7 pmol/L	Immunoassay	0.2202
Alanine aminotransferase (ALT, SGPT)	S			Kinetic method	0.01667
Female		7–30 U/L	0.12–0.50 μkat/L		
Male		10–55 U/L	0.17–0.92 μkat/L		
Albumin	S	3.1–4.3 g/dl	31–43 g/L	Colorimetry (bromocresol purple)	10
Aldolase	S	0–7 U/L	0–7 U/L	Kinetic method	1
Aldosterone (adult)				Immunoassay	
Supine, normal-sodium diet	S, P	2–9 ng/dl	55–250 pmol/L		27.74
Upright, normal-sodium diet	S, P	2–5 times supine value with normal-sodium diet			
Supine, low-sodium diet	S, P	2–5 times supine value with normal-sodium diet			
Urine, normal-sodium diet	U	2.3–21.0 μg/24 hr	6.38–58.25 nmol/24 hr		2.774
Alkaline phosphatase (adult)	S			Kinetic method	0.01667
Female		30–100 U/L	0.5–1.67 μkat/L		
Male		45–115 U/L	0.75–1.92 μkat/L		
Alkaline phosphatase, heat fractionated	S	20%–35%	0.20–0.35	Kinetic method	0.01
Alpha-fetoprotein (nonmaternal)	S	< 12.8 IU/ml	< 9.92 μg/L	Immunoassay	0.775
Ammonia	P	12–48 μmol/L	12–48 μmol/L	Enzymatic analysis	1
Amylase	S	53–123 U/L	0.88–2.05 nkat/L	Kinetic method	0.01667
	P	43–115 U/L	0.72–1.92 nkat/L		
	U	4–400 U/L	0.07–6.67 nkat/L		
Androstenedione (adult)	S	50–250 ng/dl	1.75–8.73 nmol/L	Immunoassay	0.0349
Angiotensin-converting enzyme	S			Kinetic method	1
Female		19–79 U/L	19–79 U/L		
Male		19–95 U/L	19–95 U/L		
Apolipoprotein	S			Nephelometry	
Apolipoprotein A-1		119–240 mg/dl	1.19–2.4 g/L		0.01
Apolipoprotein B		52–163 mg/dl	0.52–1.63 g/L		0.01
Apolipoprotein B:apolipoprotein A-1 ratio		0.35–0.98	0.35–0.98		1
Aspartate aminotransferase (AST, SGOT)	S			Kinetic method	0.01667
Female		9–25 U/L	0.15–0.42 μkat/L		
Male		10–40 U/L	0.17–0.67 μkat/L		
$Beta_2$-microglobulin	S, P	1.2–2.8 mg/L	1.2–2.8 mg/L	Immunoassay	1
	U	< 200 μg/L	< 200 μg/L		
Bicarbonate (HCO_3^-)	WB, S	22–26 mEq/L	22–26 mmol/L	Calculation	1
Bilirubin, direct	S	0.0–0.4 mg/dl	0–7 μmol/L	Colorimetry	17.1
Bilirubin, total	S	0.0–1.0 mg/dl	0–17 μmol/L	Colorimetry	17.1
C peptide (adult)	S, P	0.5–2.0 ng/ml	0.17–0.66 nmol/L	Immunoassay	0.33
C-reactive protein	S	0.0–12.0 mg/L	0–12 mg/L	Nephelometry	1
CA 15-3	S	0–30 U/ml	0–30 kU/L	Immunoassay	1
CA 19-9	S	0–37 U/ml	0–37 kU/L	Immunoassay	1
CA 27,29	S	0–32 U/ml	0–32 kU/L	Immunoassay	1
CA-125	S	0–35 U/ml	0–35 kU/L	Immunoassay	1
Calcitonin	S			Immunoassay	1
Female		2–17 pg/ml	2–17 ng/L		
Male		3–26 pg/ml	3–26 ng/L		
Calcium	S	8.5–10.5 mg/dl	2.1–2.6 mmol/L	Colorimetry	0.25
	U	0–300 mg/24 hr	0.0–7.5 mmol/24 hr	Colorimetry	0.025
Calcium, ionized	WB	1.14–1.30 mmol/L	1.14–1.30 mmol/L	Ion-selective electrode	1

Note: This table includes reference values, methods, and conversion factors for tests commonly ordered at the Massachusetts General Hospital (MGH) and recorded in the Case Records. The table revises the most recently published data (Normal Reference Laboratory Values. N Engl J Med 327:718–724, 1992). Laboratory values are expressed in the units used at MGH (conventional units) and the units of the Système International d'Unités (SI units), with a factor to convert conventional units to SI units by multiplication. The table is not intended to provide a comprehensive review of reference values, since this information is widely available in standard textbooks. Detailed information on specific methods and instruments is not provided, to avoid suggesting an endorsement of commercial products. Because reference values are affected by many variables, table reference ranges may differ from those of other laboratories as well as from the values given in subsections of *Scientific American Medicine*. Furthermore, the methods and units reported should not be interpreted as a judgment about the optimal way to perform or report a given laboratory test.

Specimen abbreviations: CSF—cerebrospinal fluid JF—joint fluid P—plasma S—serum U—urine WB—whole blood

Chemistry *(continued)*

Analyte	*Specimen*	*Conventional Units*	*SI Units*	*Method or Instrument*	*Factor for Conversion to SI Units*
Carbon dioxide content, total	P	24–30 mmol/L	24–30 mmol/L	Carbon dioxide electrode	1
Carbon dioxide, partial pressure, arterial (P_aco_2)	WB	35–45 mm Hg	4.7–6.0 kPa	Carbon dioxide electrode	0.1333
Carboxyhemoglobin	WB	< 5% of total hemoglobin	< 0.05 fraction of total hemoglobin saturation	Co-oximetry	0.01
Carcinoembryonic antigen (CEA)	P, S	0.0–3.4 ng/ml	0.0–3.4 µg/L	Immunoassay	1
Catecholamines (adult)	U			High-pressure liquid chromatography	
Epinephrine		2–24 µg/24 hr	11–131 nmol/24 hr		5.458
Norepinephrine		15–100 µg/24 hr	89–591 nmol/24 hr		5.911
Dopamine		52–480 µg/24 hr	340–3,134 nmol/24 hr		6.53

PRACTICE OF MEDICINE

Update on Influenza: The Bird Flu Threat

JOHN T. BATTAILE, MD
MICHAEL J. HOLTZMAN, MD
Washington University School of Medicine

Influenza viruses are major causes of morbidity and mortality throughout the world. In the United States alone, between 1990 and 1999, an average of 36,000 deaths a year were attributed to influenza.[1] Recently, there has been renewed concern that influenza virus may cause pandemic disease. The capacity of influenza virus to cause such problems is based on variations in two viral envelope glycoproteins—hemagglutinin and neuraminidase. Point mutations in the RNA genes encoding these proteins allow the virus to evade immunity and cause disease outbreaks in susceptible populations on an almost yearly basis. However, more abrupt, major changes in these proteins, so-called antigenic shifts, can give rise to strains to which the majority of humans are immunologically naive. Pandemics can result if the new virus is also capable of efficient person-to-person transmission.

There are at least two major ways for influenza viruses to develop new pathogenic capabilities. One of these mechanisms is based on gene reassortment events, which was likely the basis for the 1957 Asian and 1968 Hong Kong influenza pandemics. Reassortment events occur when two different viral strains share genes while coinfecting the same cell. For example,

Classifying Headache

The International Headache Society (IHS) criteria,[1] which were introduced in 1988 and updated in 2004, are the worldwide standard for headache classification. IHS criteria categorize headaches as primary or secondary. Primary headaches—those with no other underlying cause—account for 90% of headaches. This category includes migraine, tension, cluster, and miscellaneous headaches, such as primary exertional headaches. There are a large number of secondary headaches, which are classified according to their causes [*see Table, page 3*].

1. The International Classification of Headache Disorders: 2nd edition. Headache Classification Subcommittee of the International Headache Society. Cephalalgia 24(suppl 1):9, 2004 [PMID 14979299]

Triptans for Migraine

Over the past decade, seven triptans have become available in the United States: sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan [*see Table, page 4*].[1] In migraineurs who take oral triptans when their pain is moderate to severe in intensity, the 2-hour response rate (i.e., no pain or mild pain) is about 45% for naratriptan and frovatriptan and about 65% to 70% for the others. With all of the triptans, the 2-hour pain-free response rates are much higher if the drug is taken when the headache is mild; depending on the drug, the rate may exceed 70%.

The oral triptans may not be equally effective for all patients. If a patient has an unsatisfactory or inconsistent response, unpleasant side effects, or tachyphylaxis with one triptan, a different triptan may prove effective and tolerable. Patients who have prominent vomiting or nausea or who desire the quickest relief may benefit from subcutaneous sumatriptan (at 2 hours, 79% of patients show a response and 60% are pain free) or intranasal sumatriptan or zolmitriptan.

avian influenza genes that confer pathogenicity can be transferred to a strain that is capable of human transmission. In addition to this mechanism, it has been proposed that the pandemic H1N1 strain responsible for the 1918 Spanish influenza pandemic was not the result of gene reassortment but rather emerged when an avian influenza virus adapted to spread to humans.[2] Sporadic human infections with avian influenza viruses, such as those being reported in Southeast Asia and elsewhere, serve to increase the likelihood of antigenic shift by creating the potential for gene reassortment or adaptation.

Recent attention has been focused on the pandemic potential for the avian H5N1 strain. Human cases have been reported in several Southeast Asian nations, including China, Thailand, and Vietnam, since 1997. More recent cases have occurred as far west as northern Iraq and Turkey. Migratory waterfowl have been implicated in the westward spread of the virus. In this case, migratory birds may have acquired the virus in Southeast Asia and then infected domestic birds along their migratory routes. The virus then spreads to humans via contact with infected domestic fowl. No sustained human transmission of the virus has been reported, but there have been isolated cases of human-to-human transmission. This phenomenon raises the concern that the virus could eventually acquire the ability to spread efficiently from person to person and spark a deadly pandemic.

The concern over avian flu also derives from the apparent severity of reported cases. Reported mortality for hospitalized patients with confirmed H5N1 infection has varied from 30% to over 80%.[3] In a series of 10 patients from Vietnam infected with the H5N1 virus, the majority required mechanical ventilation within 48 hours of hospital admission. [4] Perhaps most striking is the fact that many of the fatal H5N1 infections have occurred in otherwise healthy, young individuals. This finding has led to comparisons with the 1918 pandemic strain, which killed over 40 million people in a single year,[5] many of them young and previously healthy.

Controlling the next influenza pandemic will require immune and drug strategies. In that regard, work is under way for large-scale production of an effective vaccine. Vaccines with activity against other strains with pandemic potential, such as the H9N2 and H7N7 avian strains, are also being stockpiled in preparation for a pandemic. In individuals who are not effectively vaccinated, antiviral drug therapy may be useful for disease prevention and treatment. Two classes of drugs—adamantanes and neuraminidase inhibitors—have been used for human influenza outbreaks. The adamantanes amantadine and rimantadine are effective against influenza A but not influenza B and work to reduce viral replication by inhibiting uncoating of the virus. However, most avian influenza strains are resistant to the adamantanes. Even in susceptible strains, resistance can develop rapidly with treatment. In addition, resistance among circulating human influenza strains is increasingly common. For these and other reasons, neuraminidase inhibitors and not adamantanes should be used for human infections with avian or the novel flu strains. The neuraminidase inhibitors oseltamivir and zanamivir inhibit the release of virus from infected cells, thereby impeding viral spread. They are effective against both influenza A (including the H5N1 strain) and B and can be used for both disease prevention and treatment. Resistance is less common than with the adamantanes but has been reported in some strains, including recent reports of resistance in H5N1 isolates.[6] Higher doses of oseltamivir may be required to treat certain strains. To be effective, antiviral drug therapy for influenza should be initiated as soon as possible after symptom onset, ideally within the first 12 hours.[7] In addition to the pursuit of new antiviral agents with activity against influenza, other approaches to treatment are being investigated, such as strategies that would enable the infected host to more rapidly and efficiently clear viral infec-

THIS MONTH'S UPDATES

continued from page 1

Patients may experience recurrence, which is defined as the return of headache (usually of moderate or severe intensity) within 24 hours after an initial response to acute treatment. When taken for moderate to severe pain, naratriptan, frovatriptan, almotriptan, and eletriptan have the lowest recurrence rates (about 20% to 25%). The recurrence rates for the other triptans are about 31% with zolmitriptan, 33% with sumatriptan, and 40% with rizatriptan. The time to recurrence is generally about 12 hours.[2]

2. Geraud G, Keywood C, Senard JM: Migraine headache recurrence: relationship to clinical, pharmacological, and pharmacokinetic properties of triptans. Headache 43:376, 2003 [PMID 12656709]

Best Medications for Migraine Prevention

Class I evidence indicates that the beta blocker propranolol, the tricyclic antidepressant amitriptyline, and the antiseizure medications divalproex sodium and topiramate are the most effective preventive medications, reducing the frequency of migraines by more than 50% in about 50% of patients. In general, preventive medications are more effective when patients are placed on a titration schedule with a minimum target dose. Titration schedules and minimum target doses are as follows: propranolol (either regular or long acting), 40 mg daily, increased weekly by 40 mg to a maximum daily dose of 120 to 160 mg; amitriptyline, 10 mg at bedtime, increased weekly by 10 mg to a maximum daily dose of 50 mg; divalproex sodium (either regular or extended release), 500 mg daily for 1 week and then 1,000 mg daily; and

Major Categories of Headache Disorders

Primary Headaches

Migraine

Tension-type headache

Cluster headache and chronic paroxysmal hemicrania

Miscellaneous headaches unassociated with structural lesion: idiopathic stabbing, external compression, cold stimulus, benign cough, benign exertional, associated with sexual activity

Secondary Headaches

Headache associated with head trauma

Headache associated with vascular disorder: acute ischemic cerebrovascular disorder, intracranial, hematoma, subarachnoid hemorrhage, unruptured vascular malformation, arteritis, carotid or vertebral artery pain, venous thrombosis, arterial hypertension, associated with other vascular disorder

Headache associated with nonvascular intracranial disorder: high and low cerebrospinal fluid pressure, intracranial infection, intracranial sarcoidosis and other noninfectious inflammatory disease, related to intrathecal injections, intracranial neoplasm, associated with other intracranial disorder

Headache associated with substances or their withdrawal: acute and long-term substance use or exposure, withdrawal after acute and long-term use, associated with substances with uncertain mechanism

Headache associated with noncephalic infection: viral infection, bacterial infection, other infection

Headache associated with metabolic disorder: hypoxia, hypercapnia, mixed hypoxia and hypercapnia, hypoglycemia, dialysis, other metabolic abnormality

Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures

Cranial neuralgias, nerve trunk pain, and deafferentation pain

Persistent pain of cranial nerve origin, trigeminal neuralgia, glossopharyngeal neuralgia, nervus intermedius neuralgia, superior laryngeal neuralgia, occipital neuralgia, central causes of head and facial pain other than tic douloureux

Triptans Available in the United States

Drug (Brand Name)	*Formulation*	*Strengths (mg)*
Almotriptan (Axert)	Tablets	12.5
Eletriptan (Relpax)	Tablets	20, 40
Frovatriptan (Frova)	Tablets	2.5
Naratriptan (Amerge)	Tablets	1, 2.5
Rizatriptan (Maxalt)	Tablets Orally disintegrating preparation* (Maxalt MLT)	5, 10
Sumatriptan (Imitrex)	Subcutaneous injection Tablets Nasal spray	6 25, 50, 100 5, 20
Zolmitriptan (Zomig)	Tablets Orally disintegrating preparation* (Zomig ZMT)	2.5, 5

*Dissolves on the tongue; can be taken without water (efficacy similar to that of tablet form).

topiramate, 25 mg daily for the first week, increased by 25 mg/wk in divided doses to a maximum daily dose of 100 mg administered at a dosage of 50 mg twice daily.[1]

Other beta blockers may also be effective [*see Table, page 5, top*]. Regarding the tricyclic antidepressants, the quality of evidence for nortriptyline is not as good as that for amitriptyline, but the clinical impression is one of similar efficacy with less sedation. Venlafaxine may be as effective as amitriptyline with fewer side effects.[2,3] Selective serotonin reuptake inhibitors are probably not effective for migraine prevention. Verapamil and gabapentin are only modestly effective for migraine prevention.

3. Ozyalcin SN, Talu GK, Kiziltan E, et al: The efficacy and safety of venlafaxine in the prophylaxis of migraine. Headache 45:144, 2005 [PMID 15705120]

Natural Products for Migraine Prevention

There are natural products that may be beneficial for migraine prevention, including the herb feverfew (*Tanacetum parthenium*); extract from the butterbur plant, *Petasites hybridus* (Petadolex, 75 mg twice daily); riboflavin (400 mg a day); coenzyme Q10 (100 mg three times a day[1]); and oral magnesium supplements. Botulinum toxin injections may also be of benefit, especially in intractable cases. The relative benefit of these treatments may become clearer with additional studies, but for now, some migraineurs may prefer them because they have few if any side effects.

XIII Disorders of Sleep

SUDHANSU CHOKROVERTY, MD
New York Medical College

Idiopathic Hypersomnia

The International Classification of Sleep Disorders defines idiopathic hypersomnia as a disorder of excessive sleepiness that is associated with major sleep episodes, the cause of which is presumed to lie in the central nervous system. The disorder is further categorized as with or without long sleep time (over 10 hours or from 6 to 10 hours, respectively). The disease develops insidiously, generally between the ages of 15 and 30 years. It closely resembles narcolepsy. Affected patients generally sleep for hours, and the sleep is not refreshing. The patient does not give a history of cataplexy or snoring.

Idiopathic hypersomnia is a disabling and lifelong disorder. The Multiple Sleep Latency Test shows a mean sleep latency of less than 8 minutes without sleep-onset rapid eye movements. The treatment of idiopathic hypersomnia is similar to the stimulant treatment of narcolepsy; however, the therapeutic response is unsatisfactory.

Quieting Restless Legs

Four groups of drugs are available to treat restless legs syndrome (RLS) and periodic limb movement in sleep: dopaminergic drugs (e.g., carbidopa-levodopa and dopamine agonists such as pergolide, pramipexole, ropinirole, and cabergoline); benzodiazepines (e.g., clonazepam); opioids (e.g., codeine, propoxyphene, oxycodone, and hydrocodone); and anticonvulsants (e.g., gabapentin). The best drug for initial therapy in most cases is a dopamine agonist. The only drug currently approved by the Food and Drug Administration for use in RLS is ropinirole, but several clinical trials have proved that other agents can be used for this disorder.

For Insomnia, Briefly

For transient insomnia or insomnia of short duration, treatment with sedative-hypnotics (e.g., zolpidem, zaleplon, or eszopiclone) or short- or intermediate-acting benzodiazepines (e.g., temazepam) for a few nights to a few weeks is appropriate [*see Table, page 5, bottom*]. Hypnotic medications should not be used for chronic insomnia.

Anticonvulsants	Divalproex sodium*	500–1,000 mg/day	Nausea, tremor, drowsiness, weight gain, alopecia, hematologic and liver abnormalities, fetal abnormalities
	Topiramate*	25–300 mg h.s.	Weight loss, paresthesias, cognitive disturbances, kidney stones
	Gabapentin	300–800 mg t.i.d.	Dizziness, fatigue, drowsiness

*Class I evidence indicates that these are the most effective medications for migraine prevention.

cles of patients with Duchenne muscular dystrophy (DMD), but the procedure failed to change the recipients' muscle function. Several prospective, randomized, placebo-controlled trials involving repeated myoblast injections to the same muscles failed to demonstrate any improvement in strength. The finding in dystrophic mice that aminoglycoside antibiotics can "read through" nonsense mutations and generate a full-length protein, thereby restoring dystrophin function, led to a trial examining the efficacy of gentamicin therapy in DMD patients who had a premature stop codon. The results were disappointing, although mild reduction in the serum CK level was noted. Future gene therapies may prove efficacious if proper vectors are found that can be used to effectively insert the gene into the muscle.[1]

Managing McArdle Disease

Muscle phosphorylase deficiency (also known as McArdle disease) is the prototypical glycogenosis: glycogen breakdown is inhibited, which leads to pyruvate shortage and impaired energy output. It is the second most common cause of recurrent myoglobinuria after carnitine palmitoyltransferase deficiency.

Diagnosis

This autosomal recessive disease presents as exercise intolerance and myoglobinuria in patients older than 15 years. If patients rest briefly after exercise-induced myalgia and stiffness, they can resume activity with better endurance (second-wind phenomenon), owing to increased mobilization and utilization of free fatty acids and glucose. Fixed muscle weakness may develop later in life. The resting serum creatine kinase level is often elevated. The inability to produce venous lactate after exercise has been traditionally examined with the ischemic forearm exercise test. This test, however, is falling out of favor as a diagnostic tool because it produces false positive results, is not specific, can be painful, and may result in focal muscle damage. A nonischemic exercise test is of equal diagnostic value and does not have the drawbacks of the ischemic test. Muscle biopsy shows an absence of phosphorylase, the presence of subsarcolemmal vacuoles, and increased glycogen accumulation. The diagnosis is confirmed by biochemical analysis of muscle and molecular analysis of blood cells. The defect is caused by mutations in the muscle isoform of phosphorylase on chromosome 11q13 and can be detected in the leukocytes in more than 90% of patients.

Treatment

No treatment is available for McArdle disease, but aerobic exercise training and a high-protein diet can be helpful. Vitamin B_6 supplementation has also been reported to be helpful. The results of a controlled trial indicate that creatine supplementation may

Short-Term Drug Therapy for Insomnia

Category	*Agent*	*Dose (mg)**
Sedative-hypnotics	Zaleplon	5–10
	Zolpidem	5–10
	Zolpidem extended release	6.25–12.5
	Eszopiclone	1–3
	Ramelteon	8
Short-acting or intermediate-acting benzodiazepines	Temazepam	7.5–30
	Triazolam	0.125–0.250
	Flurazepam	15–30
	Estazolam	1–2

*All agents are given at bedtime for a few nights to a few weeks.

FDA Approval Report

The following is selected from the FDA's list of recently approved products. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

New Treatment for Myelodysplastic Syndrome

Generic Name: Lenalidomide

Brand Name: Revlimid

Manufacturer: Celgene Corporation, Summit, New Jersey

The FDA has approved lenalidomide for the treatment of patients with a subtype of myelodysplastic syndrome (MDS). The subtype is that form of MDS associated with the deletion 5q cytogenetic abnormality. In clinical trials, patients treated with lenalidomide no longer needed transfusions; most patients became independent of transfusion after 3 months of therapy. The transfusion-free period lasted for an average of 44 weeks.

Lenalidomide is structurally similar to thalidomide, a drug known to cause severe birth defects. Additional studies are ongoing in animals to address whether there is a risk that lenalidomide will also cause birth defects when taken during pregnancy. While these studies are under way, lenalidomide is being marketed under a risk management plan called RevAssist, which is designed to prevent fetal exposure. Under RevAssist, only pharmacists and prescribers registered with the program will prescribe and dispense Revlimid. The program requires patients, including female patients undergoing mandatory pregnancy testing, to give informed consent before starting Revlimid. Physicians are to check pregnancy tests, limit prescriptions to a 1-month mail supply, and report any pregnancies to FDA. FDA and the manufacturer will reevaluate the risk-management plan when results of further animal testing for birth defects are completed. The labeling for lenalidomide will include a black-box warning and a medication guide regarding the prevention of fetal exposure. Additional black-box warnings include the potential need to lower the dose because of suppressed blood counts, as well as an increased risk of blood clots. Common side effects reported with lenalidomide include thrombocytopenia, neutropenia, diarrhea, pruritus, rash, and fatigue.

Easing the Course in ALS Patients

The course of amyotrophic lateral sclerosis (ALS) is invariably fatal. Therapy is primarily aimed at symptom management. For patients with dysphagia, percutaneous endoscopic gastrostomy (PEG) should be considered soon after the onset of symptoms. Initiation of noninvasive ventilation should be planned with care, with the risk of ventilator dependence balanced against that of sudden death. Algorithms outlining the indications for initiation of PEG and ventilatory assistance are available.[1] Physical therapy, rehabilitation techniques, and assistive devices such as canes, ankle-foot orthoses, and walking frames may prolong a patient's functional independence, but most patients will eventually require a wheelchair. Riluzole is the only drug available for the treatment of ALS that is approved by the Food and Drug Administration. It is believed to reduce glutamate-mediated excitotoxicity, although its exact mode of action is not well understood. Studies have shown that riluzole slows the decline in muscle strength and prolongs survival by up to 4 months[1]; it may be most useful in patients with early or mild disease. Other medications are helpful in controlling sialorrhea, pseudobulbar affect (emotional lability), dyspnea, and anxiety.[1] Hospice referral should be considered in the terminal phase.

CLINICAL ESSENTIALS

V Adult Preventive Health Care

MARK HELFAND, MD
Oregon Health & Science University

Screening for Breast Cancer Genes

In women whose family history suggests an increased risk of deleterious *BRCA1* or *BRCA2* mutations, the United States Preventive Services Task Force (USPSTF) recommends referral for genetic counseling and evaluation for *BRCA* testing (grade B recommendation). However, the USPSTF recommends against routine testing for breast cancer susceptibility genes (*BRCA1* or *BRCA2*) or routine referral for genetic counseling in women whose family history does not suggest an increased risk of deleterious mutations in these genes

(grade D recommendation). Such screening and counseling have few or no benefits and could have important adverse ethical, legal, social, and medical consequences.

Noncancer Prevention Imperatives

The USPSTF assigns an overall grade of A, B, C, D, or I to each prevention service. The grades reflect the overall strength of evidence and the magnitude of benefit, defined as benefits minus harms. A grade of A indicates services that have solid supporting evidence and at least a moderate net benefit. Several preventive measures have earned an A grade on the strength of their good supportive evidence, substantially greater benefits than harms, and broadest applicability to primary care practice [*see Table, page 8*].

7 INFECTIOUS DISEASE

XXXI Viral Zoonoses

LYLE R. PETERSEN, MD, MPH
DUANE J. GUBLER, SC.D.
Centers for Disease Control and Prevention

Dealing with Dengue

Early diagnosis and prompt management with fluid replacement therapy can substantially reduce case-fatality rates in dengue fever.[1] Initial management and treatment decisions should not be delayed pending results of serologic tests. Clinical laboratory tests should be used to monitor vascular leakage.[1]

There is no licensed vaccine for dengue/dengue hemorrhagic fever, although significant progress is being made toward the development of live attenuated and recombinant candidate vaccines using infectious clone technology.[2,3] Currently, disease prevention depends exclusively on mosquito control and personal protective measures, such as the use of mosquito repellents.

Preventing Yellow Fever

Yellow fever is an international reportable disease, and immunization is required for travelers to many countries of sub-Saharan Africa and tropical America. The live, attenuated 17D vaccine, delivered as a single 0.5 ml subcutaneous dose, is highly effective. Immunity is probably lifelong, but for travel certification, revaccination is recommended every 10 years. Information about indications for yellow fever vaccine and requirements for international travel are available at www.cdc.gov/travel/reference.htm.[1] For patients who require immunization, the locations of designated yellow fever vaccination centers can be obtained through local health departments in most areas.

Although the 17D vaccine is one of the safest vaccines, rare cases of severe and fatal infection from vaccination have been reported. The elderly may experience a higher incidence of serious adverse events.[2] Persons with documented egg allergy should not be immunized or should be skin-tested with the vaccine. The vaccine must not be given to children younger than 6 months, in whom there is a risk of postvaccinial encephalitis; it is best to delay vaccination until 9 months of age. On theoretical grounds, persons with immunosuppression, including those with clinical AIDS, should not be immunized. Immunization during pregnancy is generally contraindicated.

The Marburg Outbreak

In 2005, the World Health Organization confirmed an outbreak of Marburg virus infection in 124 persons in Angola.[1] Information for travelers to Angola is available from the CDC at http://www.dcd.gov/travel/other/marburg_vhf_angola_2005.htm. The ecology of Marburg virus remains virtually unknown. Marburg virus disease presents as an acute febrile illness; it can progress within 6 to 8 days to severe hemorrhagic manifestations. Clinical manifestations include fever, chills, headache, myalgia, maculopapular rash, nausea, vomiting, chest pain, and abdominal pain. Signs and symptoms can become increasingly more severe. Clinicians should consider the diagnosis of Marburg virus for febrile patients who, within 10 days before onset of fever, have traveled in northern Angola, had direct contact with blood or other body fluids of a person suspected of having hemorrhagic fever, or have worked in a laboratory that handles hemorrhagic fever viruses. No vaccine or curative treatment is available; treatment is supportive.

XXII Female Sexuality: Assessing Satisfaction and Addressing Problems

JENNIFER POTTER, MD
Harvard Medical School

Hysterectomy and Sexual Function

Despite its proximity to the major pelvic or paracervical ganglion, the cervix itself is a relatively insensitive structure. There are numerous theoretical reasons why removal of the uterus might be expected to interfere with sexual response, including anatomic changes (shortening of the vaginal vault, scar formation in the vaginal cuff), surgical damage to pelvic nerves and blood vessels, secondary hormonal changes, and the possibility that uter-

Strongly Recommended Noncancer Preventive Services in Adults*

Service	*Candidates*	*Established Benefits*
Aspirin for primary prevention of cardiovascular events	Adults at high cardiovascular risk	Reduces the risk of stroke
Blood pressure screening	All adults	Reduces the risk of stroke
Screening for lipid disorders	Men 35 yr of age and older; women 45 yr of age and older; and younger adults at increased risk for coronary artery disease	Reduces overall mortality, as well as mortality from cardiovascular disease
Chlamydial infection screening	Sexually active women 25 yr of age and younger; other asymptomatic women at increased risk for infection	Reduced the risk of pelvic inflammatory disease in one randomized trial
Hepatitis B virus (HBV) infection screening	Pregnant women	Reduces prenatal transmission of HBV
Syphilis screening	Persons at increased risk for infection; all pregnant women	Penicillin treatment during pregnancy reduces the risk to the fetus of acquiring congenital syphilis
HIV screening†	Pregnant women High-risk men and women	Reduces prenatal transmission of HIV Delays mortality from HIV disease and permits counseling to reduce transmission
Screening for asymptomatic bacteriuria	Pregnant women (urine culture at 12–16 weeks' gestation)	Prevents symptomatic urinary tract infections, low birth weight, and preterm delivery

*As per the United States Preventive Services Task Force. †As per the CDC.

ine contraction itself contributes substantively to orgasmic pleasure. Although studies of sexual function after hysterectomy are fraught with methodological problems, the preponderance of evidence suggests that detrimental effects of either total or supracervical hysterectomy are rare and that preoperative sexual function is the most important predictor of postoperative sexual satisfaction.

Using Sexual Questionnaires

Having patients complete a written questionnaire can sometimes help to define key issues. Several multidimensional self-report instruments on female sexual dysfunction have been developed. These include the 25-item Derogatis Interview for Sexual Functioning (DISF/DISF-SR), the 22-item Brief Index of Sexual Functioning for Women (BSFI-W), and the 19-item Female Sexual Function Index (FSFI). The FSFI, which is the most commonly used of these questionnaires, is available free of charge on the Internet (http://www.FSFIquestionnaire.com). Each of these questionnaires is well standardized, relatively unobtrusive, and inexpensive and takes 15 to 20 minutes to administer and score; moreover, normative values for both clinical and nonclinical populations are available. There is reason to believe that use of questionnaires may result in a more accurate history, because women may be more willing to answer sensitive questions privately than during a face-to-face conversation.

The Right Route for Estrogen Replacement

Most studies of systemic estrogen replacement in postmenopausal women demonstrate an improvement in sexual function in all phases of the sexual-response cycle.[1] It is not clear to what extent the effect on desire is mediated indirectly through amelioration of vaginal discomfort caused by atrophic changes or alleviation of sleep deprivation caused by vasomotor symptoms. Lubricants and local application of topical estrogen[2] can help counteract atrophy. Systemic estrogen replacement may be indicated for vasomotor symptoms, in the absence of contraindications; however, it should be remembered that oral estrogen increases sex hormone–binding globulin levels and thus may theoretically reduce rather than increase desire. Therefore, the optimal vehicle for systemic estrogen replacement may be a transdermal preparation, which avoids the hepatic first-pass effect. In patients with only minor vasomotor symptoms, topical estrogen applied to the genitalia might be a safer long-term strategy.

PRACTICE OF MEDICINE

Vitamin D and Cancer: A Goldilocks Paradox?

KAREN ANTMAN, MD
Columbia University College of Physicians and Surgeons

Skin cancers are associated with excess solar exposure. On the other hand, inadequate solar exposure may result in vitamin D deficiency, which may be linked with an increased risk of prostate, colon, breast, and other cancers.

The relevant band of sunlight is ultraviolet B (UVB) light. In the United States, UVB levels are lowest in the Northeast and highest in the Southwest. Mortality for many cancers in the United States is highest in the Northeast and lowest in the Southwest, with the notable exceptions of bronchogenic cancer in the Southeast and skin cancers in the South. Regional UVB levels in the month of July show statistically significant inverse correlations with the incidence of bladder, breast, colon, esophageal, gastric, ovarian, prostate, rectal, renal, and uterine cancer and non-Hodgkin lymphoma; in addition, UVB may possibly be associated with an increase in the incidence of laryngeal, oral, cervical, gallbladder, and pancreatic cancers and Hodgkin lymphoma.

UVB levels depend on season, time of day, exposure time, latitude, altitude, the amount of skin surface exposed, cloud cover, smog, sunscreen use, and skin pigmentation. Clouds, pollution, smog, and ozone can block UVB. Window glass blocks about

7 INFECTIOUS DISEASE

X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas

SHAWN J. SKERRETT, MD
University of Washington School of Medicine

Treating *Haemophilus influenzae* Infection

The initial antibiotic of choice for meningitis and other invasive *H. influenzae* infections is a third-generation cephalosporin such as ceftriaxone or cefotaxime. These agents are highly active against all isolates of *H. influenzae*, penetrate the cerebrospinal fluid, and eradicate nasopharyngeal carriage of *H. influenzae* type b. The pediatric dose of ceftriaxone is 50 mg/kg every 12 hours and that for cefotaxime is 50 mg/kg every 6 hours. For adults, the maximum dose of ceftriaxone is 2 g every 12 hours and that for cefotaxime is 2 g every 6 hours. The preferred alternative treatment for *H. influenzae* meningitis is chloramphenicol (75 to 100 mg/kg/day in six divided doses). Children with *H. influenzae* meningitis also should receive dexamethasone (0.6 mg/kg/day in four divided doses). Other antibiotics that are highly active against nearly all strains of *H. influenzae* include carbapenems, aztreonam, β-lactam/β-lactamase inhibitor combinations, fluoroquinolones, azithromycin, and tetracycline[1] [*see Table, page 4, top*]. Ampicillin is highly effective against sensitive strains, but 35% to 40% of North American isolates of *H. influenzae* are resistant to ampicillin. Most ampicillin resistance is mediated by β-lactamase production, but conventional susceptibility testing is recommended for invasive isolates to detect all resistant strains. Intravenous antibiotic therapy is recommended for meningitis and endocarditis and for the initial treatment of other invasive infections. Less severe *H. influenzae* infections can be managed with oral antibiotics. Most *H. influenzae* infections can be cured with 7 to 10 days of therapy, but treatment should continue for 3 to 6

PRACTICE OF MEDICINE

continued from page 1

95% of UVB light. Direct UV light on a sunny summer day allows skin to produce vitamin D; such production ceases after 10 to 20 minutes of exposure in light-skinned people. Because melanin blocks UVB, vitamin D production requires proportionately longer exposure in darker-skinned people; indeed, the need for vitamin D may provide the evolutionary explanation for lighter skin in northern latitudes. Between November and March in most of the United States, when the sun is at a lower angle and UVB is filtered through the atmosphere, even light-skinned people produce little vitamin D. Older or obese persons also produce vitamin D less efficiently.

Fortified foods are the major dietary sources of vitamin D (calciferol). Rickets in children was virtually eliminated in the 1930s by the fortification of milk with vitamin D. Vitamin D_3 (cholecalciferol) comes from fish oil, eggs, organ meats, and animal fat. Vitamin D_2 (ergocalciferol), which is less biologically active, is found in fortified foods and some supplements. Most vitamin D supplements provide 400 IU. A glass of fortified milk provides about 100 IU. For comparison, 10 to 20 minutes of exposure on a sunny beach can result in the production of 10,000 IU. Despite food fortification, a substantial fraction of the United States population is vitamin D deficient.[1] Vitamin D deficiency rates are particularly high in the elderly and dark-skinned people in northern latitudes.

In laboratory models, vitamin D reduces cell proliferation and increases cell differentiation, improves cell adhesion, and inhibits cancer progression and metastasis. Vitamin D ameliorates the growth-signaling effects of insulin-like growth factor–1 (IGF-1) and induces apoptosis and downregulation of telomerase.[2-5] Many tissues have vitamin D receptors (VDRs). Various alleles of the VDR genes may affect the risk of cancer.[4]

Clinical Studies

Skin cancer The development of basal cell cancers and melanoma correlates with intermittent weekend or vacation sun exposures and sunburns, whereas regular occupational exposure is protective. However, actinic keratosis and squamous cell carcinoma correlate with total lifetime UVB irradiation.

Colon cancer A number of studies have documented significant inverse associations of serum 25-hydroxyvitamin D_3 [25(OH)D_3] concentrations with the risk of colorectal cancer.[6-9] Analyses limited to dietary vitamin D tend to have mixed results because dietary sources provide only a portion of total vitamin D; supplements and solar UVB radiation provide the balance.[10] Thus, serum levels may be more reliable than dietary histories.

Prostate cancer Vitamin D inhibits prostate cancer growth via VDRs and increases IGF-binding protein expression. The IGF and vitamin D regulatory systems may interact to affect prostate cancer risk.[4] In a case-control study from Great Britain, prostate cancer risk correlated inversely with childhood sunburn, sunbathing, and foreign holidays; in addition, prostate cancer developed at an earlier age in men with low UV exposure than in those with higher exposure.[11]

Breast cancer In premenopausal women, consumption of vitamin D has been inversely associated with risk of breast cancer.[12] Breast cancer risk has also been correlated with lower mean 25(OH)D levels and 1,25$(OH)_2$D levels. For both metabolites, the trend was stronger in women older than 60 years.[13]

Conclusions

The interaction of sun exposure and cancer risk may be more complex than originally conceived—too much or too little vitamin D may increase cancer risk. Consensus is evolving on the "just right" level of solar exposure and whether increased oral vitamin D supplements can substitute for UVB exposure.

weeks in cases of osteomyelitis or endocarditis.

1. Johnson DM, Sader HS, Fritsche TR, et al: Susceptibility trends of *Haemophilus influenzae* and *Moraxella catarrhalis* against orally administered antimicrobial agents: five-year report from the SENTRY Antimicrobial Surveillance Program. Diagn Microbiol Infect Dis 47:373, 2003 [PMID 12967753]

The New Front Runner

Nontypeable strains of *H. influenzae* are isolated from 15% to 30% of purulent middle-ear effusions in both children and adults. *H. influenzae* is now the leading cause of persistent otitis media in children immunized with the pneumococcal conjugate vaccine.[1]

As with all cases of otitis media, infants typically present with fever and irritability, and older children and adults complain primarily of ear pain. The clinical diagnosis is made by otoscopy. A bacteriologic diagnosis requires tympanocentesis, but this procedure is warranted only for evaluation of treatment failures.

1. Casey JR, Pichichero ME: Changes in frequency and pathogens causing acute otitis media in 1995–2003. Pediatr Infect Dis J 23:824, 2004 [PMID 15361720]

Managing *Moraxella*

Moraxella catarrhalis is the third most common cause of otitis media, sinusitis, and acute exacerbations of chronic bronchitis, after *H. influenzae* and *Streptococcus pneumoniae*.[1] The majority of lower respiratory tract infections attributed to *M. catarrhalis* in adults occur in patients with underlying chronic obstructive pulmonary disease. More than 90% of clinical isolates of *M. catarrhalis* produce β-lactamases that render ampicillin and amoxicillin ineffective.[2] Penicillin–β-lactamase–inhibitor combinations, second- and third-generation cephalosporins, fluoroquinolones, macrolides, and tetracyclines are active against nearly all strains of *M. catarrhalis* [*see Table, page 4, top*].

Best Tests for Legionnaires Disease

The diagnosis of legionellosis requires the isolation of the organism in culture, detection of microbial antigens or nucleic acids in body fluids, or demonstration of serologic evidence of infection [*see Table, page 4, bottom*]. However, an early clue to the diagnosis of Legionnaires disease can be obtained from nonspecific stains of sputum, bronchoalveolar lavage fluid, or lung tissue.

Rapid Diagnosis of *Legionella* Pneumonia

Urinary antigen detection is currently the most helpful test for the rapid diagnosis of legionellosis. Antigens appear in the urine within 3 days of the onset of illness and may persist for months, although most patients stop excreting antigen within 6 weeks. The sensitivity of this test is higher in cases of severe pneumonia than in milder disease.[1] The major limitation of urinary antigen testing is that currently available tests reliably detect only *L. pneumophila* serogroup 1, which accounts for more than 80% of legionellosis cases diagnosed in the United States.

1. Blazquez RM, Espinosa FJ, Martinez-Toldos CM, et al: Sensitivity of urinary antigen test in relation to clinical severity in a large outbreak of *Legionella* pneumonia in Spain. Eur J Clin Microbiol Infect Dis 24:488, 2005 [PMID 15997369]

Pseudomonas in the Diabetic Ear

Pseudomonas aeruginosa is the causative pathogen in nearly all cases of malignant (necrotizing) exter-

Antibiotics Effective against *Haemophilus influenzae* and *Moraxella catarrhalis*

nal otitis, a chronic, invasive infection of the external auditory canal that predominantly afflicts elderly persons with diabetes mellitus.[1] Rarely, cases have been reported in AIDS patients and immunocompromised children. The infection spreads to the temporal bone and mastoid, often involving the adjacent cranial nerves as they exit the skull. Severe otalgia is the presenting symptom, and most patients have purulent otorrhea with an intact tympanic membrane. Facial nerve paresis is evident in 30% to 40% of cases; other cranial neuropathies are less common. Fever and other systemic signs of infection are usually absent. The erythrocyte sedimentation rate (ESR) is nearly always markedly elevated. Technetium-99m bone scanning is very sensitive but not specific for this condition. Computed tomography and magnetic resonance imaging are useful for defining the extent of disease, with MRI being more sensitive for delineating the soft tissue component.[1] The diagnosis can be made from the clinical presentation, imaging studies, and cultures of diseased bone or granulation tissue in the external canal.

7 INFECTIOUS DISEASE

XXIV Hyperthermia, Fever, and Fever of Undetermined Origin

HARVEY B. SIMON, MD, FACP
Harvard Medical School

Causes of Hyperthermia

Numerous clinical disorders can disrupt thermoregulatory homeostasis by causing increased heat production, decreased heat dissipation, or hypothalamic insult, thereby inducing hyperthermia [*see Table, page 5, top*]. Mild forms of hyperthermia are common. In dehydration, for example, cutaneous vasoconstriction and cessation of sweating occur in response to the decrease in intravascular volume as a means of conserving further loss of fluid and of minimizing the consequences of fluid loss. As a result, heat dissipation is impaired and body temperature may rise. The hyperthermia of dehydration is usually mild and is readily corrected by fluid replacement. In some cases, however, thermoregulatory disorders cause extreme pyrexia, in which body temperatures rise to 41.1° C (106.0° F) or higher; examples of these thermoregulatory disorders are heatstroke, malignant hyperthermia of anesthesia, thyroid storm, and hypothalamic insult caused by infection, tumor, or drugs.

A Half-century of Diagnostic Challenges

Although geographic factors are relevant, the leading causes of fever of undetermined origin (FUO) are reasonably uniform throughout the United States. The relative frequency of the etiologic categories responsible for FUO have been relatively stable over the past 5 decades [*see Table, page 5, bottom*].

The Serotonin Syndrome

The serotonin syndrome,[1] which results from excessive agonism of serotoninergic receptors in the central nervous system and periphery, has become more prevalent with the increasing use of selective serotonin reuptake inhibitors (SSRIs) and other serotoninergic agents. Because of its broad range of clinical manifestations and the large number of prescription, over-the-counter, and herbal products that have been implicated, the serotonin syndrome is often unrecognized. The actual prevalence is not known, but the syndrome occurs in 14% to 16% of patients who take overdoses of SSRIs.

Serotonin syndrome begins abruptly within 5 weeks of starting

Diagnostic Tests for Legionellosis

Test	*Specimen*	*Sensitivity (%)*	*Specificity (%)*	*Comment*

serotoninergic agents, either singly or in combination. In mild cases, patients exhibit hyperkinesia, intermittent tremors, hyperreflexia and clonus, hyperactive bowel sounds, diarrhea, mydriasis, and tachycardia. Patients with these milder cases may have shivering and diaphoresis, but body temperature is normal. In moderate to severe cases, however, hyperthermia is the rule, and it may be severe. Muscular rigidity, agitation, and ocular clonus or inducible clonus are characteristic features of the severe serotonin syndrome.

Management of the serotonin syndrome requires removal of the responsible drug or drugs and metabolic and hemodynamic support. In mild cases, agitation and tremors can often be controlled with benzodiazepines, but severely ill patients require sedation, neuromuscular paralysis, and ventilatory support. Antipyretics, beta blockers, bromocriptine, and dantrolene are not effective. Cyproheptadine, olanzapine, and chlorpromazine have been useful in isolated cases but have not been studied fully.[1]

Causes of Hyperthermia

Cause	*Example*
Excessive heat production	Delirium tremens Drug abuse (amphetamines) Exertional hyperthermia Generalized tetanus Heatstroke (exertional)* Lethal catatonia Malignant hyperthermia of anesthesia Neuroleptic malignant syndrome* Pheochromocytoma Salicylate intoxication Serotonin syndrome Status epilepticus Thyrotoxicosis
Diminished heat dissipation	Anticholinergic drugs Autonomic dysfunction Dehydration Heatstroke (classic)* Neuroleptic malignant syndrome* Occlusive dressings Drug abuse (cocaine)
Hypothalamic dysfunction	Cerebrovascular accidents Encephalitis Idiopathic hypothalamic dysfunction Neuroleptic malignant syndrome* Sarcoidosis and granulomatous infections Trauma Tumors

*Pathogenesis of these disorders is mixed.

Chill Out

Patients with strokes are at risk for additional brain injury from fever; the result is a marked increase in morbidity and mortality, especially when the pyrexia occurs soon after the stroke. Because of this, even modest elevations in temperature should be suppressed in patients with acute strokes. In addition, moderate induced hypothermia may improve the outcome of strokes, even in patients who are afebrile on presentation. Hypothermia may also improve outcome after traumatic brain injury[1] in neonates with hypoxic-ischemic encephalopathy[2] and in patients receiving cardiopulmonary resuscitation.[3]

FDA Approval Report

The following is selected from the FDA's list of recently approved products. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

New Treatment for Advanced Kidney Cancer

Generic Name: Sorafenib tosylate

Brand Name: Nexavar

Manufacturer: Bayer Pharmaceuticals Corporation, Westhaven, Connecticut

The FDA has approved sorafenib tosylate for the treatment of adults with advanced renal cell carcinoma, the most common type of kidney cancer. In two studies in patients with advanced kidney cancer, the median time to tumor progression or death was 167 days in patients treated with sorafenib tosylate, compared with 84 days in patients not treated with the drug. In the larger of the two studies, most patients had previously received treatment with interleukin-2 or interferon. Common temporary side effects reported with sorafenib tosylate are rash; diarrhea; increased blood pressure; and redness, pain, swelling, or blisters on the palms of the hands or soles of the feet.

FDA Approves New Treatment for Advanced Kidney Cancer. FDA News. U.S. Food and Drug Administration, December 20, 2005 (http://www.fda.gov/bbs/topics/NEWS/2005/NEW01282.html)

ed patients. A brain computed tomography scan may be adequate, but a magnetic resonance imaging scan without contrast enhancement will yield more clinically useful information. The fundamental purpose of a brain-imaging study is to rule out space-occupying lesions such as tumors and subdural hematomas. MRI is becoming increasingly useful for assessing the burden of cerebral infarcts, as well. Elderly persons are at increased risk for small infarcts in deep brain structures that may occur covertly.

MRI can also detect hippocampal atrophy when imaging is performed in a plane perpendicular to the axis of the temporal lobe. Hippocampal atrophy is commonly seen in Alzheimer disease (AD), but this finding is suggestive rather than diagnostic of AD because it is also seen both in normal elderly patients and in those with other dementing illnesses.

Positron emission tomography (PET) using fluorodeoxyglucose as a tracer may show reduced metabolic activity in the temporoparietal regions in AD, but it is not clear what additive value this technique provides beyond the clinical diagnosis and at what cost. More recently, a PET tracer known as Pittsburgh compound B (PIB) has been shown to label brain amyloid in patients with AD. Studies are under way to determine whether PET imaging using PIB is of value in the diagnosis of AD.[1]

1. Klunk WE, Engler H, Nordberg A, et al: Imaging brain amyloid in Alzheimer's disease with Pittsburgh Compound-B. Ann Neurol 55:306, 2004 [PMID 14991808]

Vitamin E Fails a Test

Vitamin E is often recommended for patients with AD because a 2-year study of AD patients with moderate dementia showed that vitamin E (α-tocopherol, 2,000 IU a day) delayed the progression to severe dementia by about 200 days. A subsequent study of the use of vitamin E in patients with mild cognitive impairment failed to show any benefit.[1] These results call into question the rationale for treating patients with mild AD with vitamin E.

1. Petersen RC, Thomas RG, Grundman M, et al: Vitamin E and donepezil for the treatment of mild cognitive impairment. N Engl J Med 352:23, 2005 [PMID 15829527]

A Pair for Alzheimer Treatment

Memantine is approved by the Food and Drug Administration for the treatment of AD. This agent, a glutamate modulator that is a noncompetitive receptor antagonist of *N*-methyl-D-aspartate, has been the subject of several clinical trials that reported positive results in moderate to severe dementia.[1,2] It is hypothesized that glutamatergic overstimulation is a part of the pathogenic cycle in AD. In the clinical trials, memantine delayed symptom progression. There is no evidence that memantine affects the biologic course of AD, however. Studies in patients with mild to moderate AD have been completed, but no results are yet available. On the basis of a study that paired memantine with donepezil, the current suggestion in moderate to severe AD is to use both agents.[2]

XVI Acute Viral Central Nervous System Diseases

DONALD H. GILDEN, MD
University of Colorado Health Sciences Center

The Many Faces of West Nile Infection

The neurologic complications of West Nile virus infection are protean. Patients have presented not only with meningoencephalitis but also with encephalitis involving the cerebellum, pons, and medulla oblongata (rhombencephalitis), cerebellar ataxia affecting the muscles and eyes (opsoclonus-myoclonus),[1]

unilateral brachial plexopathy with meningoencephalitis,[2] and Guillain-Barré syndrome. As with other arbovirus infections, deep-seated lesions in the basal ganglia and thalamus are often seen on brain MRI.[3] Polymerase chain reaction testing of the cerebrospinal fluid often reveals West Nile virus RNA.

Lab Tests for Viral CNS Infection

Laboratory methods that are used to identify the causative agent of viral meningitis and encephalitis include polymerase chain reaction detection of viral RNA or DNA in the cerebrospinal fluid, culturing virus from the CSF, antigen or antibody detection in the CSF, serologic tests (e.g., enzyme immunoassays and Western blot assay), and brain biopsy [*see Table, top, right*].

Lymphocytic Choriomeningitis Infections

The arenaviruses are RNA viruses endemic in rodents. Human infection, which occurs mostly in South America and Africa, produces various hemorrhagic fevers that are often fatal. In the United States, the most common arenavirus infection is produced by lymphocytic choriomeningitis (LCM) virus. Infection is acquired from mice or pet hamsters or through occupational exposure in laboratory personnel working with the virus. Most cases present as aseptic meningitis, but fatal meningoencephalitis also occurs. LCM preceded by a lupuslike syndrome that included rash and the presence of a circulating anticoagulant has been described. In 2005, a cluster of cases of meningoencephalitis deaths in solid organ transplant recipients was associated with LCM infection.[1] As with mumps, orchitis and parotitis may develop concurrently with central nervous system disease; profound mononuclear pleocytosis and low glucose levels in the cerebrospinal fluid also occur. A specific diagnosis can be made by observing the development of choriomeningitis in weanling or adult mice inoculated intracerebrally with infected CSF or the development of LCM-specific antibody in the serum or CSF of infected humans.

1. Lymphocytic choriomeningitis virus infection in organ transplant recipients—Massachusetts, Rhode Island, 2005. MMWR Morb Mortal Wkly Rep 54:537, 2005 [PMID 15931158]

Epstein-Barr in Neurologic Clothing

Despite the prevalence of Epstein-Barr virus (EBV) infection, neurologic disease is rare. The most common presentation is meningoencephalitis, which is often associated with acute cerebellar ataxia. More serious meningoencephalopathy, presenting as athetosis and chorea or as stupor and coma, has been described. In a fascinating case of acute demyelinating encephalopathy after EBV infection, a patient presented with behavioral abnormalities, visual illusions, and a seizure. EBV mononucleosis may also be followed by recurrent aseptic meningitis. Chronic active EBV infection has been associated with calcification in the basal ganglia. EBV-associated cranial neuropathies, including acute autonomic neuropathy, have been described. In a comprehensive study of four patients with EBV myeloradiculitis and encephalomyeloradiculitis, none of the patients died or had brain swelling, but residual neurologic deficits were evident. A case of myeloradiculitis in an immunocompetent 72-year-old woman who was seronegative for EBV was proved to be caused by EBV by the detection of EBV DNA in both serum and CSF; quantitative polymerase chain reaction revealed an EBV DNA load not detected in healthy persons who have latent infection or are not infected.[1] Detection of EBV DNA in CSF and reductions in the ratio of EBV antibody in serum to EBV antibody in CSF have been used to diagnose infection in the peripheral nervous system and CNS.

Tools for Staying Current

The current best evidence for clinical practice is becoming more and more accessible to clinicians. Resources include electronic access to MEDLINE and its clinical subsets, specialized compendia of studies such as Clinical Evidence and Physicians' Information and Educational Resource (PIER [http://pier.acponline.org/index.html?hp]); systematic reviews of studies, such as the Cochrane Library (http://www.update-software.com/cochrane); and alerting services for new, clinically relevant evidence, such as the British Medical Journal Updates (www.bmjupdates.com) and MEDSCAPE Best Evidence alerts (https://profreg.medscape.com/px/newsletter.do).

Test Results in Context

A physician should never interpret a test result in isolation but should always take into account the individual patient's pretest probability. The posttest probability after a positive test result will be greater if the pretest index of suspicion was high than if the pretest index of suspicion was low. The most important practical application of this reasoning is to be suspicious when a test result is negative in a patient whose clinical findings strongly point toward a disease or when a test is positive in a patient for whom the likelihood of disease is very low.

The evaluation of suspected pulmonary embolism (PE) using helical CT scanning is a good example of the practical use of these statistical terms and methods. To calculate the posttest odds of PE, the physician must combine the patient's pretest odds with the test's likelihood ratio by means of the odds ratio format of Bayes' theorem. The same logic can be applied to all screening and diagnostic tests for PE, such as D-dimer, a sensitive test with low specificity that is therefore more useful for ruling out pulmonary embolism when negative than ruling it in when positive.[1] It can also be used for calibrating clinical observations to enhance the quantitation of pretest probabilities.[2]

1. Stein PD, Hull RD, Patel KC, et al: D-dimer for the exclusion of acute venous thrombosis and pulmonary embolism. Ann Intern Med 140:589, 2004 [PMID 15096330]

2. Chunilal SD, Eikelboom JW, Attia J, et al: Does this patient have pulmonary embolism? JAMA 290:2849, 2003 [PMID 14657070]

Judging Diagnostic Tests

In the past, articles usually described the performance of a diagnostic test only in terms of sensitivity and specificity. However, these two familiar terms do not directly describe the effect of a test result on the probability of disease. In addition to sensitivity and specificity, other clinically useful measures of diagnostic test performance include, for example, the likelihood ratio. Clinically useful measures of test interpretation include pretest odds, pretest probability, probability after a positive test result, and probability after a negative test result [*see Table, below*]. Physicians should memorize and internalize the definitions of these terms to avoid becoming muddled when they are attempting to use information that has been gathered from diagnostic tests in decision making.

Definitions of Clinically Useful Measures of Diagnostic Test Performance and Interpretation

The typical approach to evaluation of most diagnostic tests, particularly those with so-called binary outcomes (e.g., a positive or a negative test result, with no other categories), makes use of a 2 × 2 table, as follows:

Diagnostic Test Result	*Presence or Absence of Disease on a Reference Test (Gold Standard)*		*No. of Patients with Given Test Result*
	Present	*Absent*	
Positive	*a*	*b*	*a* + *b*
Negative	*c*	*d*	*c* + *d*
Total	*a* + *c*	*b* + *d*	

Measures of diagnostic test performance, defined below, are calculated from this table.

- Sensitivity: the proportion of people with a disease of interest who are detected by a diagnostic test; calculated as $a/(a+c)$.
- Specificity: the proportion of people who do not have a disease who are correctly identified by a negative result on a diagnostic test; calculated as $d/(b+d)$.
- Likelihood ratio: the amount by which the odds of having a disease change after a test result; calculated as $[a/(a+c)]/[b/(b+d)]$ for a positive test result and as $[c/(a+c)]/[d/(b+d)]$ for a negative test result.
- Pretest probability: the proportion of people with the disorder of interest in a group suspected of having the disorder; calculated as $(a+c)/(a+b+c+d)$.
- Odds: calculated as probability/(1 – probability).
- Probability: calculated as odds/(1+ odds).
- Posttest odds: calculated as pretest odds × likelihood ratio.
- Probability after a positive test: the proportion of people with a positive test result who have the disease of interest; calculated as $a/(a+b)$.
- Probability after a negative test: the proportion of people with a negative test result who have the disease of interest; calculated as $c/(c+d)$.

PRACTICE OF MEDICINE

Quality Improvement in Acute Myocardial Infarction

RAYMOND J. GIBBONS, MD
Mayo Clinic College of Medicine

There is a growing interest in improving the quality of care for patients with acute myocardial infarction. Over the past few years, the Joint Commission on Accreditation of Healthcare Organizations has collected data from hospitals on discharge performance measures in the care of patients with acute myocardial infarction. The public release of these sobering data has generated media attention, including this quote from an editorial in *USA Today*: "If you became seriously ill, you'd expect a hospital to provide what the medical profession considers essential care. At many hospitals, you'd be wrong. Thousands of patients needlessly die each year…."

The Center for Medicare and Medicaid Services has started several initiatives to improve the quality of care, including a new Web site (www.hospitalcompare.hhs.gov), which lists performance measures for four different conditions (i.e., heart attack, heart failure, pneumonia, and surgery). This Web site permits a consumer to examine individual performance measures for a local hospital and graphically compare the hospital's performance with that of other hospitals. The URL for this Web site has been

Pancreatitis on the Upswing

Estimates of the incidence of acute pancreatitis range from about five to 25 cases per 100,000 population. In the United States, 166,000 to 224,000 patients are admitted each year with a primary diagnosis of acute pancreatitis.[1] The number of patients discharged from the hospital with a diagnosis of acute pancreatitis has shown a steady increase over the past 20 years.[2] Similar trends have been seen in other developed countries.[3] The explanation for this increase is unclear but may relate to increased risk of gallstones (one of the major causes of acute pancreatitis)[4]; the prevalence of gallstones is rising in most developed countries, as a result of both the aging of the population and the obesity epidemic.[5]

PRACTICE OF MEDICINE

continued from page 1

published in many newspapers and in *Newsweek* magazine.

Although these well-publicized, evidence-based performance measures have been carefully reviewed by multiple professional organizations, clinicians can reasonably question whether better performance at a given hospital with respect to these measures translates into better outcomes. Preliminary data from the National Registry of Myocardial Infarction (NRMI) suggest that this is the case. Using data from more than 250,000 patients in the NRMI registry, hospitals were divided into four quartiles on the basis of a composite of these discharge performance measures. There was a clear difference in patient mortality between hospitals in the poorest quartile (15.3%) and those in the best quartile (8.3%).

Some physicians have concluded that they can't correct the multiple systems problems that affect the quality of inpatient care. Nevertheless, several well-publicized efforts have suggested that rapid systems change is indeed possible with the assistance of highly motivated physician leaders. The American College of Cardiology's Guidelines Applied in Practice (GAP) project published results from 10 hospitals that showed significant improvement in nearly all performance indicators, particularly for hospitals that employed the available admission and discharge tools.[1] Similar improvement has been documented by the Get With The Guidelines project, sponsored by the American Heart Association, which has now been adopted by more than 1,000 hospitals across the United States.[2] The Intermountain Health Care System showed that a discharge medication program could improve compliance with medications and subsequent patient outcomes.[3]

The most dramatic evidence in support of quality-improvement efforts has recently been published by the ACC's GAP project.[4] During the project, hospital mortality after acute myocardial infarction declined from 13.6% to 10.4%, and 1-year mortality declined from 38.3% to 33.2%. The authors reported that use of the standard discharge document alone was able to reduce adjusted 1-year mortality by almost one half (odds ratio, 0.53; 95% confidence interval, 0.36 to 0.76; $P = 0.0006$).

In summary, the care of patients with acute myocardial infarction too often fails to conform to existing practice guidelines, and these shortcomings have drawn the attention not only of physicians but also of the general public. Several different quality-improvement efforts have proven ability to improve performance measures and patient mortality. All physicians and other health care professionals, individually and through their respective organizations, including the American College of Physicians, should take the lead in local and national efforts to improve the quality of care in acute myocardial infarction.

THIS MONTH'S UPDATES

continued from page 1

atitis. Accurate measurement of lipase was difficult in the past, but new methods provide high levels of precision. The lipase level is in fact slightly more sensitive and somewhat more specific for acute pancreatitis than is serum amylase.[1] In addition, it stays elevated longer and can confirm a diagnosis of acute pancreatitis up to 5 to 10 days after the onset of symptoms, by which time amylase levels have generally returned to normal. Like amylase, lipase may be elevated in other intra-abdominal conditions (e.g., intestinal ischemia and perforation, bowel obstruction, choledocholithiasis, cholelithiasis with cholecystitis, and acute appendicitis), as well as in renal failure. Elevations that are more than three times the upper limit of normal have the greatest diagnostic sensitivity and specificity, but this threshold may need to be increased to five times the upper limit of normal in patients with renal failure. Lipase measurement is probably preferable to amylase measurement as a confirmatory test because in addition to its greater specificity, it is no more costly and, in most hospitals, has equally rapid availability.

The Enteral Alternative

Nutritional support is useful for patients with severe pancreatitis and for those with milder pancreatitis who nonetheless are unable to eat for more than 5 to 7 days. The preferred route of providing exogenous nutrients has changed. For years, total parenteral nutrition (TPN) has been the standard practice, but accumulating evidence suggests that enteral feeding is equivalent to or better than TPN.[1,2] Prospective, randomized trials have demonstrated that enteral feeding infused distal to the ligament of Treitz is associated with a decreased rate of complications (i.e., infection and hyperglycemia) and lower cost than TPN. Although the evidence is not yet definitive,[2] it has led to a shift in the preferred method of providing nutrition to patients with acute pancreatitis. The main practical challenge in using enteral jejunal feeding is placing and maintaining position of the nasojejunal tube.

The Questionable Value of Antibiotic Prophylaxis

The role of antibiotics in the prevention of pancreatic infection is controversial. Early studies using prophylactic ampicillin demonstrated no reduction in pancreatic infections. It was then found, however, that ampicillin does not penetrate necrotic pancreas at adequate concentrations. Subsequent studies used regimens with adequate penetration into necrotic pancreas (e.g., imipenem, cefuroxime, and ofloxacin plus metronidazole); a meta-analysis of these studies concluded that intravenous prophylactic antibiotic therapy for 10 to 14 days reduces the risk of superinfection of pancreatic necrosis and mortality.[1] However, this meta-analysis did not include the most recently reported study—the only double-blind randomized trial to date—which did not demonstrate any benefit from prophylactic treatment with ciprofloxacin plus metronidazole.[2] This has led to differing opinions on the overall utility of prophylactic antibiotics, with both advocates and opponents of this practice.

Pancreatitis in the Genes

Hereditary pancreatitis is an autosomal dominant disease that typically presents in childhood or early adulthood and frequently is accompanied by steatorrhea, diabetes mellitus, and diffuse pancreatic calcifications. Pain and acute episodes of pancreatitis flares may also occur but are somewhat less common in hereditary pancreatitis than in alcoholic chronic pancreatitis. The initially identified genetic abnormality is a defect in the cationic trypsinogen (*PRSS1*) gene on chromosome 7.[1] Multiple mutations have been described, but two are more common. The described mutations appear to produce a trypsinogen that, once activated, is difficult or impossible to inactivate. The activated enzyme, trypsin, can in turn activate all the other pancreatic enzymes. Chronic pancreatitis appears to be caused in this situation by prolonged low-grade pancreatic injury from the activated proteases. Pancreatic adenocarcinoma frequently complicates the condition, with a 30% risk by age 70. The risk may be substantially higher in patients with paternal inheritance.

II Depression and Bipolar Disorder

MICHAEL T. COMPTON, MD, MPH
CHARLES B. NEMEROFF, MD, PHD
Emory University School of Medicine

Depression or Dementia?

In the elderly, depression with cognitive impairment that is reversed by antidepressant treatment may be an early predictor of the development of an irreversible dementia. Patients with late-onset depression are more likely to have cognitive impairment and to have deeper white-matter lesions on imaging studies. However, the so-called pseudodementia of depression is common and should not be mistaken for a primary dementia.

User-Friendly MAOIs?

In the United States, three monoamine oxidase inhibitors (MAOIs) are currently available: phenelzine, isocarboxazid, and tranylcypromine.

FDA Approval Report

The following is selected from the FDA's list of recently approved products. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

First Oral Drug for Chronic Iron Overload

Generic Name: Deferasirox

Brand Name: Exjade

Manufacturer: Novartis Pharmaceuticals Corp., Stein, Switzerland

The FDA has approved deferasirox, an oral iron chelator developed to treat chronic iron overload resulting from multiple blood transfusions. Deferasirox is the first orally administered medication to be approved for this use. Previously, treatment for iron overload required daily intravenous infusions lasting 8 to 12 hours.

Deferasirox was approved under a program that allows accelerated approval of products to treat serious or life-threatening diseases on the basis of early evidence of efficacy. The evidence for deferasirox was derived from clinical studies of 48 weeks' duration, which demonstrated reductions in liver iron concentrations in adult and pediatric patients who were receiving red blood cell transfusions on an ongoing basis. Deferasirox has also received Orphan Drug Designation, which is granted to products that treat diseases affecting fewer than 200,000 people in the United States.

In clinical studies of deferasirox, common side effects included nausea and abdominal pain. Elevations in measures of kidney and liver function were also noted. Less common side effects included hearing and visual disturbances and rashes. Monitoring of kidney and liver function and testing of hearing and vision before and during treatment are recommended.

Source:
FDA Approves First Oral Drug for Chronic Iron Overload. FDA News. U.S. Food and Drug Administration, November 9, 2005 (http://www.fda.gov/bbs/topics/NEWS/2005/NEW01258.html)

These agents are rarely used because their use is complicated by side effects (including hypotension), lethality in overdose, and lack of simplicity in dosing. Patients treated with MAOIs must follow a specific tyramine-free diet because of the potential for a pharmacodynamic interaction with tyramine that can result in a hypertensive crisis. Drugs that have been reported to interact with MAOIs include carbamazepine, cyclobenzaprine, dextromethorphan, fenfluramine, certain hypoglycemics, L-tryptophan, meperidine, selective serotonin reuptake inhibitors (SSRIs), stimulants, sympathomimetics, and tricyclic antidepressants. Nonetheless, the MAOIs appear to be more effective than other antidepressants in the treatment of atypical depression, though their use is usually limited to psychiatrists who have experience with these agents. MAOIs are also often effective in patients with depression that is refractory to treatment with other antidepressants.

Selective MAOIs (e.g., moclobemide), which are available outside of the United States, are easier to use because of the lack of dietary constraints and drug-drug interactions. A transdermal system for delivery of selegiline, an MAOI approved by the Food and Drug Administration for the treatment of Parkinson disease, may be effective in the treatment of depression.[1,2]

1. Bodkin JA, Amsterdam JD: Transdermal selegiline in major depression: a double-blind, placebo-controlled, parallel-group study in outpatients. Am J Psychiatry 159:1869, 2002 [PMID 12411221]

2. Amsterdam JD: A double-blind, placebo-controlled trial of the safety and efficacy of selegiline transdermal system without dietary restrictions in patients with major depressive disorder. J Clin Psychiatry 64:208, 2003 [PMID 12633131]

SSRIs and Side Effects

SSRIs have a relatively mild side-effect burden. Sexual side effects of these medications (i.e., delayed ejaculation, anorgasmia, and decreased libido) are being increasingly recognized and studied and are one of the leading causes of discontinuance or noncompliance. Although the correlation between SSRI treatment and increased suicide risk remains controversial, the potential for increased risk has prompted the Food and Drug Administration to require that manufacturers of all antidepressants include in their labeling a boxed warning (http://www.fda.gov/cder/drug/antidepressants/default.htm).[1,2]

1. Khan A, Khan S, Kolts R, et al: Suicide rates in clinical trials of SSRIs, other antidepressants, and placebo: analysis of FDA reports. Am J Psychiatry 160:790, 2003 [PMID 12668373]

Atypical Antipsychotics in Bipolar Disorder

The atypical antipsychotic agents are effective for the treatment of acute mania. Olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole have FDA indications for bipolar mania. The risks of weight gain and metabolic disturbances are increasingly being recognized with some of these agents; therefore, clinical monitoring is necessary.[1,2]

7 INFECTIOUS DISEASE

XXVIII Enteric Viral Infections

NINO KHETSURIANI, MD, PhD
UMESH D. PARASHAR, MD, MPH
Centers for Disease Control and Prevention

Fever from Enteroviruses

Enteroviruses are a common cause of febrile illness, particularly during the summer and fall months. Fever may be the sole symptom, or infection may be accompanied by rashes or respiratory symptoms (the "summer cold"); in infants, symptoms include irritability, lethargy, anorexia, vomiting, and diarrhea. Because of the need to rule out potentially serious bacterial infections, a high proportion of infants with enteroviral febrile illness require evaluation for bacterial sepsis or meningitis.[1]

1. Rittichier KR, Bryan PA, Bassett KE, et al: Diagnosis and outcomes of enterovirus infections in young infants. Pediatr Infect Dis J 24:546, 2005 [PMID 15933567]

The End of Polio?

Through successful immunization programs, control of poliomyelitis has been achieved in numerous countries worldwide, including the entire Western Hemisphere, but wild polioviruses continue to circulate in some countries of sub-Saharan Africa and Southeast Asia. It is likely that the large-scale Polio Eradication Initiative, led by the World Health Organization since 1988, will result in global polio eradication[1]; until that occurs, there remains a risk of importation of poliomyelitis into the United States.

1. Progress toward interruption of wild poliovirus transmission—worldwide, January 2004–March 2005. MMWR Morb Mortal Wkly Rep 54:408, 2005 [PMID 15858461]

Rotavirus Vaccine, Round Two

A vaccine against severe rotavirus disease was licensed in the United States in 1998, but it was withdrawn in 1999 because its use was associated with intussusception. Efforts are ongoing to develop other rotavirus vaccines. Two large clinical trials that each involved more than 60,000 infants have been completed. The trials examined two leading vaccine candidates: a multivalent bovine-human reassortant rotavirus vaccine[1] and an attenuated single-human-strain rotavirus vaccine.[2] These trials demonstrated the safety of both vaccines with respect to intussusception and other potential adverse events,[3,4] and they indicated that the vaccines have an efficacy of more than 90% against severe rotavirus disease.[1,2] Data on the multivalent vaccine, which is administered orally to infants in three doses at 2, 4, and 6 months of age, were submitted for licensure to the FDA in April 2005; a decision is expected in 2006.

4. Vesikari T, Matson D, Dennehy P, et al: Protection against rotavirus gastroenteritis of multiple serotypes by a pentavalent (human-bovine) reassortant rotavirus vaccine (PRV). Annual Meeting of the European Society for Paediatric Infectious Diseases (ESPID), Valencia, Spain, May 18–20, 2005

8 INTERDISCIPLINARY MEDICINE

I Management of Poisoning and Drug Overdose

KENT R. OLSON, MD, FACP
University of California, San Francisco, Schools of Medicine and Pharmacy
MANISH M. PATEL, MD
Emory University School of Medicine

Ipecac out

Ipecac-induced emesis has been almost completely abandoned in the clinical setting.[1] In 2003, the American Academy of Pediatrics advised against routine use of ipecac in the home and recommended disposing existing ipecac in the home.[2] One reason it has fallen out of favor is that treated patients run the risks of sudden, unexpected deterioration from the effects of overdose and subsequent pulmonary aspiration; more important, however, is the lack of evidence of the efficacy of ipecac-induced emesis, especially when emesis is induced more than 1 hour after the ingestion.

In addition to emesis, other techniques for gut decontamination include gastric lavage, administration of activated charcoal, and whole bowel irrigation [*see Table, page 6*]. However, nowhere in the field of toxicology is there more controversy than in the debate about gastrointestinal decontamination.

2. Poison treatment in the home. American Academy of Pediatrics Committee on Injury, Violence, and Poison Prevention. Pediatrics 112:1182, 2003 [PMID 14595067]

Parenteral Treatment for Acetaminophen Overdose

Acetylcysteine is highly effective in preventing liver damage from acetaminophen toxicity, especially if therapy is initiated within 8 to 10 hours after the ingestion of acetaminophen. Occasionally, however, patients cannot tolerate oral aetylcysteine because the drug has a disagreeable odor and they are already vomiting. In such cases, it is advisable to administer the drug by the intravenous route. In 2004, the FDA approved a 20-hour protocol for intravenous acetylcysteine treatment of acetaminophen overdose.[1]

The initial loading dose is 150 mg/kg in 200 ml of 5% dextrose in water (D5W) over 15 minutes. This is followed by 50 mg/kg in 500 ml D5W over 4 hours, then 100 mg/kg in 1 L D5W over the next 16 hours. Intravenous administration can cause an anaphylactoid reaction (i.e., skin flushing and hypotension); this can be minimized by slowing the rate of the initial loading dose, giving it over 45 to 60 minutes.

1. Safety labeling changes approved by FDA Center for Drug Evaluation and Research (CDER)—April 2004. Acetadote (acetylcysteine) injection. http://www.fda.gov/medwatch/SAFETY/2004/apr_PI/Acetadote_PI.pdf

Ephedra, Gone and Back Again

Ephedra (Ma Huang) is a common ingredient in herbal weight-loss products (herbal fen-phen), stimulants (herbal ecstasy), decongestants, and bronchodilators. The active moiety in ephedra is ephedrine and related alkaloids. Serious adverse reactions, in-

Methods of Gastrointestinal Decontamination

Method and Technique	*Useful Situations*	*Comments*
Emesis: give syrup of ipecac, 30 ml p.o. in adults (15 ml in children), along with one to two glasses of water; may repeat after 30 min if no emesis occurs; alternatively, give 1–2 tbsp of liquid handwashing or dishwashing soap	Possible benefit in rare circumstances after a potentially lethal ingestion when medical care is more than 60 min away, but only under the guidance of a poison control center	No longer used in emergency departments; American Academy of Pediatrics recommends against routine home use of ipecac; contraindicated in ingestions of corrosive agents and most hydrocarbons, when the patient is lethargic, or when the ingested substance is likely to cause abrupt onset of coma or seizures
Gastric lavage: insert large-bore nasogastric or orogastric tube, empty stomach contents, and lavage with 100–200 ml aliquots of water or saline until clear	Useful in obtunded or comatose patients, in recent ingestions (< 1 hr), or in ingestion of anticholinergic agents or salicylates (delayed gut emptying)	Obtunded patient should have prior endotracheal intubation to protect airway; best position is left lateral decubitus to reduce movement of poison into small intestine
Activated charcoal: give 50–60 g of charcoal slurry p.o. or by gastric tube; goal is approximately 10:1 ratio of charcoal to ingested poison; usually given with one dose of a cathartic agent	Often useful because it adsorbs most drugs and poisons; may be equally effective when given alone as when given after emesis or lavage	Not effective for ingestions of iron, lithium, potassium, sodium, or alcohols; may need to repeat two or three times or more for large ingestions; repeated dosing may also enhance elimination of some drugs
Whole bowel irrigation: give Colyte or GoLYTELY, 1–2 L/hr p.o. or by gastric tube, until rectal effluent is clear or x-ray is negative for radiopaque materials	Useful in ingestions of iron, lithium, sustained-release or enteric-coated pills, and drug packets or other foreign bodies	Generally well tolerated; no significant fluid or electrolyte gain or loss occurs; most useful in awake, ambulatory patients; may reduce effectiveness of activated charcoal

cluding hypertension, seizures, arrhythmias, heart attack, stroke, and death, have been reported. In 2004, the FDA declared dietary supplements containing ephedra to be unsafe and banned ephedra-containing supplements.[1] However, a federal judge reversed the ban in early 2005, and the future of this substance remains uncertain.

1. Final rule declaring dietary supplements containing ephedrine alkaloids adulterated because they present an unreasonable risk: final rule. Fed Regist 69:6787, 2004 [PMID 14968803]

11 NEUROLOGY

VII Anoxic, Metabolic, and Toxic Encephalopathies

MICHAEL J. AMINOFF, MD, DSC
University of California, San Francisco, School of Medicine

Will This Patient Awaken from Coma?

In the first several days after the onset of ischemic encephalopathy, diffusion-weighted magnetic resonance imaging may be useful in determining prognosis; hyperintense cortical lesions are associated with a poor outcome.[1,2]

Studies of evoked potentials can also have prognostic utility. In a systematic review of somatosensory evoked potentials performed early after onset of coma, rates of awakening in adults with hypoxic-ischemic encephalopathy ranged from 0% when somatosensory evoked potentials were absent to 52% when somatosensory evoked potentials were normal.[3] In a prospective study of 346 comatose patients, pupillary reflex was the strongest prognostic variable for awakening. The probability of awakening was higher when late auditory evoked potentials were also present, and it was higher still when middle-latency evoked potentials were present. No patient with cognitive potentials became permanently vegetative.[4]

Encephalopathy at High Altitude

High-altitude sickness can lead to an encephalopathy characterized by headache, fatigue, anorexia, nausea, poor concentration, and sleep disturbances.[1] Symptoms of high-altitude sickness begin within hours or days of ascent to altitudes above 10,000 ft. In severe cases or at higher altitudes, consciousness is impaired and coma may occur—sometimes with a fatal outcome. Cerebral edema causes papilledema, retinal hemorrhages, cranial neuropathies, a variety of sensorimotor deficits, and behavioral disturbances. High-altitude cerebral edema arises because the low barometric pressure encountered at high altitudes causes a reduction in the partial pressure of oxygen (P_{O_2}); the condition often follows acute mountain sickness and may be an extreme form of that disorder. Acetazolamide (250 mg once or twice a day) or dexamethasone (2 mg every 6 to 8 hours) may prevent acute mountain sickness. High-altitude cerebral edema is treated with prompt descent to a lower altitude and administration of oxygen and dexamethasone (8 mg, then 4 mg every 6 hours).[1]

1. West JB: The physiologic basis of high-altitude diseases. Ann Intern Med 141:789, 2004 [PMID 15545679]

Encephalopathy with and without Anemia

Encephalopathy is a well-recognized complication of vitamin B_{12} deficien-

cy. It may be accompanied by myelopathy, optic neuropathy, peripheral neuropathy, or any combination of these conditions. The neurologic complications do not reflect the presence or the severity of any associated megaloblastic anemia. Folic acid masks the hematologic abnormality and fails to prevent the neurologic complications. It was feared that fortification of cereal grains with folic acid, which began in 1994 in the United States, might result in an increase in the incidence of vitamin B_{12} deficiencies in persons who are not anemic. However, a 2003 Veterans Affairs study found no evidence that such an increase has occurred since fortification began.[1]

1. Mills JL, Von Kohorn I, Conley MR, et al: Low vitamin B-12 concentrations in patients without anemia: the effect of folic acid fortification of grain. Am J Clin Nutr 77:1474, 2003 [PMID 12791626]

16 WOMEN'S HEALTH

Introduction to Women's Health: The Primary Care of Women

JANET B. HENRICH, MD
Yale University School of Medicine

Drugs and Women's Hearts

When obtaining the medication history, clinicians need to be aware of important sex differences in the effects of certain classes of medications that may put women at increased risk for adverse drug reactions.[1] For example, because women have longer baseline QT intervals than men, the use of drugs that further prolong the QT interval, such as certain antibiotics, antihistamines, antiarrhythmics, and antipsychotics, may put women at increased risk for torsade de pointes, a potentially lethal ventricular arrhythmia.[2] The University of Arizona Health Sciences Center maintains an online registry of drugs that prolong the QT interval or induce torsade de pointes (http://www.arizonacert.org/medical-pros/drug-lists/drug-lists.htm). Also, women with depressed left ventricular function who use digoxin for heart failure are at greater risk of death than men with a similar diagnosis. This risk is attributed partly to higher serum digoxin levels in women. Because of this potential harm, clinicians are advised to weigh carefully the risks versus benefits of digoxin therapy in women with heart failure.[3]

1. Anderson GD: Sex and racial differences in pharmacological response: where is the evidence? Pharmacogenetics, pharmacokinetics, and pharmacodynamics. J Womens Health (Larchmt) 14:19, 2005 [PMID 15692274]

3. Rathore SS, Krumholz HM: Digoxin therapy for heart failure: safe for women? Ital Heart J 4:148, 2003 [PMID 12784740]

Oral Contraceptives versus Antibiotics

The hepatic cytochrome P-450 family of enzymes is involved in the metabolism of endogenous and exogenous steroids and many other drugs. Anticonvulsants can lead to oral contraceptive (OC) failure by inducing the cytochrome P-450 enzyme system to metabolize estrogen more rapidly. A similar mechanism has been attributed to antibiotics, leading to drug warnings about the risk of pregnancy when antibiotics are prescribed to women on OCs. Because the evidence supporting drug interactions between antibiotics and OCs is weak, the Council on Scientific Affairs of the American Medical Association convened a panel to review the data and provide recommendations. The panel concluded that rifampin, acting primarily as an inducer of the cytochrome P-450 3A4 isoenzyme, is the only antibiotic tested that significantly reduces plasma concentrations of OC-derived estrogens and increases OC failure rates. However, women using several other commonly prescribed antibiotics have wide variations in OC-derived hormone levels; some women have elevated follicle-stimulating hormone levels or breakthrough bleeding, suggesting that ovulation may occur.

On the basis of these findings, the panel concluded that even though the risk of OC failure with these antibiotics is very small, some women may be at risk, particularly those using low-dose or very low dose OCs. The panel recommended nonhormonal contraceptive methods for women who are concomitantly using OCs and rifampin, as well as for women who are taking other antibiotics and are concerned about a small risk of pregnancy, have had previous contraceptive failure, or develop breakthrough bleeding.

Answering the Aspirin Question

On the basis of findings from studies that were conducted primarily in men, the United States Preventive Services Task Force currently recommends that clinicians discuss the use of aspirin for the primary prevention of coronary heart disease (CHD) with postmenopausal women and with younger women with risk factors for CHD. However, results from the first randomized trial that assessed the risks and benefits of aspirin as chemoprevention for CHD in women found a beneficial effect only in women 65 years of age and older.[1] In younger women, aspirin reduced the risk of thromboembolic stroke but had little effect on CHD—findings opposite to those described in men. As in men, the use of aspirin in older women was associated with an increased risk of hemorrhagic stroke and major gastrointestinal hemorrhage. Until more information is available about aspirin's effects in women, discussions about its use should be individualized for each patient.

Best Dx/Best Rx by *ACP Medicine*

Best Dx/Best Rx is a free tool that provides fast access to expert guidance at the point of care. Each module of Best Dx/Best Rx is based on a chapter of ACP Medicine, *whose authors are recognized authorities in clinical medicine. Their recommendations in Best Dx/Best Rx are intended for use in clinical settings to help answer these essential questions:*

• How do I diagnose? • How do I treat? • What is the evidence?

Best Dx/Best Rx is available within chapters on *ACP Medicine Online*. The modules may also be accessed on any HTML browser, including wireless PDAs and computers.

Below is our new module on tachycardia. Other topics include rheumatoid arthritis, cirrhosis, hypertension, alzheimer disease, and many more. Go to www.acpmedicine.com/dxrxpromo1.htm to read other modules and for more information on how to get Best Dx/Best Rx.

Atrioventricular Nodal Reentry Tachycardia (AVNRT)

Melvin M. Scheinman, M.D., F.A.C.P.
University of California, San Francisco, School of Medicine

Definition/Key Clinical Features

- AVNRT is the most common form of supraventricular tachycardia; it results from conduction through a reentrant circuit comprising fast and slow atrioventricular nodal pathways
- Heart rate, 150–250 beats/min
- Neck pounding
- Palpitations, light-headedness, near-syncope
- Narrow QRS complexes on ECG
- Abrupt onset and termination of episodes
- More common in women than in men
- Frequently presents after 20 yr of age

Differential Diagnosis

- Atrial fibrillation
- Atrial flutter
- AV reentrant tachycardia

Best Tests

- 12-lead ECG
  - The P wave is either buried within the QRS complex or inscribed just after the QRS complex
- The P wave inscribed by retroconduction over the AV node is negative in the inferior leads and positive in lead V1; PSVT may manifest as small negative deflections in the inferior leads and a small positive deflection in V1 (pseudo r^1 pattern)

Best Therapy

Acute Therapy

Nonpharmacologic

- Carotid sinus massage

Pharmacologic

- Adenosine: for use when carotid massage fails to convert SVT
  - Possible adverse effects: headache, wheezing, flushing, which will disappear within 45–60 sec; atrial, ventricular, and junctional premature beats; atrial fibrillation in 3% to 5% of cases, which may result in serious problems for patients with accessory pathways
  - An external defibrillator should be readily available when adenosine is administered
  - Dose: initial dose: rapid bolus of 6 mg I.V., followed by a saline flush; if necessary, a 12 mg dose and finally an 18 mg dose can be given
- Metoprolol (5 mg I.V.) or verapamil (0.1 mg/kg I.V.) for patients who fail to respond to adenosine

Long-term Therapy

- Associated with frequent recurrences and adverse effects

Pharmacologic

- Beta blockers
- Sotalol
  - Common side effects: torsade de pointes, heart failure, bradycardia, exacerbation of chronic obstructive or bronchospastic lung disease
  - Adjust dose for renal function and QT-interval response during in-hospital initiation phase
  - Dose: 240–320 mg/day
  - Cost/mo: $138
- Calcium channel blockers (verapamil, diltiazem)
- Digoxin
  - Dose: 0.1 mg/day
  - Cost/mo: $9
- Antiarrhythmic agents: for patients without structural cardiac disease; more effective than beta blockers and calcium channel blockers, but with 25% to 35% recurrence rates
- Amiodarone
  - Common side effects: photosensitivity, pulmonary toxicity, polyneuropathy, GI upset, bradycardia, torsade de pointes (rare), hepatic toxicity, thyroid dysfunction
  - Dose: 100–400 mg/day
  - Cost/mo: $94
- Disopyramide
  - Common side effects: torsade de pointes, heart failure, glaucoma, urinary retention, dry mouth
  - Dose: 400–750 mg/day
  - Cost/mo: $84
- Dofetilide
  - Common side effect: torsade de pointes
  - Dose: 500–1,000 mg/day
  - Cost/mo: N/A
- Flecainide
  - Common side effects: ventricular tachycardia, heart failure, enhanced AV nodal conduction (conversion to atrial flutter)
  - Dose: 200–300 mg/day
  - Cost/mo: $115
- Procainamide
  - Common side effects: torsade de pointes, lupuslike syndrome, GI symptoms
  - Dose: 1,000–4,000 mg/day
  - Cost/mo: $59
- Propafenone
  - Common side effects: ventricular tachycardia, heart failure, enhanced AV nodal conduction (conversion to atrial flutter)
  - Dose: 490–900 mg/day
  - Cost/mo: $198
- Quinidine
  - Common side effects: torsade de pointes, GI upset, enhanced AV nodal conduction
  - Dose: 600–1,500 mg/day
  - Cost/mo: $67
- Single-dose agents for p.r.n. use: diltiazem, 120 mg, or propranolol, 80 mg; p.r.n. dosing regimens are used with caution and only after efficacy and safety have been established for the individual patient under ECG monitoring

Nonpharmacologic

- Catheter ablation
  - Procedure of choice for patients in whom drug therapy fails and those with milder symptoms who prefer to avoid long-term drug therapy
  - Success rate > 96%
  - AV block occurs in ~ 1% of patients

PRACTICE OF MEDICINE

Sensing a Role for Innate Immunity in Chronic Disease

JOHN P. ATKINSON, MD, FACP
Washington University School of Medicine

The immune system has a hard job. It must defend against infectious agents that can mutate at alarming rates. It must distinguish self from nonself, or the body will suffer the consequences of autoimmunity. At epithelial borders, it has the particularly difficult task of separating dangerous from benign microorganisms. This task, which is carried out by the innate immune system, has two primary components: sensing when a microorganism is present, and then triggering the appropriate response. Both components are critical. The timely recognition of a "bad guy" and the eventual destruction of same are necessary events. Otherwise, an acute infection may become lethal or lead to a chronic process. At the other extreme, mistaking the harmless for the perilous can result in an allergic response.

Progress in the understanding of the innate immune system maps the early history of the field of immunology. Phagocytosis and the lytic activity of the complement system were two innate immune processes recognized in the late 19th century. Investigation of antibody, complement, and phagocytosis dominated the field of immunology until the middle of the 20th century. The study of the host response to infectious

XXXVI Bacterial Infections of the Central Nervous System

JAN V. HIRSCHMANN, MD
University of Washington School of Medicine

Classic versus Likely Signs of Meningitis

The most common features of bacterial meningitis are headache, fever, nuchal rigidity, and neurologic findings. Less than half of patients have the classic triad of fever, neck stiffness, and a change in mental status; however, almost all have at least two of the four manifestations of headache, fever, neck stiffness, and altered mental status.[1] Fever is present in approximately 95% of patients and typically lasts 4 to 8 days after appropriate therapy has begun. Stiff neck is apparent in about 90% of patients. Mental changes ranging from lethargy to confusion, stupor, and coma occur in about 80% of patients, somewhat more frequently in the elderly.

1. van de Beek D, de Gans J, Spanjaard L, et al: Clinical features and prognostic factors in adults with bacterial meningitis. N Engl J Med 351:1849, 2004 (erratum in N Engl J Med 352:950, 2005) [PMID 15509818]

Tap First, Don't Scan?

In patients with suspected meningitis, clinicians commonly obtain a computed tomography scan before doing a lumbar puncture, on the basis of two beliefs: that brain herniation is a frequent risk in meningitis and that CT scans can accurately predict its development. Neither belief is correct. Herniation occurs in approximately 1% of patients with bacterial meningitis, sometimes without a preceding lumbar puncture. CT scans are often normal in those who later experience brain herniation, and most patients who develop this complication have focal neurologic findings before the lumbar puncture that suggest that herniation has already begun: dilated, fixed pupils; Cheyne-Stokes respiration; decerebrate posturing; hemiplegia; and coma.

In addition to focal neurologic deficits and an abnormal level of consciousness, findings that justify per-

continued from page 1

organisms and to vaccination, as well as the analysis of blood transfusion reactions, contributed much to our understanding of the workings of the immune system. A surprising discovery was that two components of blood that are required to opsonize and lyse microorganisms—namely, antibody and complement—also mediate mismatched transfusion reactions and autoimmunity. Thus, early on, the immune system was recognized as a double-edged sword, protecting us against infections on the one hand but mediating tissue damage through allergic, autoimmune, and transfusion reactions on the other.

With the discovery of B and T cells, the attention of immunologists turned to the adaptive immune system. Research into the generation of the adaptive response dominated immunology from the 1960s to the present and brought remarkable gains in both basic and clinical knowledge about adaptive immunity. For example, the discovery over 3 decades ago of the role of cytokines and lymphokines in immune responses led to highly effective therapeutic agents (i.e., interleukin-1 and tumor necrosis factor antagonists).

Interest in the innate immune system was rekindled about a decade ago by the discovery that Toll receptors act as sensors of microbes. Toll receptors are expressed on epithelial cells, where they interface with the environment. They recognize structural features of microorganisms that are distinct from those expressed by the host—for example, endotoxin, peptidoglycans, flagellin, and unique structural features of viral and bacterial DNA and RNA. These structures form the backbone of microorganisms and thus cannot be altered to any major degree. To do so would be like primates changing the basic elements of muscle or bone.

In addition to Toll receptors, the innate immune system has many other sensors for pathogens, including natural antibodies, lectins, natural killer cells, the complement system, and phagocytes themselves. These sensors are responsible for identifying pathogens in the skin, the gut, the upper airway, and the urogenital tract. This recognition event (which may occur either outside or inside the cell) calls forth an inflammatory response. In addition, instructions are sent to the adaptive immune system regarding the location and nature of the problem. For example, the innate immune sensors can distinguish gram-positive from gram-negative bacteria and between bacteria and viruses. The information from the innate immune system about who is trying to invade provides vital direction for the adaptive immune system.

An exciting discovery for clinical medicine is that many stubborn conditions whose cause has been obscure—for example, psoriasis, inflammatory bowel disease, sarcoidosis, and certain arthritides—may originate from defects in innate immune sensing. Thus, one could envision Crohn disease arising in two general ways: (1) from an overly active sensor on the epithelial cells that sparks an innate immune reaction to normal gut flora or (2) from a failure to properly regulate the tonic signals being sent by normal sensors from an epithelial surface (i.e., the gut) that is bathed in microorganisms. Recent genetic studies of familial forms of these perplexing syndromes have identified mutations in such sensors or in regulators of the response that is triggered by these sensors. In addition, defects in this system appear to be the source of rare, recurrent, inflammatory diseases such as familial Mediterranean fever and several related periodic syndromes. Similar types of defects may be at the heart of allergies and autoimmunity, as well.

forming CT before lumbar puncture include the following: immune compromise; a history of central nervous system disease (e.g., mass lesion, stroke, or focal infection); papilledema (although the presence of venous pulsations suggests that the patient does not have increased intracranial pressure); and seizures within 1 week before presentation (some experts will not perform a lumbar puncture in patients with prolonged seizures, and they will delay lumbar puncture for 30 minutes in patients who have experienced short, convulsive seizures).[1] In the absence of such findings in patients with suspected bacterial meningitis, clinicians should not delay lumbar puncture to obtain a CT scan [*see Figure, right*].

The Role of Steroids in Meningitis Treatment

In adults with acute pneumococcal meningitis, adjuvant treatment with dexamethasone has been shown to lower the risk of an unfavorable outcome and to lower mortality without increasing the likelihood of gastrointestinal bleeding.[1] Consequently, guidelines from the Infectious Diseases Society of America recommend that adults with suspected or proven pneumococcal meningitis receive adjunctive dexamethasone.[2] The dosage is 0.15 mg/kg every 6 hours for 2 to 4 days, with the first dose given 10 to 20 minutes before, or at least concomitant with, the first dose of antibiotics. Dexamethasone should be continued only if the cerebrospinal fluid Gram stain reveals gram-positive diplococci, or if blood or CSF cultures are positive for *Streptococcus pneumoniae*. Dexamethasone treatment is unlikely to improve the outcome in adult patients who have already received antimicrobial therapy and hence should not be used in this circumstance.

12 ONCOLOGY

V Colorectal Cancer

BERNARD LEVIN, MD, FACP
University of Texas M. D. Anderson Cancer Center

Testing for Colon Cancer Genes

Genetic testing is now the standard of care for familial adenomatous polyposis (FAP). Despite the detailed genetic knowledge of FAP that is now available, genetic testing is often poorly interpreted. Consequently, genetic counseling is an integral part of management and should precede genetic testing. Testing for FAP in a family is most informative when it begins with the affected family member, to identify the mutation responsible for FAP within that family. Once a causal mutation has been identified in an affected person, predictive testing can be done to identify other family members at risk.[1] DNA testing for *APC* gene mutations has a sensitivity of 70% to 90% and a specificity of 100%.

FDA Approval Report

The following is selected from the FDA's list of recently approved products. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

New Drug for T Cell Leukemia and Lymphoma

The FDA has approved nelarabine for the treatment of adults and children with T cell acute lymphoblastic leukemia (T-ALL) and T cell lymphoblastic lymphoma (T-LBL) whose disease has not responded to at least two chemotherapy regimens or has relapsed after such treatment. Nelarabine is the first drug to treat this limited population of patients.

Nelarabine was approved under a program that allows accelerated approval of products to treat cancer or other serious or life-threatening diseases on the basis of early evidence of efficacy. In this case, this evidence consisted of complete remission in 23% of 39 pediatric patients, with remission lasting 3.3 to 9.3 weeks, and complete remission in 21% of 28 adult patients, with remission lasting from 4 to more than 195 weeks. In those patients who responded to nelarabine, the disappearance of cancer cells was sometimes accompanied by the return of normal blood cell counts. Further studies are required to verify nelarabine's clinical benefit. Nelarabine also received Orphan Drug Designation, which is granted to products that treat rare diseases (i.e., those that affect fewer than 200,000 people in the United States). Approximately 1,600 patients are newly diagnosed with T-ALL/T-LBL each year in the United States. Of those, an estimated 500 patients have relapsed or refractory T-ALL/T-LBL; approximately 200 of these patients are children. Common side effects reported with nelabarine treatment are fatigue, nausea, vomiting, and diarrhea.

Generic Name: Nelarabine

Brand Name: Arranon

Manufacturer: GlaxoSmithKline (GSK), Research Triangle Park, North Carolina

Source:
FDA Approves Arranon for Rare Leukemia and Lymphoma: Drug Approved under Agency's Orphan Drug and Accelerated Approval Programs. FDA News. U.S. Food and Drug Administration, October 31, 2005
(http://www.fda.gov/bbs/topics/NEWS/2005/NEW01251.html)

MYH is a base excision repair gene that is involved in repairing oxidative damage to DNA. Loss of *MYH* is associated with G:C to T:A transversions in APC, leading to polyp formation and carcinoma. The two most common *MYH* mutations, G382D and Y165C, account for approximately 85% of MYH-associated polyposis. Appropriate candidates for mutational analysis testing are patients with multiple adenomas or FAP who have a family history compatible with a recessive pattern of inheritance (e.g., colon cancers or multiple adenomas in only one generation or in skipped generations) and in whom testing has failed to show a germline *APC* mutation.

Postmenopausal Hormone Therapy and Cancer Risk

Many epidemiologic studies have examined the possible associations between exogenous estrogens and colorectal neoplasia risk. In a meta-analysis of 18 epidemiologic studies, postmenopausal hormone therapy (HT) was associated with a 33% reduction in the risk of colon cancer in recent users; the relative risk was 0.67, compared with a relative risk of 0.92 in women who had used HT more than 1 year ago. Similarly, HT may protect against adenoma formation. In the Women's Health Initiative trial, which included over 16,000 postmenopausal women, the combination of estrogen and progesterone was associated with a reduction in the risk of colorectal cancer (hazard ratio, 0.56; 95% confidence interval, 0.38–0.81; $P = 0.003$).[1] Invasive colorectal cancers in the hormone-treated group were similar in histologic features and grade to those in the group receiving placebo. However, in patients who received HT, the number of positive lymph nodes was slightly greater, and the cancer was more advanced regionally or metastatically.

1. Chlebowski RT, Wactawski-Wende J, Ritenbaugh C, et al: Estrogen plus progestin and colorectal cancer in postmenopausal women. Women's Health Initiative Investigators. N Engl J Med 350:991, 2004 [PMID 14999111]

Molecular Detection of Colon Cancer

Detection of gene mutations in the stool has been possible for over a decade. It is technically feasible to detect *APC* and *p53* mutations, long DNA, and K-*ras* mutations. In addition, right-sided lesions can be detected by the identification of *BAT-26* mutations. In a 2004 study of over 2,500 persons, a fecal DNA mutation panel detected 29 of 71 (41%) invasive cancers and adenomas with high-grade dysplasia. The specificity was 94%. This is a rapidly advancing field, and improvements in technology are likely to enhance the sensitivity of detection.[1] The cost of such techniques is high, however, and it remains to be seen whether their use will be cost-effective relative to other techniques, including newer immunochemical tests for fecal occult blood.

1. Imperiale TE, Ransohoff DF, Itzkowitz SH, et al: Fecal DNA versus fecal occult blood for colorectal cancer screening in an average-risk population. N Engl J Med 351:2704, 2004 [PMID 15616205]

Monoclonal Antibodies for Treating Colorectal Cancer

After decades in which fluorouracil (5-FU) was the only chemotherapeutic agent available, the advent of new and more effective agents has completely changed the management of colorectal cancer. Although 5-FU remains the backbone of most regimens, new chemotherapeutic agents (i.e., irinotecan, oxaliplatin, and capecitabine) and new biologic agents (i.e., the monoclonal antibodies cetuximab and bevacizumab) offer additional benefit.

Cetuximab is a chimeric monoclonal antibody that bonds to the external growth factor receptor, which is commonly expressed on colorectal carcinoma cells. Dysregulation of cell signaling through this receptor is thought to be an important factor in the growth of many epithelial malignancies.

Patients treated with combinations of cetuximab and irinotecan have shown a higher response rate and a longer time to worsening of the metastatic disease than patients treated with either drug alone.[1] Side effects of cetuximab include an acneiform rash, malaise, and diarrhea.

Bevacizumab is a human chimeric antibody to vascular endothelial growth factor that stimulates angiogenesis. New blood vessel formation is important in tumor growth and invasion.

The addition of bevacizumab to combination therapy with irinotecan, leucovorin, and 5-FU has been shown to increase therapeutic efficacy: patients receiving the four-drug combination survived for approximately 20 months—about 5 months longer than those receiving the three-drug combination.[2] Combinations of bevacizumab and cetuximab are also being assessed because of preclinical and early clinical data indicating synergistic activity.

1. Cunningham D, Humblet Y, Siena S, et al: Cetuximab monotherapy and cetuximab plus irinotecan in irinotecan-refractory metastatic colorectal cancer. N Engl J Med 351:337, 2004 [PMID 15269313]

2. Hurwitz H, Fehrenbacher L, Novotny W, et al: Bevacizumab plus irinotecan, fluorouracil and leucovorin for metastatic colorectal cancer. N Engl J Med 350:2335, 2004 [PMID 15175435]

4 GASTROENTEROLOGY

III Diarrheal Diseases

LAWRENCE R. SCHILLER, MD, FACP
Baylor University Medical Center

Antibiotic Selection by Geography for Shigellosis

Because of growing resistance to the fluoroquinolones in the United States, trimethoprim-sulfamethoxazole is the recommended initial treatment for most patients with shigellosis. Shigellosis contracted overseas is initially treated with fluoroquinolones, because those strains are more likely to be resistant to trimethoprim-sulfamethoxazole.

Confirming and Curing Giardiasis

Enzyme-linked immunosorbent assay (ELISA) for *Giardia* antigen is superior to microscopic inspection of stool (so-called ova and parasites testing) for the detection of giardiasis. Therapy with tinidazole, metronidazole, or nitazoxanide is effective in most patients, but reinfection can occur.[1]

1. Ali SA, Hill DR: *Giardia intestinalis*. Curr Opin Infect Dis 16:453, 2003 [PMID 14501998]

Drugs in, Diarrhea out

Drug therapy is a key cause of secretory diarrhea.[1] Many drugs have diarrhea as a side effect. These include antibiotics; cardiovascular agents, such as beta-adrenergic antagonists, digitalis, and quinidine; cancer chemotherapy; nonsteroidal anti-inflammatory drugs; and colchicine. Thus, in taking the history of a patient with chronic diarrhea, it is critical to formulate a detailed drug list, including over-the-counter and alternative medications. A special category of drug-induced secretory diarrhea is surreptitious ingestion of stimulant laxatives.

1. Cappell M: Colonic toxicity of administered drugs and chemicals. Am J Gastroenterol 99:1175, 2004 [PMID 15180742]

Neoplastic Diarrhea

Endocrine causes of secretory diarrhea include a group of rare tumors of the endocrine cells of the gut, including gastrinomas, carcinoid tumors, vasoactive intestinal peptide tumors (VIPomas), somatostatinomas, and medullary carcinoma of the thyroid.[1,2] These tumors produce peptides and other mediators that affect intestinal mucosal and muscle function and thereby produce diarrhea. In most cases, rapid intestinal transit seems to be the major mechanism producing diarrhea in these disorders, although this remains controversial.

Other tumors that produce secretory diarrhea include colon cancer (mechanism uncertain), villous adenoma of the rectum, lymphoma, and mastocytosis. Mastocytosis (and probably some lymphomas) produce diarrhea by release of histamine or other mediators that affect gut function. Infiltration of the mucosa also may play a role in some cases.

2. Modlin IM, Kidd M, Latich I, et al: Current status of gastrointestinal carcinoids. Gastroenterology 128:1717, 2005 [PMID 15887161]

Diagnosis at a Gulp?

The role of capsule endoscopy in the evaluation of patients with chronic diarrhea is under investigation; studies suggest that it may be helpful in detecting Crohn disease and, perhaps, celiac disease.[1-3] However, capsule endoscopy does not allow for biopsy of abnormalities that are visualized during the procedure, which limits its utility. Double-balloon enteroscopy offers the possibility of visualizing and obtaining biopsies from the entire small intestine; this technique may find a place in the evaluation of patients with watery secretory diarrhea.[4]

1. Petroniene R, Dubcenco E, Baker JP, et al: Given capsule endoscopy in celiac disease: evaluation of diagnostic accuracy and interobserver agreement. Am J Gastroenterol 100:685, 2005 [PMID 15743369]

2 DERMATOLOGY

II Papulosquamous Disorders

ELIZABETH A. ABEL, MD
Stanford University School of Medicine

Light and Dark on Pityriasis Rosea

Pityriasis rosea lesions resolve spontaneously after 6 to 8 weeks. The patient should be reassured that the disorder is benign and self-limited; such reassurance, together with educating the patient about the disease, is the most important aspect of treatment. Lesions are variably pruritic. Symptoms should be treated with bland emollients or systemic antipruritics. Sun exposure may accelerate clearing. Irradiation with ultraviolet B (UVB) sunlamps is beneficial in decreasing the severity of disease, especially when treatment is initiated within the first week of the eruption. One study found that 10 erythemogenic exposures of UVB substantially decreased the extent of pityriasis rosea, although it neither altered the duration of the disorder nor improved the itching. Other evidence suggests that UVB therapy may hasten resolution of the rash but may cause hyperpigmentation.[1]

1. Stulberg DL, Wolfrey J: Pityriasis rosea. Am Fam Physician 69:87, 2004 [PMID 14727822]

What Is the Link between Hepatitis and Lichen Planus?

The prevalence of viral hepatitis, especially hepatitis C, is increased in patients with lichen planus. In a multicenter study of 303 sequential patients with lichen planus, the prevalence of hepatitis C virus (HCV) was 19.1%, compared with 3.2% in control subjects.[1] The role of HCV in the pathogenesis of lichen planus is not clearly understood; some investigators suggest that the cause of lichen planus may relate to the pattern of immune dysregulation induced by HCV.[2] There are a number of reports of lichen planus occurring after administration of different types of hepatitis B vaccine.[3] This is a rare occurrence, considering the widespread use of this vaccine; several cases have been reported from France and Italy, and one case has been reported from the Middle East. An immunologic mechanism has been postulated as the cause. The latency period ranges from several days to 3 months after any one of the three usual injections of vaccine.

2. Harden D, Skelton H, Smith KJ: Lichen planus associated with hepatitis C virus: no viral transcripts are found in the lichen planus, and effective therapy for hepatitis C virus does not clear lichen planus. J Am Acad Dermatol 49:847, 2003 [PMID 14576663]
3. Callista D, Morri M: Lichen planus induced by hepatitis B vaccination: a new case and a review of the literature. Int J Dermatol 43:562, 2004 [PMID 15304176]

Treating Lichen Planus in the Mouth

For lichen planus that is localized to the oral mucosa, a high-potency corticosteroid such as clobetasol in a vehicle that is adherent to the mucosal surface (Orabase) is helpful. Intralesional injections of corticosteroids may be used to treat localized, recalcitrant lesions. Use of miconazole gel in combination with chlorhexidine mouth rinses is effective for prophylaxis against oral candidiasis. Topical isotretinoin gel is an effective alternative to corticosteroids, although relapses often occur after discontinuance of this medication. In a double-blind, placebo-controlled study of 22 patients with biopsy-proven oral lichen planus, an 8-week course of 0.1% isotretinoin gel was found to be effective. Cyclosporine mouth rinses have been helpful for some patients. A 6-month course of hydroxychloroquine, 200 to 400 mg daily, was successful in nine of 10 patients with oral lichen planus; ulcers healed and pain decreased after 1 to 2 months.

Topical tacrolimus, a macrolide that suppresses T cell activation, may be effective in treating erosive mucosal lichen planus that is resistant to conventional treatment; however, relapse after cessation of therapy is common. Topical pimecrolimus cream is being evaluated as a treatment for oral erosive lichen planus.[1] The role of these agents in the treatment of lichen planus must be further investigated, particularly in view of the 2005 Food and Drug Administration alert about a possible link between use of topical tacrolimus and pimecrolimus and cases of lymphoma and skin cancer.

1. Swift JC, Rees TD, Plemons JM, et al: The effectiveness of 1% pimecrolimus cream in the treatment of oral erosive lichen planus. J Periodontol 76:627, 2005 [PMID 15857105]

What Works for Seborrheic Dermatitis

Seborrheic dermatitis on the scalp usually responds well to frequent—as often as daily—shampooing with a preparation containing 3% to 5% sulfur and 2% to 3% salicylic acid. Good response has also been reported with use of ciclopirox 1% shampoo twice weekly.[1] For the face and nonhairy areas, a mild cream containing precipitated 3% sulfur and 3% salicylic acid is effective. Involved areas also respond well to low-potency topical glucocorticoids, such as 1% hydrocortisone cream or desonide cream. Caution, however, must be exercised in the use of high-potency fluorinated steroid preparations, especially on the face and in skin folds; prolonged application may lead to chronic skin changes, such as atrophy and telangiectasia. Wet dressings followed by a topical antibiotic preparation are helpful in treating intertriginous areas, in which maceration and superficial secondary infection may occur.

Topical antifungal agents have been used in the treatment of seborrheic dermatitis. In addition to their antifungal properties, certain azoles (e.g., bifonazole, itraconazole, and ketoconazole) have demonstrated anti-inflammatory activity, which may be beneficial in alleviating symptoms.[2]

Are Human-Bite Wounds Not So Bad?

Traditionally, human-bite wounds have had a reputation for frequent

and severe complications. Current data, however, suggest an infection rate from human-bite wounds on the order of 10% to 50%, depending on the wound type and location. Occlusional/simple bite wounds to areas other than the hand probably are no more at risk for infection than any other type of bite wound and minimally more than for nonbite lacerations.[1] However, human-bite wounds to the hand are associated with infection rates of almost 50%. A clenched-fist injury is considered the most serious of all human-bite wounds.[1] These injuries may appear innocent at first but progress to serious infections that may include the joint, tendons, or various compartments of the hand. These injuries require meticulous wound care, appropriate antibiotic therapy, and consultation with a hand surgeon.

1. Broder J, Jerrard D, Olshaker J, et al: Low risk of infection in selected human bites treated without antibiotics. Am J Emerg Med 22:10, 2004 [PMID 14724871]

Prophylactic Antibiotics for Bite Wounds

The use of prophylactic antibiotics for any bite wound is debatable, but there is general consensus that certain wounds in all patients and most wounds in certain patients deserve prophylactic antibiotics [*see Table, upper right*]. The antibiotic of choice for prophylaxis of most mammalian bite wounds is amoxicillin-clavulanate. For the penicillin-allergic patient, a third-generation fluoroquinolone (e.g., moxifloxacin)[1] or a cephalosporin (e.g., cefotaxime)[2] serves as a good alternative. The timing of prophylactic antibiotics is important. Prophylactic antibiotics should be given as soon after the bite injury as possible. A systematic review suggests that prophylactic antibiotics may reduce the incidence of infection in all hand-bite wounds and human bites, regardless of location.[1]

1. Talan DA, Abrahamian FM, Moran GJ, et al: Clinical presentation and bacteriologic analysis of infected human bites in patients presenting to emergency departments. Clin Infect Dis 37:1481, 2003 [PMID 14614671]

2. Turner TW: Evidence-based emergency medicine/systematic review abstract. Do mammalian bites require antibiotic prophylaxis? Ann Emerg Med 44:274, 2004 [PMID 15332071]

Bite Wounds Requiring Prophylactic Antibiotics

Wound characteristics	Puncture wounds Full-thickness wounds Hand or foot wounds Wounds requiring surgical repair Treatment delay (> 24 hr) Human bites* Cat bites*
Patient characteristics	Age > 50 yr Immunosuppression (e.g., asplenia, alcoholism, corticosteroid use) Diabetes mellitus Peripheral vascular disease

*There is debate, but many authors recommend prophylactic antibiotic treatment for virtually all human and cat bites because of the high rate of infection.

Brown Recluse Bites That Aren't

The brown recluse spider is found in the south central United States, especially in Missouri, Kansas, Arkansas, Louisiana, eastern Texas, and Oklahoma. It is occasionally found in other states, but these cases likely represent spiders uprooted and transported from the endemic areas.[1] The diagnosis of true *Loxosceles* spider bites in the United States is considered to be far less than the number of patients who are treated for recluse spider envenomations. Strict inclusion criteria for recluse envenomation includes sighting of the biting spider and identification of that specific spider. In studies from areas endemic for *Loxosceles*, patients present with almost no true *Loxosceles* bites or envenomations despite exposure to dozens to hundreds of spiders; these results suggest that nonendemic areas should have minimal to no true *Loxosceles* bites.[2,3]

CLINICAL ESSENTIALS

XI Management of Psychosocial Issues in Terminal Illness

JENNIFER RHODES-KROPF, MD
Mount Sinai School of Medicine
NED H. CASSEM, MD, FACP
Harvard Medical School

Cultural and Individual Attitudes toward Truth Telling

The desire for truth telling may vary among different ethnic groups.[1] In a study of elderly persons in the United States, Korean Americans and Mexican Americans were less likely than African Americans and European Americans to believe that a patient should be told the diagnosis of metastatic cancer. However, a population study in Hong Kong reported that the majority of persons canvassed would want to know if they had terminal cancer; this finding is at odds with the cultural preference of many Chinese, who usually prefer to withhold diagnostic information from terminally ill family members.[2] This study emphasizes that cultural preferences give only general indications of a patient's readiness to hear bad news; truth telling ultimately depends on the physician's assessment of what the patient wants to know and is prepared to know about the diagnosis.

2. Tse CY, Chong A, Fok SY: Breaking bad news: a Chinese perspective. Palliat Med 17:339, 2003 [PMID 12822851]

Talk about Religion

Studies find that people who have a strong internalized faith possess a resource that helps significantly in coping with a fatal illness.[1,2] It is a well-documented finding that religious persons usually belong to a community that can be unusually thoughtful and generous in providing support.

Introduction to Women's Health: The Primary Care of Women

However, the community may not know of the patient's plight and may need to be contacted. Thus, the appreciation of a person's religion or spirituality is extremely important. Studies suggest that patients welcome inquiries about their spiritual well-being from the physicians, although interventions to address spiritual distress have not been well developed or well evaluated.[3]

Truth and Silence

Even when the prognosis is grave, a calm statement of the treatments planned to counteract and contain the disorder is of value to the anxious patient. The more ominous the prognosis, the more important it is to encourage the patient to specify the fear, so that correspondingly true reassurances (e.g., "the medication can control pain") can be given. False comfort is not recommended. It robs the physician of credibility and, therefore, of the ability to reassure the patient as the illness progresses. An empathetic yet silent presence can sometimes be more helpful than well-meant counsel.[1]

PRACTICE OF MEDICINE

The ACP and *ACP Medicine*

JOHN TOOKER, MD, MBA, FACP
Executive Vice President and Chief Executive Officer
American College of Physicians
STEVEN WEINBERGER, MD, FACP
Senior Vice President, Medical Knowledge and Education
American College of Physicians

More than at any time in the past, physicians are under great pressure to meet new educational and professional requirements. They are being asked to learn more and do more at the cost of time to spend on their patients, as well as on their personal lives and other interests. Yet, despite these demands, physicians everywhere are continuing to step forward to accept the additional burdens placed upon them.

The American College of Physicians (www.acponline.org) takes special pride in its role as an advocate for the practicing physician and as a contributor of increased medical education requirements that are fair and reasonable benchmarks of a physician's skills. One of the College's educational efforts is its sponsorship of *ACP Medicine*, which is published by WebMD in partnership with the College. The excellent 2006 bound edition of *ACP Medicine* is the latest manifestation of our joint efforts.

The partnership between the College and WebMD was the culmination of an extensive review of *ACP Medicine's* content and editorial processes by the College, as well as a

X Obesity

JONATHAN Q. PURNELL, MD
Oregon Health and Science University

Laboratory Tests for Obese Patients

Screening of obese patients for macrovascular risk involves obtaining an electrocardiogram when appropriate. A fasting lipid profile should be obtained to complete the cardiovascular risk assessment, and, if necessary, treatment should be instituted according to guidelines from the National Cholesterol Education Program Expert Panel. This panel incorporated several nonlipid risk factors for cardiovascular disease into its recommendations for clinical care by defining criteria for a condition that has become known as the metabolic syndrome (also called syndrome X or the insulin-resistance syndrome). The metabolic syndrome includes the most common abnormalities of lipid and glucose metabolism that accompany abdominal obesity [*see Table, page 3, top*]. Identifying these abnormalities in a patient allows the practitioner to better assign that patient's risk for diabetes and coronary artery disease.[1] Laboratory screening tests for hepatosteatosis include a liver panel. In addition, for all overweight patients, normal thyroid function should be documented by measurement of the thyroid-stimulating hormone level.

Diabetes Treatment and Weight Gain

Patients with type 1 or type 2 diabetes often gain weight after starting therapy. This weight gain is proportional to the degree of improved glycemic control; it results from a reduction in glucosuria and improvement in metabolic efficiency. Long-term studies have shown that intensive insulin treatment of type 1 diabetes can result in excessive weight gain and obesity in up to 25% of patients; in type 2 diabetes, intensive glycemic control with insulin, a sulfonylurea, or one of the thiazolidinediones may also result in greater weight gain than predicted by

PRACTICE OF MEDICINE

continued from page 1

shared and long-standing commitment to helping physicians achieve excellence in clinical practice. David C. Dale, M.D., F.A.C.P., the Editor-in-Chief of *ACP Medicine*, reports to the College regarding content development and editorial standards related to the publication. A strong connection has long existed between the College and WebMD, with many of *ACP Medicine's* editors and authors having also been active in the College's educational programs and publications.

One of the many benefits of the College's sponsorship of *ACP Medicine* is that the text includes coverage of evolving programs and professional requirements, such as performance measurement and other quality-improvement programs. These requirements will obviously have great implications for how physicians practice medicine on a daily basis. Medicare already has started a series of pilot programs offering financial incentives on the basis of improved outcomes. Because of the importance of such performance measures, the front matter of the 2006 edition of *ACP Medicine* contains special coverage of this information by Kevin B. Weiss, M.D., F.A.C.P., and colleagues. Dr. Weiss is chair of the ACP Performance Measures Subcommittee, which has created a "starter set" of performance measures. In addressing these topics, Dr. Weiss provides an important overview of the changes to come in performance measures. Updated information on this topic and numerous others is available at the *ACP Medicine* Web site (www.acpmedicine.com).

Clearly, the need for medical education continues after completion of residency—it is a lifelong commitment. The fact that the educational requirements now include understanding and following new professional obligations, as well as remaining current on the latest diagnostic and therapeutic practices, makes the need for access to a textbook such as *ACP Medicine* all the more significant.

Physicians share a professional commitment to excellence in clinical practice through the use of evidence-based practice guidelines in the care of their patients. We hope that *ACP Medicine* provides an expedient and authoritative resource for physicians to achieve this goal of translating knowledge into care.

THIS MONTH'S UPDATES

continued from page 1

improved glycemic control alone. Therapy with metformin plus nighttime long-acting insulin may reduce or prevent this extra weight gain, and newer diabetes medications, such as pramlintide and exenatide, can improve glycemic control in both type 1 and type 2 diabetes with a modest weight loss.

Reasonable Expectations for Obesity Treatment

The weight loss goal for the treatment of obesity is a sustained loss of 5% or more of initial body weight. Although this goal does not result in attainment of a normal body weight (i.e., a body mass index [BMI] of 19 to 25) in the majority of patients, it still represents a weight loss that can be achieved with available intervention modalities and that has been associated with lower morbidity, including reductions in the risk of diabetes and heart disease.

For some patients who are experiencing a period of weight gain, weight stability may be their primary goal. This is especially common in patients

who have just completed a low-calorie weight loss program and are struggling to remain below their initial weight.

Obesity under the Knife

A National Institutes of Health expert panel has suggested that patients with a BMI of 40 or more or a BMI of 35 or more who also have obesity-related risk factors could be considered for surgical therapy. In general, these procedures can be classified into three types: restriction of food passage, malabsorption of nutrients, or a combination of the two [*see Table, below*]. As an example of a strictly restrictive procedure, vertical-banded gastroplasty involves the formation of a small stoma for the passage of food. The rationale behind this procedure is to increase a sense of fullness and reduce food intake.

Procedures resulting in malabsorption typically involve bypassing sections of small or large intestine. Early procedures in which large sections, or even the entire length, of the small intestine was bypassed often resulted in severe malabsorption and sometimes hepatic failure and death. Subsequent procedures involved bypass of shorter sections, which lowered morbidity. Patients must understand that bypass surgery is anatomically irreversible in most cases and has a potentially high postoperative complication rate.

A more recent technique, known as laparoscopic gastric banding, in which a restrictive band is placed around the upper stomach, has been shown to lead to sustained weight loss in studies of up to 4 years. However, this weight loss is generally felt to be similar to that of vertical-banded gastroplasty and is not as great as that obtained with the gastric bypass operation.[1]

Criteria for Metabolic Syndrome

Any Three of the Following:

- Increased waist circumference
  - Men: > 102 cm (40 in)
  - Women: > 88 cm (35 in)
- Fasting plasma glucose ≥ 100 mg/dl
- Elevated blood pressure
  - Systolic ≥ 130 mm Hg
  - Diastolic ≥ 85 mm Hg
- Serum triglyceride level ≥ 150 mg/dl
- Decreased high-density lipoprotein (HDL) cholesterol level
  - Men < 40 mg/dl
  - Women < 50 mg/dl

Most Commonly Used Bariatric Procedures

Type of Surgery	*Procedure*	*Average Weight Loss*	*Medical Complications*	*Management*
Restrictive	Vertical-banded gastroplasty	~17% (5 yr)	Nausea, vomiting Gastric distention	Reversal of procedure if complications unacceptable
	Laparoscopic adjustable gastric banding	17%–21% (3 yr)	Nausea, vomiting Slippage Erosion and leakage	Adjustment of band to minimize nausea; reversal of procedure if necessary
Malabsorptive	Biliopancreatic diversion	~27% (5 yr)	Diarrhea, fatty stools Protein-calorie malnutrition Anemia (low iron) Deficiency of vitamin D (and other fat-soluble vitamins) Hypocalcemia Hyperparathyroidism Metabolic bone disease Vitamin B_{12} deficiency, Wernicke encephalopathy (rare)	Monitoring of levels and replacement of nutritional deficiencies; patients often require high oral or parenteral doses
Combination	Gastric bypass	~27% (5 yr)	Dumping syndrome Reductions in levels of iron, vitamin B_{12}, folate, calcium, vitamin D Nesidioblastosis (rare)	Small, frequent meals; monitoring of nutrient levels and oral supplementation with iron tablets (325 mg), vitamin B_{12} (500 µg), folate (1 mg), calcium (500–1,000 mg), and vitamin D

FDA Approval Report

The following is selected from the FDA's list of announcements. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

Strengthened Risk Management Program for Isotretinoin

The FDA has approved a strengthened distribution program for isotretinoin. This program, called iPLEDGE, is intended to prevent use of isotretinoin during pregnancy. Isotretinoin (Accutane and its generics) is a highly effective drug for severe recalcitrant nodular acne, but it carries a significant risk of birth defects. Women who are pregnant or who might become pregnant should not take the drug.

Starting December 31, 2005, physicians and patients must register with the iPLEDGE program before receiving authorization to prescribe or use the drug. Compliance with iPLEDGE requires office visits, counseling, birth control, and other responsibilities. Key requirements for patients include completing an informed consent form, obtaining counseling about the risks and requirements for safe use of the drug, and, for women of childbearing age, complying with required pregnancy testing.

As of October 31, 2005, wholesalers and pharmacies have had to register with iPLEDGE to obtain isotretinoin from a manufacturer, to distribute the product, and to dispense it.

Physicians, patients, and pharmacies can obtain program information and can register with iPLEDGE via the Internet (www.ipledgeprogram.com) or by telephone (1-866-495-0654).

A reporting and collection system for serious adverse events associated with the use of isotretinoin has also been implemented. All pregnancy exposures to isotretinoin must be reported immediately to the FDA via MedWatch (1-800-FDA-1088); pregnancy exposures must also be reported to the iPLEDGE pregnancy registry, either by telephone (1-866-495-0654) or through the iPLEDGE Web site (www.ipledgeprogram.com).

In addition to approving the iPLEDGE program, the FDA has approved changes to the existing warnings, patient information, and informed consent document so that patients and prescribers can better identify and manage the risks of psychiatric symptoms and depression before and after prescribing isotretinoin.

7 INFECTIOUS DISEASE

VIII Infections Due to Escherichia coli and Other Enteric Gram-Negative Bacilli

MICHAEL S. DONNENBERG, MD

University of Maryland School of Medicine

Treating Traveler's Diarrhea

As with all diarrheal disease, the initial management of enterotoxigenic *Escherichia coli* (ETEC) infection involves ensuring adequate fluid repletion. Several well-conducted clinical trials have demonstrated that traveler's diarrhea that is partly caused by ETEC responds rapidly to treatment with any of several regimens containing antibiotics, with or without antimotility agents. Ciprofloxacin, taken every 12 hours for 3 days in combination with loperamide, is a particularly effective regimen. Rifaximin, a nonabsorbable agent, is approved by the Food and Drug Administration for traveler's diarrhea caused by noninvasive strains of *E. coli*. Studies have found rifaximin to be comparable in efficacy to ciprofloxacin. Azithromycin is another effective alternative.[1] Rifaximin can be used as a single agent or in combination with loperamide. ETEC organisms are generally susceptible to fluoroquinolones; however, should resistance to fluoroquinolones increase, rifaximin may prove an important alternative to ciprofloxacin for the treatment of traveler's diarrhea.

1. Adachi JA, Ericsson CD, Jiang ZD, et al: Azithromycin found to be comparable to levofloxacin for the treatment of travelers with acute diarrhea acquired in Mexico. Clin Infect Dis 37:1165, 2003 [PMID 14557959]

The Wide Reach of *E. coli* O157:H7

Of the many Shiga toxin–producing *E. coli* strains that have been described in the literature, enterohemorrhagic *E. coli* (EHEC) of serotype O157:H7 is the most important, having caused both the largest number of outbreaks and the outbreaks involving the greatest number of patients. There are approximately 0.9 cases of EHEC O157:H7 infections per 100,000 persons annually in the United States.[1] The reservoir for EHEC is infected cattle, but the organism can be found in a variety of other ruminants. The disease often appears in outbreaks associated with the consumption of contaminated food. Undercooked ground beef has been associated with many outbreaks and is the leading risk factor for sporadic cases, but a variety of other foods and beverages, including other beef products, lettuce, sprouts, fruit, fruit juices, and milk, have been implicated. The disease has a low inoculum and can spread from person to person, particularly in day care centers or within the families of young children. An outbreak of EHEC infection resulting from airborne dispersal of bacteria after a country fair emphasizes the highly infectious nature of this pathogen.[2] It can also be spread through contamination of the water supply or through contamination of swimming pools, lakes, or

water parks, and it can be contracted directly from infected animals at farms and petting zoos.

Polymyxins Return

Polymyxins are cationic polypeptides that disrupt the bacterial cell membrane through a detergentlike mechanism. With the development of less toxic agents, such as extended-spectrum penicillins and cephalosporins, parenteral polymyxin use was largely abandoned, except for the treatment of multidrug-resistant pulmonary infections in patients with cystic fibrosis. More recently, however, the emergence of multidrug-resistant gram-negative bacteria, such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii*, and the lack of new antimicrobial agents have led to the revived use of the polymyxins, particularly colistin (polymyxin E) and polymyxin B.[1] Colistin is bactericidal against gram-negative bacilli, including strains of *Acinetobacter, P. aeruginosa, Klebsiella, Enterobacter, E. coli, Citrobacter, Morganella, Haemophilus influenzae*, and some strains of *Stenotrophomonas maltophilia*. It is not active against *P. mallei, Bacteroides cepacia, Proteus, Providencia*, or *Serratia*. Colistin sulfate is available as an oral formulation for the treatment of bowel decontamination; colistimethate sodium can be administered intravenously, intramuscularly, or by nebulization. The recommended intravenous dose is 2.5 to 5 mg/kg/day divided into two to four equal doses; however, dosing must be reduced if renal insufficiency is present.

Polymyxin B has been used extensively in topical otic and ophthalmic solutions, but there is more limited parenteral experience with it than with colistin. Originally, colistimethate sodium was thought to be less toxic than polymyxin B; however, if the drugs are administered at comparable doses, their toxicities may be similar.

Given the concern for potential toxicity, the use of colistin and polymyxin B should be viewed as a treatment of last resort for patients who have serious infections caused by multidrug-resistant gram-negative pathogens for which no other therapeutic options exist.

1. Falagas ME, Kasiakou SK: Colistin: the revival of polymyxins for the management of multidrug-resistant gram-negative bacterial infections. Clin Infect Dis 40:1333, 2005 [PMID 15825037]

The First of a New Family

Tigecycline received approval by the Food and Drug Administration in 2005 as the first member of the glycylcycline family. Tigecycline is a semisynthetic derivative of minocycline. Its mechanism of action is similar to that of minocycline[1]; however, tigecycline avoids the two major forms of tetracycline resistance—namely, ribosomal protection and drug efflux. Tigecycline has a broad spectrum of bacteriostatic activity against gram-positive, gram-negative, atypical, and anaerobic bacteria. It is active against multidrug-resistant bacteria, such as penicillin-resistant *Streptococcus pneumoniae*, methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), *E. coli* containing extended-spectrum β-lactamases, and *Klebsiella pneumoniae*. It is also active against some strains of *Acinetobacter*; however, it is not active against *Pseudomonas* or *Proteus*. Tigecycline is currently indicated in the treatment of complicated intra-abdomial infections and complicated skin and soft-tissue infections.

Tigecycline is available only as an intravenous formulation. Excretion is primarily through the biliary system. Side effects are similar to those of the tetracyclines, with gastrointestinal disturbances such as nausea and emesis being the most common.

1. Rubinstein E, Vaughan D: Tigecycline: a novel glycylcycline. Drugs 65:1317, 2005 [PMID 15977966]

Using Linezolid Wisely

Linezolid has been used successfully in the treatment of multidrug-resistant gram-positive bacterial infections, including VRE and MRSA,[1] but clinical experience with deep-seated infections such as endocarditis and osteomyelitis is limited. Although resistance is uncommon, it can develop during therapy. As a result, it may be wise to reserve this unique antibiotic for serious infections caused by MRSA, VRE, or coagulase-negative staphylococci that do not respond to vancomycin. It also has a role in decreasing hospital stay for some patients with resistant gram-positive infections,[2] although these patients require close outpatient monitoring.

7 INFECTIOUS DISEASE

XXXVIII Mycotic Infections in the Compromised Host

JO-ANNE VAN BURIK, MD, FACP

University of Minnesota Medical School

New Antifungals

In the first years of the 21st century, several new antifungal agents have gained important roles in the treatment of candidiasis and other fungal infections. Voriconazole, a new triazole with wide-spectrum antifungal activity and high bioavailability, has proved effective as empirical antifungal therapy in patients with neutropenia and persistent fever. Caspofungin is the first in a new class of antifungal agents called echinocandins, which inhibit synthesis of an integral component of the fungal cell wall, β-(1,3)-D-glucan. The Food and Drug Administration has approved caspofungin for the first-line treatment of candidemia, esophageal candidiasis, and other *Candida* infections (e.g., intra-abdominal abscesses, peritonitis, and pleural space infections).[1] A comparison study found caspofungin to be at least as

JEFFREY ECKER, MD
Harvard Medical School

Postpartum Thyroiditis or Postpartum Depression?

About 2 months after delivery, women with postpartum thyroiditis may experience hyperthyroidism as a result of leakage of thyroid hormone from the inflamed thyroid gland. This phase is often missed because of its short duration (usually 4 weeks or less) and because the patient and her caregivers tend to ascribe its symptoms of anxiety and palpitations to the stress of being a new mother. The thyroid-stimulating hormone (TSH) level is low at this time. About 6 months after delivery, the hypothyroid phase develops. At this time, patients usually present with fatigue and weight gain or an inability to lose pregnancy-associated weight. Depression can also be a presenting symptom; for that reason, it is important to check the TSH level before making a diagnosis of postpartum depression.

The Expectant Asthmatic

As many as 6% of pregnant women have asthma. This disease has a variable course during pregnancy: it is equally likely to worsen, improve, or remain unchanged. In contrast to past reports, current studies indicate that asthma is not associated with an increased risk of preterm delivery and growth restriction.[1] The clinical course in an individual patient may be linked, at least in part, to the patient's and her clinician's willingness to use needed medications during pregnancy. Guidelines from the National Institute of Child Health and Human Development emphasize that continued use of beta agonists and steroids during pregnancy is safe and appropriate.[2] As in nonpregnant women, clinical evaluations such as peak flow measurements can be used to judge disease activity and guide therapy.

Proven and Unproven Treatments of Gestational Diabetes

If a patient with gestational diabetes mellitus (GDM) continues to have elevated glucose levels despite dietary intervention, insulin therapy should be initiated. Although this recommendation has been made routinely for some time, evidence supporting the benefit of treatment for pregnancy outcome was lacking until 2005, when a study demonstrated that perinatal complications were less frequent in newborns of women with GDM who were randomized to management with home glucose monitoring, dietary therapy, and insulin, compared with the newborns of women who received routine care.[1] A 2004 study suggested that GDM may be effectively managed with oral glyburide rather than insulin,[2] but further studies are needed before this approach is advocated.

effective as amphotericin B for the treatment of invasive candidiasis and, more specifically, candidemia. Caspofungin is also approved by the FDA for the empirical treatment of presumed fungal infection in febrile neutropenic patients; it appears to be as effective as liposomal amphotericin B when used for this purpose, and it is generally better tolerated than amphotericin.[2] Micafungin, the second echinocandin to become clinically available, is approved by the FDA for intravenous treatment of esophageal candidiasis and for *Candida* prophylaxis in hematopoietic stem cell transplant recipients.[3,4]

Early Diagnosis of Aspergillosis

An enzyme-linked immunosorbent assay for the detection of *Aspergillus* galactomannan antigen in serum is commercially available and has become an important tool for the early diagnosis of invasive aspergillosis.[1] In one study, the test had a sensitivity of 75% and a specificity of 100%.[2] The assay is increasingly being used on specimens of body fluids other than serum, including urine, bronchoalveolar lavage fluid, and cerebrospinal fluid.[3]

3. Klont RR, Mennink-Kersten MA, Verweij PE: Utility of *Aspergillus* antigen detection in specimens other than serum specimens. Clin Infect Dis 39:1467, 2004 [PMID 15546083]

Treating Zygomycosis

Zygomycosis is currently treated with maximal-dosage intravenous amphotericin, 1.0 to 1.5 mg/kg daily for 2 to 12 weeks or for the duration of clinical disease. In addition to intravenous infusions, intracavitary or topical amphotericin may be required for central nervous system disease; topical amphotericin can be applied to cutaneous disease. Posaconazole, an orally administered triazole, is effective against zygomycosis[1] but is not yet approved by the FDA.

Treatment should include adjunctive measures such as debridement of any adherent mycelial masses at accessible sites of infection. Debridement should be repeated as often as every other day until cultures of the debrided tissues are negative. Some patients may be candidates for granulocyte transfusions or hyperbaric oxygen.

Stanford University School of Medicine

Helicobacter pylori and ITP

The role of *Helicobacter pylori* eradication in the management of idiopathic thrombocytopenic purpura (ITP) is controversial. Eradication of *H. pylori* may have a limited value in improving the thrombocytopenia in young patients who have evidence of *H. pylori* infection and have relatively mild thrombocytopenia of short duration (i.e., platelet counts of 30,000 to 70,000/μl for less than 2 years). Eradication is not useful in patients with chronic, severe ITP.[1]

1. Stasi R, Rossi Z, Stipa E, et al: *Helicobacter pylori* eradication in the management of patients with idiopathic thrombocytopenic purpura. Am J Med 118:414, 2005 [PMID 15808140]

Monoclonal Antibodies for Refractory ITP

Rituximab, a chimeric anti-CD20 monoclonal antibody, administered intravenously at 375 mg/m^2 once weekly for 4 weeks, produces a lasting and substantial response in approximately one third of patients with chronic refractory ITP, although long-term follow-up is still limited.[1] The majority of the responses occur within 8 weeks of the first infusion. The therapy is generally well tolerated, with most of the side effects (i.e., fever, chills, mild hypotension, and bronchospasm) being infusion related and occurring with the first infusion. Rituximab produces a profound and prolonged peripheral B-cell depletion in all patients, which can last for more than a year, but serious infection is rare. Because of the concern of long-term bone marrow toxicity with older treatment regimens (i.e., azathioprine and cyclophosphamide), rituximab should be considered the first-line therapy in refractory ITP patients, if treatment is indicated.

1. Cooper N, Stasi R, Cunningham-Rundles S, et al: The efficacy and safety of B-cell depletion with anti-CD20 monoclonal antibody in adults with chronic immune thrombocytopenic purpura. Br J Haematol 125:232, 2004 [PMID 15059147]

Thrombocytopenia from Antiplatelet Drugs

Three parenteral platelet glycoprotein (GP) IIb-IIIa receptor antagonists—abciximab, eptifibatide, and tirofiban—have been approved for use in the treatment of acute coronary syndrome and as adjunctive therapy in coronary angioplasty. Treatment with GPIIb-IIIa antagonists can result in acute, often profound thrombocytopenia within a few hours of drug administration. This complication occurs in about 1% of patients with the first exposure to abciximab. After a second exposure, the incidence of thrombocytopenia rises to 4%. The incidence of drug-induced thrombocytopenia associated with eptifibatide and tirofiban is probably in a similar 1% range.[1] Consequently, a platelet count should be obtained in all patients before and within 2 to 4 hours after the initiation of an intravenous GPIIb-IIIa antagonist.

Because eptifibatide and tirofiban have very short half-lives and are cleared from the circulation within hours, thrombocytopenia resolves quickly once these drugs are discontinued. Abciximab, however, has a much longer half-life, with inhibition of platelet function reported up to 1 week after drug discontinuance; thrombocytopenia from this drug can persist for 5 to 7 days. It should be noted that in some patients, abciximab causes a delayed thrombocytopenia that develops 5 to 8 days after treatment. Limited published experience suggests that it is safe to administer eptifibatide or tirofiban to patients who are sensitive to abciximab, and vice versa.[1]

Factor XI Deficiency, Surgery, and Childbirth

Patients with factor XI deficiency frequently come to medical attention when a prolonged activated partial thromboplastin time is detected in preoperative screening. It is most frequently observed in Ashkenazi Jews, although sporadic cases have been described in people of different ethnic origins. Factor XI deficiency is inherited as an autosomal recessive trait, and heterozygous deficiency is not associated with any clinical bleeding. Patients with homozygous or compound heterozygous deficiency generally have factor XI levels of less than 15%, and most bleeding manifestations in these patients are related to trauma or surgery, especially at sites of high fibrinolytic activity (e.g., the urinary tract, tonsils, and tooth sockets).[1] Factor XI plays a supportive role in the clotting cascade. It is activated by thrombin and then functions in a positive feedback manner to augment thrombin generation and clot stabilization. Thus, factor XI is primarily required in situations in which there is a significant hemostatic challenge; this explains the mild bleeding diathesis in factor XI deficiency. For patients with severe factor XI deficiency (< 15%) who require surgery, fresh frozen plasma should be used to replenish the plasma level to more than 50%. ε-Aminocaproic acid given orally at a dosage of 3 g three or four times daily is also effective for minor surgical or dental procedures. APC versus DIC

Recombinant human activated protein C (APC, or drotrecogin alfa [activated]) has been shown to significantly reduce mortality in patients with severe sepsis (mortality was 24.7% in patients given APC versus 30.8% in patients given placebo). Although it is associated with a slightly increased risk of bleeding, APC appears to be an effective agent in the treatment of severe disseminated intravascular coagulation (DIC) in patients with sepsis, even for patients with normal protein C levels.[1] In large randomized trials, neither recombinant tissue factor pathway inhibitor nor antithrombin concentrate reduced mortality in septic patients.[2] In cases of DIC associated with solitary or multiple hemangiomas, the hemangiomas can be excised when they are localized and occasionally show a good response to local irradiation. Attempts to control DIC with heparin, corticosteroids, aspirin, and estrogens have not been successful. The key to successful management of DIC associated with certain snakebites is identification of the type of snake and prompt administration of appropriate antivenin.

PRACTICE OF MEDICINE

Announcing *ACP Medicine* 2006

DAVID C. DALE, MD, FACP
Editor-in-Chief, ACP Medicine

We are proud to announce the publication of the 2006 edition of *ACP Medicine*, a medical textbook designed for the practicing physician.

The chapters in *ACP Medicine* are written with the goal of supporting the diagnostic and therapeutic decisions made daily in clinical practice. Our authors, who are among today's medical leaders, base their recommendations on the best current evidence, as well as on their substantial clinical experience. Because we realize that medicine is more than just searching for the latest study results, each chapter also explains the pathophysiology essential for making informed decisions and puts medical advances into context within existing knowledge.

The 2006 bound edition of *ACP Medicine* is larger than ever, with more than 3,000 pages, over 1,100 figures and algorithms, nearly 1,000 tables, and over 16,500 references. We start this edition off with a discussion of one of the key issues facing physicians in practice today: performance measurement. In the front matter of Volume 1, we have added a special review by Kevin B. Weiss, M.D., F.A.C.P., and colleagues of current work in performance measures. Dr. Weiss, who is Chair of the ACP Performance Measures Subcommittee, includes in his review a discussion of how these measures are struc-

The Murphy Sign Validated

Physical examination in patients with acute cholecystitis may reveal upper quadrant subcostal tenderness and pain on inspiration, often with inspiratory arrest (the Murphy sign). Of all physical examination findings, the Murphy sign has the highest positive likelihood ratio (LR) for acute cholecystitis (LR, 2.8; 95% confidence interval, 0.8 to 8.6).[1]

1. Trowbridge RL, Rutkowski NK, Shojania KG: Does this patient have acute cholecystitis? JAMA 289:80, 2003 [PMID 12503981]

Early Is Best for Laparoscopic Cholecystectomy

In acute cholecystitis, laparoscopic cholecystectomy should be performed within 96 hours of onset of symptoms because the increasing inflammatory changes that occur over time have been implicated in bile duct injury; these changes may necessitate converting the procedure to an open cholecystectomy.[1] Early laparoscopic cholecystectomy is recommended for acute cholecystitis, because a delay in surgery does not reduce morbidity, mortality, rate of conversion to open surgery, or mean hospital stay.[2,3] In skilled hands, the laparoscopic procedure carries approximately the same risk as that of open cholecystectomy, but it is associated with much less postoperative pain and a shorter convalescence. In patients with cirrhosis, laparoscopic cholecystectomy is performed for more emergent reasons and is associated with higher morbidity; however, the laparoscopic approach offers advantages of less blood loss, shorter operative time, and shorter length of hospitalization in patients with compensated cirrhosis.[4] In addition, laparoscopic cholecystectomy can be safely performed during pregnancy. Laparoscopic cholecystecto-

PRACTICE OF MEDICINE

continued from page 1

tured and what they will mean for the individual physician. Other examples of expanded coverage include new chapters on breast mass, pelvic mass, and the Pap smear, which have been added to our Gynecology and Women's Health section, as well as a new rheumatology chapter on fibromyalgia. In addition, we have updated our cardiac resuscitation and adult preventive care chapters to include the latest guidelines. Overall, 45% of the material in the book either has been updated or is new.

ACP Medicine is available in four formats. In addition to the bound edition, we also publish a CD-ROM edition, our original loose-leaf edition, and an online edition, available at www.acpmedicine.com. Both the loose-leaf and the online editions are updated monthly. Our Web site provides more detailed information on *ACP Medicine*, including one development we are very excited about: the launch of a peer review process for new or updated chapters. While this process has only just started, new or revised chapters are now read before publication by two to four peer reviewers, who are invited to comment formally on content, clarity, the weighting of topic coverage, and the quality of evidence; they are also encouraged to suggest additional material for inclusion (especially information on therapies). We list our new peer review board in the front matter. Included free with purchase of the bound edition is 3 months of access to *ACP Medicine Online*.

ACP Medicine provides an economical online CME program, through which you can earn 120 Category 1 CME credits a year. The program is conveniently linked to the related chapters and has an easy-to-use logbook, which bookmarks your tests so that you can return to them later. It also tracks your credits, and you can print out an award certificate as needed.

We want our readers to play a role in the continuing evolution of *ACP Medicine*. For example, in response to numerous requests, we have included an index at the end of both Volume 1 and Volume 2 of the bound edition to make it easier for you to look up what you need right away; our recently redesigned Web site, with more flexible search and navigational features, reflects reader input as well. We welcome your ongoing comments and questions.

I'm sure you will find *ACP Medicine* to be a convenient and helpful tool for your daily practice of medicine.

often detect dilatation of the common bile duct and intrahepatic ducts. The sensitivity of TUS for detecting common duct stones increases to 76% when ductal dilatation of more than 6 mm is used as the primary end point for choledocholithiasis. CT is no more sensitive or specific than TUS. Cholescintigraphy may show common bile duct obstruction, particularly when symptoms are of recent onset, but not all common bile duct stones will cause complete bile duct obstruction. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasonography have similar accuracies in detecting common bile duct stones. MRCP is noninvasive and may be preferred in cases where the suspicion of choledocholithiasis is mild to moderate.[1,2]

Where Skin Cancer Rates Are Climbing

Several lines of data suggest significant increases in the incidence of cutaneous squamous cell carcinoma (SCC). In Australia, for example, the incidence of SCC increased by 51% between the years 1985 and 1990. In the United States, some of the highest rates of nonmelanoma skin cancer have been detected in the southwest. A population-based survey in New Mexico found the incidence of SCC doubled in both males and females between 1978 and 1999.[1]

1. Athas WF, Hunt WC, Key CR: Changes in nonmelanoma skin cancer incidence between 1977–1978 and 1998–1999 in Northcentral New Mexico. Cancer Epidemiol Biomarkers Prev 12:1105, 2003 [PMID 14578151]

Staying Up to Date on Skin Cancer Treatment

Small SCCs evolving from an actinic keratosis can be adequately treated with simple curettage and electrodesiccation. Larger actinic lesions, as well as lesions arising in non–sun-exposed areas of skin, are best treated with definitive surgical excision with confirmation of negative margins. High-risk, ill-defined lesions, especially those occurring in the surgically sensitive areas of the face, genitalia, hands, and feet, are often best treated by Mohs micrographic surgery.

Fractionated radiation therapy is an alternative treatment of primary SCC in older patients who are poor surgical candidates. The benefits of adjuvant radiation therapy are less clear, as are the benefits of sentinel lymph node biopsy and elective lymph node dissection for patients with high-risk SCC of the head and neck.

Cytotoxic chemotherapy and biologic response modifiers have been used in patients who have advanced SCC; this therapeutic approach has been reported to have complete response rates up to 68%, but there are few long-term survivors. Actinic keratoses are treated with cryotherapy, curettage, topical therapies (e.g., fluorouracil, imiquimod, or diclofenac), photodynamic therapy, and laser resurfacing to prevent progression to SCC.[1] Regularly updated guidelines for the treatment of SCC and basal cell carcinoma are available through the National Comprehensive Cancer Network (NCCN).[2]

Diagnostic Aids for Melanoma

Several specialized aids to the diagnosis of melanoma in patients with dysplastic nevi are under development. Dermoscopy entails the use of a handheld otoscopelike device to magnify a pigmented lesion while applying pressure and oil to the surface. The technique allows the visualization of pigment patterns and features not apparent with simple visual inspection. With experience and training, dermoscopy can be a useful aid in distinguishing melanoma from benign pigmented lesions; however, when used inexpertly, dermoscopy may actually decrease diagnostic accuracy.[1,2]

Another aid to melanoma detection in high-risk individuals is photographically assisted follow-up. A baseline set of whole-body photographs of the skin is used during self-examination and professional follow-up examination to assess change in the lesions. This procedure helps to prevent unnecessary excision of stable lesions and improves the sensitivity of examinations in detecting change. New imaging technologies such as in vivo confocal scanning laser microscopy hold promise for future improvements in the noninvasive diagnosis of melanoma.[3]

Kinder Cuts for Melanoma

Primary cutaneous melanoma is managed surgically with definitive reexcision. The wide excisions of the past have given way to resections with more modest margins. Multiple prospective, randomized trials have investigated the surgical resection of primary cutaneous melanoma utilizing different margins of resection; these studies have focused on varied and overlapping patient populations. On the basis of these data, the National Comprehensive Cancer Network recommends resection margins of 1 cm for melanomas less than 1 mm in thickness; margins of 1 to 2 cm for melanomas between 1 and 2 mm in thickness; and margins of 2 cm for melanomas greater than 2 mm in thickness.[1,2] Primary closure and

FDA Approval Report

The following is selected from the FDA's list of recently approved products. Complete, updated information on FDA approvals and notifications is available on the FDA Web site (http://www.fda.gov).

New Drug Combination for Heart Failure in Black Patients

The FDA has approved a combination of two older drugs, hydralazine and isosorbide dinitrate—neither of which had been approved for heart failure—for treatment of heart failure in black patients.

Generic Name: Hydralazine and isosorbide dinitrate

Brand Name: BiDil

Manufacturer: NitroMed, Inc., Lexington, Massachusetts

The approval of hydralazine and isosorbide dinitrate was based in part on the results of the African-American Heart Failure Trial (A-HeFT). A-HeFT, which included 1,050 self-identified black patients with severe heart failure who had already been treated with the best available therapy, was conducted because two previous trials of the use of these drugs for severe heart failure found no benefit in the general population of patients but suggested a benefit in black patients. In A-HeFT, patients on hydralazine and isosorbide dinitrate had 43% lower mortality and 39% lower rates of hospitalization for heart failure than patients receiving placebo; treated patients also experienced a decrease in symptoms of heart failure.

As an antihypertensive agent, hydralazine is an arterial dilator and decreases the work of the heart. Isosorbide dinitrate is an antianginal agent that causes dilatation of both veins and arteries. Isosorbide seems to work by releasing nitric oxide at the blood vessel wall, but its effect usually wears off after half a day. Hydralazine may prevent this loss of effect, but how the two drugs work together is not fully known. Common side effects with the use of hydralazine and isosorbide dinitrate include headache and dizziness.

IX The Eating Disorders

W. STEWART AGRAS, MD
Stanford University School of Medicine

Medical Complications of Refeeding in Anorexia

The medical treatment of anorexia nervosa includes rehydration and correction of electrolyte disturbances. The patient should be examined frequently, and the levels of electrolytes (sodium, potassium, chloride, bicarbonate, phosphorus, and magnesium) should be monitored frequently. It is important to warn the patient that temporary edema may occur because of rehydration and electrolyte correction; this information helps allay the patient's concerns about weight and shape. Congestive heart failure occasionally occurs early in the refeeding period; hence, careful evaluation of cardiovascular status during the early stages of refeeding is necessary. Hypophosphatemia may also develop at this time, when reserves are depleted.[1]

1. Ornstein RM, Golden NH, Jacobson MS, et al: Hypophosphatemia during nutritional rehabilitation in anorexia nervosa: implications for refeeding and monitoring. J Adolesc Health 32:83, 2003 [PMID 12507806]

Failure and Success in Anorexia Pharmacotherapy

Various psychopharmacologic approaches to the treatment of anorectic patients have been evaluated in controlled trials and have included the use of tricyclic antidepressants, fluoxetine, lithium, and antipsychotic compounds. There are various rationales for the use of these compounds—for instance, the observation that patients who take antipsychotic agents such as chlorpromazine tend to gain weight and the finding that anorectics often suffer from depressive symptoms. The results of these trials have been disappointing: no evidence of clinically useful effectiveness for any of these medications in the acute phase of treatment has been established.[1] Moreover, patients with anorexia nervosa are often reluctant to take medication, particularly if the medication might lead to weight gain. Symptoms such as depression often disappear as weight is gained.

Because obsessive-compulsive disorder is associated with anorexia nervosa and because the genetic findings implicate serotonin metabolism, interest has focused on the use of the selective serotonin reuptake inhibitors (SSRIs) that are effective in patients with obsessive-compulsive disorder. Small controlled and uncontrolled trials suggest that fluoxetine may be useful in helping patients maintain their weight gain. Open-label trials also suggest that the newer antipsychotics, such as olanzepine, may be effective in

reducing depression, anxiety, and core eating-disorder symptoms (e.g., food obsessions and distorted body image) and in enhancing weight gain.[2]

The Most Effective Treatment for Bulimia

It is generally agreed that the most effective treatment of bulimia nervosa is an outpatient trial of cognitive-behavioral therapy. A large number of controlled trials have demonstrated that such therapy is more effective than no treatment, other forms of psychotherapy, antidepressant medication, and placebo.[1] The usual course of treatment is 20 sessions over 6 months. Approximately 50% of patients who complete treatment with cognitive-behavioral therapy recover, and an additional 20% to 30% show significant improvement. Gains made during cognitive-behavioral therapy are well maintained over the long term.[1]

IV Focal and Multifocal Lung Disease

GERALD W. STATON, JR, MD, FACP
Emory University School of Medicine

Imaging and Managing Alveolar Cell Carcinoma

Alveolar cell carcinoma may result in one or more areas of air-space opacity, presenting as an area of focal indistinct infiltrate or, sometimes, mimicking lobar pneumonia. Chest CT often shows areas of "ground glass opacity"; less commonly, the infiltrates are consolidative.[1] Patients cough and produce mucoid sputum; a few patients produce large volumes of sputum (bronchorrhea) that in rare instances has a salty taste. Weight loss and malaise are common. Fever and chills are absent. Metastases are less common than with other primary lung neoplasms, and the course of the illness is longer. Alveolar cell carcinoma is not related to smoking. Diagnostic tests should begin with sputum cytology, followed by fiberoptic bronchoscopy with bronchoalveolar lavage and transbronchial biopsy or, if needed, open lung biopsy by a traditional or a video-assisted thoracoscopic approach.

1. Sabloff BS, Truong MT, Wistuba II, et al: Bronchioalveolar cell carcinoma: radiologic appearance and dilemmas in the assessment of response. Clin Lung Cancer 6:108, 2004 [PMID 15476596]

Pneumonia by Mouth

Lipoid pneumonia is a noninfectious, inflammatory lung disorder caused by the aspiration of mineral oil or other oily substances. It is most common in elderly patients and others with impaired swallowing. With or without impaired swallowing, lipoid pneumonia can result from the use of petroleum jelly or other oily substances applied to the lips or nose to relieve chronic dryness or mineral oil taken by mouth for relief of constipation. The most common symptom is a chronic cough, which may be caused by coexisting lung disease rather than lipoid pneumonia; fever is uncommon. Often, the disease is discovered on a routine chest radiograph that shows a focal, dense infiltrate, usually in a lower lobe or in the right middle lobe.[1]

The radiographic appearance of such an infiltrate in a relatively asymptomatic patient suggests chronic pneumonia or lung cancer. CT scanning may show an extremely low density infiltrate produced by accumulated lipid; the density typically ranges from –60 to –150 Hounsfield units (water is 0). In contrast, the density of lung cancers usually ranges from +60 to +150 Hounsfield units.

1. Baron SE, Haramati LB, Rivera VT: Radiological and clinical findings in acute and chronic exogenous lipoid pneumonia. J Thorac Imaging 18:217, 2003 [PMID 14561906]

Ankylosing Spondylitis and the Lungs

Chest wall expansion is impaired in ankylosing spondylitis, and lung volumes are somewhat reduced. Patients may develop characteristic dense fibrous or fibrobullous infiltrates that are often limited to the upper lung zones. These chest radiographic findings mimic those of tuberculosis, and cavitation may occur. Once cavities have developed, abnormal air spaces may become colonized with *Aspergillus* species, causing fungus balls and even a locally invasive disease termed chronic necrotizing aspergillosis. Studies of groups of patients with ankylosing spondylitis using CT have found interstitial lung disease that is more diffuse and not confined to the apices of the lung.[1] The lung disease associated with ankylosing spondylitis does not progress to respiratory insufficiency. Dyspnea on exertion and nonproductive cough are the usual symptoms.

Once *Aspergillus* colonization or infection has occurred, symptoms from the local fungal infection may predominate; such symptoms include hemoptysis, productive cough, and mild to moderate constitutional symptoms. Locally invasive *Aspergillus* infection may extend directly to the pleura but almost never spreads hematogenously to distant sites.

CLINICAL ESSENTIALS

VI Occupational Medicine

LINDA ROSENSTOCK, MD, MPH, FACP
University of California, Los Angeles, School of Public Health

MARK R. CULLEN, MD
Yale University School of Medicine

Occupational Medicine on the Internet

Awareness of the impact of the work environment on health has increased dramatically in the past few decades. An increasing amount of information about occupational medicine is available on the Internet from the National Institute for Occupational Safety and Health (http://www.cdc.gov) and the Occupational Safety and Health Administration (http://www.osha.gov).

A Vicious Synergy

Many workplace hazards and toxins interact with one another and with nonoccupational factors to cause disease. Dose-response correlations for industrial hazards may be markedly shifted in the presence of other haz-

ards, habits, or medications. An important example is the likelihood of disease resulting from thermal stress (i.e., heat or cold) in the presence of hemodynamically active agents, such as calcium channel blockers, autonomic agents, and diuretics. Likewise, the effects of vibration trauma on wrists and digits may be amplified by nicotine. The effects of one hazard may be significantly altered in the presence of another; for example, the combined effect of noise and solvents on hearing loss and of asbestos and smoking on lung cancer are greater than the effect of exposure to each hazard alone.

Cancer from the Workplace

Only a small number of hazards found in the workplace have been clearly established as carrying substantive cancer risk for workers. An additional group of hazards are suspected, but additional studies are needed. The list of potential carcinogens is expanding; for example, evidence suggests that exposure to cadmium may play a role in the development of prostate cancer. Studies provide some indication that workers in print shops, service station employees, farm product vendors, horticulturists, farmers, and aircraft mechanics are at increased risk for renal cell carcinoma [*see Table, right*].[1]

Established Occupational Carcinogens

Cancer Site	*Hazard*	*Setting*
Lung	Asbestos	Insulation, textiles
	Ionizing radiation	Uranium mining
	Arsenic	Refining
	Polyaromatic hydrocarbons	Coke ovens
	Nickel	Nickel refining
	Chromium	Tanning, pigments
	Alkylating agents	Chemical industry
	Silica	Mining, stonecutting
	Ceramic fibers	Insulation
	Formaldehyde	Chemicals, plastics
	Beryllium	Nuclear weapons, aerospace industry
	Cadmium	Batteries
	Acrylonitrile	Plastics
	1,3-Butadiene	Rubber, plastics
Pleura and peritoneum	Asbestos	Construction materials
Upper respiratory tract	Wood dust	Carpentry
	Nickel	Refining
	Chromium	Plating
	Asbestos	Friction products
	Formaldehyde	Chemicals, plastics
Urinary bladder	Benzidine and related amines	Dyes, chemicals
	Polyaromatic hydrocarbons	Aluminum reduction
Liver	Vinyl chloride monomer	Plastics
	Arsenic	Pesticides
Upper GI tract	Asbestos	Shipbuilding
	Coal dust	Mining
	Acrylonitrile	Plastics
Hematologic system	Benzene	Chemicals, rubber
	Ionizing radiation	Defense industry
	Ethylene oxide	Chemicals, sterilizers
Soft tissue	Dioxin	Chemical industry
Brain	Vinyl chloride	Chemical industry
	Formaldehyde	Chemical industry

When Work Gets under Their Skin

Overwhelmingly, the major skin problem in the workplace remains dermatitis, either irritant induced or caused by allergy. Many agents may be responsible, including organic and inorganic chemicals, plastics and rubber, oils and lubricants, metals and construction materials, paints, and coatings.[1] The key to correct diagnosis is the history of skin contact and the temporal relation between contact and manifestations. Unfortunately, there is seldom a perfect or obvious correlation between the two, and some sleuthing is necessary, especially to discern the extent to which chemical contact may spread to places like the groin or areas where hand contact occurs. Airborne exposure may cause lesions in apparently untouched areas, such as the face; such occurrences are signs of likely hypersensitivity. Vexingly, symptoms do not always abate dramatically over weekends or during short periods in which exposure is avoided; removing the patient from the toxin for a week or two may be necessary to observe response. This, combined with observation of the patient during reexposure, is often the most valuable diagnostic test. Patch testing, performed by an experienced clinician aware of the exposures of concern, may be useful in difficult cases, though the clinician should keep in mind that irritants may yield false negative results and that even many healthy atopic persons will experience reactions to common contactants, such as nickel.[2]

7 INFECTIOUS DISEASE

XXXIX Infections Due to Mycobacterium leprae and Nontuberculous Mycobacteria

MICHAEL K. LEONARD, JR, MD
HENRY M. BLUMBERG, MD
Emory University School of Medicine

Diagnosing MAC Infection

Mycobacterium avium complex (MAC) comprises two closely related species, *M. avium* and *M. intra-*

cellulare. MAC is encountered most often as an opportunistic pathogen in immunosuppressed patients, especially those with advanced HIV infection or AIDS. However, MAC infection can occur in immunocompetent hosts; it is especially likely to cause pulmonary infections in persons with underlying chronic lung disease. The American Thoracic Society has developed criteria for the diagnosis of pulmonary infection by MAC, as well as infections from other nontuberculous mycobacteria [*see Table, below*]. Criteria for the diagnosis of these infections include repeated isolation of a potentially pathogenic species, the absence of other pathogens, and a compatible clinical, radiologic, or pathologic picture.

Adverse Reactions to Beneficial Effects

Immune reconstitution syndromes can be an adverse event in the treatment of patients with HIV infection who have disseminated infection from MAC. These syndromes sometimes occur in HIV-infected patients with unrecognized MAC who are started on antiretroviral agents. Pathogen-specific immune responses to MAC can occur in the first few months after the initiation of highly active antiretroviral therapy.[1] Immune reconstitution reactions to MAC usually manifest themselves as fever and lymphadenopathy (peripheral, intrathoracic, or intra-abdominal). Bacteremia does not occur. In severe cases, treatment with corticosteroids or nonsteroidal anti-inflammatory drugs may be necessary to ameliorate the symptoms associated with the immune response.

1. Lawn SD, Bekker L, Miller RF: Immune reconstitution associated with mycobacterial infections in HIV-infected individuals receiving antiretrovirals. Lancet Infect Dis 5:361, 2005 [PMID 15919622]

Mycobacteria in the Fast Lane

Rapidly growing mycobacteria produce mature growth on agar plates within 7 days. The skin and soft tissues are the most common sites of infection from these organisms; indeed, of all nontuberculous mycobacteria species, rapidly growing mycobacteria are the most common cause of skin and soft tissue infections. Furunculosis from *Mycobacterium fortuitum* and other organisms in the *M. fortuitum* group has been reported in association with whirlpool footbaths in customers of nail salons.[1] Shaving the legs with a razor before a pedicure was a risk factor for infection. In these cases, molecular typing techniques were used to match rapidly growing mycobacteria recovered from the footbaths with isolates recovered from patients.

Rapidly growing mycobacteria are also associated with skeletal infections (e.g., infections of bone, joint, or tendon) and pulmonary disease. Nosocomial or health care–associated infections caused by these organisms include infections from colonization of long-term venous access devices or peritoneal dialysis catheters, postinjection abscesses, and surgical wound infections (e.g., after cardiac bypass surgery, augmentation mammoplasty, facelifts,[2] and other plastic surgery; postoperative keratitis has been reported after ophthalmic surgery). Clusters of infections and outbreaks of true infection and pseudoinfections have occurred from contaminated fluids, irrigation with or exposure to tap water, injectable medicines, and topical skin solutions and markers.

16 WOMEN'S HEALTH

XXI Musculoskeletal Problems in the Female Athlete

CAROL C. TEITZ, MD
University of Washington School of Medicine

Not Just Rest for Stress Fractures

Recommending that the patient rest the affected body part—the standard treatment for stress fractures—is insufficient for female athletes. Instead, the physician also needs to address any features of the athlete's training habits, nutritional and menstrual status, or equipment that may have contributed to the stress fracture. This will ensure that once the fracture heals, the patient will not be exposed to the same factors that led to the fracture.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are contraindicated in the treatment of pain related to stress fractures, because there is evidence that NSAIDs may interfere with fracture healing.[1,2] When pharmacologic pain control is needed, acetaminophen usually suffices.

1. Warden SJ: Cyclo-oxygenase–2 inhibitors: beneficial or detrimental for athletes with acute musculoskeletal injuries? Sports Med 35:271, 2005 [PMID 15831058]

2. Seidenberg AB, An YH: Is there an inhibitory effect of COX-2 inhibitors on bone healing? Pharmacol Res 50:151, 2004 [PMID 15177303]

Knees at Risk

Noncontact anterior cruciate ligament (ACL) tears are two to eight times more common in females than in males. Investigators agree that there is no one identifiable cause of the increased incidence of ACL injuries in female athletes and that hormonal, anatomic, and proprioceptive factors may play a role. Studies on hormonal influences are inconclusive. In contrast, a study at West Point found that a combination of increased body mass, generalized joint laxity, and decreased intercondylar notch width significantly increased the risk of ACL injury.[1]

1. Uhorchak JM, Scoville CR, Williams GN, et al: Risk factors associated with noncontact injury of the anterior cruciate ligament: a prospective four-year evaluation of 859 West Point cadets. Am J Sports Med 31:831, 2003 [PMID 14623646]

An Ounce for the ACL

Current prevention programs are resulting in a decreased incidence of ACL injuries.[1] Neuromuscular training is the mainstay of these prevention programs and includes one or more of the following: stretching and strengthening exercises; aerobic, agility, kinesthetic, and plyometric exercises; and risk-awareness education. Strength training and endurance training focus on hip abductor and external rotator muscles. Agility and skill drills emphasize rapid directional changes and therefore stimulate maximum cocontractions of agonist-antagonist muscle pairs to increase stiffness and reduce the number of unanticipated joint movements. Agility drills also improve reflex and cortical response time. Kinesthetic training emphasizes keeping the center of gravity forward and the athlete on her toes. Plyometric training decreases the time to peak torque and increases dynamic joint stability by decreasing landing forces and varus/valgus moments through increased muscle activation.

1. Griffin LY, Albohm MS, Arendt EA, et al: Update on ACL injury prevention: theoretical and practical considerations. A review of the Hunt Valley II meeting, February 2005. Am J Sports Med (in press)
