MMR—mismatch repair

Dietary Factors

Dietary factors have been linked to pancreatic cancer[104]; however, more convincing evidence is needed to confirm such associations. High levels of folate seem to reduce the risk of pancreatic cancer in smokers.[105] Coffee and alcohol consumption do not seem to increase the risk of pancreatic cancer.[106]

Predisposing Medical Conditions

The abrupt onset of diabetes in a previously healthy, nonobese middle-aged or older patient with no family history of diabetes can be the first sign of pancreatic cancer. Long-standing chronic pancreatitis is associated with pancreatic cancer, and the increased risk is independent of the cause of pancreatitis, gender, and nation of origin.

Medications

A large prospective study examined the association between the use of asprin and other nonsteroidal anti-inflammatory drugs (NSAIDs) and the incidence of pancreatic cancer in 28,283 postmenopausal women.[107] The data from the study showed a trend of decreasing risk of pancreatic cancer with increasing frequency of aspirin use. There was no association shown between nonaspirin NSAID use and the incidence of pancreatic cancer.

Genetic Factors and Familial Syndromes

Inherited genetic predisposition is observed in patients diagnosed with pancreatic cancer. Up to 10% of patients report pancreatic cancer in a first-degree relative.[108] The data from the National Familial Pancreatic Tumor Registry (NFPTR) demonstrated an 18-fold risk of pancreatic carcinoma in first-degree relatives of familial pancreatic carcinoma kindreds. When three or more members in a kindred are affected, the risk is increased 57-fold.

A variety of familial syndromes have been described [*see Table 5*]; however, some remain without a known genetic basis.[109] Meticulous attention to family history is required to detect these genetic syndromes, because a familial syndrome may present as a clustering of pancreatic cancers among several first- and second-degree relatives, or it may be even more subtly distributed among extended family members.

SCREENING AND PREVENTION

Pancreatic cancer is a poor candidate for population-based screening because of relatively low incidence, lack of cost-effec-

tive or clinically proven screening tools, and limited options for effective management, even with early tumors. For patients at high risk for pancreatic cancer, such as those with a familial syndrome, screening may have true value, although the efficacy of screening has not been demonstrated. CA19-9, a serum tumor marker, may have value for following the therapeutic response of patients with pancreatic cancer[110]; however, it has not proved to be useful in screening, because (1) approximately 10% to 15% of individuals do not secrete CA19-9; (2) the CA19-9 level may be within normal range in the early stage of pancreatic cancer; and (3) the CA19-9 may be elevated in benign conditions (e.g., chronic pancreatitis or acute cholangitis).[111,112] Given that K-*ras* mutations are present in approximately 90% of pancreatic cancers and as relatively early transforming events, they have been sought in pancreatic juice, duodenal juice, feces, and serum.[113-115] However, K-*ras* mutations can be present in pancreatitis or dysplastic lesions that may not necessarily progress to pancreatic cancers, and so these mutations lack sensitivity and specificity as markers for pancreatic cancer. Improved screening and early detection may derive from increased knowledge of molecular events in pancreatic cancer and new techniques (e.g., measurement of telomerase activity and comprehensive cellular protein analysis).

MOLECULAR MUTATIONS AND PATHOGENESIS

In the past 10 years, the understanding of the molecular progression of pancreatic cancer has increased, making this malignancy one of the best genetically characterized tumors and leading to the formation of a progression model based on histopathologic, clinical, and genetic evidence.

Genetic analysis of pancreatic carcinomas has proved that the so-called multi-hit model of carcinogenesis applies to this tumor type [*see Table 6*].[116] Precursor lesions of pancreatic cancer have been recognized in careful morphologic studies; however, a variety of terms were previously used to refer to these precursor lesions. The nomenclature for the precursor lesions was recently standardized to four categories of pancreatic intraepithelial neoplasia (PanIN) [*see Table 7*].[117] Examination of pancreatic duct precursor lesions and pancreatic adenocarcinomas by modern molecular techniques has led to the identification of certain key genetic alterations that are expressed at different points in the progression of the lesions. Point mutations in K-*ras* and overexpression of HER-2/*neu* are identified in the earliest pancreatic ducts lesions (PanIN-1A and PanIN-1B) and are thought to be early genetic events in the development of pancreatic cancer. Inactivation of the *p16* tumor suppressor gene occurs in the higher-grade duct lesions (PanIN-2 and PanIN-3). The tumor suppressor genes *p53, DPC4* (deleted in pancreatic carcinoma locus 4), and *BRCA2* are lost even later in the development of pancreatic neoplasia (PanIN-3).[118] These morphologic and genetic data support the progression model for the development of pancreatic neoplasm from low-grade PanIN to carcinoma in situ (PanIN-3) and, subsequently, to infiltrating carcinoma [*see Figure 6*]. This progression model may be very important in the development of screening tests to detect early, potentially curable pancreatic neoplasms and may also help find targets for prevention.

Table 6 Mutations Involved in Pancreatic Cancer[116]

Gene	*Chromosomal Locus*	*Frequency (%)*
K-*ras*	12p13	*> 90*
p16	9p21	*> 80*
p53	17p13	*50–75*
DPC	18q21	*50*
HER-2/neu	17q21	*20–25*
BRCA2	13q12	*7*

Table 7 Pancreatic Intraepithelial Neoplasia (PanIN)[117]

Nomenclature	*Description*
PanIN-1A	A flat mucinous epithelium, no sign of atypia
PanIN-1B	With a papillary architecture, no sign of atypia
PanIN-2	A prevalence of papillary architecture, sign of atypia, low- to moderate-grade dysplasia
PanIN-3	A prevalence of papillary architecture, sign of atypia, high-grade dysplasia

DIAGNOSIS

Clinical Manifestations

Initial symptoms experienced by pancreatic cancer patients are insidious and relatively nonspecific (e.g., weight loss, anorexia, abdominal discomfort or pain, and nausea), which may delay the diagnosis for several months. Specific symptoms usually relate to localized invasion of peripancreatic structures. Pain can be a presenting symptom and is usually associated with localized invasion of peripancreatic structures (e.g., splanchnic plexus and retroperitoneum), particularly from lesions located in the body or tail of the pancreas. Pain is typically described as gnawing and severe, radiating to the back and worsening in the supine position. Jaundice as a presenting symptom is most commonly related to compression of the common bile duct by tumors in the head of the pancreas. Anorexia and weight loss partly result from cytokines released by tumor cells, although decreased caloric intake and malabsorption may also play a role. Invasion of the duodenum or gastric outlet may give rise to nausea or vomiting as a presenting symptom. The Courvoisier sign, a palpable gallbladder in the absence of cholecystitis or cholangitis, presents in about 25% of all patients with pancreatic cancer. Trousseau syndrome (migratory superficial phlebitis) and venous thrombosis may present as initial symptoms of the disease.

Diagnostic Evaluation

The early diagnosis of a potentially resectable pancreatic cancer is extremely difficult because of nonspecific initial symptoms and poor sensitivity of noninvasive techniques such as CT and ultrasonography. Compared to ultrasound, CT provides better definition of the tumor and surrounding structures and is less operator dependent. CT correctly predicts unresectable tumors in 85% of patients and resectable tumors in 70% of patients. Spiral CT increases the accuracy of staging pancreatic carcinoma and visualization of vessel encasement. MRI improves the visualization of pancreatic tumor and may detect distant metastatic disease not seen on CT scan [*see Figure 7*]. Endoscopic retrograde cholangiopancreatography (ERCP) may prove useful as a complement to CT or MRI in diagnosing and staging ambiguous cas-

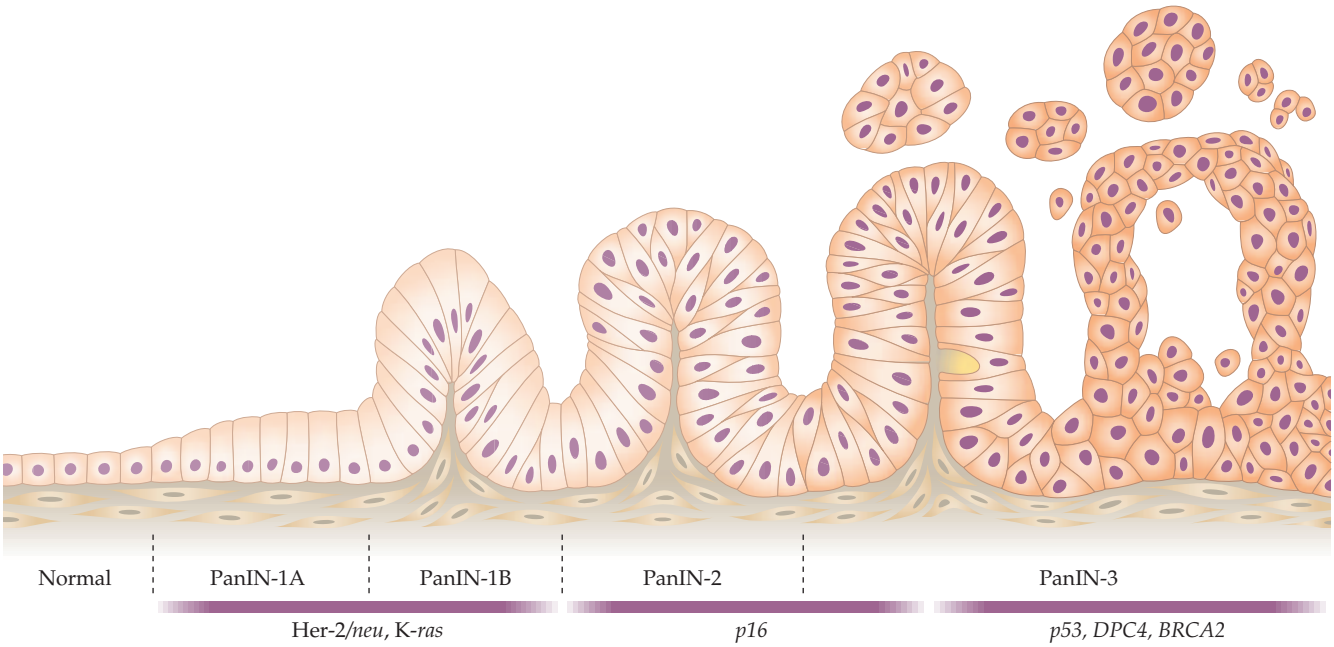

Figure 6 **Progression model for pancreatic cancer.**

es; ERCP may also supply cytologic information. Endoscopic ultrasonography (EUS) is the single most accurate test for imaging and staging pancreatic carcinoma [*see Figure 8*][119] and can clearly evaluate pancreatic mucosal, vascular, ductal, and parenchymal abnormalities, as well as lymph node metastases.[120]

Patients with clinical symptoms that may represent pancreatic cancer should have an initial standard CT scan or an abdominal ultrasound. If a pancreatic mass is suspected on one of these initial tests, further evaluation is necessary. If the tumor appears to be larger than 4 cm or appears unresectable, spiral CT with intravenous contrast and ERCP with fine-needle aspiration (FNA) should be considered. On the basis of size alone, masses greater than 4 cm have less than a 10% chance of being resectable and nonmetastatic.[121] If a patient has only a dilated duct and no obvious mass or a tumor smaller than 4 cm with no other signs of unresectability (e.g., metastasis), EUS is performed for further evaluation. EUS improves the prediction of resectability for tumors, which may prevent unnecessary laparotomy.

STAGING

Because surgical resection is the only curative modality for pancreatic cancer and because only 10% to 15% of patients present with resectable disease, the diagnosis, stage, and management are based on resectability. The sixth edition of the American Joint Committee on Cancer TNM classification contains changes in both clinical and pathologic staging [*see Table 8*].[74]

TREATMENT

Local, Resectable Disease

Surgery If the tumor is deemed to be resectable after an extensive workup, a standard pancreaticoduodenectomy (Whipple procedure) or pylorus-preserving Whipple procedure is performed. Total pancreatectomy is also performed occasionally in selected patients. Experienced surgeons should perform these operations, because greater surgical experience and a high case volume are associated with better and safer outcomes.[122] Operative results have improved dramatically in the past decade, owing to better staging of the disease, improved surgical techniques and perioperative care, and the identification of high-volume centers. Although the mortality has decreased to below 5%, morbidity rates have remained at 30% to 50%.[123] The pylorus-preserving Whipple procedure theoretically eliminates nutritional problems caused by a reduced gastric reservoir and gastric dumping. Tumor recurrence and long-term survival appear unaffected by the choice of procedure; instead, prognosis is related to the size of the primary tumor, status of the resected lymph nodes, and margins.[124] The median survival for those patients who have had complete resection is approximately 20 months.

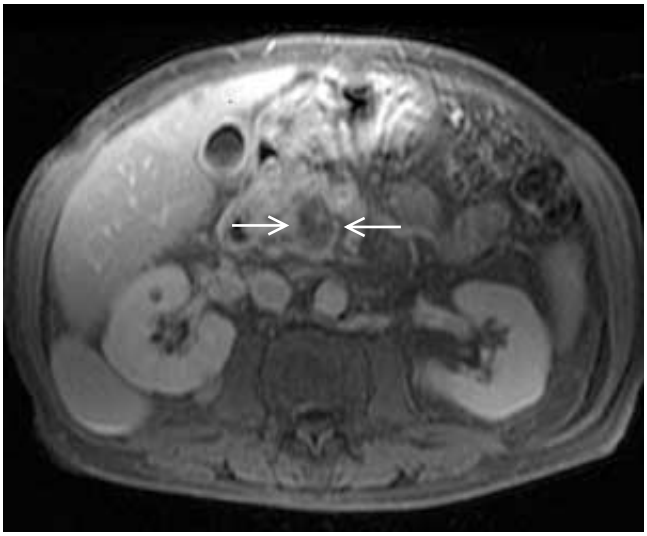

Figure 7 **Magnetic resonance image of pancreatic cancer. An axial T_1-weighted MRI shows the low-signal intensity of a mass located at the pancreatic head (arrows) .**

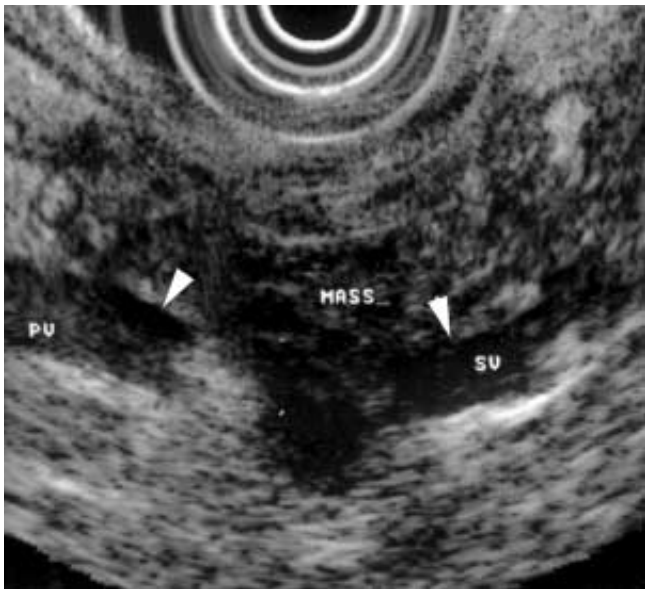

Figure 8 **An EUS of pancreatic cancer shows direct invasion of the superior mesenteric vein (SV). Arrows show extent of invasive mass. (PV—portal vein)**

Surgery combined with other modalities The issue of adjuvant chemoradiation therapy after complete resection for pancreatic cancer remains somewhat unsettled, although it is frequently recommended in the United States. The benefit of adjuvant chemoradiation therapy was suggested from a small, randomized study of the Gastrointestinal Tumor Study Group (GITSG). Twenty-one patients who received a combination of an intravenous bolus of 5-FU and radiotherapy after surgery had a median survival of 20 months, compared to a survival of 11 months for 22 patients treated with surgery alone.[125] Similar results were demonstrated in a larger, single institutional nonrandomized study, which showed a median survival of 19.5 months in patients who received adjuvant chemoradiation therapy and 13.5 months in patients who received no further treatment.[126] However, a large study from the European Study Group for Pancreatic Cancer (ESPAC) showed no survival benefit for adjuvant chemoradiation therapy (median survival of 15.5 months in the treatment group, 16.1 months in the control group) but suggested a potential benefit for adjuvant chemotherapy (median survival, 19.7 months in the treatment group, 14.0 months in the control group; $P = 0.0005$).[127] There have been no large, definitive, well-designed studies assessing the true benefit of adjuvant treatment in cases of pancreatic cancer, although adjuvant therapy is recommended for most patients in the United States on the basis of the GITSG trial. The most recently completed United States intergroup trial compared two chemoradiation therapies without a surgery-alone control arm.

Locally Advanced, Unresectable Disease

For locally advanced, unresectable pancreatic cancer, either chemoradiation or chemotherapy alone is a reasonable treatment option. External-beam irradiation (3,750 to 5,500 cGy) may relieve local symptoms by reducing the tumor size.

Chemoradiation Chemoradiation in regimens including 5-FU has become the accepted standard of care.[128] In an attempt to improve local control and prevent radiation toxicity to the normal tissue, intraoperative radiotherapy (IORT) has been evaluated but has failed to show superiority to external-beam irradiation.[129] Gemcitabine, which is the standard agent in chemotherapy for pancreatic cancer, is a potent radiation sensitizer and is tolerated concomitantly with radiotherapy only at low doses.[130] Studies of this combination are under way to establish whether there is superiority of gemcitabine with radiation (concurrently and sequentially) over the current standard of radiation with 5-FU. A current United States trial is comparing gemcitabine alone with chemoradiation to assess the contribution of radiation in patients with locally advanced disease. It is reasonable to assume that radiotherapy may not be required for a subset of patients who have locally advanced disease and no local symptoms or that initiation of radiotherapy can be delayed, in the absence of metastatic disease, until local control is needed.

Chemotherapy Gemcitabine, as compared with 5-FU, is now considered the standard chemotherapeutic agent for advanced and metastatic pancreatic cancer on the basis of clinical-benefit response (reduction in pain intensity, analgesic use, and weight gain and improvement of performance status) and survival benefit.[131] The overall results of chemotherapy for patients with advanced metastatic pancreatic cancer are still disappointing, and there are many ongoing studies of new molecular targeting agents or combinations of cytotoxic agents,[132,133] but as yet, none has been reported to have clinical benefit superior to that of gemcitabine alone.

Table 8 TNM Staging of Pancreatic Cancer[74]

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to the pancreas, 2 cm or less in greatest dimension
T2	Tumor limited to the pancreas, more than 2 cm in greatest dimension
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N1	No regional lymph node metastasis
N2	Regional lymph node metastasis
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M1	No distant metastasis
M2	Distant metastasis

Stage Grouping			
Stage 0	Tis	N0	M0
Stage 1A	T1	N0	M0
Stage 1B	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Symptom management It should be emphasized that supportive care and symptom relief are important for patients with advanced and metastatic pancreatic cancer; pain control may be accomplished with analgesics or celiac plexus neurolysis, and biliary drainage may be achieved either by surgical bypass procedures or by use of metal stents placed endoscopically or percutaneously.

Hepatocellular Carcinoma

EPIDEMIOLOGY AND ETIOLOGY

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor of the liver. It is the fifth most common malignancy in the world (564,000 cases a year) and the third cause of cancer-related deaths worldwide.[134]

HCC is most often a complication of liver cirrhosis caused by chronic infection by the hepatitis B virus (HBV), hepatitis C virus (HCV), or alcohol.[135] Its incidence varies widely internationally, with more than 85% of cases occurring in countries with a high prevalence of HBV infection. HCC is considerably less common in Europe and North America (two to seven per 100,000 population) than in Taiwan and southeastern China (30 per 100,000 population).[136] However, the incidence of HCC in the United States has increased from 1.4 per 100,000 population for the period from 1976 through 1980 to 2.4 per 100,000 for the period from 1991 through 1995. This increase is considered to be primarily related to an increase in HCV infection.[137] It has been reported that in the United States, approximately 1.8% of the population has anti-HCV antibody, and four million persons are infected with HCV, which is a risk factor for chronic liver disease. The incidence of HCC in patients with cirrhosis is about 3% to 5 % a year.[138] It is estimated that 7% to 14% of HCV-infected patients with cirrhosis in the United States will develop HCC within 10 years.[139]

Concomitant with the rising rates of HCC, there has been a shift of incidence from elderly to relatively younger populations (40 to 60 years).[140] A Canadian epidemiologic study also showed an increased incidence of HCC in Canada since 1991, which is consistent with the reported increase in the prevalence of HCV and HBV infection.[141] In Japan, because of passive and active immunoprophylaxis of HBV, approximately 16% of cases of HCC are caused by HBV, whereas 80% of cases are associated with HCV infection.[142]

Hereditary hemochromatosis is also a risk factor for the development of HCC.[143] Diabetes mellitus may be associated with HCC in patients with chronic HCV infection,[144] and a significant synergy exists between heavy alcohol consumption, hepatitis virus infection (both HBV and HCV), and diabetes mellitus and the development of HCC.[145] Patients with other metabolic disorders or conditions that may lead to cirrhosis (e.g., α_1-antitrypsin deficiency, type I glycogen storage disease, tyrosinemia, and even biliary atresia) are also at risk of developing HCC.[146] Other risk factors include long-time ingestion of food contaminated with aflatoxins, metabolites of the mold *Aspergillus flavus*, and long-term use of oral contraceptives and exogenous androgens.[147-149]

SCREENING AND PREVENTION

In some Asian countries in which there is a high prevalence of HBV and HCC, screening programs have been developed to detect small tumors and to allow treatment at an early stage of the disease and have resulted in favorable outcomes.[150] Mother-to-baby transmission of HBV has been prevented by a combined passive and active immunoprophylaxis with hepatitis B immune globulin and vaccine, which has reduced the chronic carrier state by 10-fold,[151] suggesting that the incidence of HBV-associated HCC will decline gradually over the next several decades.

Because aflatoxin contamination of food and excessive alcohol consumption are important risk factors for HCC development, improvement of public health standards and avoidance of known carcinogens may also be important. Antiviral therapy in patients with chronic HBV infection may increase survival and decrease HCC development; however, the data are limited and still controversial.[152] Prevention of initial HCV infection is the key to preventing HCV-related HCC. Evidence suggests that effective control of HCV infection or HCV-related inflammation with interferon may decrease the incidence, or at least delay the development, of HCC.[153,154]

Surveillance and screening for HCC in patients with recognized risk factors remain controversial.[155] There are no randomized, controlled trials confirming that surveillance for HCC improves disease-related or overall survival. AFP is not an accurate surveillance test because of low sensitivity and specificity. Periodic ultrasound examination may be the best choice for surveillance; however, the optimal screening interval has not been defined, and there are no adequate analyses of cost efficacy.

DIAGNOSIS

Clinical Manifestations

The most common clinical feature of HCC is right upper quadrant or epigastric pain. Patients may initially present with ascites, weight loss, anorexia, malaise, vomiting, and jaundice. Some patients may present with an acute abdomen resulting from a tumor rupture. The most common physical signs are hepatomegaly and the stigmata of cirrhosis, but abdominal bruits secondary to increased vascularity, splenomegaly, Budd-Chiari syndrome, and Virchow node may also occur. Abrupt worsening of portal vein hypertension may also be the first sign of HCC. A variety of paraneoplastic syndromes may occur, including hypoglycemia, hypercalcemia, erythrocytosis, and porphyria cutanea tarda.

Common laboratory abnormalities include elevated levels of liver transaminases, alkaline phosphatase, and bilirubin; but normal liver tests do not exclude HCC. A low albumin level may reflect poor synthetic function of the liver. The AFP level is elevated in 85% of patients with HCC. An AFP level greater than 400 ng/ml (normal range: 0 to 20 ng/ml) is considered diagnostic for HCC. False positive results may be due to acute or chronic hepatitis, germ cell tumors, or pregnancy. The *des*-γ-carboxy prothrombin protein induced by vitamin K is elevated in more than 90% of HCC patients, but it is not specific for the disease.[156]

Diagnostic Evaluation

A variety of imaging studies are available to assist in the diagnosis, staging, and evaluation of HCC. Ultrasonography is inexpensive, widely available, and useful for screening high-risk populations. CT can provide information on the extent of hepatic involvement, invasion or thrombosis of hepatic and portal veins, regional lymph nodes, splenomegaly, and ascites. MRI with intravenous gadolinium and angiography can provide details about vascular anatomy and can detect small hepatic tumors, which is important in determining resectability of lesions and guiding local-regional treatment.

Table 9 TNM Staging of Hepatocellular Carcinoma[74]

Primary Tumor (T)			
TX	Cannot be assessed		
T0	No evidence of primary tumor		
T1	Solitary tumor without vascular invasion		
T2	Solitary tumor with vascular invasion or multiple tumors ≤ 5 cm

Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
IIIB	T4	N0	M0
IIIC	Any T	N1	M0
Stage IV	Any T	Any N	M1

STAGING AND PROGNOSIS

HCC arises from epithelial cells and histologically is an adenocarcinoma. HCC may present as a nodular, diffuse, or massive form. The spectrum includes typical HCC, undifferentiated HCC, mixed HCC with cholangiocarcinoma, and the fibrolamellar variant of HCC. The fibrolamellar variant of HCC has a more favorable prognosis, occurring in young females without cirrhosis. Invasion of the hepatic vein is common with HCC, and advanced-stage HCC may be complicated by thrombosis in the hepatic vein, vena cava, and portal vein.

Treatment options and prognosis in most HCC patients take into account the stage and etiology of the underlying cirrhosis. Besides the TNM staging system [*see Table 9*], the Child-Pugh classification for staging of cirrhosis should always be considered in the evaluation of treatment options for HCC patients. The Chinese University Prognostic Index (CUPI) assigns points for TNM stage, presence or absence of symptoms and ascites, AFP, total bilirubin, and alkaline phosphatase [*see Table 10*].[157]

TREATMENT

Local, Resectable Disease

Surgical resection Surgery is the only treatment modality with curative intent. Asymptomatic patients with a single HCC tumor, no significant portal hypertension, and preserved liver function are optimal candidates.[158] Ultrasound examination should be performed intraoperatively to detect additional lesions and to guide anatomic resection. Partial hepatectomy is considered safe and carries a perioperative mortality of less than 5% in specialized centers.[159]

The high rate of recurrence of HCC (up to 70% at 5 years) and underlying diseases limit the long-term outcome after surgical resection.[160] Factors associated with poor prognosis are the presence of vascular invasion, multifocal or satellite lesions, tumors larger than 5 cm, and poor histologic differentiation.[161,162]

Preoperative therapies Preoperative (neoadjuvant) therapies may be given to reduce tumor bulk and to eradicate microscopic disease, thus facilitating resection and possibly improving survival. It has been shown that transarterial chemoembolization (TACE) may downstage previously unresectable HCC, but this has not translated into long-term improved survival.[163] In a single trial, biochemotherapy with 5-FU, cisplatin, doxorubicin, and interferon-alfa (PIAF) may convert 25% of unresectable HCC to resectable HCC and may induce complete pathologic remission.[164]

Postoperative therapies Various treatments have been used as adjuvant therapy in HCC, but the benefit of postoperative treatment is uncertain. A potential benefit from adjuvant therapy has been shown by some studies[165,166] but not by others.[167] The development of adjuvant-therapy programs is hampered by the inability to define significantly active regional or systemic therapy for patients with HCC. Recent studies suggest that postoperative interferon-alfa may improve the outcome after resection of HCV-related HCC.[168]

Total hepatectomy and adjuvant chemotherapy Total hepatectomy with orthotopic liver transplantation (OLT) may be the optimal treatment for HCC because it removes the primary tumor and the abnormal liver, both of which reduce life expectancy. OLT results in overall survival of 60% to 70% at 5 years for highly selected patients with HCC, but the recurrence rate is also high (30% in 5 years).[169] Recurrence of the disease is associated with the presence and grade of the vascular invasion, bilobar and multifocal tumor distribution, tumor size greater than 5 cm, positive surgical margins, and male sex.[170] Adjuvant chemotherapy has been associated with increased survival for patients

Table 10 Chinese University Prognostic Index (CUPI)[157]

Characteristic	*Weight*
TNM Stage	
I and II	–3
IIIa and IIIb	–1
IVa and IVb	0
Asymptomatic	–4
Ascites	3
α-Fetoprotein ≥ 500 ng/ml	2

34–51 μmol/L (2.0–3.0 mg/dl)	3
> 52 μmol/L (> 3.0 mg/dl)	4
Alkaline phosphatase ≥ 200 IU/L	3
Stage	*Score*
Low-risk group	≤ 1
Intermediate-risk group	2–7
High-risk group	> 8

with a high risk of recurrence of HCC, but there have been no randomized trials to prove such a benefit.[171,172]

Advanced, Unresectable Disease

Unfortunately, most HCC patients are not candidates for surgical treatment. Multiple approaches to locoregional nonsurgical therapy have been investigated to control symptoms and improve quality of life. Because the hepatic artery supplies most of the tumor, TACE will devascularize the tumor and induce tumor necrosis. Various agents may be used to embolize the hepatic artery (e.g., gelatin sponge, polyvinyl alcohol foam, collagen, lipiodol, and angiotensin II), and one or more embolization agents are frequently given in conjunction with chemotherapeutic agents.[173]

TACE is contraindicated in patients who have portal hypertension, portal vein occlusion, or decompensated liver cirrhosis. In a single trial, TACE demonstrated a survival benefit over conservative treatment.[174] Hepatic arterial infusion of yttrium-90–labeled glass microspheres (TheraSphere) appears to also be a viable option for unresectable HCC.[175] Radiofrequency ablation (RFA), which is performed with a needle electrode and a high–frequency alternating current, also induces necrosis of tumor cells. RFA is associated with few side effects and can be performed either percutaneously or intraoperatively. The procedure is most successful in the treatment of tumors 3 cm or smaller, and complete necrosis can usually be achieved after two treatments. It has been reported that the success rate of ablation can reach 100%, with 1- and 2-year survival rates in highly selected patients; however, these studies have a short follow-up, and the degree of benefit may be based as much on patient selection as on tumor ablation.[176] One recent study showed that RFA achieved significantly higher disease-free survival than that achieved by percutaneous ethanol injection (PEI).[177] Other local-regional methods include cryosurgery, microwave coagulation therapy or laser-induced thermotherapy, and intra-arterial chemotherapy.

Patients with advanced disease that is not amenable to local treatment may be considered for systemic therapy. Because many patients have underlying chronic liver disease, which may affect the efficacy or toxicity of chemotherapeutic agents, survival may also be influenced by severity of the underlying liver disease. Doxorubicin and 5-FU are the agents most widely used in single-agent chemotherapy regimens, and both have response rates of approximately 20%.[178] Combination chemotherapy may improve the response rate, but response duration is short, and overall survival is not improved.[179] Over the past several years, biologic agents have also been tested. A small prospective, randomized study demonstrated a significant improvement in survival with octreotide, a somatostatin analogue, compared with no treatment.[180] A combination of interferon-alfa with doxorubicin, cisplatin, and 5-FU (PIAF) has shown encouraging results.[164] Benefit has also been suggested in treatment with other agents, including pravastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor[181]; thalidomide, a sedative agent with anti-angiogenic properties that inhibit tumor necrosis factor–α (TNF-α) activity[182]; and vaccination with dendritic cells, which induces cellular immunity.[183]

Biliary Tract Cancer

Biliary tract cancer is the second most common primary hepatobiliary cancer. Biliary tract cancers include gallbladder cancer, extrahepatic bile duct cancer, ampullary cancer, and intrahepatic bile duct cancers. Cholangiocarcinoma was initially used only to describe intrahepatic bile duct cancer, but it now refers to the entire spectrum of tumors arising from the bile ducts, including intrahepatic, perihilar, and distal extrahepatic carcinomas.[184] The designation Klatskin tumor is reserved for perihilar bile duct cancer involving the bifurcation of the hepatic duct.[185]

Gallbladder cancer is relatively rare in the United States, compared with South America, Japan, and Eastern Europe.[186] It occurs more frequently in women than in men, at a ratio of 1.5:1 to 2:1.

ETIOLOGY AND RISK FACTORS

Cholelithiasis has been widely recognized as a risk factor for gallbladder cancer, especially if the gallstones are large and cause symptoms.[187] Inflammation and bacterial infection have also been associated with gallbladder cancer, particularly with *Salmonella typhi*, *Escherichia coli*, and *Helicobactor* species.[186] Other risk factors include advanced age, obesity, and an anomalous pancreaticobiliary ductal junction.[188]

The risk factors of cholangiocarcinoma are less well described than those of gallbladder cancer, but inflammation (e.g., HCV-related cirrhosis and parasitic infestation) appears to be important.[189] Patients with primary sclerosing cholangitis (PSC) have at least a 10% lifetime risk for cholangiocarcinoma.[190] Patients with ulcerative colitis, in the absence of PSC, also have an increased risk for cholangiocarcinoma.

A variety of genetic mutations and factors related to antiapoptosis have been investigated in biliary tract cancers (i.e., K-*ras*, c-*myc*, c-*erb*-B2, *p53*, and *bcl*-2); these may help in designing future chemobiologic therapy for the disease.[188]

DIAGNOSIS

Clinical Manifestations

The most common clinical presentation of gallbladder cancer is right upper quadrant abdominal pain, suggestive of gallstones, but is complicated by the fact that 50% to 100% of patients have concurrent stones.[189] The incidental pathologic finding of gallbladder cancer in patients undergoing cholecystectomy for suspected gallstones is often reported. Other common symptoms are nausea, vomiting, fatty-food intolerance, and anorexia with weight loss. Jaundice is a late sign, often suggesting advanced disease. On the other hand, cholangiocarcinomas rarely present symptomatically before biliary tract obstruction.

Diagnostic Evalulation

Serum carbohydrate antigen 19-9, or CA19-9, is widely used for detecting cholangiocarcinoma, especially for those patients with PSC. However, neither the sensitivity nor the specificity of the test is optimal, and it may be more useful in the assessment of the effect of treatment and the detection of tumor recurrence. Ultrasonography and CT are the most common initial imaging procedures. Cholangiography (either ERCP or percutaneous cholangiography [PTC]) is an important procedure for assessing the resectability of a tumor. MRI and magnetic resonance cholangiopancreatography (MRCP) permit excellent visualization of hepatic parenchymal abnormalities for the evaluation of resectability [*see Figure 9*].

TREATMENT

Surgery

Radical surgical removal is the only modality associated with improved 5-year survival. Unfortunately, most patients present

with advanced disease, and the overall survival is poor. Both location (intrahepatic, extrahepatic, perihilar, or gallbladder) and extent of disease are important for both the choice of surgical procedure and overall outcome. Liver transplantation may achieve long-term survival for selected patients with early-stage intrahepatic cholangiocarcinoma and possibly for carefully selected patients with unresectable hilar cholangiocarcinoma.[191]

Palliative symptomatic control of pain and jaundice with plastic or metal stents, narcotics, and celiac plexus block may improve quality of life.

Adjuvant Therapy

Although there are no randomized studies demonstrating a survival benefit for adjuvant treatment for biliary tract cancer, radiation (external or transcatheter brachytherapy) in combination with chemotherapy is frequently utilized, and survival benefit is suggested by the findings of nonrandomized studies.[192,193] Significant palliation and occasional long-term survival can be achieved with combined-modality treatment with chemoradiation for locally advanced unresectable biliary tract cancers. Many chemotherapeutic agents, such as 5-FU, mitomycin, methotrexate, etoposide, and cisplatin, have been tested for treatment of biliary tract cancer and have resulted in objective response rates of 10% to 20%. Other potential agents include gemcitabine, irinotecan, docetaxel, and oral fluoropyrimidine (capecitabine).[194-197]

Anal Cancer

Anal cancer is a rare malignancy and accounts for only 1% to 2% of all large bowel cancers. The majority of anal cancers are SCCs. Other histologic types include transitional cell (cloacogenic) carcinoma and mucinous adenocarcinoma.

ETIOLOGY AND RISK FACTORS

Environmental factors are implicated in the carcinogenesis of anal cancer, and human papillomavirus (HPV) infection and condylomata acuminata have been identified as preneoplastic lesions.[198] HIV is also associated with both anal cancer and its precursor lesion, anal squamous intraepithelial lesions (SILs), both of which are associated with immunosuppression and anal-receptive intercourse.[199,200] The relative risk for development of anal cancer is 37-fold higher for HIV-positive men than for the general population, and HIV-positive men who have had anal-receptive intercourse have a 60-fold higher risk of developing anal cancer.

Diseases that cause chronic anal irritation are risk factors for anal cancer and include anal fistulae, fissures, chronic local inflammation, chronic hemorrhoids, Crohn disease, and history of carcinoma of the cervix and the vulva.

Previous radiation exposure and immunosuppression (e.g., immunosuppression in preparation for organ transplantation) may increase the incidence of anal cancer. In the general population, anal cancers develop more often in women than in men (ratio, 2:1) and are more common in middle-aged persons. There are no known racial, dietary, or genetic risk factors.

Regular surveillance with sigmoidoscopy or anoscopy may be indicated for high-risk groups.

DIAGNOSIS

Anal cancers usually present with local symptoms (i.e., bleeding, perianal pruritus, pain, and the sensation of a perianal mass), and the diagnosis of the disease is delayed in most cases because the presentation is mistaken for more common benign conditions (e.g., hemorrhoids). An incisional biopsy is preferred to confirm the diagnosis. Inguinal lymph nodes should be examined because they are frequently involved at early stages of the disease. Endoanal ultrasonography may accurately determine the depth of infiltration of cancer into the sphincter muscle.[201]

TREATMENT

Combined-modality chemoradiation is the treatment of choice for anal cancer, except for very small, localized, superficial tumors (carcinoma in situ or tumor < 2 cm). Multiagent chemotherapy (5-FU with mitomycin-C) used concurrently with radiation for SCC of the anal canal was initially administered as preoperative therapy in patients selected for abdominoperineal resection (APR). The sensitivity of the tumors was such that many patients were found to have complete pathologic respons-

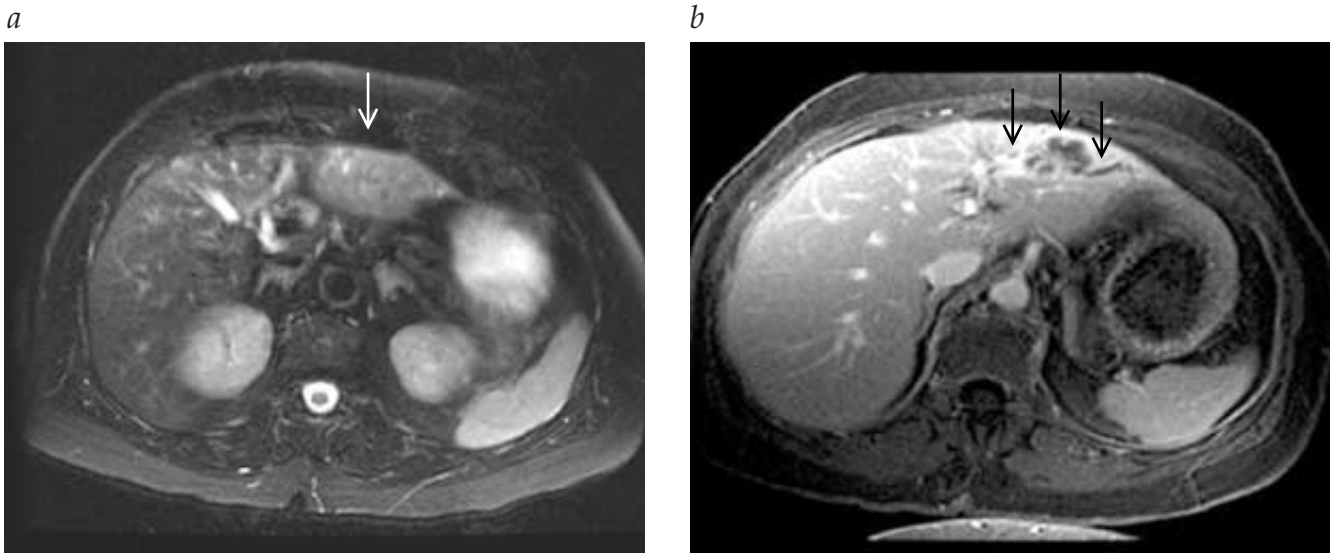

Figure 9 **MRI views of intrahepatic bile duct carcinoma (cholangiocarcinoma). MRI images (T_1- and T_2-weighted) show (*a*) an infiltrative mass (white arrow) of the left lobe of the liver and (*b*) resulting peripheral duct dilatation (black arrows).**

es with treatment, and surgery as part of primary therapy was deleted, resulting in equivalent, if not superior, local control and survival compared with radical surgery.[202] Chemoradiation therapy produces 5-year survival of up to 85% and results in sphincter preservation in in up to 70% of cases. Trials have demonstrated the superiority of chemoradiation over radiation alone and the benefit of mitomycin-C added to infusional 5-FU during radiation.[203] A trial is exploring whether cisplatin is superior to mitomycin-C in this setting. APR may still play an important role in the salvage of treatment failures, as well as provide benefit to patients with preexisting incontinence or patients who are unlikely to tolerate chemoradiation treatment.[204] Recurrences of the disease after initial chemoradiation or surgery are most often local or in inguinal nodes and may be treated with additional surgery, radiation, or chemotherapy, with an average 5-year survival of 40% to 50%.

Other Gastrointestinal Cancers

GASTROINTESTINAL STROMAL TUMOR

Gastrointestinal stromal tumor (GIST) has received tremendous attention in recent years because of successful treatment of unresectable and advanced GISTs with imatinib mesylate (STI571, signal transduction inhibitor), which has proved the concept that selective inhibition of aberrant signal transduction can provide anticancer activity if signaling pathways are identified and blocked.[205]

GISTs are mesenchymal neoplasms of the gastrointestinal tract, related to the intestinal cell of Cajal, with similar differentiation markers.[206,207] The frequency of malignant GIST is estimated to be 20% to 30% of all gastrointestinal soft tissue tumors [*see 12:XIII Sarcoma of Soft Tissue and Bone*], but small benign GISTs are often found incidentally during unrelated surgery or autopsy.[208] GISTs have been documented in all parts of the GI tract, most often in the stomach (60% to 70%) and small intestine (25% to 35%).

Diagnosis

The most common symptom at presentation is gastrointestinal bleeding. The prediction of the malignant potential and prognosis of GISTs is mainly based on histologic characteristics, and it is often very difficult. Tumors that have mitotic activity counts exceeding 5 per 50 high-power fields (HPF) or those larger than 5 cm have a high frequency of intra-abdominal recurrence and liver metastasis. In contrast, tumors smaller than 2 cm and those with mitotic activity counts less than 5 per 50 HPF are likely to be benign,[209] leading to controversy in distinguishing benign from malignant tumors.

Treatment

GISTs express the cell-surface transmembrane receptor KIT, a protein production of the *c-KIT* proto-oncogene that has tyrosine kinase activity.[210,211] KIT is universally phosphorylated in GISTs. A high frequency of mutations leads to constitutive activation of KIT tyrosine kinase without stimulation from its ligand, which subsequently causes uncontrolled stimulation of downstream signaling cascades with aberrant cellular proliferation and resistance to apoptosis. Imatinib mesylate is a selective inhibitor of certain protein tyrosine kinases that was initially designed to target the chimeric BCR-ABL fusion protein, which is responsible for the pathogenesis of chronic myelogenous leukemia (CML).[212] Subsequently, it was shown that imatinib blocks KIT tyrosine kinase as well, and it arrests proliferation and induces apoptotic cell death of GIST cells.[212-214]

A multicenter clinical trial has demonstrated that imatinib is safe and effective in the treatment of patients with advanced GISTs. More than half of patients with advanced unresectable or metastatic GISTs achieve sustained objective response.[205] PET has been shown to be a useful method for the assessment of tumor response to treatment, as compared with more traditional imaging studies (i.e., CT or MRI).[215]

GASTRIC LYMPHOMA

Epidemiology

Primary extranodal lymphoma constitutes 25% of non-Hodgkin lymphoma (NHL) cases in North America.[216] The most common site of extranodal NHL is the stomach, which represents approximately 24% of all primary extranodal lymphoma, according to the End Results Groups Cancer Registries in the United States. Compared with carcinoma incidence, gastric lymphoma is rare, representing 2% to 8% of all gastric malignancies in the United States, but its incidence is increasing.[217] Most patients with gastric lymphoma are older than 50 years. Men are affected more often than women, and it is relatively more common in whites than blacks.

Etiology and Risk Factors

New insights into gastric lymphomas and their etiology and pathogenesis continue to be gained. The multistep pathogenesis by which chronic inflammation of *H. pylori* gastritis converts to low-grade gastric mucosa–associated lymphoid tissue (MALT) lymphoma and progresses to a tumor of higher stage and grade is characterized by multiple molecular biologic events.[218]

Diagnosis

The initial symptom is vague, nonspecific upper gastric discomfort, resembling peptic ulcer disease or gastritis, for many months before diagnosis.[219] The most common complaints are epigastric pain, weight loss, and nausea and vomiting.[220] Unlike in nodal lymphoma, night sweats are not a common feature. Occasionally, an abdominal mass is palpable. Lymphadenopathy is rare, and patients often have no physical signs. Gastric perforation, bleeding, and obstruction are uncommon.

The most common endoscopic finding is a diffuse infiltrative process with thick, rigid folds; and multiple biopsies are often needed to improve the diagnostic accuracy, because the primary lesion is submucosal.[221] Abdominal CT scans may show the extent of the lesion and rule out other metastatic disease, but they cannot reliably differentiate between metastatic lymphadenopathy and reactive lymphoid hyperplasia. Endoscopic ultrasonography is particularly important and considered mandatory in detection of the depth of invasion and the presence of perigastric lymphadenopathy.[222]

Staging and Prognosis

The most frequent site of gastric lymphoma is the distal portion of the stomach, as is the epidemiologically related adenocarcinoma of the stomach. The primary lesion is submucosal, originating from the lymphoid tissue in the lamina propria. It usually invades outwardly through the serosa, and the mucosa is involved later in the disease process. Lymph node involvement usually precedes distant metastases.

The prognosis of patients with gastric lymphoma is better overall than that of patients with gastric carcinoma and is based on

grade, depth of invasion in the gastric wall, and lymph node involvement.[223] Younger patients may have a better prognosis than older patients at the same stage. T cell lymphoma is less common but more aggressive than its B cell counterpart. Other poor prognostic factors include aneuploid tumors, a high proliferation index by antibody Ki-67, and histiocytic histologic subtype. Lymph node involvement usually precedes distant metastases.

Treatment

Eradication of *H. pylori* is considered to be first-line treatment in patients with low-grade superficial gastric MALT lymphoma, and the benefit of treatment may be sustained[224]; however, there is still a lack of long-term follow-up. Surgical resection, radiotherapy, chemotherapy, and the combination of these modalities have proved to be effective in the management of gastric lymphoma, but controversy remains as to whether operative or conservative therapeutic strategies should be favored as the primary treatment. Large prospective, randomized studies are needed to more accurately define the optimal therapeutic options in gastric lymphoma.

VII BREAST CANCER

Nancy E. Davidson, m.d.

Invasive breast cancer, the most common nonskin cancer in women in the United States, will be diagnosed in approximately 216,000 women in this country in 2004 and is expected to result in approximately 40,000 deaths.[1] Incidence and mortality have reached a plateau and appear to be dropping in both the United States[2] and parts of western Europe.[2] This decline has been attributed to several factors, such as early detection through the use of screening mammography and appropriate use of systemic adjuvant therapy. Breast cancer and its treatment have been comprehensively reviewed.[3]

Etiology and Epidemiology

The incidence of breast cancer in the United States has increased steadily since World War II. Multiple risk factors for its development have been identified. Breast cancer is predominantly a disease of women, although it does occur in men, with an incidence of approximately 1% of that seen in women. Chief among the risk factors are advancing age and family history. Incidence increases with age, and about 75% of breast cancer cases in the United States are diagnosed in women older than 50 years. The diagnosis of breast cancer in first-degree relatives younger than 50 years is associated with a threefold to fourfold increased risk. Approximately 5% to 8% of cases of breast cancer occur in high-risk families. Several familial breast cancer syndromes and their associated molecular abnormalities have been identified. These include the breast-ovarian cancer syndrome, which is attributed to germline mutations in either of two breast cancer–susceptibility genes, *BRCA1* and *BRCA2*. These mutations are inherited as an autosomal dominant trait and can therefore be transmitted through both the maternal and the paternal line. Initial linkage studies suggested that a germline mutation in either of these genes was associated with a lifetime risk of breast cancer of up to 85%. However, more recent population-based studies suggest that breast cancer develops in 50% to 60% of carriers.[4] Other hereditary breast cancer syndromes are the Li-Fraumeni syndrome, which is associated with germline mutations in the *p53* tumor suppressor gene,[5] and Cowden disease, which is linked to inherited mutations in the *PTEN* gene.[6]

Reproductive risk factors include early menarche, late menopause, late first pregnancy, and nulliparity. All are felt to lead to a condition of prolonged estrogen exposure to the breast. Careful pathologic study has demonstrated that certain types of breast pathology, such as atypical hyperplasia and lobular carcinoma in situ, are also associated with increased risk. Furthermore, certain environmental factors increase the risk of breast cancer. These factors include exposure to ionizing radiation during adolescence,[7] prolonged use of hormone replacement therapy,[8] ongoing use of oral contraceptives,[9] and consumption of alcohol.[10] Large-scale epidemiologic studies have failed to show any convincing linkage between exposure to certain pesticides[11] or a high-fat diet[12,13] and development of breast cancer.

Prevention

CHEMOPREVENTION

There has been much interest in the development of breast cancer prevention strategies. Pharmacologic approaches are the most developed at this time. The nonsteroidal selective estrogen receptor modulator (SERM) tamoxifen, a mainstay in the management of breast cancer, has also been tested as a chemopreventive agent. A large United States trial randomized 13,388 high-risk women to receive either tamoxifen or placebo for 5 years.[14] Eligibility for this trial was based on increased risk of breast cancer; risk factors used to determine eligibility were age greater than 60 years, a diagnosis of lobular carcinoma in situ, or age of 35 to 59 years with a constellation of risk factors that, when combined, resulted in a 1.67% or greater risk of breast cancer developing within 5 years. Risk was calculated for the last group of women by a modification of a previously validated risk model. Use of tamoxifen was associated with a reduction in the diagnosis of breast cancer of about 50%; benefit was noted in all age groups. Other effects of tamoxifen are summarized [*see Table 1*]. As a general rule, an increase in serious adverse events such as endometrial cancer or thromboembolic events was confined largely to women older than 50 years. On the basis of these data, the Food and Drug Administration (FDA) has approved the use of tamoxifen to reduce the occurrence of breast cancer in high-risk women, as defined by the eligibility requirements for this prevention trial. Two other tamoxifen prevention trials, conducted in the United Kingdom[15] and Italy,[16] did not show any advantage with tamoxifen; this finding has been attributed to the smaller size and variations in eligibility criteria of the two studies. In particular, the small sample size and lower baseline breast cancer risk may have limited the ability of these trials to detect a tamoxifen effect. A fourth trial, the International Breast Cancer Intervention Study, also showed a reduction in diagnosis of invasive breast cancer in tamoxifen recipients.[17] These four trials were analyzed in a meta-analysis that confirmed a 38% reduction in invasive breast cancer with tamoxifen.[18] Salient features of reported trials are summarized [*see Table 2*].

Other selective estrogen receptor modulators are under investigation. One such agent, raloxifene, is approved for use in the prevention of osteoporosis in postmenopausal women. Early results from the osteoporosis trials suggest that raloxifene may also reduce the risk of breast cancer.[19] However, its cancer preventive effects have not been examined directly. Raloxifene's potential for preventing breast cancer is being compared with that of tamoxifen in the current United States breast cancer prevention trial, which is targeting postmenopausal women at increased risk for breast cancer. In addition, on the basis of preclinical models, the vitamin A derivative fenretinide was assessed as a breast cancer chemopreventive agent in an Italian study of about 3,000 breast cancer survivors and showed no overall impact after 5 years of treatment.[20]

LIFESTYLE MODIFICATION

Prevention strategies that involve alterations in lifestyle have been suggested. The Women's Health Initiative is examining the

value of a low-fat diet as a means of breast cancer prevention. Regular exercise, especially during adolescence, may be associated with diminished breast cancer risk. By inference from the epidemiologic studies mentioned above, abstinence from alcohol may slightly reduce the risk of breast cancer.

PROPHYLACTIC MASTECTOMY

Prophylactic mastectomy has been considered as a means of decreasing breast cancer risk, particularly for women at high risk because of a strong family history or because the women are carriers of mutant breast cancer susceptibility genes. Database studies have suggested that prophylactic bilateral mastectomy may decrease development of breast cancer by up to 90%.[21] It is critical that women contemplating such an approach be aware of reports of cancer development in remnants of breast tissue after the prophylactic surgery. It is not known whether prophylactic surgery is superior to aggressive screening coupled with appropriate management of any breast cancer that is diagnosed.

Screening

Screening strategies for breast cancer include the triad of breast self-examination (BSE), clinical breast examination by a health care professional, and screening mammography. Although widely touted as an important component of early detection, BSE is of uncertain value. A large randomized trial that compared conventional BSE with observation in over 260,000 female Chinese textile workers failed to show any clinical advantage with BSE.[22] As a consequence, some experts, including the

American Cancer Society, now promote breast awareness rather than regular BSE.

In contrast, regular screening by mammography[23] and clinical breast examination appear to decrease mortality from breast cancer by 25% to 30% in women older than 50 years. Considerable controversy continues over the value of screening mammography and clinical breast examination in women 40 to 50 years of age. Currently, the American Cancer Society and the National Cancer Institute recommend annual screening mammography for women older than 40 years who are at standard risk for breast cancer. A second area of controversy is the age at which screening mammography may be ceased. No randomized trial has assessed the role of screening mammography in women older than 70 years. However, it would seem reasonable to continue mammography in older women whose life expectancy exceeds 5 years; women whose survival is limited because of other medical conditions are not likely to benefit. There have been no trials of mammographic strategies directed explicitly at high-risk women, particularly those with *BRCA1* and *BRCA2* mutations. In the absence of relevant data, a reasonable approach is to begin mammographic screening at 25 years of age or 5 years earlier than the age of the person with the earliest diagnosis of breast cancer in the immediate or extended family.

Much work is focused on the value of ultrasonography, magnetic resonance imaging, and technetium-99m sestamibi imaging in screening. Currently, these modalities are used largely as ancillary diagnostic tools and have no defined place in the screening of asymptomatic persons. Further testing of these modalities as screening tools is driven in part by the knowledge that 10% to 15% of breast cancers are not detected by mammography. Evaluation of these modalities as screening tools is of particular interest in women who are at high risk, such as carriers of *BRCA1* and *BRCA2* gene mutations.

Staging and Prognosis

The TNM classification of clinical staging rests on the clinical assessment of tumor size, nodal status, and evidence of metastatic disease. However, pathologic staging is preferable because it provides the most accurate estimate of tumor involvement and prognosis. The staging system for breast cancer was recently revised.[24] Most patients present with stage I or II breast cancer. In these patients, extensive laboratory evaluation is of little value. Studies in the asymptomatic patient with apparent stage I or II breast cancer can be limited to a hemogram, chemistry panel, and chest x-ray. More sophisticated radiologic or laboratory staging is not warranted because of low yield. However, patients with symptoms suggestive of metastatic disease or women with clinical evidence of stage III or IV breast cancer should undergo more intensive evaluation of common sites of metastasis, such as bone, liver, and lung, by use of radionuclide scanning and computed tomography. Current staging guidelines are presented [*see Tables 3 and 4*].

Staging is the most important component in establishing prognosis. Indeed, axillary lymph node status and tumor size are the two most important determinants of outcome for patients with early breast cancer. Other established factors that help define prognosis are estrogen receptor–alpha (ER-α) and progesterone receptor (PR) content of the primary tumor mass and histologic grade of the tumor. Biologic factors that are still under evaluation for determining prognosis include expression of the *HER-2/neu* (also known as *c-erb-B2* or *neu*) and *p53* oncogenes and various measures of cellular proliferation, such as S-phase fraction or Ki67. Factors associated with poorer prognosis are lymph node involvement, increasing tumor size, high histologic grade, and absence of ER and PR expression. In addition, overexpression of the oncogenes, as well as increased cellular proliferative measures, may be associated with adverse clinical outcome. A new area of research is predictive factors—that is, identification of biologic features correlated with sensitivity or resistance of a tumor to a particular therapy. There are three established predictive factors for breast cancer: ER, PR, and HER-2/neu. The majority of tumors that express ER, PR, or both are initially sensitive to endocrine therapies, whereas tumors that lack ER and PR rarely respond to such treatment. Similarly, overexpression of the HER-2/neu protein or amplification of the *HER-2/neu* gene is associated with response to the HER-2/neu-targeted monoclonal antibody trastuzumab. Investigators are examining the possibility that overexpression of the HER-2/neu protein may indicate a need for doxorubicin-based chemotherapy; it may also predict relative resistance to certain hormone therapies, such as tamoxifen.

Early Breast Cancer (Stages I and II)

DIAGNOSIS

Many cases of early, clinically occult breast cancer are diagnosed on the basis of architectural changes or microcalcification seen on a mammogram. Women with clinically evident breast cancer generally present with breast-specific complaints, such as a palpable mass, a change in breast contour, or skin or nipple changes. For both clinically occult and clinically apparent cancer, pathologic evaluation is mandatory to establish a diagnosis. In the past, incisional or excisional biopsies were routinely employed for this purpose. Today, fine-needle aspiration and core-needle biopsy are the standard diagnostic modalities. These procedures can be performed in the office in patients with suspicious palpable lesions. For women with nonpalpable lesions, biopsies guided by mammography, ultrasonography, or MRI are now routine. These technologies permit an accurate diagnosis, which can be followed by definitive treatment planning; consequently, only a single surgical procedure is required. Alternatively, women whose diagnoses are unequivocally negative can be spared an open surgical biopsy. However, it is axiomatic that further evaluation be undertaken for suspicious lesions that yield an equivocal diagnosis after needle aspiration or core biopsy. In addition, bilateral breast imaging is required to identify any unsuspected lesions in the contralateral breast that may also mandate further evaluation.

LOCAL TREATMENT OF EARLY-STAGE BREAST CANCER

In Situ Carcinoma

Because of increased use of screening mammography and heightened breast cancer awareness, in situ carcinomas now account for about 20% of newly diagnosed cases of breast cancer.[25] The majority of these carcinomas are ductal carcinoma in situ (DCIS). Such lesions are associated with an approximately 30% risk of subsequent invasive breast cancer in the ipsilateral breast. The risk of metastatic breast cancer is small with DCIS; as a consequence, axillary lymph node evaluation is not routinely performed. Thus, management decisions are centered largely on the involved breast. Total mastectomy, the tradition-

al therapy, has a high likelihood of cure. Studies suggest that breast conservation is appropriate for many women with DCIS. Contraindications are poor cosmesis or multifocal disease. Several models using pathologic factors to predict outcome have been devised to guide decisions about local therapy; key factors are size and grade of lesion and status of surgical margins. If breast conservation is the goal, then an adequate excision to obtain tumor-free margins is important. Careful mammographic examination of the specimen and postexcision mammography of the breast are crucial to ascertain whether the lesion has been fully excised. A large randomized trial has demonstrated that radiotherapy along with lumpectomy, compared with lumpectomy alone, decreases the likelihood of recurrence of invasive or in situ breast cancer.[26] Nonetheless, some women with favorable lesions who are willing to undergo close surveillance are candidates for local excision alone. In one trial, a small benefit was demonstrated with the use of a 5-year regimen of tamoxifen in women with DCIS who underwent excision and radiotherapy.[26] Both ipsilateral breast cancer recurrence and contralateral breast cancer development were reduced by about 50%. A second trial did not show any advantage for the use of tamoxifen.[27]

Controversy exists as to whether lobular carcinoma in situ (LCIS) is a truly malignant lesion. Diagnosis of LCIS is usually an incidental finding on breast biopsy, and it appears to be associated with a 30% risk of development of invasive breast cancer in either breast. Women with LCIS are generally regarded as candidates for careful surveillance with regular breast examination and mammography. Bilateral total mastectomy may be considered for women with LCIS who have other risk factors or who are extremely concerned. The United States Breast Cancer Prevention Trial suggested that a 5-year regimen of tamoxifen therapy decreases the risk of invasive breast cancer by one half in women with LCIS; thus, tamoxifen chemoprevention can also be considered for these women.[14]

Invasive Breast Cancer

Surgical therapy Although radical mastectomy (removal of the involved breast, axillary contents, and underlying chest wall musculature) was the mainstay for breast cancer treatment for many decades, it is seldom performed today. Multiple randomized trials have uniformly and unequivocally shown that breast conservation therapy (BCT) that involves lumpectomy with radiotherapy and modified radical mastectomy that involves removal of the breast and axillary nodes provide identical survival rates for women with stage I or II breast cancer.[28] Patient preference (rather than physician preference) should guide decision making regarding these two options. Medical contraindications for BCT are multifocal disease, ongoing pregnancy that precludes timely administration of radiotherapy, and previous radiotherapy. Although the number of patients being managed with BCT has risen substantially over the past 10 years, wide geographic differences exist in the use of breast conservation in the United States. Patients who undergo mastectomy should be counseled about the availability of breast-reconstruction alternatives.

Because the likelihood of distant micrometastatic spread is highly correlated with the number of involved lymph nodes, axillary dissection has traditionally been used to provide prognostic information about the extent of pathologic lymph node involvement. Therapeutic benefit from axillary dissection is minimal and is likely limited to the minority of women who have lymph node–positive disease. The morbidity associated with breast cancer surgery is largely related to side effects from axillary dissection. Unfortunately, use of prognostic factors derived from the primary tumor has not proved to be an acceptable alternative to assessment of axillary lymph node status. In recent years sentinel lymph node mapping has become the method of choice to evaluate the ipsilateral axillary nodes.

Sentinel lymph node mapping involves injection of a radioactive tracer, vital blue dye, or both into the area around the primary breast tumor. The injected substance tracks rapidly to the dominant axillary lymph node—the so-called sentinel lymph node. This node can be located by use of a small axillary incision and visual inspection or by use of a handheld counter. If the sentinel node is tumor free, the remaining lymph nodes are likely to be tumor free as well, and further axillary surgery can be avoided. Women in whom the sentinel node is found to contain a tumor are currently advised to undergo standard axillary dissection. Initial studies suggest that the surgeon's experience is a key factor in identifying the sentinel lymph node. A small, randomized trial of sentinel node management versus standard axillary lymph node dissection has suggested similar outcomes with the two strategies.[29] Several extremely large randomized trials are expected to definitively resolve the role of sentinel node approaches. Sentinel node mapping is indicated only for women with invasive breast cancer without palpable axillary lymph nodes. Women with palpable nodes should undergo standard axillary dissection.

Adjuvant radiotherapy Radiotherapy is a critical component of BCT; women who undergo lumpectomy by itself have a breast cancer recurrence rate of up to 40%, whereas the rate of recurrence is less than 10% with appropriate radiotherapy. Attempts to identify women whose tumors are so favorable that radiotherapy can be safely withheld have not been successful. In addition, efforts to routinely omit radiotherapy from treatment algorithms for elderly women cannot be condoned, because local failure rates are unacceptably high. Such a strategy of mini-

mal local therapy is appropriate only for patients with significant comorbidities that limit their life expectancy. Current research is focused on the possibility that radiotherapy can be safely and effectively delivered to a smaller field (partial-breast radiotherapy) and over shorter time periods.

A continuing controversy concerns the value of postmastectomy radiotherapy. Once routine, this practice was largely abandoned because a number of randomized trials and a meta-analysis failed to show any benefit in survival from use of this practice. In these trials, the incidence of locoregional recurrence was reduced by 50% to 75%, although cardiac toxicity increased.[30] As a result, postmastectomy radiotherapy was limited to women with extensive local disease, such as skin or chest wall invasion or extensive lymph node involvement. Interest in this field has been revived by the publication of two randomized trials of mastectomy with or without subsequent radiotherapy.[31,32] These trials showed a survival advantage for women with node-positive breast cancer who received radiation. Unlike many of the older trials, these two trials incorporated appropriate adjuvant systemic therapy and modern radiotherapy techniques. Many radiation oncologists now recommend postmastectomy radiotherapy for women with more than three involved lymph nodes and discuss its use with younger women who have one to three positive lymph nodes. Skeptics have argued that the local recurrence rate in the women treated with mastectomy alone in these two trials is higher than that observed in the United States today; thus, the seemingly positive results from the addition of radiotherapy may simply reflect salvage of patients who received inadequate surgery.

SYSTEMIC TREATMENT OF EARLY-STAGE BREAST CANCER

A driving force behind the use of systemic therapy for early-stage breast cancer has been the understanding that many women with primary breast cancer already have distant micrometastases at the time of diagnosis. Over time, overt metastatic disease develops in most of these women despite treatment with state-of-the-art surgery and radiotherapy. Thus, systemic therapy is frequently used in these women to prevent or delay recurrence of disease. The treatment algorithms that are currently in use are the result of over 40 years of clinical trials; the results of these trials have been compiled in sequential overview analyses that have evaluated the worldwide experience with use of ovarian ablation, tamoxifen therapy, and chemotherapy. The most recent results of the meta-analysis for each modality of therapy are summarized below.[33-35] In addition, a new class of agents, the aromatase inhibitors, is entering the adjuvant arena for postmenopausal women with steroid receptor–positive breast cancer.

Ovarian Ablation

Ovarian ablation by way of surgery or radiotherapy is the oldest form of systemic therapy for advanced breast cancer. It was also the first adjuvant systemic therapy studied in a systematic fashion. The 1995 meta-analysis for ovarian ablation focused on 2,102 women younger than 50 years who were participants in one of 12 randomized trials begun before 1990.[33] Young age was used as a surrogate marker for premenopausal status. Some, but not all, of these studies of ovarian ablation involved chemotherapy. In these studies, positive hormone receptor status was generally not an entry criterion. Overall, these studies showed a 25% reduction in the annual odds of recurrence and a 24% reduction in the annual odds of death for women who underwent ovarian ablation in the absence of chemotherapy. The benefit was more modest for women treated with both ablation and chemotherapy—an 8% to 10% reduction. This finding is not surprising, because adjuvant chemotherapy can lead to the onset of menopause, and it is likely that the benefit of ovarian ablation is limited to women who are not menopausal. Benefits were enjoyed by both node-negative and node-positive women, but the absolute benefit was greatest in node-positive women who had a higher baseline risk of recurrence. For example, the 15-year recurrence-free survival rate for node-positive women was 37% for those who underwent ovarian ablation without adjuvant chemotherapy and 24% for those who received neither ablation nor chemotherapy; for node-negative women, the 15-year survival rates were 75% for those who underwent ablation and 66% for those who had neither ablation nor chemotherapy. Thus, the absolute improvement in survival was 13% for node-positive women and 9% for node-negative women. The meta-analysis also included 1,354 women 50 years of age or older who participated in these trials. Not surprisingly, there was no significant effect of ovarian ablation in these women, who were presumably already postmenopausal for the most part.

Interest in this general approach has been renewed by the advent of the luteinizing hormone–releasing hormone (LHRH) agonists. These agents effect a temporary so-called medical castration through their effects on the hypothalamic-pituitary axis; their use ultimately results in a decrease in the production of ovarian steroids. Randomized trials in metastatic breast cancer patients suggest that these drugs, which include goserelin and leuprolide, are as effective as oophorectomy. Several trials have compared the efficacy of LHRH therapy with that of chemotherapy alone, as well as the efficacy of a combination of LHRH therapy and chemotherapy with that of either LHRH therapy alone or chemotherapy alone.[36] In these trials, the regimens are given for 2 to 5 years. These trials are largely directed toward women whose tumors express hormone receptors and who therefore have a greater likelihood of benefiting from an endocrinologic approach. The trials suggest that in certain circumstances, ovarian suppression represents a viable adjuvant strategy for premenopausal women with steroid receptor–positive breast cancer.

Tamoxifen

The mixed estrogen agonist-antagonist tamoxifen has become the most commonly prescribed antineoplastic drug. Its clinical application was recently comprehensively reviewed.[37] After initial studies documented its efficacy in advanced breast cancer, a number of trials investigated its usefulness in women with early-stage breast cancer. Information from most of the randomized trials is collected in the 1995 overview analysis of tamoxifen, which included 37,000 women enrolled in 55 trials.[34] About 8,000 women in these studies were found to have low expression or no expression of ER in their tumors. Tamoxifen had minimal effect on outcome. These findings support preclinical and clinical data suggesting that tamoxifen's major mode of action is through its interaction with the ER. Thus, the major analysis was restricted to 18,000 women with steroid receptor–positive tumors and 12,000 women with untested tumors, 8,000 of whom were predicted to have steroid receptor–positive tumors. In these patients, the benefit of tamoxifen increased with the duration of treatment; the proportional reductions in 10-year recurrence and mortality were 47% and 26%, respectively, with 5-year regimens of tamoxifen therapy. Benefit appeared to extend be-

yond the 5-year period of drug administration. Again, the proportional reductions were similar for node-negative and node-positive women, but absolute improvements were greater in node-positive women. For node-positive women, the 10-year survival rates were 61% with tamoxifen and 50% with placebo; for node-negative women, the 10-year survival rates were 79% and 73%, respectively. Benefit was observed regardless of age, menopausal status, tamoxifen dose, and use of chemotherapy. This overview also provided information on non–breast cancer outcomes, documenting a small increase in uterine cancer and a decrease in contralateral breast cancer. Tamoxifen had no effect on the incidence of other cancers or on the incidence of death from other causes.

Aromatase Inhibitors

The aromatase inhibitors represent a new treatment strategy for postmenopausal women with steroid receptor–positive breast cancer. In older women, the primary source of circulating estrogen is the conversion of androgens (synthesized by the adrenal glands) to estrogen via the action of the enzyme aromatase, which is found in certain tissues, including adipose and mammary tissues. The aromatase inhibitors specifically inhibit this conversion leading to further estrogen deprivation in older women. Randomized trials have shown that the aromatase inhibitors (e.g., anastrozole, letrozole, and exemestane) provide efficacy similar or superior to that of tamoxifen and an acceptable side-effect profile for postmenopausal women with metastatic breast cancer.[38] One of the aromatase inhibitors, anastrozole, has been approved by the FDA as a second form of adjuvant endocrine therapy for postmenopausal women with steroid receptor–positive breast cancer.[39] Two new studies suggest that the aromatase inhibitors letrozole and exemestane can reduce breast cancer recurrence when used after several years of tamoxifen therapy, raising the possibility of sequential endocrine therapy as an effective strategy.[40,41]

Because information about long-term effects of aromatase inhibitors is sparse, some experts have urged a cautious approach to their general use.[42] Studies suggest that these agents are associated with postmenopausal symptoms, arthralgias, osteoporosis, and fractures. Unlike tamoxifen, aromatase inhibitors do not appear to be associated with uterine cancer risk or thromboembolic events. There is uncertainty about long-term side effects such as cardiac risk or effects on cognition. Optimal duration of aromatase-inhibitor therapy is not known, nor is it clear whether one agent offers certain advantages over another. Given their mechanism of action, aromatase inhibitors should not be used in treating premenopausal women.

Chemotherapy

The 1995 overview summarized results of 40,000 women who participated in 69 chemotherapy trials.[35] These trials addressed three general issues: polychemotherapy compared with no chemotherapy; chemotherapy of long duration compared with that of short duration; and anthracycline-containing regimens compared with the classic combination of cyclophosphamide, methotrexate, and fluorouracil (CMF). Combination chemotherapy reduced recurrence by 35% in women younger than 50 years and by 20% in women 50 to 69 years of age. Mortality was reduced by 27% in the younger women and 11% in the older women. As with the other modalities, the proportional reductions were similar in node-negative and node-positive patients. The absolute benefit was greatest for node-positive women younger than 50 years, in whom the 10-year survival rate increased from 43% to 53%. In contrast, node-negative women 50 to 69 years of age had an absolute gain in 10-year survival of only 2%—from 67% to 69%. In this analysis, 3 to 6 months of therapy was as effective as longer durations of therapy. Anthracyclines such as doxorubicin and epirubicin resulted in a slightly greater improvement in 5-year survival than that shown with CMF (72% for anthracycline and 69% for CMF). Chemotherapy outcome was not affected by estrogen receptor status or use of tamoxifen, nor was chemotherapy associated with an increase in deaths from causes other than breast cancer.

Other Chemotherapy Considerations

Selection of agents Initial studies of adjuvant chemotherapy used single agents such as melphalan. Because combination chemotherapy was found to effect higher response rates in metastatic disease, the use of multiagent chemotherapy was introduced into the adjuvant setting. The landmark trial of Bonadonna and coworkers established CMF as a beneficial regimen for women with node-positive breast cancer. The survival advantage of CMF persisted after 20 years of follow-up.[43] Given the efficacy of the anthracyclines (e.g., doxorubicin and epirubicin) in metastatic disease, combination regimens containing anthracyclines were also explored. Trials that compared CMF with combination regimens of cyclophosphamide, doxorubicin (or epirubicin), and fluorouracil (CAF or FEC), as well as similar combination regimens, have shown anthracycline to provide a small benefit . One large trial that compared CAF with CMF in the management of node-negative breast cancer showed 5-year recurrence-free survival rates of 85% and 82%, respectively, thereby demonstrating a modest advantage with the use of CAF.[44] Selection of a regimen containing doxorubicin or epirubicin should be guided by patient and physician preference about relative toxicity and benefit.

Current trials are evaluating the role of the taxanes (i.e., paclitaxel and docetaxel) as adjuvant therapy. Two trials comparing the value of four cycles of doxorubicin and cyclophosphamide (AC) with that of four cycles of AC followed by four cycles of paclitaxel for node-positive breast cancer demonstrated a small early improvement in recurrence-free survival with the addition of paclitaxel.[45,46] A combination of docetaxel, doxorubicin, and cyclophosphamide provided results superior to those achieved with CAF in women with node-positive breast cancer.[47] Other trials of taxanes, either in sequence or in combination, are in progress. Some standard adjuvant chemotherapy regimens are described [*see Table 5*].

Duration Early adjuvant chemotherapy trials investigated therapies lasting up to 2 years. Sequential trials demonstrated that therapy lasting 2 years was no better than therapy lasting 1 year; it was subsequently found that 6 months of therapy was equivalent to 1 year of therapy. Toxicity was greater with the prolonged regimens, and compliance diminished with longer treatment duration. Other trials compared a single cycle of chemotherapy in the perioperative period with longer periods of administration and invariably showed improved outcome with prolonged therapy. Because of these trials, current adjuvant chemotherapy is generally administered for 3 to 6 months, depending on the regimen chosen.[35]

As noted, sequential trials have shown that a 5-year regimen of tamoxifen therapy gives better results than regimens of shorter duration. However, studies of regimens lasting longer

Table 5 Some Commonly Used Adjuvant Chemotherapy Regimens

Acronym	*Drugs*	*Dose*	*Schedule*
CMF	Cyclophosphamide Methotrexate Fluorouracil	100 mg/m^2/day p.o. × 14 days 40 mg/m^2 I.V. days 1 and 8 600 mg/m^2 I.V. days 1 and 8	Repeated every 28 days for six cycles
CAF	Cyclophosphamide Doxorubicin Fluorouracil	100 mg/m^2/day p.o. × 14 days 30 mg/m^2 I.V. days 1 and 8 500 mg/m^2 I.V. days 1 and 8	Repeated every 28 days for six cycles
FAC	Fluorouracil Doxorubicin Cyclophosphamide	500 mg/m^2 I.V. days 1 and 8 50 mg/m^2 I.V. day 1 500 mg/m^2 I.V. day 1	Repeated every 21 days for six cycles
AC	Doxorubicin Cyclophosphamide	60 mg/m^2 I.V. day 1 600 mg/m^2 I.V. day 1	Repeated every 21 days for four cycles
AC → T	Doxorubicin Cyclophosphamide *followed by* Paclitaxel	60 mg/m^2 I.V. day 1 600 mg/m^2 I.V. day 1 175 mg/m^2 I.V. day 1	Repeated every 21 days for four cycles Repeated every 21 days for four cycles
Dose-dense AC → T	Same as AC → T	Same as AC → T	Repeated every 14 days for four cycles with G-CSF support
AC → docetaxel	Doxorubicin Cyclophosphamide *followed by* Docetaxel	60 mg/m^2 I.V. day 1 600 mg/m^2 I.V. day 1 100 mg/m^2 I.V. day 1	Repeated every 21 days for four cycles Repeated every 21 days for four cycles
TAC	Docetaxel Doxorubicin Cyclophosphamide	75 mg/m^2 I.V. day 1 50 mg/m^2 I.V. day 1 500 mg/m^2 I.V. day 1	Repeated every 21 days for six cycles
FEC	Fluorouracil Epirubicin Cyclophosphamide	Various doses	Various schedules

G-CSF—granulocyte colony-stimulating factor

than 5 years have failed to show an advantage beyond 5 years of therapy.[48] The 5-year tamoxifen regimen is currently regarded as standard.

Dose Preclinical data support the hypothesis that the chemotherapy dose is an important determinant of cell kill. As a consequence, the value of dose escalation has been studied extensively. Several trials now provide convincing evidence that reducing the dose to below a standard level is associated with inferior outcome. In a pivotal trial addressing this issue, 1,550 women with node-positive breast cancer were randomly assigned to receive low, medium, or high doses of CAF.[49] Low-dose CAF was clearly associated with higher recurrence rates and poorer survival after 9 years of median follow-up. The high dose of CAF in this study is the same as the standard dose used in adjuvant therapy today. Preliminary studies suggest that the high-dose regimen was superior only in patients whose tumors had poor prognostic biologic factors. In contrast, further dose escalation, made possible through the use of colony-stimulating factors, has not been beneficial. Three large randomized trials failed to show any value of a fourfold increase in the dose of cyclophosphamide[50,51] or a 50% increase in the dose of doxorubicin.[45] Thus, routine administration of high-dose chemotherapy is not warranted, because it can increase toxicity without improving outcome. In addition, several randomized trials have shown that the administration of very high dose chemotherapy combined with autologous bone marrow transplantation or peripheral progenitor cell support does not improve outcomes when compared with standard-dose therapy.[52] Once popular for women with high-risk breast cancer, this approach has been largely abandoned.

Timing Conventional adjuvant chemotherapy usually begins within a few months after surgery. Unnecessary delay is not advisable. Use of primary chemotherapy (i.e., chemotherapy administered before surgery or radiotherapy) has also been advanced and has been tested in several randomized trials. The combined results of these trials show that primary chemotherapy can increase the rate of breast conservation because of its ability to reduce tumor size. However, no reproducible advantage in other clinical outcomes has emerged. In the largest trial, about 1,500 women with palpable breast cancer were randomized to receive four cycles of AC chemotherapy either before or after surgery.[53] After 5 years, disease-free survival and overall survival were identical. Therefore, primary chemotherapy is a safe alternative to traditional adjuvant chemotherapy, particularly for women who desire breast conservation and who are not considered appropriate candidates for breast-conserving surgery at the time of diagnosis.

Given the prevalence of BCT, a second issue concerns the timing of chemotherapy in relation to radiotherapy. A randomized trial compared the outcome of women treated with AC

chemotherapy followed by breast radiotherapy with the outcome of women who received radiotherapy first, followed by identical AC chemotherapy. This trial showed a trend toward improved outcome for the women who received chemotherapy first.[54] Other strategies include concomitant chemotherapy and radiotherapy and so-called sandwich therapy, in which several cycles of chemotherapy are administered, followed by radiotherapy and then the remaining cycles of chemotherapy. Concurrent chemotherapy and radiotherapy requires that certain drugs, such as doxorubicin and methotrexate, be omitted during the period of radiotherapy to prevent toxicity. The available data are not sufficient to definitively judge the effects of concurrent or sandwich therapy on long-term outcome.

Chemoendocrine Therapy

Chemotherapy and tamoxifen or an aromatase inhibitor In light of the benefits of adjuvant chemotherapy and endocrine therapy when administered singly, a logical question concerns the role of combination therapy. Several pivotal trials have examined the value of chemotherapy combined with tamoxifen in node-positive and node-negative breast cancer. One such trial analyzed the value of tamoxifen alone, the combination of tamoxifen with CMF, and the combination of tamoxifen with methotrexate and fluorouracil (MF) for women with node-negative, steroid receptor–positive breast cancer.[55] Although reduced recurrence rates and improved survival rates were noted for all women who received combination therapy, the magnitude of the benefit of combination therapy was greatest in younger women or those with larger tumors.

The efficacy of chemotherapy in combination with tamoxifen for postmenopausal women with node-positive, steroid receptor–positive breast cancer has been addressed.[56,57] Several recent trials suggest that the addition of tamoxifen to chemotherapy reduces recurrence rates by 5% to 7% at 5 years, making the combination of chemotherapy and tamoxifen a reasonable choice for these women. Similarly, the addition of tamoxifen to chemotherapy for premenopausal women with node-positive, steroid receptor–positive breast cancer leads to a 10% improvement in 5-year recurrence-free survival.[58] Not surprisingly, the addition of tamoxifen to chemotherapy has not improved clinical outcome for women with steroid receptor–negative breast cancer in two randomized trials.[44,59]

Together, these trials suggest that chemohormonal therapy is a reasonable consideration for many women with steroid receptor–positive breast cancers. However, an explicit discussion of the magnitude of the potential benefits and side effects is critical, because some women may find the benefit of combined therapy to be too small to warrant its toxicities.

If chemotherapy and tamoxifen are both planned, a sequence of chemotherapy followed by tamoxifen is advisable. An Intergroup trial comparing the efficacy of combined CAF and tamoxifen with the efficacy of CAF followed by tamoxifen in postmenopausal women with node-positive, steroid receptor–positive breast cancer showed an advantage to the sequential approach.[57]

No information is available concerning how to integrate chemotherapy with the use of an aromatase inhibitor. Extrapolating from the information on chemotherapy and tamoxifen, a prudent strategy is to use the sequence of chemotherapy followed by an aromatase inhibitor.

Chemotherapy and ovarian ablation The combination of chemotherapy and ovarian ablation has been assessed in trials using surgical oophorectomy or the administration of LHRH analogues for 2 to 5 years. One large trial showed no overall advantage after 5 years for CAF chemotherapy followed by 5 years of goserelin in 1,500 premenopausal women with node-positive, steroid receptor–positive breast cancer.[60] Follow-up continues; the overview analysis suggests that the benefits of ovarian ablation may not emerge for many years. One side effect of adjuvant chemotherapy in young women is induction of menopause; therefore, any beneficial effects of ovarian ablation likely would be limited to women who remained premenopausal after adjuvant chemotherapy. This hypothesis is under study in a large randomized trial.

Combination endocrine therapy Because different endocrine agents have different mechanisms of action, combination hormone therapy may have better results than either approach used alone. Indeed, combined endocrine therapy in metastatic breast cancer can increase response rate, albeit with higher toxicity and no effect on long-term outcome. Ovarian ablation combined with tamoxifen or an aromatase inhibitor is being studied in premenopausal women. The combination of tamoxifen and anastrozole was shown to be no better than tamoxifen alone in a large randomized trial in postmenopausal women.[39]

Guidelines for Adjuvant-Therapy Administration

An important factor in the decision to use adjuvant therapy is an accurate assessment of the likelihood of breast cancer relapse and mortality with and without therapy. Several tools can help guide this discussion.[61,62] In addition, several groups have devised guidelines for use of adjuvant therapy. Those from the 2003 St. Gallen Breast Cancer Conference, a gathering of international breast cancer experts, are outlined [*see Table 6*].[63] Recommendations from the 2000 NIH Consensus Conference[64] and an algorithm derived from an evidence-based analysis from the National Cancer Center Network (NCCN) are also available.[65] The latter group comprises breast cancer experts from a consortium of cancer centers designated by the National Cancer Institute. These are guidelines, not mandates; they represent a framework for individualized patient counseling about prognosis and therapy. Finally, adjuvant therapy remains imperfect. Numerous clinical trials continue, and participation in clinical trials represents an excellent treatment choice for many patients.

Toxicity of Adjuvant Chemotherapy

Increased use of adjuvant chemotherapy and longer survival have led to concerns about toxicity.[66] Acute side effects of therapy are nausea and vomiting, bone marrow suppression, and hair loss; all are reversible. Induction of menopause is a common concern for younger women. Its likelihood is related to the type of chemotherapy and the age of the patient. CMF and similar regimens are more likely to induce permanent menopause than AC therapy. With either type of regimen, the incidence of menopause is greatest for women 40 years of age and older, the majority of whom will suffer a drug-induced menopause.

Given its association with breast cancer, hormone replacement therapy (HRT) is not generally recommended in breast cancer survivors.[8] Doxorubicin-related cardiomyopathy is another long-term consequence; clinical evidence of congestive heart failure is noted in about 1% of women who receive doxorubicin-containing adjuvant chemotherapy at standard doses. Use of common adjuvant-chemotherapy regimens results in a very small incidence of acute leukemia, but there is no evidence

Table 6 Adjuvant Treatment for Patients with Operable Breast Cancer[63]

Risk Group	*Endocrine-Responsive Disease*		*Endocrine-Nonresponsive Disease*	
	Premenopausal	*Postmenopausal*	*Premenopausal*	*Postmenopausal*
Node-negative disease, minimal risk*	Tamoxifen or none	Tamoxifen or none	NA	NA
Node-negative disease, average risk†	GnRH analogue (or ovarian ablation) + tamoxifen [± chemotherapy], *or* Chemotherapy → tamoxifen [± GnRH analogue (or ovarian ablation)], *or* Tamoxifen, *or* GnRH analogue (or ovarian ablation)	Tamoxifen *or* Chemotherapy → tamoxifen	Chemotherapy	Chemotherapy
Node-positive disease	Chemotherapy → tamoxifen [± GnRH analogue (or ovarian ablation)], *or* GnRH analogue (or ovarian ablation) + tamoxifen [± chemotherapy]	Chemotherapy → tamoxifen *or* Tamoxifen	Chemotherapy	Chemotherapy

*Minimal risk: estrogen and progesterone receptor **expressed**, and **all** of the following features: pathologic tumor size ≤ 2 cm, tumor grade 1, and patient age ≥ 35 yr.
†Average risk: estrogen and progesterone receptor **expressed**, and **at least one** of the following features: pathologic tumor size ≥ 2 cm or tumor grade 2 through 3, or patient age ≤ 35 yr.

of increased incidence of other second tumors. Concerns about cognitive impairment are under investigation.

FOLLOW-UP OF EARLY BREAST CANCER SURVIVORS

Most women present with stage I or II breast cancer and receive appropriate local and systemic therapy. A critical issue is how longitudinal follow-up should be conducted in these patients. Two randomized trials have addressed this issue.[67,68] Both compared a schedule of physician visits and regular laboratory testing (i.e., chest x-ray, bone scanning, and blood studies) with a program of physician visits and laboratory testing that was restricted to evaluation of symptoms. Together, they showed that routine laboratory screening did not enhance survival or quality of life when compared with a program of careful clinical examination with testing tailored for symptoms and physical findings. About 70% of metastases were first detected by the patients themselves, even those patients undergoing physician and laboratory evaluation every 3 months. On the basis of these and other studies, the American Society of Clinical Oncology has published evidence-based guidelines for follow-up of asymptomatic survivors of early-stage breast cancer.[69] These guidelines are summarized [*see Table 7*].

Stage III Breast Cancer

Stage III breast cancer accounts for about 10% of all breast cancers; it is characterized by a primary tumor measuring more than 5 cm, neoplastic invasion of the skin or chest wall, or a fixed tumor or lymph nodes. Inflammatory breast cancer falls into this category. Inflammatory breast cancer has a clinical presentation of breast swelling, erythema, warmth, and a peau d'orange appearance (characterized by a dimpled appearance caused by tumor infiltration of intradermal lymphatics); it may or may not be associated with a mass. These lesions are associated with a high risk of local disease recurrence and distant metastases. Because as many as one third of women with clinical stage III breast cancer have metastases at the time of diagnosis, many oncologists perform a metastatic evaluation at that time, even in asymptomatic patients. Diagnosis is usually established by fine-needle aspiration or core-needle biopsy. Combined-modality therapy is preferred for this stage of breast cancer. Several months of preoperative chemotherapy or hormone therapy result in partial tumor regression in most patients, thereby allowing mastectomy or breast-conserving surgery to be undertaken. Definitive surgery at the time of diagnosis should be avoided because of the high risk of subsequent chest wall recurrence. Radiotherapy is then employed to enhance local control. Some studies suggest that administration of further chemotherapy, hormone therapy, or both is then desirable. Multimodality therapy results in a 5-year disease-free survival rate of about 50%. Follow-up algorithms are similar to those recommended for women with stage I or II disease.

Stage IV or Metastatic Breast Cancer

Although seldom curable, advanced breast cancer is a highly treatable disease. Palliation or prevention of symptoms is the primary goal of treatment. The median survival after diagnosis of metastatic disease is about 2 years, although the range is great. Longitudinal studies have documented a few long-term survivors, most of whom were patients with indolent disease.[70] Several recent clinical trials have documented small improvements in survival with some of the newer therapies.

DIAGNOSIS

As noted, most women with advanced disease present with symptoms or abnormal physical findings. Common sites of relapse are bone, local soft tissues, lung, and liver. If metastasis is suspected, relevant imaging studies (e.g., nuclear medicine, CT scanning, or both) and routine hematologic and biochemical blood studies to assess location and severity of involvement are warranted. Because of the gravity of the diagnosis, pathologic confirmation is preferred. This permits verification of recurrent disease and exclusion of other diagnoses, such as a second primary cancer that would warrant different therapy. Elevated tumor markers such as CA2729 or carcinoembryonic antigen (CEA) are not pathognomonic for recurrent disease, although they may be useful adjuncts in the assessment of the effects of therapy.

TREATMENT

Unlike in early-stage breast cancer, the role of surgery in

metastatic disease is limited. It may be appropriate in some cases, such as excision of a solitary chest wall nodule, removal of a solitary brain metastasis, or orthopedic stabilization to prevent or treat a long-bone fracture. Radiotherapy is a mainstay in the management of advanced disease. It may be used at any time during the disease course to treat localized disease, such as brain metastases or painful bony metastases. In the end, however, systemic treatment with endocrine therapy and chemotherapy is the primary mode of management of disseminated disease. Guiding principles for selection of therapy include maximal palliation of symptoms, prevention of disease-related complications, and the minimizing of therapy-related toxicity. For achieving these goals, endocrine therapy is preferred wherever feasible. An algorithm for systemic treatment selection in stage IV breast cancer is presented [*see Figure 1*].

Endocrine Therapy

Factors that support the use of hormone therapy are the expression of hormone receptors, a long disease-free interval, nonvisceral disease, and the absence of symptoms. Over half of the women who meet these criteria respond to their initial course of endocrine therapy. This response lasts for 9 to 12 months on average; the length of response is a predictor of the likelihood of response to a second course of hormone therapy when the first choice fails. A second course of hormone therapy is less likely to be effective, and the duration of response is shorter; again, the period of response provides an indication of the response to a third course of endocrine therapy. In this way, some women can receive serial endocrine therapy with good disease control for several years.

Numerous types of hormone therapy are now available. Surgical therapy (with the exception of oophorectomy) and first-generation therapies, such as high-dose estrogen, progesterone, and aminoglutethimide therapy, have been largely supplanted by agents with specific mechanisms of action, such as antiestrogens, aromatase inhibitors, and LHRH agonists. Selection is usually made on the basis of efficacy, menopausal status, and toxicity. An algorithm for the selection of endocrine therapy is presented [*see Figure 2*].

Several months of therapy are necessary before the efficacy of a newly introduced hormone regimen can be judged. In addition, hormone-related tumor flare—a syndrome of worsening symptoms and rising tumor markers occurring within the first weeks of treatment—may occur in a few patients. This paradoxical response is usually of short duration and should not be confused with disease progression.

Chemotherapy

Eventually, most women with breast cancer experience hormone-refractory disease and become candidates for chemotherapy. Serial chemotherapy is again the rule. Patients receive two to four cycles of therapy and are then evaluated for evidence of disease stabilization or improvement. Duration of therapy is not fixed. Several trials have compared the strategy of continuing therapy until time of disease progression with the strategy of employing several cycles of therapy followed by a cessation of therapy, with reintroduction of therapy at the time of disease progression.[71,72] In aggregate, these studies have shown survival to be the same with these two approaches, but quality of life as judged by the patients themselves is sometimes better with continuing therapy. Thus, decisions about continuation or termination of a particular therapy will be driven by patient and physician perception of side effects and benefits.

Several alternative first-line therapies now exist. Traditionally, AC, CAF, or CMF was used as initial chemotherapy, with a 40% to 80% response rate, depending on the characteristics of the patient. A meta-analysis of randomized trials suggests that anthracycline-containing regimens may be slightly more effective, but toxicity is also greater.[73] Combinations of taxanes and anthracycline result in response rates and durations that are at least as good as those seen with AC and CAF. Caution should be exercised about their continued use, however, because the doxorubicin-paclitaxel combination is associated with high rates of congestive heart failure. In addition, in a randomized trial, the use of paclitaxel alone and the use of CMF had similar response rates, response duration, and survival rates for women with newly diagnosed stage IV breast cancer.[74] Of note, patient-assessed quality-of-life scores improved during paclitaxel therapy but decreased during CMF therapy.

The scope of chemotherapy has changed dramatically over the past few years, with the availability of new agents such as paclitaxel, docetaxel, vinorelbine, capecitabine, gemcitabine, and carboplatin. All these agents are active individually and in combination. There is debate about the value of combination therapy compared with sequential single-agent therapy for metastatic breast cancer. The taxanes in particular have been shown to improve outcome for women with anthracycline-resistant breast cancer when compared with older regimens such as mitomycin and vinblastine therapy.[75] Thus, paclitaxel and docetaxel represent excellent choices for therapy in this setting. Trials evaluating their optimal dose and schedule of administration, as well as their relative efficacy, are in progress. As with hormone therapy, response rates and durations diminish with each successive change in therapy. A difficult question is when to stop chemotherapy altogether. Although no fixed rules exist, many patients and physicians opt for a program of supportive care if two successive chemotherapy regimens fail to elicit a tumor response or to delay tumor progression. A summary of newer agents available for the treatment of advanced breast cancer is provided [*see Table 8*]. As with early-stage breast cancer, the usefulness of high-dose chemotherapy combined with autologous bone marrow transplantation or stem cell support has not shown benefit and should be viewed as investigational.

Table 7 Guidelines for Surveillance of Asymptomatic Early Breast Cancer Survivors from the American Society of Clinical Oncology[69]

Recommended	Patient education about signs and symptoms of recurrence History and physical examination every 3–6 mo for first 3 yr, every 6–12 mo for next 2 yr, and annually thereafter Monthly breast self-examination Annual mammography Age-appropriate screening for other cancers
Not recommended	Complete blood count Automated chemistry panel Tumor markers (e.g., CEA, CA2729, CA15-3) Bone scan Chest x-ray CT of chest, abdomen, pelvis, and brain

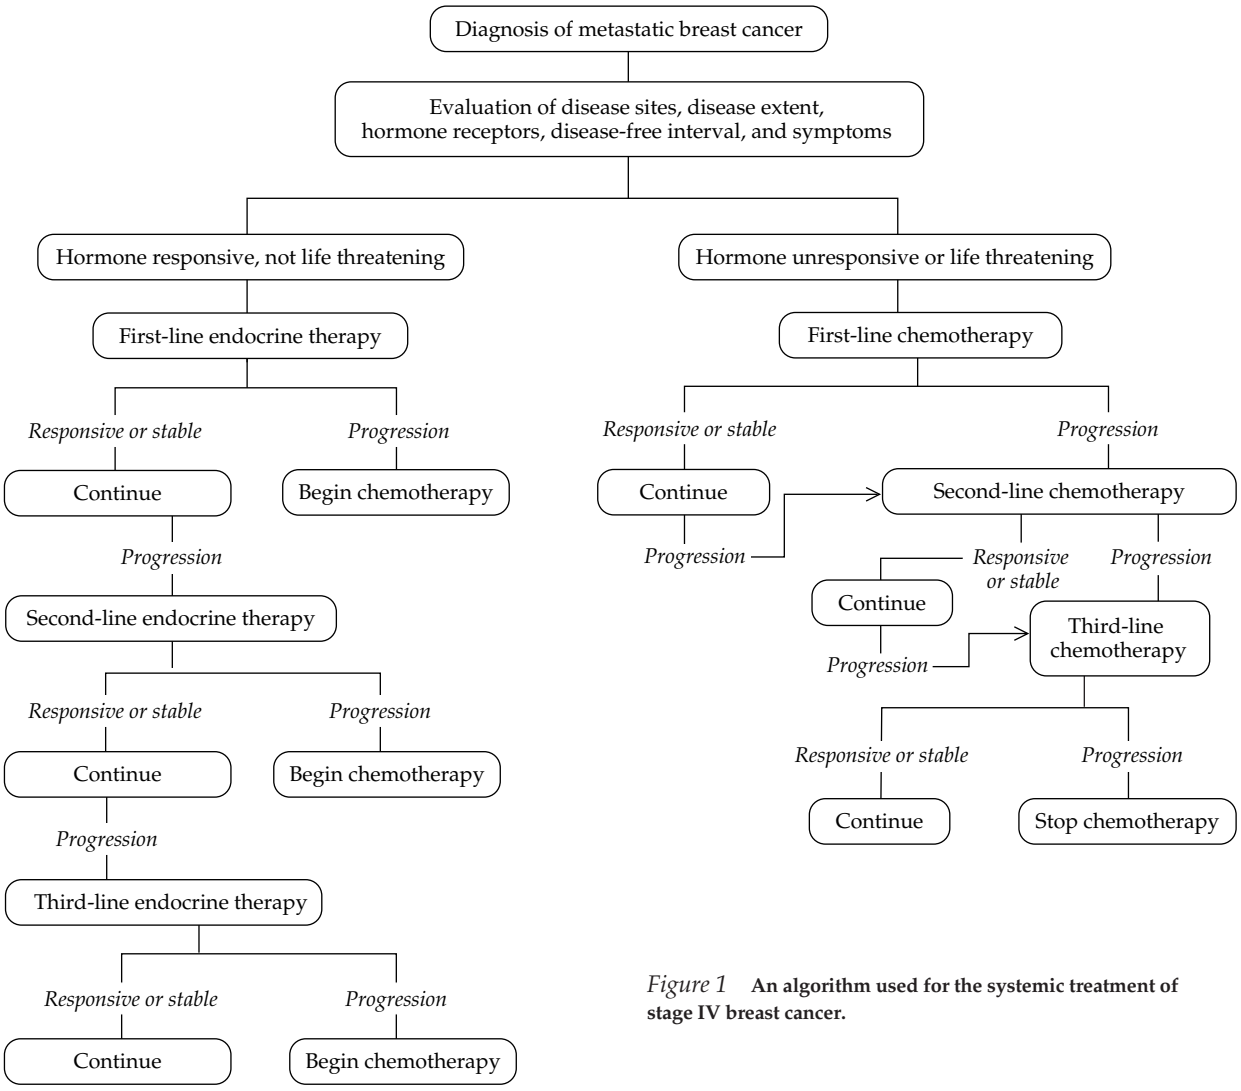

Figure 1 **An algorithm used for the systemic treatment of stage IV breast cancer.**

Biology-Based Therapy

An increased understanding of breast cancer biology has resulted in the identification of new targets for therapy. The first of these to be approved by the FDA is the monoclonal antibody trastuzumab (Herceptin), which is active against the transmembrane HER-2/neu protein. HER-2/neu protein is overexpressed in 20% to 30% of breast cancers; such overexpression may be associated with poorer prognosis and resistance to certain therapies. Weekly administration of trastuzumab resulted in partial or complete tumor regression in 15% of heavily pretreated women whose tumor overexpressed HER-2/neu[76] and in more than 30% of women with untreated HER-2/neu–overexpressing breast cancer.[77] Concomitant administration of trastuzumab with certain cytotoxic agents has also been tested. In a recent randomized trial, concurrent treatment with trastuzumab and paclitaxel increased response rate, response duration, and survival, compared with paclitaxel alone, for women with newly diagnosed metastatic breast cancer.[78] These promising results have led to four randomized trials that are testing the value of adjuvant use of trastuzumab in chemotherapy regimens. Trastuzumab also enhanced the antitumor effects of AC chemotherapy, but the combination was associated with a 20% incidence of congestive heart failure. This unexpected finding highlights the need for careful evaluation of new biology-based therapies as they are introduced into the clinic.

Other molecular targets under investigation include the epidermal growth factor receptor. One such agent is gefitinib, a small molecule that targets the epidermal growth factor receptor tyrosinase kinase. Initial studies of gefitinib in women with very advanced breast cancer showed little activity; however, this agent is the subject of ongoing study. In particular, preclinical models suggest that gefitinib may be useful in subverting some types of hormone resistance. Molecules that might block tumor angiogenesis are also under investigation. One such agent is bevacizumab, a monoclonal antibody that targets vascular endothelial growth factor; this agent has modest activity as a single agent in advanced breast cancer, and its use with chemotherapy is being explored.[79] Finally, new selective estrogen receptor modulators and pure antiestrogens are in development. The drug fulvestrant, which downregulates ER expression, is now being used in clinical practice. The effects of fulvestrant appear to be similar to those of anastrozole for postmenopausal women with advanced breast cancer who have previously received tamoxifen.[80]

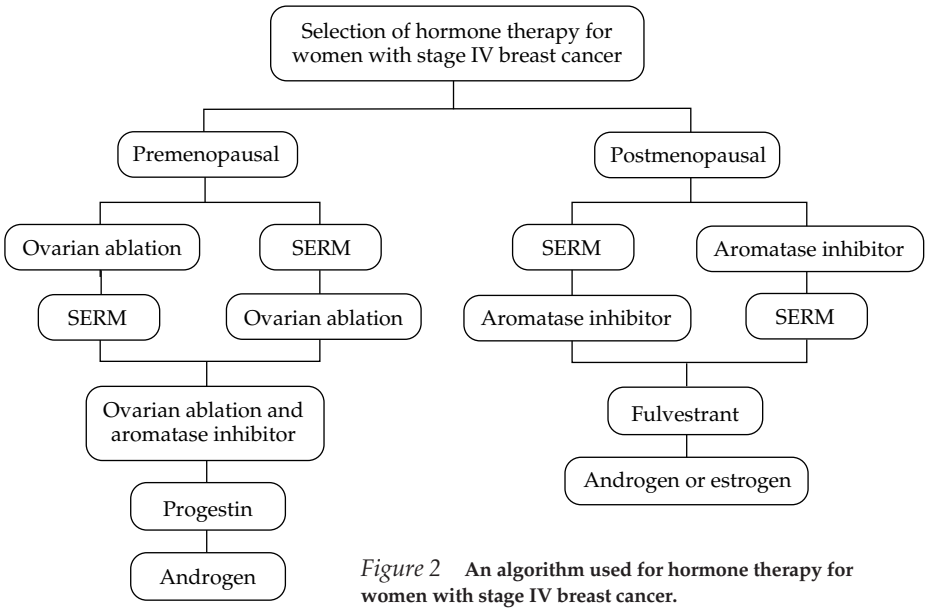

Figure 2 **An algorithm used for hormone therapy for women with stage IV breast cancer.**

Supportive Care

Because palliation of symptoms and prevention of disease complications are the primary goals of treatment of stage IV breast cancer, meticulous attention to supportive care is critical. Bone is the most common site of metastasis in breast cancer, and bony involvement can lead to significant morbidity. Several trials have demonstrated that regular administration of a bisphosphonate (zolendronate, pamidronate, or clodronate), in addition to hormone therapy or chemotherapy, can reduce pain and lower the incidence of several types of bony complications. These findings are derived from the ability of this class of drugs to inhibit osteoclast activity rather than from a specific antineoplastic effect. Thus, the FDA has approved the use of zolendronate and pamidronate as adjunctive therapy for women with lytic bony metastasis from breast cancer. A number of issues remain unanswered, including the optimal treatment interval and duration of therapy. Small trials have raised the possibility that clodronate may help prevent or delay the development of metastasis in women with early-stage breast cancer; randomized adjuvant trials are testing this possibility. Currently, evidence-based guidelines from the American Society of Clinical Oncology suggest that bisphosphonates be used only as part of a palliative program for women with metastatic bone disease.[81] Cardiotoxicity of doxorubicin may be reduced through the use of the cardioprotective agent dexrazoxane[82] or liposomal preparations. Judicious application of colony-stimulating factors or erythropoietin may help diminish symptoms of chemotherapy-related bone marrow hypoplasia. Whether these strategies are superior to reduction in chemotherapy dose or red blood cell transfusion remains to be determined. Adequate pain control should now be achievable in most patients through the use of sustained-release oral and transdermal narcotic preparations. Excellent antiemetics, such as the serotonin receptor inhibitors and a neurokinin-1 antagonist, are available to reduce chemotherapy-related emesis. Skillful application of these measures is critical in reducing morbidity from disease and its treatment.

Table 8 Newer Agents for Metastatic Breast Cancer Commercially Available in the United States[3]

Drug	*Category*	*Response Rate (%)*
Hormonal		
Toremifene (Fareston)	SERM	19–54
Anastrozole (Arimidex)	Aromatase inhibitor	12–39
Letrozole (Femara)	Aromatase inhibitor	12–39
Exemestane (Aromasin)	Aromatase inhibitor	44
Fulvestrant (Faslodex)	SERM	20
Cytotoxic		
Docetaxel (Taxotere)	Taxane	13–68
Paclitaxel (Taxol)	Taxane	13–68
Vinorelbine (Navelbine)	Vinca alkaloid	18–52
Capecitabine (Xeloda)	Thymidylate synthase inhibitor	20–36
Gemcitabine (Gemzar)	Purine analogue	25–46
Monoclonal antibody		
Trastuzumab (Herceptin)	Anti-HER-2	15–35

SERM—selective estrogen-receptor modulator

The author serves on the speaker board of AstraZeneca and is a member of the Data and Safety Monitoring Board for Eli Lilly and Company.

The drugs exemestane, letrozole, goserelin, leuprolide, and gefitinib have not been approved by the FDA for uses described in this chapter.

VIII LUNG CANCER

Jeffrey Crawford, m.d.

Definition and Classifications

Bronchogenic carcinoma of the lung—lung cancer—comprises a group of malignant neoplasms that arise from bronchial epithelium. The four major pathologic cell types of lung cancer are small cell carcinoma, adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. Because they have overlapping clinical behavior and response to treatment, adenocarcinoma, squamous cell carcinoma, and large cell carcinoma are generally grouped together in the category of non–small cell lung cancer (NSCLC). NSCLC represents 75% to 80% of all cases of lung cancer. Classification systems for the four major types of lung cancer have been formulated by the World Health Organization, the Armed Forces Institute of Pathology, and the Working Party for Lung Cancer [*see Table 1*].

Epidemiology and Etiology

In the United States, lung cancer is the second most common cancer in both men and women, surpassed only by prostate cancer in men and breast cancer in women. For 2003, a total of 169,400 new cases were predicted [*see Table* 2]. Lung cancer was expected to constitute 14% of all cancer diagnoses in men and 12% of those in women. However, lung cancer is the leading cause of cancer deaths, accounting for 31% and 25% of all cancer-related deaths in men and women, respectively. For 2003, expected deaths from lung cancer were 154,900 [*see Table 2*].[1]

The epidemiology of lung cancer in the United States directly reflects patterns in cigarette smoking, albeit with a 10- to 15-year lag time.[2] Over recent decades, the prevalence of cigarette smoking in men has decreased from nearly 50% to approximately 25%, and the incidence of lung cancer in men has declined somewhat. During that same period, the prevalence of cigarette smoking in women has declined only 11%, to approximately 22%, and the incidence of lung cancer in women is only now leveling off.

In men, the incidence of lung cancer peaked in 1984, at 86.5 per 100,000 population, and by 1996 had declined to 70 per 100,000 population. For women, the incidence in 1996 was 42.3 per 100,000 population. Since 1987, more women have died each year from lung cancer than from breast cancer, and the margin between the two diseases continues to widen. Estimates suggest that in 2003, over 50% more women died of lung cancer than of breast cancer.[1]

Unfortunately, cigarette smoking became increasingly popular in teenagers in the 1990s. In the United States, the prevalence of cigarette smoking in high-school students increased during the 1990s, peaking during 1996 to 1997, then began a gradual decline.[3] The popularity of smoking varied by ethnicity and race. In a 1999 survey of high-school students, smoking rates were 15.8% in blacks, 25.8% in Hispanics, and 32.8% in whites.[4]

smoking cessation and lung cancer

Cigarette smoking continues to contribute to the risk of lung cancer long after a person has stopped smoking. The American Cancer Society evaluated this relationship in a 6-year prospective study involving more than 900,000 persons.[5] This study included persons who had never smoked, current smokers, and former smokers. As expected, the risk of dying of lung cancer was lower in patients who had quit smoking early in life than in those who quit later on, and the risk was significantly lower in those who quit than in those who did not. In a person who smoked 26 cigarettes a day starting at 17 years of age and stopped smoking between the ages of 30 and 49, the risk of death from lung cancer is slightly greater than that for persons who never smoked. For a person quitting smoking between the ages of 50 and 64, the risk of death from lung cancer plateaus at the risk level at the time of quitting and remains level until about the age of 75, when the risk appears to increase further. In this model, the annual lung cancer mortality for current smokers at age 75 is 1% for men and 0.5% for women, which is approximately 20 times higher than that of nonsmokers. Nonsmokers (i.e., persons with a lifetime exposure of less than 100 cigarettes) have a rela-

Table 1 Major Classifications of Lung Cancer

System	*Non–Small Cell Lung Cancer*			*Small Cell† Cancer*
	Squamous Cell Carcinoma*	*Adenocarcinoma*	*Large Cell Carcinoma*	
World Health Organization, No. 2 (WHO–No. 2)	Spindle cell variant	Acinar Papillary Bronchioloalveolar Solid carcinoma with mucin	Giant cell Clear cell	Oat cell Intermediate cell Combined
Armed Forces Institute of Pathology (AFIP)	Well differentiated Moderately differentiated Poorly differentiated	Well differentiated Moderately differentiated Poorly differentiated Bronchioloalveolar	Undifferentiated Giant cell Clear cell	Lymphocyte-like (oat cell) Polygonal (intermediate) Combined (usually squamous)
Working Party for Lung Cancer (WPLC)	Well differentiated Moderately differentiated Poorly differentiated	Well differentiated Moderately differentiated Poorly differentiated Bronchioloalveolar/papillary	With mucin production With stratification Giant cell Clear cell	Lymphocyte-like (oat cell) Intermediate cells (fusiform, polygonal, others)

Note: both the WHO–No. 2 and AFIP systems have a fifth category, adenosquamous cell carcinoma; benign lesions, dysplasia, carcinoma in situ, carcinoid tumors, soft tissue sarcomas, and other respiratory tract lesions, which account for only a few percent of all lung cancers, are not included in this table.
*For the WPLC system, the classification is epidermoid.
†For the WPLC system, the classification is small cell anaplastic.

Table 2 Epidemiology of Lung Cancer in the United States, 2003[1]

	New Cases	*Deaths*
Men	90,200	89,200
Women	79,200	65,700
Total	169,400	154,900

tive risk of lung cancer of 0.05 or less as compared with current smokers. For former smokers, the relative risk of lung cancer death depends on the age of smoking cessation. The risk was 0.45 for smokers who quit in their early 60s, 0.2 for those who stopped smoking in their early 50s, and 0.1 for those who stopped smoking in their 30s. All available data indicate that the lung cancer risk for former smokers is still consistently greater than for those who never smoked. Stopping smoking at any age can reduce lung cancer mortality, but the risk reduction is much greater for smokers who quit at a younger age.

In addition to age effects, there is a dose-response relationship for smoking and lung cancer. The risk for lung cancer increases with the duration of smoking and the number of cigarettes smoked. Earlier age of starting to smoke, deeper inhalation, and use of cigarettes that are unfiltered or have a high tar and nicotine content also increase the risk of lung cancer. In the current United States population over the age of 50, 23% are current smokers and 35% are former smokers. Because both groups remain at elevated risk for lung cancer for their lifetimes, clinicians should take an accurate quantitative smoking history in all patients.

GENETIC SUSCEPTIBILITY AND MOLECULAR MECHANISMS

The risk of lung cancer is affected by genetic susceptibility. Women smokers may be at higher risk for the development of lung cancer than men with a similar smoking history. Furthermore, lung cancer mortality appears to be higher in African Americans.

Mechanisms for genetic susceptibility to lung cancer include genes that govern smoking behavior, which affect dopamine reward mechanisms related to nicotine and nicotine metabolism, as well as gender[6]; individual capacity for carcinogen metabolism; germline mutations coding for dysfunctional genes; and capacity to repair DNA damage from carcinogens. Several genetic abnormalities have been associated with lung cancers [*see Table 3*].

LUNG CANCER IN NONSMOKERS

Given the dominant role of cigarette smoking in the etiology of lung cancer, determining the risk posed by other substances is difficult.[7] As many as 25% of cases of lung cancer in nonsmokers may result from second-hand tobacco smoke. A small percentage of lung cancers result from occupational exposure to carcinogens, including asbestos, arsenic, cadmium, chromium, radiation, radon, and chemicals such as chromoethyl ether. Heavy residential exposure to radon may be synergistic with cigarette smoking in promoting lung cancer, but the risk from residential radon for nonsmokers remains unclear.[8]

Pathophysiology and Pathogenesis

The prevalences of histologic subtypes of lung cancer in men and women have changed in ways that mirror the changes in smoking habits. In the early studies that established the association between smoking and lung cancer, cigarettes were unfiltered, most of the participants were men, and squamous cell carcinoma was the most common cell type. Now, with filtered cigarettes widely popular and larger numbers of women smoking, adenocarcinoma is the most common type of lung cancer in both young men and women. This changing pattern of histology correlates temporally with the change from unfiltered to filtered cigarettes and with reductions in the tar and nicotine content of cigarettes. Those changes in cigarette manufacturing have led to deeper inhalation of smoke into the lungs, which exposes the distal airways more heavily to the carcinogenic influences of tobacco smoke. Other factors likely play a part as well. In nonsmokers, adenocarcinomas are the most common histologic type of lung cancer.

The initiation of carcinogenesis from cigarette smoke is related to a complex mixture of carcinogens and tumor promoters combined with the delivery vehicle of inhalation. Serial studies of bronchial epithelium in smokers demonstrate an evolution from dysplasia to metaplasia to neoplastic changes.[9-12] Each stage has been associated with a number of genetic alterations, and the pivotal mechanisms are a topic of intense investigation. Factors associated with genetic susceptibility have yet to be identified and may emerge from studies of lung cancer in nonsmokers. Thus, the main clinical criterion for susceptibility remains a history of current or former smoking.

Table 3 Selected Molecular Genetic Abnormalities Associated with Lung Cancer

Abnormal Genes	*Mutation*	*Frequency of Abnormal Expression (%)*	
		NSCLC	*SCLC*
Oncogenes			
K-*ras*	Point mutation (codon 12)	30	Not reported
myc family	DNA amplification/overexpression	10	10–40
HER-2/*neu*	Increased expression of p185*neu*	25	Not reported
Tumor suppressor genes			
p53	Deletion Point mutation Overexpression	50	80
Rb	Deletion	15	> 90
3p	Deletion	50	90

NSCLC—non–small cell lung cancer SCLC—small cell lung cancer

Prevention

PRIMARY PREVENTION

Given that 87% of cases of lung cancer occur in smokers and that the risk of lung cancer is lower by at least 20-fold in persons who have never smoked, the obvious strategy for primary prevention is to keep young persons from starting to smoke and to promote smoking cessation in smokers of all ages [*see CE:III Reducing Risk of Injury and Disease*]. Although public health measures that discourage smoking in public places and in the workplace, as well as the development of negative societal attitudes toward smoking, are helpful in reducing the prevalence of smoking in adults, progress against smoking has been slow and teenage smoking rates remain unacceptably high.

SECONDARY PREVENTION

The use of nutritional supplements by smokers as a strategy to reduce lung cancer was suggested by an epidemiologic association of lower serum levels of β-carotene, vitamin E, and retinoids with a higher risk of lung cancer.[13] Unfortunately, in clinical trials, these agents did not reduce lung cancer risk.

One of the best known trials, the CARET (β-Carotene and Retinol Efficacy Trial), comprised over 18,000 smokers of both sexes randomized to receive a retinoid drug, retinol palmitate, in combination with β-carotene or placebo.[14] In this trial, patients who received β-carotene and retinol palmitate had a higher rate of development of lung cancer (relative risk = 1.36) and higher lung cancer mortality (relative risk = 1.59). In another placebo-controlled trial, from Finland, that studied the effects of vitamin E and β-carotene, smokers who received β-carotene were more likely to develop lung cancer (relative risk = 1.16). Vitamin E produced no effect. The risk of harm from β-carotene in this trial was more pronounced in heavy smokers. In a placebo-controlled trial in patients with resected stage I NSCLC, the use of 13-*cis*-retinoic acid increased the rate of lung cancer recurrence and mortality in patients who continued to smoke. Thus, at present, no evidence supports recommending vitamins to prevent lung cancer, and there is some evidence that β-carotene and retinoids may have harmful effects in smokers, as well as in persons with occupational exposure to asbestos.[15]

Diagnosis

SCREENING

Most patients with lung cancer present with advanced inoperable disease. Screening for detection of lung cancer at an earlier stage is therefore an attractive idea, especially because persons at high risk for lung cancer can be readily identified by a smoking history.

Early studies of screening produced disappointing results. Randomized trials of screening, conducted in the United States and in the former Czechoslovakia, suggested that chest x-ray alone was not a satisfactory screening tool to detect early lung cancer tumors.[16] Curable tumors are often too small or indistinct to be detected on a standard chest x-ray.

Spiral CT scanning may be a more sensitive technique for lung cancer screening. With this technique, radiologists obtain a low-resolution image of the entire thorax in a single breathhold, with low radiation exposure and relatively rapid throughput compared with standard CT scans. A number of studies have demonstrated the feasibility of spiral CT scanning in screening for lung cancer. In the Early Lung Cancer Action Project (ELCAP), 1,000 asymptomatic persons older than 60 years with a smoking history of 10 or more pack-years underwent both spiral CT and chest x-ray.[17] CT detected malignant nodules in 2.7% of the patients, compared with 0.6% by chest x-ray. Benign nodules were detected at a rate of 20.6% by CT versus 6.1% by chest x-ray, so careful follow-up is critical for avoiding unnecessary biopsy. A Mayo Clinic study of spiral CT[18] also demonstrated enhanced detection of malignant nodules, most of which were early-stage lung cancer, but an even higher yield of benign nodules (60%), which emphasizes the potential drawback of this technique.

At present, no data from randomized trials exist to allow an evidence-based recommendation either for or against lung cancer screening. Despite encouraging results from nonrandomized trials, several issues remain to be addressed, including lead-time bias, generalization to a broader population, application to younger patients at lower risk of lung cancer, and long-term benefit in terms of lower lung cancer mortality. Furthermore, a decision and cost-effectiveness analysis has suggested that the cost of implementing such a strategy would be substantial.[19] Currently, spiral CT screening cannot be recommended except in the context of a clinical trial. Other new technologies that deserve consideration as potential screening methods include analysis of sputum cytology by molecular markers and localization of tumors by fluorescence bronchoscopy.[20]

The National Cancer Institute is currently enrolling patients in the National Lung Screening Trial (NLST), a randomized, controlled trial that will compare standard chest x-rays with spiral CT as a screening method for lung cancer.[21] The NLST will enroll 50,000 current or former smokers between the ages of 55 and 74 years at clinical trial sites throughout the United States. Study participants will receive either a chest x-ray or a spiral CT once a year for 3 years and will then undergo monitoring until 2009. The researchers will be looking for a reduction in mortality of 20% or more with either modality. In addition to the screenings, some NLST centers will test for biologic markers that may have potential for screening.

CLINICAL MANIFESTATIONS AND LABORATORY STUDIES

The signs and symptoms of lung cancer vary with the anatomic location of the tumor, its extension into surrounding structures, metastatic spread, and the systemic effects of paraneoplastic syndromes. Unfortunately, only 6% of patients with lung cancer are asymptomatic at the time of diagnosis. The remainder of the patients present with symptoms resulting from regional spread of the tumor, mediastinal lymph node involvement, or distant metastases.

Pulmonary Manifestations

The most common manifestation of the primary tumor is cough, which results from endobronchial erosion and irritation. Others are, in decreasing order of frequency, dyspnea, chest pain, hemoptysis, and postobstructive pneumonia or pneumonitis [*see Table 4*]. Centrally located tumors also typically cause stridor, wheezing, hemoptysis, dyspnea, or chest pain, often central in location. Occlusion of the airway by a tumor can lead to a postobstructive infiltrate or pneumonia. Large tumors may cavitate and present as a lung abscess.

Manifestations of Intrathoracic Disease

Intrathoracic extension of the tumor or spread to mediastinal

Table 4 Common Signs and Symptoms of Lung Cancer at Diagnosis

Site of Tumor Involvement	*Signs or Symptoms*	*Percentage of Patients Affected*
Pulmonary	Cough	50–75
	Dyspnea	30–40
	Chest pain	25–40
	Hemoptysis	15–30
	Pneumonia/pneumonitis	10–25
Intrathoracic	Hoarseness	< 10
	Dysphagia	< 10
	Facial/arm swelling	< 10
	Shoulder/arm pain	< 10
	Pleural/chest wall pain	< 10
	Pleural/pericardial effusion	< 10
	Paraneoplastic syndromes	< 10
Extrathoracic	Anorexia/weight loss	30–50
	Generalized weakness	20–40
	Bone pain	20–30
	Liver abnormalities	10–20
	Headache/CNS abnormalities	5–15
	Flank pain	< 10
	Other (e.g., subcutaneous nodule, distant lymph nodes)	< 10

lymph nodes may produce a variety of symptoms [*see Table 4*]. Although individually these symptoms occur in fewer than 10% of patients with lung cancer, collectively they represent significant complications of locally advanced NSCLC, either at diagnosis or during the subsequent disease course. Hoarseness may result from invasion of the recurrent laryngeal nerve and resultant vocal cord paralysis. Dysphagia may be a sign of compression of the esophagus. Extensive tumor involvement of the right mediastinal lymph nodes often results in the superior vena cava syndrome, which is characterized by plethoric appearance; distention of the venous drainage of the arm and neck; and edema of the face, neck, and arms. Vena caval obstruction usually progresses gradually, allowing the development of collateral venous drainage that may be detected on physical examination.

Shoulder and arm pain from superior sulcus (Pancoast) tumor syndrome is a commonly misdiagnosed sign of lung cancer. The pain results from local extension of a tumor in the apex of the lung, with involvement of the eighth cervical and first thoracic nerves. Unfortunately, this condition is often mistaken for arthritis. In many cases, careful physical examination will identify ipsilateral Horner syndrome, which is characterized by ptosis, meiosis, and anhydrosis. The Horner syndrome is related to paravertebral extension and sympathetic nerve involvement of the tumors.

Pleuritic pain and chest wall pain occur most commonly in patients with primary tumors in the lung periphery that spread to the pleura and, in some cases, extend directly to the chest wall. Associated pleural effusion may occur in such cases; large effusions may cause dyspnea. Malignant pericardial effusions may also develop and can cause cardiac tamponade.

Paraneoplastic syndromes A minority of lung cancer patients present with paraneoplastic manifestations. The biology of these syndromes remains poorly characterized, but the syndromes appear to be cytokine-mediated responses to antigens from the intrathoracic lung tumor, rather than the result of distant spread of cancer.

The most common paraneoplastic feature associated with lung cancer is clubbing of the fingers from periosteal swelling of the distal phalanges, which may occur in 5% to 15% of patients. In a small percentage of patients, clubbing may be part of a symptomatic hypertrophic osteoarthropathy. These patients often complain of a distal symmetrical arthritis that most commonly involves the ankles or knees but can also involve the wrists, elbows, and other joints. Misdiagnosis of this condition as a strictly rheumatologic phenomenon often results in delayed recognition of the underlying neoplasm.

Although weight loss and fatigue are commonly an indication of distant metastasis, they can also represent a paraneoplastic phenomenon that occasionally occurs even with early-stage tumors. Especially in patients with small cell lung cancer (SCLC), paraneoplastic manifestations can also take the form of specific neurologic syndromes, such as the Lambert-Eaton syndrome. These patients present with muscle weakness, a variety of peripheral neuropathies, and central nervous system involvement such as subacute cerebellar degeneration or limbic encephalitis.

Another category of neoplastic syndromes relates to aberrant hormone or peptide production by lung cancer tumor cells. The most common of these is hyponatremia secondary to production of antidiuretic hormone (SIADH). Hypercalcemia can result from tumors that secrete parathyroid hormone; and Cushing syndrome, from tumors that secrete adrenocorticotropic hormone. In general, these hormonal syndromes are more common in SCLC than in NSCLC, because of the neuroendocrine nature of SCLC. However, hypercalcemia can have a range of causes—including both remote effects and direct interactions between tumor and bone—and is much more common in NSCLC than in SCLC.

Manifestations of Extrathoracic Disease

Extrathoracic manifestations of lung cancer relate to the extent and site of distant spread [*see Table 4*]. The most common of these are anorexia, weight loss, and fatigue. Bone pain commonly accompanies metastasis to bone, but with the increased use of imaging, asymptomatic bony metastases are commonly found. Liver abnormalities may be detected on clinical examination or on laboratory or imaging studies, but they are generally asymptomatic. The frequency of CNS involvement varies with the extent of other known disease, with a low incidence in patients who have no nodal spread of cancer. However, in patients with other signs of mediastinal or distant involvement, the incidence of occult brain metastases is in the range of 5% to 15%, even in NSCLC.

Occasionally, flank pain will be a presenting feature of adrenal metastases. Although flank pain occurs in fewer than 10% of patients, the adrenal gland is the most frequent site of distant metastatic spread of lung cancer, as detected by CT imaging. Adrenal insufficiency is an unusual but potentially fatal complication of adrenal metastasis from lung cancer, and it is often overlooked because the weight loss and fatigue it causes are common features in lung cancer patients. In selected cases, an adrenal stimulation test may identify patients with limited reserve who may benefit from steroid-replacement therapy.

Patients who have bronchial carcinoid tumors metastatic to liver or other sites may experience the carcinoid syndrome. This dramatic but rare syndrome is characterized by episodic

Table 5 Common Causes of a Solitary Pulmonary Nodule

flushing that may be associated with abdominal pain, diarrhea, and wheezing.

CLINICAL STAGING

When the results of the clinical examination and chest x-ray indicate early-stage lung cancer, imaging studies may be limited to a chest CT. However, in patients who have clinical, laboratory, or radiologic signs of regional tumor spread, a search for occult bone and CNS metastases is warranted. For patients with suspected metastatic disease, the standard imaging evaluation should include a chest CT with images through the adrenal glands, a bone scan, and a CT or MRI scan of the brain.

The role of PET scanning in the evaluation of lung cancer patients is currently under study. F-18 fluorodeoxyglucose (FDG) uptake is greater in malignant cells than in normal, benign cells. Several series have suggested that FDG-PET imaging can be very useful in determining whether abnormalities seen on CT—particularly in the adrenal gland and bone—likely represent metastatic disease.[22] The sensitivity and specificity for mediastinal lymph node metastases is still being clarified. PET scans are also useful for evaluation of solitary pulmonary nodules, with a sensitivity of 90% to 95% and specificity of 80% to 100% for the detection of cancer. Because PET imaging can detect unsuspected metastatic disease in 11% to 14% of patients and thus help avoid futile surgery in these cases, Medicare in the United States provides coverage for FDG-PET for the staging of NSCLC.[23] Meanwhile, PET technology is evolving rapidly, improving its sensitivity for the detection of smaller lesions. Although PET scanning can detect lesions between 0.5 and 1.0 cm, most series have limited the analysis to lesions greater than 1.0 cm. In addition, techniques that incorporate simultaneous CT and PET image analysis are currently being developed.

The diagnostic approach used to confirm the presence of lung cancer and determine the subtype depends on the clinical stage at presentation. In patients with advanced disease, a needle biopsy of a metastatic site (e.g., liver, bone, or a subcutaneous nodule) is often the best choice, providing both confirmation of the diagnosis and identification of the disease stage. In patients with no extrathoracic signs of cancer, the choice of initial diagnostic procedure often depends on whether the patient is likely to be a candidate for surgery. For the surgical population, the primary diagnostic procedure in most patients should be a bronchoscopy and mediastinoscopy by the thoracic surgeon, to determine the type and stage of cancer with respect to mediastinal lymph node involvement, as well as to determine resectability. For patients with more peripheral lung masses or solitary pulmonary nodules, the procedure of choice for confirming the presence of cancer and the prospects for definitive surgery is an initial needle biopsy performed under radiologic guidance or resection by video-assisted thoracoscopic surgery (VATS). In patients with solitary pulmonary nodules, biopsy may show that the cause is not cancer but rather a benign tumor or an inflammatory, infectious, or congenital disorder [*see Table 5*].

For patients who have evidence of bulky intrathoracic disease but who are not likely to be surgical candidates, the preferred method of evaluation is bronchoscopy. During the bronchoscopy, the surgeon may perform brushings, washings, or transbronchial biopsies of the primary lesion or any associated central mediastinal lymph nodes.

Patients presenting with pleural effusions can be evaluated by diagnostic thoracentesis. In some cases, VATS can provide both definitive diagnosis and management of pleural effusions.

In addition to the clinical stage, the so-called physiologic stage of the patient is also important for determining which diagnostic strategy is best. In patients who are not candidates for surgery because of constraints such as severe comorbid disease or limited pulmonary reserve, transthoracic needle biopsy or bronchoscopy alone may suffice.

Improvements in needle-biopsy techniques have reduced the complications of these procedures, and improvements in cytology have enhanced its diagnostic power. Although these cytologic exams often cannot differentiate subtypes of NSCLC, they are 95% accurate in distinguishing SCLC from NSCLC. Definitive staging is particularly important in patients with NSCLC because of the evolution in treatment strategies for both operable (stage I to IIIA) and inoperable (stage IIIB) cases. Definitive surgical staging with bronchoscopy and mediastinoscopy remains the preferred approach for most patients with apparent early-stage lung cancer who would be candidates for surgery. If cervical mediastinoscopy is performed, nodal sampling should include the upper paratracheal (level 2), lower paratracheal (level 4), and subcarinal (level 7) stations [*see* Surgical Staging, *below*]. For patients with a left upper lobe tumor, an anterior mediastinal approach may also be indicated to sample the AP window lymph nodes (level 5).

SURGICAL STAGING

Cancer stage is by far the most important prognostic factor in lung cancer. Histology (i.e., SCLC versus NSCLC) may influence choice of treatment options. Survival rates for patients with the same stage of lung cancer are quite similar, regardless of whether they have SCLC or NSCLC. Other characteristics that can affect outcome are patient characteristics such as performance status, recent weight loss, and significant comorbid conditions. In addition, studies suggest that stage for stage, outcome with both SCLC and NSCLC is better for women than

for men. As with other cancers, advanced age may have an adverse effect on outcome, but age per se seems to be less important than the comorbid conditions that are more common in the elderly.

Staging of lung cancer is by the TNM (tumor, node, metastases) classification [*see Figure 1*].[24,25] It is based on the size, location, and regional extension of the primary tumor; on the location of regional malignant lymph nodes that drain the region; and on the absence or presence of distant metastases. T1 and T2 tumors are operable tumors differentiated predominantly by size. T1 tumors are 3 cm or less in their greatest dimension, surrounded by lung or visceral pleura, and without bronchoscopic evidence of invasion more proximal than the lobar bronchus. T2 tumors have any one of the following characteristics: size greater than 3 cm, main bronchus involvement, location 2 cm or more distal to the carina, invasion of the visceral pleura, or association with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung.

T3 tumors are tumors of any size that directly invade the chest wall, diaphragm, mediastinal pleura, parietal pleura, or pericardium; are located in the main bronchus less than 2 cm distal to the carina but do not involve the carina; or are associated with atelectasis or obstructive pneumonitis of the entire lung. T3 tumors can be considered marginally operable but require a more extensive operation that may involve removal of the chest wall or pericardium or, for more proximal tumors, a sleeve resection.

T4 tumors are grossly inoperable because they invade the mediastinum, heart, great vessels, trachea, esophagus, a vertebral body, or the carina. Tumors are also classified as T4 if they are associated with a malignant pleural or pericardial effusion or with satellite tumor nodules within the same lobe as the primary tumor.

Lymph node status is determined as N0 (no lymph node involvement), N1 (metastases to the lymph nodes within the confines of the lung), and N2 or N3 (extrapulmonary metastases). N2 represents involvement of ipsilateral mediastinal lymph nodes, whereas N3 represents involvement of contralateral lymph nodes or more distant nodes, including hilar or supraclavicular nodes.

N1 and N2 nodes are further denoted by specific location (station) [*see Figure 2*].[26] Other than level-10 hilar nodes, which may be enlarged on CT, N1 nodal involvement is generally not suspected until it is discovered at the time of surgery. Although N2 and N3 nodes can be suspiciously enlarged on CT, 40% of nodes greater than 2 cm are enlarged because of inflammation, and 10% of normal-sized nodes contain malignancy. Thus, mediastinoscopy is essential for providing pathologic definition of nodal involvement so that treatment options can be finalized.

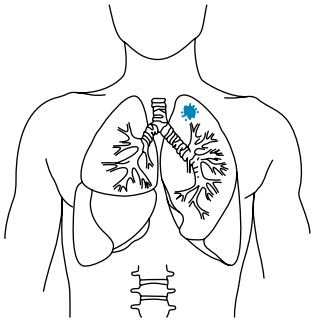
Treatment

NSCLC

The treatment of NSCLC is based on the stage of disease, as determined by the TNM staging system. For stage I or stage II disease, surgical resection is the standard treatment. Stage III disease is treated with definitive radiation therapy and chemotherapy; in addition, a subset of patients with stage IIIA disease have been shown to have improved outcome with the addition of sur-

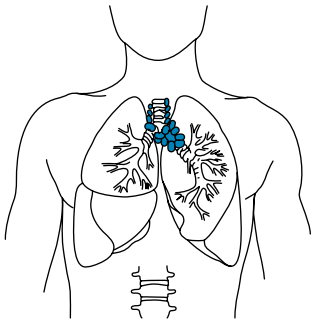
Tumor (T)

T1 ≤ 3 cm
T2 > 3 cm; visceral pleura invasion
T3 Direct extension to chest wall, mediastinal pleura, or pericardium
T4 Malignant pleural effusion, superior vena cava syndrome, or involvement of the heart, great vessels, trachea, esophagus, or vertebral bodies



Nodes (N)

N0 Negative regional lymph nodes
N1 Peribronchial or ipsilateral hilar nodes
N2 Ipsilateral mediastinal nodes
N3 Contralateral hilar mediastinal nodes; any supraclavicular nodes



Metastasis (M)

M0 No distant metastases
M1 Distant metastases

gical resection. Stage IV disease is treated with chemotherapy, palliative radiation, and supportive care [*see Table 6*].

Stages I and II Disease

Surgery Before a patient with stage I or II lung cancer undergoes surgery, the physician must undertake a determination of operability, which includes assessment of the medical risk of thoracotomy, as well as the risk of removal of the requisite pulmonary parenchyma. Cardiopulmonary disease, which is usually a consequence of tobacco use, is the major cause of postoperative morbidity and mortality in patients with stage I or II disease and, consequently, is the most significant medical factor in determining operability.

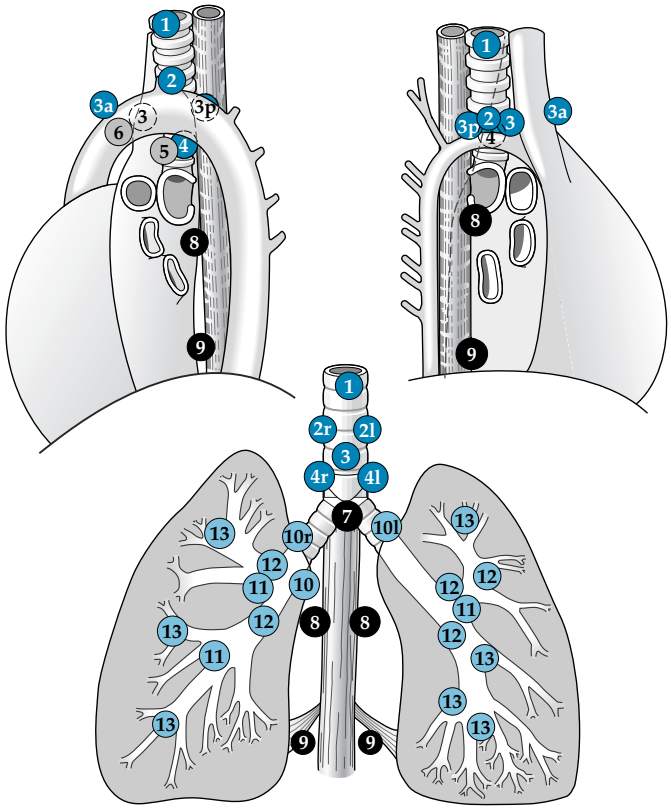
Pulmonary function testing and arterial blood gas analysis are used to determine the feasibility of pulmonary resection. Postoperative pulmonary function is estimated on the basis of the patient's preoperative function and the projected resection of pulmonary parenchyma. Resection is generally contraindicated when the predicted postoperative forced expiratory volume at 1 second (FEV_1) and forced vital capacity are less than 30% of predicted values. In patients with marginal results on preoperative pulmonary function studies, ventilation-perfusion scanning may be required to determine resectability. Postoperative FEV_1 may be predicted after assessing the contribution to overall pulmonary function made by each lung and by specific pulmonary segments.

In patients who have a history of angina or whose preoperative electrocardiogram shows ischemia or arrhythmia, radionuclide evaluation of myocardial perfusion or function is indicated. Normal results with these studies reliably exclude significant coronary artery disease; patients with positive results should undergo coronary arteriography. Recent myocardial infarction, uncontrolled heart failure, or uncontrollable arrhythmia precludes thoracotomy for pulmonary resection.

The final determination of resectability is made at thoracotomy. Contraindications to pulmonary resection at the time of thoracotomy include pleural metastases, extensive mediastinal lymph node involvement (N3 disease), or direct extension of the tumor to critical structures (T4 disease). In addition, pulmonary resection is aborted if the extent of resection required would leave the patient with inadequate pulmonary reserve, as determined by preoperative pulmonary function studies.

Four main oncologic principles guide resection for lung cancer: (1) removal of the entire tumor with an anatomically complete portion of lung (lobectomy or pneumonectomy), to ensure removal of all intraparenchymal lymphatic drainage; (2) en bloc resection of adjacent structures, if technically possible, including the chest wall, diaphragm, and pericardium, without transgressing the tumor; (3) assessment of questionable resection margins by frozen-section analysis to optimize the potential for complete resection; and (4) sampling or complete dissection of all accessible mediastinal lymph nodes to improve staging.

In patients with small (< 3 cm) peripheral nodules and no mediastinal lymphadenopathy by CT criteria (i.e., no lymph nodes > 1 cm in diameter), the procedure of choice is lobectomy and mediastinal lymph node dissection. Less extensive resection, such as wedge resection or segmentectomy, has been shown to be associated with significantly greater risk of local recurrence and cancer-specific death.[27] In patients with T2 or T3 tumors or with mediastinal adenopathy on chest CT, cervical mediastinoscopy should be performed before exploration for pulmonary resection.



N2 Nodes

Superior Mediastinal Nodes
1. Highest mediastinal
2. Upper paratracheal (2r, 2l)
3. Pretracheal and retrotracheal (3a, 3p)
4. Lower paratracheal (including azygos nodes) (4r, 4l)

Anterior Mediastinal Aortic Nodes
5. Subaortic (aortopulmonary window)
6. Para-aortic (ascending aorta or phrenic)

Inferior Mediastinal Nodes
7. Subcarinal
8. Paraesophageal (below carina)
9. Pulmonary ligament

N1 Nodes

10. Hilar, peribronchial (10r, 10l)
11. Interlobar
12. Lobar
13. Segmental

Figure 2 **Draining lymph node sites (nodal stations) in the chest that can be involved by lung cancer are noted. Clinical staging of cancer of the mediastinum is carried out by CT scanning; surgical staging is performed by mediastinoscopy, mediastinotomy, thoracoscopy, or, sometimes, thoracotomy. A lymph node larger than 1 cm on CT scan is considered abnormal, but cancer involvement must be proved by biopsy. The upper paratracheal nodal stations are designated as 2r (*right*) and 2l (*left*); the lower paratracheal nodal stations are designated as 4r and 4l. Stations 8r, 8l, 9r, and 9l are contiguous with the mediastinum, but positive nodes in these sites are not common. Station 10 nodes, when confirmed as positive by mediastinoscopy, are classified as tracheobronchial angle nodes (10r and 10l) and signify mediastinal involvement. In the drawing, r is right; l, left; a, anterior; and p, posterior.**

Table 6 Therapy and Prognosis for Non–Small Cell Lung Cancer

Stage (%)	*Surgery*	*Radiotherapy*	*Chemotherapy*	*Five-Year Survival (%)**
I (10)	T1N0 (coin lesion): lobectomy (poor pulmonary function, segmental resection) T2N0: lobectomy	None	Research	T1N0: 45–80 T2N0: 35–65
II (10)	T1N1 or T2N1: lobectomy; pneumonectomy usually required when hilar nodes are grossly involved	May reduce local recurrence but does not affect survival	Research	T1N1: 20–52 T2N1: 20–40
IIIA (20)	T3 (potentially resectable): radical resection of chest wall lesions; used after RT of Pancoast tumors	Used after surgery; may reduce local recurrence; used preoperatively for Pancoast tumors	Combined with RT and surgery†	T3 (chest wall): 30–55 T3 (Pancoast tumors): 20–40
	N2 (potentially resectable): radical resection of early intranodal disease; not indicated for extranodal or fixed, matted nodes	Used after surgery; may reduce local recurrence; used preoperatively in some patients with early intranodal disease	Combined with RT and surgery†	N2: 10–50
IIIB (20)	T4, N3, or both (unresectable)	Standard treatment for palliation of pain, hemoptysis, atelectasis, hoarseness, SVC syndrome	Combined with RT*	Median, 30 wk
IV (40)	Used rarely for isolated metastases	Useful for palliation of pain or other local problems	Response rates of 30%–40%; prolongation of survival	Median, 13–18 wk

*Survival is higher in patients staged by surgery than in patients staged clinically.
†Randomized trials show prolonged survival when chemotherapy is added to radiotherapy, surgery, or both.
RT—radiotherapy SVC—superior vena cava

Chemotherapy The benefit of chemotherapy for patients with stage I or II NSCLC is controversial. In clinical practice, treatment recommendations for such cases do not routinely include chemotherapy. Nevertheless, in reviewing treatment options with these patients, it is important to discuss the evolving data from clinical trials of chemotherapy.

A meta-analysis found that adjuvant treatment with alkylating agents in this setting resulted in a 5% decrease in survival, compared with surgery alone ($P = 0.005$).[28] Cisplatin-based regimens were associated with a 5% improvement in 5-year survival, but this effect did not reach statistical significance ($P = 0.08$). On the other hand, the clinical trials included in this meta-analysis were performed between 1965 and 1991, and both chemotherapy and supportive care have improved significantly since that time. Therefore, randomized trials of adjuvant chemotherapy versus supportive care alone in stage I and II NSCLC are currently under way. An intergroup trial sponsored by the Cancer and Leukemia Group B (CALGB) is comparing carboplatin and paclitaxel with supportive care in patients with stage IB disease. An intergroup trial sponsored by the National Cancer Institute of Canada (NCI-C) has compared cisplatin and vinorelbine with supportive care alone in patients with stage IB, IIA, and IIB disease; results of this trial are pending. The International Adjuvant Lung Cancer Trial (IALT), in which patients with stages I through IIIA resected NSCLC were randomized to cisplatin-based chemotherapy versus observation, found a 4% absolute improvement in survival with chemotherapy.[29] It is hoped that ongoing studies will confirm this benefit. In the meantime, the option of adjuvant chemotherapy should be discussed with patients after definitive surgical resection.

Another treatment strategy for stage I and II disease is the use of induction (preoperative) chemotherapy. Because of encouraging results from a phase II trial in patients with completely resected stage IB, IIA, or IIB NSCLC,[30] the Southwest Oncology Group is leading a prospective, randomized trial of induction chemotherapy with three cycles of paclitaxel and carboplatin followed by surgery, compared with surgery alone. Other randomized clinical trials of both induction and adjuvant chemotherapy are currently being conducted for patients with stage IB, IIA, or IIB NSCLC. Eligible patients should be encouraged to enroll in these clinical trials, so that oncologists can determine whether chemotherapy is beneficial in this setting.

Radiation therapy Surgery is the treatment of choice for stage I NSCLC, but patients with medical contraindications to surgery can be treated with radiation therapy alone. Retrospective studies of such cases have shown 5-year survival rates ranging from 10% to 30%.[31] Better local control was found in patients with smaller tumors (< 3 cm) and in those treated with higher doses of radiation (> 65 Gy). Consequently, recommended radiation doses range from 65 to 70 Gy; the total dose is typically given in 2-Gy fractions. Omission of regional nodal areas from the treatment fields has been found to reduce morbidity and has resulted in a nodal failure rate of only 4% to 9%. Therefore, in most cases, the primary tumor is treated with a standard margin of 1.5 to 2 cm. It is important to take into account any movement of the tumor from respiration, and this is best done under fluoroscopy. Unfortunately, most patients treated with radiation therapy succumb to recurrent lung cancer, and at least 60% experience local failure.

Stage III–Operable Patients

Patients with stage IIIA disease who appear to be candidates for surgical resection but in whom mediastinoscopy shows ipsilateral mediastinal lymph node involvement are evaluated for induction therapy (chemotherapy alone or chemotherapy and radiation therapy). Induction therapy with systemic chemotherapy has the potential to treat occult metastatic disease, which is common in patients with stage IIIA disease, even when organ-specific scans are negative. Three randomized, prospective trials that compared induction chemotherapy before surgery with surgery alone in patients with operable stage IIIA NSCLC were small in sample size, but all demonstrated

benefit from induction chemotherapy, with at least a doubling in 3-year survival.[32-34]

The addition of radiation therapy to induction therapy may improve local control in conjunction with surgical resection and may also decrease distant metastatic spread during therapy.[27] A prospective study has suggested that chemoradiation before surgery is beneficial in patients with stage IIIA NSCLC.[33] A randomized intergroup comparison of chemoradiation alone with chemoradiation followed by surgery has been conducted[35]; preliminary results suggest longer disease-free survival in the surgical arm but higher initial mortality, which complicates the analysis. Important questions remain about induction therapy, including the following: What are the optimum agents for chemotherapy? Should chemotherapy be used alone or in combination with radiation treatment? Does radiation therapy or surgery provide better local control? Should all three modalities of therapy be utilized? To answer these questions, enrollment of patients with stage IIIA NSCLC in clinical trials is critical.

After induction therapy, staging studies are repeated. Repeat mediastinoscopy is useful for reassessing the mediastinal lymph nodes, although this is more difficult than the primary procedure. Alternatively, the ipsilateral mediastinal lymph nodes may be assessed at exploratory thoracotomy. Pulmonary resection is not recommended if the involved lymph nodes have not responded to induction therapy or if there is evidence of disease progression, because the prognosis for extended survival is dismal in such patients.

Patients with involvement of the chest wall, diaphragm, or pericardium may be surgical candidates but only if the tumor can be completely resected. Incomplete resection of NSCLC provides no curative or palliative benefit.

Postoperative radiation therapy The treatment of patients found to be in stage II or III after resection is somewhat controversial. These patients are at a high risk for local and regional recurrences after surgery alone; however, they also have a very high likelihood of distant disease.[36] In a study of patients with stage II or III disease who had undergone a complete resection and were randomized to receive radiation therapy or no further treatment, the patients who received radiation therapy were found to have a significantly lower rate of local failure (3% versus 21% for patients who did not receive postoperative radiation).[37] However, there was no evidence of a survival benefit for the patients receiving postoperative radiation. Two caveats regarding this study are that it included only patients with squamous cell carcinoma and that most of the patients in the study had N1 nodal disease, precluding a valid subgroup analysis of the relationship between nodal status and survival.

A meta-analysis of nine published and unpublished randomized trials of postoperative radiation therapy—which included 2,128 patients with stage I, II or III lung cancer treated from 1966 to 1994, largely with cobalt radiation techniques—found that overall, mortality was approximately 7% higher for patients who received postoperative radiation therapy.[38] On subgroup analysis, the adverse effect was most apparent in patients with N0 and N1 disease; survival of patients with N2 disease was the same in the two groups. The results of this study indicate that radiation therapy is detrimental to patients with early stage (I and II) lung cancer that has been completely resected; the question of whether postoperative radiation therapy benefits patients with N2 disease remains unanswered. This meta-analysis has been critiqued for its inclusion of patients treated with a wide variety of radiation doses and techniques, many of them now outdated, which may have skewed the data from showing a survival benefit with postoperative radiation therapy.

In summary, the use of postoperative radiation therapy in patients with stage II or III NSCLC yields a significant increase in local control, which may be particularly important in patients with positive surgical margins. However, because of the high frequency of metastatic disease in these patients, postoperative radiation therapy appears to provide no survival benefit. Patients offered postoperative radiation therapy should clearly understand that its goal is improved local control. Meanwhile, the possible role of combination radiation therapy and chemotherapy as an adjuvant to surgery is the subject of ongoing clinical trials.

Adjuvant chemotherapy As in stage I and II NSCLC, the role of adjuvant chemotherapy in resected stage III disease is not well supported by the results of randomized clinical trials, although the IALT results (see above) may provide such support.[28,29] On the other hand, a trial comparing adjuvant cisplatin and etoposide plus radiation with radiation alone in resected stage II and IIIA disease found no survival advantage for the group receiving adjuvant chemotherapy.[39]

Stage IIIB disease A small subgroup of patients with stage IIIB NSCLC may be candidates for surgical resection. In general, T4 tumors are considered unresectable; however, there are two exceptions to this generalization. First, patients with a single satellite nodule within the same pulmonary lobe as the primary tumor are offered resection if the disease is apparently resectable by lobectomy and the results of both mediastinoscopy and organ-specific staging studies are negative. Second, in rare cases of very limited involvement of the vena cava, main pulmonary artery, or aorta by the primary tumor, en bloc resection and vascular reconstruction may be offered to selected patients; long-term survival in such cases ranges from 10% to 20%.

Some patients with contralateral mediastinal lymph node involvement (N3) are treated with induction therapy followed by surgical resection. However, the standard of care for these cases is chemotherapy and radiation therapy.

Stage III–Inoperable Patients

Radiation therapy Without treatment, most patients with stage IIIB NSCLC will succumb to their disease within 1 year. Radiation therapy does result in an improved outcome, with up to 20% of patients surviving 2 years and up to 5% surviving 5 years, but there is a high likelihood of local recurrence, ranging from 25% to 50% in some studies.[40] Distant recurrence is also common. An analysis of several studies reveals that patients with weight loss greater than 5%, performance status of less than 80%, and higher T and N stage have the worst prognosis.[41]

In an attempt to increase the efficacy of radiation therapy, fractionation schemes have been tested, including treatments given two or three times daily. A randomized trial, performed in Europe, is comparing the effectiveness of continuous hyperfractionated accelerated radiation therapy (HART), given three times a day, with conventional radiation treatment. Results of this protocol reveals a statistically significant survival benefit of 9% at 3 years for patients treated in the continuous HART arm.[42] There is also a significant increase in local control, with 7% fewer failures at 3 years in the CHART arm. These benefits

are most prominent in patients with squamous cell carcinoma. The results of several trials indicate that the addition of chemotherapy to radiation therapy leads to an improved survival. A multigroup, randomized study found that patients with unresectable cancer who received chemotherapy and radiation therapy in combination had a statistically improved overall survival compared with those who received only radiation either once or twice daily. For chemoradiation, standard radiation, and hyperfractionation, 3-year survival rates were 17%, 11%, and 9%, respectively, and median survival rates were 13.2 months, 11.4 months, and 12 months.[43] In a comparison of HART with once-daily radiation therapy after induction chemotherapy, the 2-year survival was 40% for the HART arm, compared with 33% for the standard radiation therapy group; toxicities, particularly esophagitis, were also increased.[44]

Clinical trials are currently evaluating the use of three-dimensional treatment planning systems to increase the dose of radiation therapy delivered to the primary tumor. Preliminary results show that dose escalation is feasible and does not lead to increased toxicity and that outcomes are comparable to or better than historical controls.[45]

Chemoradiotherapy The standard treatment for inoperable stage III NSCLC is a combination of chemotherapy and radiation therapy. The chemotherapy should be a platinum-based combination regimen; the radiation should be given at conventional doses, generally 66 Gy. The use of chemoradiotherapy in these cases is supported by level I-A evidence.[46] For unresectable stage III disease, chemotherapy plus radiation therapy is appropriate for patients with a good performance status (an Eastern Cooperative Oncology Group [ECOG] score of 0 to 1 or, possibly, 2).

The optimal strategy for coordinating chemotherapy with radiation therapy is evolving. Possibilities include chemotherapy before, during, or after radiation treatment. Promising results have been reported from a recent randomized phase II trial of induction chemotherapy followed by concurrent chemotherapy and radiation treatments.[47] Median survival in this trial was approximately 18 months, which compares favorably with the 13 to 14 months reported in previous trials. This trial utilized cisplatin-based chemotherapy along with vinorelbine, paclitaxel, or gemcitabine, which are all agents with documented benefit in stage IV NSCLC (see below). A randomized phase III trial is needed to determine whether the apparent improvement in median survival stems from the sequencing of chemotherapy and radiation treatment, the use of the new agents, or both.

Concurrent administration of chemotherapy and radiation therapy has also been found to be beneficial. In a randomized trial of chemotherapy with mitomycin, vinblastine, and cisplatin given either before or along with thoracic radiation, the 2-year survival rates with sequential and concurrent treatment were 27% and 35%, respectively.[48] Subsequent trials point to a survival benefit from concurrent chemotherapy and radiation treatment compared with sequential therapy, as well as an increase in toxicity, particularly esophagitis and pneumonitis.

Treatment Strategies in Stage III Disease

The optimal approach to management of stage III NSCLC remains undefined. At present, it is clear that chemotherapy, when used in combination with surgery or radiation treatment, can improve patient survival in both operable and inoperable disease. In patients with inoperable stage III NSCLC, long-term survival is better with platinum-based combination chemotherapy and radiation therapy than with either modality alone. Every attempt should be made to enroll patients in clinical trials to further clarify the optimal strategy.

Because the benefits of combination therapy have been largely demonstrated in only younger patients with higher performance status, physicians should use caution in applying these approaches to elderly patients or those with poor performance status. In the absence of data from elderly and poor-performance patient populations, low-dose chemotherapy and concurrent radiation can be considered. An alternative strategy that may result in less toxicity from esophagitis would be the use of combination chemotherapy followed by radiation treatment. This strategy allows individualization of treatment based on the patient's tolerance of induction chemotherapy. However, older patients with good performance status should not be denied the potential benefit of combined-modality therapy. In this setting, it would appear that the most appropriate choice for chemotherapy is a cisplatin-based or carboplatin-based regimen with one of the newer agents used in the management of stage IV disease.

Stage IV Disease

For patients with stage IV NSCLC, chemotherapy plus supportive care improves both survival and quality of life, compared with supportive care alone. Because 5-year survival in stage IV disease is 1% or less, discussions of outcomes in the literature often describe median survival, which can be measured in months. For a physician who is speaking with an individual patient, however, it is more meaningful to discuss the probability of living 1 or 2 years. A statement based on median survival in a large population of patients, such as "You have 6 months to live," does not help that patient understand the range of survival that occurs even in stage IV NSCLC. It gives the patient a better idea of the probabilities if the physician instead specifies the percentage of patients with advanced NSCLC who are alive at 1 year after diagnosis. According to a National Cancer Center database, untreated patients with stage IV disease had a 1-year survival of 9% to 11%, whereas patients receiving chemotherapy had a 1-year survival of 20% to 25%.[49] These data are robust, because the population includes more than 700,000 patients with lung cancer, diagnosed between 1985 and 1995, and includes all stages and treatment categories for lung cancer. However, because this represents a database rather than a randomized comparison of groups, the survival data do not reflect the clinical factors that would guide the decision to forgo treatment in some patients. Such factors might include low performance status, comorbid disease, and advanced age, all of which may adversely affect survival.[50]

Which chemotherapeutic agents are best for stage IV disease? A meta-analysis of trials of supportive care alone versus supportive care with chemotherapy for advanced-stage disease demonstrated a 6% decrease in 1-year survival with the use of alkylating agents alone and a 4% improvement in 1-year survival with the use of vinca alkaloids or etoposide. Neither of these results reached statistical significance, however. By contrast, randomized trials of cisplatin-based combination chemotherapy versus supportive care showed an absolute increase of 10% in 1-year survival ($P < 0.0001$).[28] These studies generally restricted eligibility to patients with higher performance status and enrolled a disproportionate number of younger patients

with less comorbid disease than commonly seen in the community. Nevertheless, it is of interest that the magnitude of benefit in this trial is similar to that documented in the National Cancer Center database.

On the basis of this meta-analysis and additional data, an expert panel for the American Society of Clinical Oncology has concluded that in stage IV disease, platinum-based combination chemotherapy prolongs survival and is most appropriate for patients with good performance status, including an ECOG score of 0 or 1 or, possibly, 2.[46] Although randomized trials of platinum-based chemotherapy have almost all involved cisplatin, carboplatin has a more favorable safety profile and lower toxicity. Furthermore, randomized trials comparing cisplatin and carboplatin with etoposide in NSCLC have shown comparable efficacy.[51] Although a European study has suggested a small survival benefit for cisplatin therapy, compared with carboplatin-based therapy,[52] in the United States carboplatin continues to be the most widely used agent in the palliative management of patients with advanced lung cancer.

The 1990s brought the advent of newer agents in the treatment of NSCLC, including vinorelbine, paclitaxel, and gemcitabine, all three of which have received Food and Drug Administration approval for use (in combination with cisplatin) in the treatment of advanced disease. The approval of these newer agents was based on the results of randomized clinical trials that compared them, in combination with cisplatin, with either cisplatin alone or cisplatin in combination with older agents. In these trials, vinorelbine and cisplatin were associated with 1-year survival of 40%[53] and 36%.[54] These differences were statistically superior to vinorelbine alone, cisplatin and vindesine, or cisplatin alone; 1-year survival with cisplatin as a single agent was only 20%. Similarly, the combination of cisplatin and gemcitabine provided a 1-year survival of 39%, compared with 26% for cisplatin alone.[55] In the study that led to the approval of paclitaxel for NSCLC, 1-year survival was 32% in the control groups that received cisplatin and etoposide, compared with 37% to 40% for patients receiving paclitaxel. Survival with paclitaxel depended on the dose used; patients receiving a higher dose required supportive therapy with granulocyte colony-stimulating factor.[56] A randomized trial has demonstrated a better survival rate with cisplatin and docetaxel than with cisplatin and vinorelbine.[57] In this study, survival for a carboplatin and docetaxel group was similar to that for a cisplatin and vinorelbine group, but the former had a more favorable side-effect profile.

Overall, comparative trials have suggested that several different combination regimens may be equally effective in advanced disease, although toxicities vary.[58-60] The optimal regimen should comprise two chemotherapy drugs, including a platinum agent and one of the newer chemotherapeutic agents. Of the newer agents, paclitaxel, vinorelbine, gemcitabine, or docetaxel would all be reasonable choices.

Palliative radiation therapy Radiation therapy is used for palliation of symptoms caused by metastatic NSCLC. These include obstructive symptoms, bone pain, and neurologic compromise from spinal cord compression or brain metastasis. In randomized trials, palliative radiation has been shown to produce some pain relief in 75% to 90% of patients and complete pain relief in at least 50%.[61] Several fractionation schemes seem equally effective, but there is some evidence that prolonged treatment provides longer-lasting pain relief.

Superior vena cava syndrome responds to radiation treatment in approximately 50% of cases, but a substantial number of patients do not respond. Approximately 75% of patients have resolution of hemoptysis, and 50% will have cessation of cough after palliative radiation therapy. About 50% to 75% of patients with brain metastasis have a symptomatic response.

Spinal cord compression can also be treated with radiation therapy. Of patients who have only pain, 75% remain ambulatory, but only 30% to 35% of patients with muscle weakness improve.

Quality-of-life considerations Studies of chemotherapy for advanced NSCLC have largely focused on length of survival. In view of the modest benefits of treatment, however, the impact of chemotherapy on quality of life is a critical consideration. Although earlier trials often did not assess quality of life, virtually all of the current randomized clinical trials have quality-of-life measures as a significant component. These studies suggest that combination chemotherapy often results in the improvement of symptoms such as cough, dyspnea, chest pain, and hemoptysis, often even when there is minimal evidence of tumor response.[62] In general, these studies have shown that chemotherapy produces symptomatic improvement in more than 50% of patients. This figure is significantly higher than the objective response rate, which generally varies between 20% and 40% for combination regimens. The seeming discrepancy between these figures likely reflects the fact that even minor responses, or simply stabilizing the growth of the cancer, may bring at least short-term improvement in symptoms. With the improved toxicity profiles of the newer agents, improvements in quality-of-life differences may be easier to demonstrate.[63]

The elderly and other special populations Now that the benefits of chemotherapy have been established in younger patients with good performance status, researchers are evaluating its benefits in older patients and those with lower performance status. The first randomized trial of chemotherapy versus supportive care in the elderly (≥ 70 years), the Elderly Lung Cancer Vinorelbine Italian Study group (ELVIS) trial, assessed the effects of vinorelbine, as compared with supportive care alone, on both quality of life and survival of patients with advanced NSCLC.[64] In this study, 1-year survival was 32% for the vinorelbine-treated group, compared with 14% for best supportive care alone. On the basis of this trial, the FDA has approved vinorelbine for single-agent use in NSCLC. Because of the superior outcome with the combination of cisplatin and vinorelbine, single-agent treatment has not been widely used in high-performance-status populations. However, the ELVIS trial suggests that single-agent chemotherapy is beneficial in elderly patients, many of whom may not be eligible for combination chemotherapy. However, for the fit elderly, a subset analysis of a randomized trial of carboplatin and paclitaxel compared with paclitaxel alone demonstrated a survival advantage for the combination regimen in patients older than 70 years; this result was comparable to that in younger patients.[60]

Relapse of disease For patients in whom initial chemotherapy has failed, two randomized trials have now demonstrated the benefit of salvage chemotherapy. A trial comparing docetaxel with either ifosfamide or vinorelbine showed a survival advantage for patients receiving docetaxel, particularly at the dose of 75 mg/m^2.[65] A trial comparing docetaxel with best

Table 7 Therapy and Prognosis for Small Cell Lung Cancer

Stage	*Surgery*	*Radiotherapy*	*Chemotherapy*	*Median Survival (months)*	*Two-Year Disease-Free Survival (%)*
Limited I	T1N0, T2N0: Lobectomy	None	T1N0, T2N0: Research	> 48 > 14	T1N0 > 60 T2N0 > 30
Limited II	T1N1, T2N1: Lobectomy; pneumonectomy rarely used	Rarely used	Several regimens available	> 14	T1N1, T2N1: 15–30
Limited IIIA IIIB	T3, N2, or both: research T4 or N3: not indicated	Decreases local recurrences; used prophylactically for CNS	Several regimens available; high-dose programs with autologous marrow rescue are being researched Complete response: 50%–80%	> 12	15–20
Extensive IV	Not indicated	Useful for palliation of pain, atelectasis, SVC syndrome	Several regimens available Complete response: 30%–50%	> 8	≤ 5

SVC—superior vena cava

supportive care showed that docetaxel produced improvement in both survival and quality of life.[66] On the basis of these trials, the FDA has approved docetaxel for salvage chemotherapy in this setting.

Gefinitib, a tyrosine kinase inhibitor, has received FDA approval as monotherapy for patients with locally advanced or metastatic NSCLC that has failed to respond to both platinum-based therapy and docetaxel. Approval was granted under accelerated-approval regulations; although no controlled trials have shown an improvement in symptoms or survival with the agent, gefinitib has produced objective responses and symptomatic improvement in this heavily pretreated population. Toxicities include a skin rash, which is common, and interstitial lung disease, which is a rare but potentially fatal complication of gefinitib.[67] There is reason to hope that this agent, which targets epidermal growth factor receptors, will usher in an era of more precise therapy for lung cancer.

SMALL CELL CARCINOMA OF THE LUNG

Whereas the management of NSCLC changed substantially during the past decade, the management of SCLC has evolved more slowly. Important refinements in therapy have occurred, however. Currently, new directions in therapy are being developed, on the basis of better understanding of the biology of this disease.

As in NSCLC, the outcome in patients with SCLC is determined largely by stage at presentation [*see Table 7*]. The difference between the two diseases lies in the stage distribution. In NSCLC, 25% to 30% of patients present with stage I or II disease; in SCLC, that figure is well below 5%. Several factors may contribute to this difference, but a principal one appears to be that small cell carcinoma arises from neuroendocrine cells, which normally reside below the bronchial epithelium in the mucosa and submucosa. This region is much more heavily supplied with lymphatics, which would facilitate the earlier spread of these cancer cells to regional and distant lymph nodes, as well as hematogenous spread. In addition, in the 1960s it was learned that SCLC was more sensitive to chemotherapy than NSCLC. Because of the advanced stage at presentation and this chemosensitivity, SCLC fell largely into the domain of medical oncologists and radiation therapists rather than that of thoracic surgeons.

Early-Stage Disease

Early-stage solitary pulmonary nodules have been referred to as peripheral small cell carcinoma. In patients without mediastinal nodal involvement, this disease is associated with a 5-year survival in the 30% to 60% range, depending on the series. Long-term follow-up of these patients suggests a high tendency for distant relapse, both systemically and in the CNS. Surgery should be the therapy of choice for patients with no evidence of distant disease or of mediastinal nodal involvement. Because the number of patients presenting at this stage is small, no definitive randomized trials of adjuvant therapy have been performed and there is no consensus on adjuvant therapy. In the United States, it has been standard to recommend adjuvant chemotherapy, either alone or in combination with prophylactic cranial radiation or chest radiation.

Surgery with mediastinal lymph node dissection, followed by four cycles of adjuvant platinum and etoposide, was the subject of a phase II trial in patients with stage I to IIIA SCLC conducted by the Japanese Collaborative Oncology Group.[68] In patients with stage I disease, who constituted the bulk of the study population, 5-year survival was 69%. In the limited number of patients with stage II or IIIA disease, survival was 38% to 40%. No prophylactic cranial irradiation was done, and the rate of CNS relapse was 17%, even in the stage I population, which suggests that prophylactic cranial radiation should have a role in this population.

Limited-Stage or Extensive-Stage Disease

At least 95% of patients with SCLC present with either limited-stage or extensive-stage disease. Limited-stage SCLC corresponds to stage IIIA or IIIB NSCLC without malignant pleural effusion but, generally, with supraclavicular lymph node involvement. Simplistically, limited-stage SCLC patients include those in whom the primary tumor and involved nodes, including supraclavicular nodes, can be encompassed in a standard radiation port. By contrast, patients with extensive disease have a malignant pleural effusion, contralateral lung involvement, or metastases at more distant sites. This staging separation has been important for selecting treatment and determining prognosis. Patients with limited-stage disease have a 5-year survival of 15% to 20% when treated with the combination of

chemotherapy and radiation. In contrast, patients with extensive-stage disease generally have a 5-year survival of 1% to 2% and have been treated primarily with chemotherapy, plus adjunctive radiation as needed. The distinction between limited- and extensive-stage disease has largely been based on clinical examination, as well as on the standard imaging studies of chest CT through the adrenal glands, bone scan, and brain CT or MRI. Of patients with no evidence of distant metastases on these studies, an additional 5% will be found to have distant disease by bone marrow evaluation. Currently, approximately 25% to 30% of patients with SCLC present with limited-stage disease, and the remainder present with extensive-stage disease; however, with the development of more sophisticated imaging techniques and the increased use of PET imaging, some degree of stage migration is likely to occur.

Limited-stage disease Chemotherapy has been the mainstay of treatment for limited-stage disease for the past 30 years. For at least the past 10 years, the standard treatment has been based on etoposide, either as a single agent or combined with either cisplatin or carboplatin, generally for four to six cycles. Most of the advances in the understanding of treatment of limited-stage SCLC have come from trials evaluating the role of radiation therapy.[69] These trials have shown that cure in limited-stage SCLC is associated with the use of full-dose combination chemotherapy, along with thoracic and cranial radiation therapy. Thoracic radiation appears to be more beneficial if it is done concurrently with chemotherapy, rather than sequentially. Secondly, starting radiation therapy during the first few cycles of chemotherapy appears to provide a survival advantage over beginning radiation therapy at the end of chemotherapy.[70] The explanation for this is that drug resistance may evolve rapidly in small cell carcinoma, so in some patients, delaying thoracic radiation even for a few months may result in escape of drug-resistant cells from the lung and mediastinum to distant sites. Early intervention with radiation may result in the destruction of these cells and an increase in the rate of cure. However, as with NSCLC, the benefit of concurrent chemotherapy and radiation must be balanced against its higher toxicity (e.g., esophagitis).

Although clinical practice varies, most oncologists initiate radiation therapy with chemotherapy cycle one or with cycles two or three. The choice of timing depends on the clinical situation. The advantage of delaying radiation for one or two cycles is that during this time the tumor mass may be significantly reduced, therefore easing the patient's symptoms and often improving performance status, so that the patient is better able to cope with combination treatment. Most initial trials of concurrent therapy have used pretreatment tumor volumes to determine radiation fields. However, newer strategies of radiation therapy will take advantage of chemotherapy-induced tumor reduction and use higher doses of radiation delivered to a smaller tumor volume. In one major trial, twice-daily radiation, compared with once-daily treatment, has been associated with improved surgical outcome,[71] but twice-daily treatment is also associated with significantly higher toxicity rates. The use of twice-daily radiation can be considered in some patients with high performance status. The standard dose of daily radiation therapy that is given concurrently with chemotherapy has increased from 45 Gy to 60 Gy.

Another significant advance in the understanding of SCLC involves the role of prophylactic cranial irradiation. Early trials that used prophylactic cranial irradiation along with chemotherapy reported a high incidence of both immediate and delayed neurologic toxicity. Studies have used prophylactic cranial irradiation at lower dose fractions and have delayed its initiation until chemotherapy has been completed. These adjustments seem to be associated with substantially diminished immediate and delayed neurotoxicity. Moreover, a meta-analysis of the use of prophylactic cranial irradiation from randomized clinical trials (largely composed of patients with limited-stage disease) has demonstrated not only a reduction in CNS relapse but also an increase in long-term survival by approximately 5%.[72]

Several issues involving prophylactic cranial irradiation remain to be settled. One is its role in elderly patients, who appear to be at higher risk for neurotoxicity. Also, although trials of SCLC have often included patients in complete remission from either limited or extensive disease, most of the patients have had limited disease. Therefore, the strength of the recommendation for prophylactic cranial irradiation in patients in complete remission from extensive-stage SCLC is less certain.

A number of trials have evaluated maintenance chemotherapy or the addition of other treatments after chemoradiotherapy for SCLC. Phase II studies of high-dose chemotherapy for patients in remission have suggested an encouraging long-term survival rate,[73] and a potential long-term benefit has also been reported in a small number of patients who received a vaccine against a tumor ganglioside (BEC-2)[74]; the latter approach is currently the subject of a randomized phase III trial. No benefit for these approaches has yet been proved, however, so maintenance therapy after completion of standard therapy cannot be recommended for SCLC patients, except in the context of a clinical trial.

Extensive-stage disease Progress in the treatment of extensive-stage SCLC over the past 10 years has been slower than that of limited-stage SCLC.[69] As with limited-stage disease, treatment centers on chemotherapy. Although several different chemotherapy combinations have been demonstrated to have equivalent survival outcomes, etoposide-based regimens have been shown to be superior to older regimens such as cyclophosphamide, doxorubicin, and vincristine. Secondly, most clinical trials in SCLC have used cisplatin, but as noted above, carboplatin has a better therapeutic ratio, is equally effective, and causes significantly less nausea, vomiting, and neurotoxicity.[75,76] Currently, however, cisplatin and carboplatin are used with roughly equal frequency for SCLC in community practice in the United States. Both agents are generally administered every 3 to 4 weeks, depending on hematologic recovery. Although the combination of platinum and etoposide remains the most commonly used regimen in the United States, cisplatin and irinotecan has been approved for treatment of SCLC in Japan, and randomized trials of this combination are ongoing in the United States.

Special populations Adaptation of treatment to special populations is another very important principle in the management of SCLC. Standard combination chemotherapy regimens, which were developed for younger, healthier patients, pose a greater risk of severe myelosuppression and life-threatening complications in elderly patients with significant comorbid disease and in patients with poor performance status. Modified regimens should be considered in such patients. If combination therapy is employed, the use of carboplatin (dosed according

to renal function) rather than cisplatin may produce less toxicity in this population. Although monotherapy with low-dose etoposide is certainly a consideration, most elderly patients should be considered for combination carboplatin and etoposide therapy if permitted by their level of functional illness and degree of comorbid illness. Whether these patients should receive significantly reduced doses or near-standard doses plus hematopoietic growth factor has not been well studied.

Relapse of disease Although SCLC typically responds to therapy, the majority of patients with limited-stage disease and nearly all patients with extensive-stage disease will experience relapses. For limited-stage patients, the duration of remission may range from months to years. For most patients with extensive-stage disease, remission generally lasts only weeks to months after completion of chemotherapy. In both groups of patients, a major issue is the emergence of drug resistance, which has severely hampered the benefit of second-line or so-called salvage chemotherapy.

In this setting, a critical factor in choosing therapy is the time to relapse. For patients who have had a prolonged remission (longer than 1year), retreatment with the same regimen will often produce a response. On the other hand, in patients who fail to respond to initial therapy (primary drug resistance), no therapy has been convincingly shown to be beneficial, so these patients are best enrolled in experimental trials.

For patients who have had a remission of at least 2 months after initial therapy, topotecan has been shown to produce a significant improvement in disease-related symptoms—particularly dyspnea, but also anorexia, hoarseness, and fatigue—and has been approved for second-line therapy for patients with SCLC.[77] The other commonly used approach in relapses of SCLC has been prolonged courses of oral etoposide for 10 to 21 days per cycle. Other agents that have shown promise for salvage therapy include paclitaxel, irinotecan, vinorelbine, and gemcitabine.[69,78] These agents, as well as more novel approaches, warrant further investigation.[79]

SUPPORTIVE CARE

Supportive care is important across all stages of both NSCLC and SCLC. In patients with advanced or refractory disease, it often becomes the principal form of therapy. As the ability of oncologists to deliver both chemotherapy and radiation safely has improved, it is clear that one of the best supportive care approaches is to palliate disease-related symptoms with chemotherapy, radiation, or both.

Over the past 10 years, management of pain, depression, nausea, weight loss, and constipation in cancer patients has been improved by the development of pharmacologic agents with better efficacy and less toxicity [*see CE:X Symptom Management in Palliative Medicine*]. In patients who are receiving myelosuppressive chemotherapy and so are at high risk for neutropenic complications, the use of colony-stimulating factors has been demonstrated to substantially reduce the risk of fever, neutropenia, and infection.[80] How to identify the populations who are at highest risk and are thus candidates for primary prophylaxis with colony-stimulating factors is an area that needs further investigation.

Anemia and fatigue are now appreciated as especially important concerns in patients with lung cancer.[81] Analysis of the 1,748 lung cancer patients enrolled in the prospective trials of recombinant human erythropoietin for cancer patients with anemia has shown that amelioration of anemia led to significant improvements in quality of life; these improvements applied to patients with SCLC or NSCLC receiving a variety of chemotherapy regimens.[82] Although all anemic cancer patients may benefit from higher hemoglobin levels, those with lung cancer may reap particular benefits because of dyspnea and fatigue related to the cancer itself, as well as comorbid diseases and the treatments used. In addition to substantially enhancing quality of life, normalization of hemoglobin levels may also improve therapeutic outcome, perhaps by improving tolerance to treatment or by reducing tumor hypoxia. Studies evaluating the role of hemoglobin maintenance in reducing cognitive dysfunction during treatment are ongoing.

TREATMENT UPDATES

The National Cancer Center Network (NCCN) provides evidence-based, expert-panel guidelines for the management of cancer, as well as supportive care guidelines. Clinicians are encouraged to review the NCCN Web site (http://www.nccn.org) for annual updates of lung cancer management guidelines.

Prognosis

At present, the 5-year survival rate for lung cancer is approximately 14%. The chance of survival is heavily dependent on stage at presentation, however. For example, 5-year survival in patients with stage I NSCLC is approximately 63%. Unfortunately, more than 40% of all patients with NSCLC have stage IV disease at diagnosis, and in this population the survival at 5 years is 1% or less. In patients with SCLC, 5-year survival ranges from 30% to 60% for peripheral disease (stage I/II) to 1% to 3% for patients with extensive disease (stage IIIB/IV). Unfortunately, approximately 65% to 70% of patients with small cell lung cancer present with extensive disease.

Acknowledgment

The author would like to acknowledge the Ruth and Herman Albert Thoracic Oncology Program at Duke Comprehensive Cancer Center for support of this work and, in particular, Thomas A. D'Amico, M.D., Joseph A. Govert, M.D., Michael J. Kelly, M.D., and Timothy Shafman, M.D., for their participation in the multidisciplinary development of this chapter.

IX PROSTATE CANCER

Philip W. Kantoff, m.d.

Epidemiology

Prostate cancer is the most commonly diagnosed noncutaneous malignancy in men in the United States. It is expected that by the end of 2004, 230,110 men in the United States will have been diagnosed with the disease and that 29,900 men will have died of it.[1] Incidence varies greatly, with African Americans having the highest incidence in the world (224 cases per 100,000 population). The incidence of prostate cancer in African Americans is remarkably higher than the incidence in white Americans (150 per 100,000), Western Europeans (39.6 per 100,000), Japanese (8.5 per 100,000), and Chinese (1.1 per 100,000).[2]

Throughout the latter half of the 20th century, the annual incidence of prostate cancer in the United States increased slowly but steadily, probably because of an increase in life expectancy and therefore an increase in the population of men in the susceptible age range (> 50 years). However, other factors likely contributed as well—in particular, the introduction and widespread use of the prostate-specific antigen (PSA) blood test. PSA testing identified a large number of asymptomatic men with prostate cancer, or so-called prevalence cases. Since peaking in 1993 at more than 350,000 cases, the rate of prostate cancer diagnosis initially decreased, presumably because of prior identification of prevalence cases, but is now increasing once more, for unknown reasons.[3] Despite the dramatic changes in the rates of prostate cancer diagnosis, mortality from prostate cancer in the United States declined 2.6% a year from 1990 to 1998.[4]

Risk Factors

Although the etiology of prostate cancer is unknown, several factors increase the risk of prostate cancer. These include age, race, family history, diet, and hormone levels.

age and latent disease versus clinical disease

Advancing age is the most obvious risk factor for prostate cancer; perhaps no other cancer is as age dependent. At the cellular level, however, the onset of prostate cancer appears to occur at an early age: prostate cancer has been detected at autopsy in the prostates of men in their 20s and 30s. Latent, or autopsy, prostate cancer (i.e., disease identified as an incidental finding at postmortem examination) is defined as microscopic quantities of low-grade cancer incidentally found in the prostate. In one study, 20% of men younger than 40 years had histologic evidence of prostate cancer.[5] In contrast, clinically detected prostate cancer is rare in men younger than 40 years. The prevalence of both latent and clinically detected prostate cancer increases dramatically with age: 20% to 30% of men older than 50 years and, perhaps, 50% of men older than 80 years may harbor latent prostate cancer. Most clinically detected prostate cancers are detected in the seventh and eighth decades of life. The relationship between latent and clinically detected prostate cancer is uncertain. Whether they represent two distinct diseases or latent prostate cancer is a precursor of clinically detected prostate cancer remains an unanswered question. If the latter is the case, the distinction may blur with earlier detection of prostate cancer.

racial and environmental variability

Other risk determinants of prostate cancer are race and geographic origin. African Americans have the highest incidence of prostate cancer. The lowest incidence rates are in Japan and China. When members of a racial group move from geographic regions of low incidence of prostate cancer to regions of higher incidence, the incidence of prostate cancer increases in that group. These migration studies demonstrate the probable importance of environmental factors. Genetic factors, however, may be operative as well. For example, the androgen receptor gene (which is coded on the X chromosome) contains a polymorphic cystosine-adenosine-guanine (CAG) repeat sequence. Several studies indicate that individuals with fewer CAG repeats in androgen receptor genes have a higher risk of prostate cancer.[6-9] African Americans have been found to have fewer CAG repeats than do Hispanic and non-Hispanic whites and Asians. Part of the increased risk of prostate cancer observed in African Americans may be attributed to this factor. Other, undefined genetic factors are probably involved as well. African Americans may develop a more virulent form of prostate cancer, leading to a higher mortality. A variety of factors, including genetics, diet, socioeconomics, and health care access, have been proposed to explain this observation.[10,11]

family history

The incidence of prostate cancer is higher in men who have relatives with prostate cancer. The risk increases with the number of affected relatives. First-degree relatives of men with prostate cancer have a twofold to threefold higher risk; men with two or more relatives with prostate cancer have a fivefold greater risk.[12] Overall, men who have relatives with other forms of cancer, including breast cancer, do not appear to be at significantly higher risk for prostate cancer.

diet

The relation between diet and prostate cancer is probably very important, although it is difficult to prove because most of the supporting data are from epidemiologic studies rather than prospective intervention studies. Nonetheless, the dramatic differences between the Asian and Western diets may contribute to the significant difference in risk. Data from large cohort studies and case-control studies support the contentions that red meat, animal fat, and higher total fat consumption increase risk.[13] Other dietary factors may also be important. Higher consumption of lycopene, a carotenoid present in tomatoes and beets, may decrease risk.[14] Micronutrients have been implicated: selenium, vitamin E, soy (isoflavones), and vitamin D consumption may lower risk, whereas a high dietary calcium intake may increase risk, perhaps by lowering levels of the vitamin D_3 metabolite 1,25-dihydroxyvitamin D[1,25$(OH)_2$D].

hormones and growth factors

Serum hormone and growth factor levels influence risk of prostate cancer. The relation between serum androgen level and prostate cancer risk is controversial. The prostate requires exposure to androgens both to increase in size and to develop cancer. Furthermore, individuals with very low androgen levels, such as

eunuchs, rarely develop prostate cancer. However, whether variations in the serum levels of androgen within the normal range are associated with differences in risk is debated. In the largest prospective study (conducted as part of the Physicians' Health Study), the higher the level of free testosterone, the greater the risk of subsequent prostate cancer.[15] In another analysis of the Physicians' Health Study, higher serum levels of insulinlike growth factor–1 (IGF-1) correlated with a greater risk of prostate cancer.[16] In the Health Professionals Follow-up Study, men with lower testosterone levels who subsequently developed prostate cancer were more likely to develop higher-grade prostate cancers, whereas men with higher testosterone levels tended to develop lower-grade prostate cancers.[17]

Pathogenesis

Prostate cancer is a complex, heterogeneous disease that likely results from a series of genetic events in the prostatic epithelial cell. These genetic events and many of the environmental factors that promote the development or progression of the cancer are as yet poorly defined.

A small subset of prostate cancers may result from the inheritance of one of several predisposition genes that confer a high risk of prostate cancer. Familial prostate cancer constitutes an estimated 5% to 10% of all prostate cancers and perhaps as many as 50% of prostate cancers in men younger than 55 years.[18] Six candidate loci have been identified in familial prostate cancer; the gene at one of these loci, hereditary prostate cancer–1 (*HPC-1*), has been found to be ribonuclease L (*RNase L*). *HPC-1* linkage may be associated with more severe prostate cancer.[19]

Several genes that participate in cell cycle regulation and in growth factor signaling (*Rb, p53*, and *PTEN*) have been implicated in the development and progression of prostate cancer. The prevalence of mutations of these genes has varied from study to study, and the role that the genes play in the development and progression of prostate cancer has yet to be defined. Similarly, a variety of proto-oncogenes have been implicated in the pathogenesis of prostate cancer. Although there is strong evidence of dysregulation of a variety of growth factors (e.g., IGF-1, epidermal growth factor [EGF], and platelet-derived growth factor), as well as growth factor receptors (e.g., Her-2/neu, EGF receptor, and transforming growth factor–β receptor), their exact roles are not yet understood.

Screening for Prostate Cancer

The goal of screening for prostate cancer is to detect organ-confined prostate cancer, which is potentially curable with definitive local therapy. Historically, the digital rectal examination (DRE) was used to screen for prostate cancer. DRE is inadequate, however, because its interpretation is highly variable, many cancers are not palpable, and most of the cancers detectable by DRE are not organ confined and therefore are not curable. Measurement of the serum acid phosphatase level also is a poor screening test, for similar reasons.

PROSTATE-SPECIFIC ANTIGEN TESTING

Screening by PSA testing greatly enhances detection of organ-confined prostate cancer. A member of the kallikrein family, PSA is a glycoprotein with serine protease activity. It is abundant in semen,[20] where it dissolves the seminal coagulum. PSA is produced by both normal and malignant prostatic epithelial cells; production may actually be higher in normal cells than in malignant cells. Thus, conditions such as benign prostatic hyperplasia (BPH), acute prostatitis, seminal ejaculation, and genitourinary instrumentation all increase the serum PSA level. When prostate cancer develops, the serum PSA level is frequently elevated because of the absolute increase in volume of epithelial cells and possibly because of leakage of PSA from tissue to serum.

Optimal screening for prostate cancer combines use of the PSA test and the DRE,[21] because most cancers are nonpalpable and some cancers do not produce enough PSA to increase the serum PSA level. Although no randomized studies have confirmed that screening with PSA decreases prostate cancer mortality, some evidence supports its use. In population-based studies from before the 1990s, when PSA screening became widespread, fewer than 50% of diagnosed cancers were organ confined. In contrast, most cancers that are currently detected by combined PSA and DRE screening are organ confined.[22] The PSA blood test can detect prostate cancer an average of 5.5 years before clinical detection becomes possible.[23] The majority of cancers now detected by PSA-based screening are nonpalpable, asymptomatic cancers that are potentially curable. Although these observations may represent no more than lead-time and length-time bias, perhaps the most compelling evidence to support PSA-based screening is the estimated 25% decrease in annual mortality from prostate cancer over the past 5 years.

The American Cancer Society currently recommends annual DRE and PSA tests for men older than 50 years who have a life expectancy of more than 10 years. For men at high risk (i.e., African Americans and men with a family history of prostate cancer), screening is recommended to begin at 40 years of age. Annual screening has been challenged, however; in one study, screening all men at ages 40 and 45 and then screening every 2 years starting at age 50 appeared to be more efficient.[24]

Troubling issues exist regarding PSA-based screening. The detection of clinically insignificant cancers may lead to unnecessary treatment for many men. Also, an elevated PSA level lacks specificity. Despite the increased likelihood of prostate cancer in men with a moderately elevated serum PSA level (4 to 10 ng/ml), biopsy in such cases usually reveals BPH rather than prostate cancer.

Although most men with serum PSA levels above 10 ng/ml have prostate cancer, their cancers are highly likely to be non–organ confined. The lack of specificity of a serum PSA between 4 and 10 ng/ml has led to intense research over the past 10 years. Different strategies have been explored to distinguish malignancy from BPH.

Because serum PSA levels normally increase with age, the use of age-specific PSA levels can enhance the sensitivity of screening for prostate cancer in young men and increase the specificity of an elevated serum PSA in older men [*see Table 1*].[25] This strate-

Table 1 Age-Specific PSA Reference Ranges

Age	*PSA Level*
< 50 yr	≤ 2.5 ng/ml
50–59 yr	≤ 3.5 ng/ml
60–70 yr	≤ 4.5 ng/ml
> 70 yr	≤ 6.5 ng/ml

Table 2 Free PSA and Probability of Cancer in Patients with PSA Levels between 4 and 10 ng/ml[28]

Free PSA (%)	*Probability of Prostate Cancer (%)*
0–10	56
10–15	28
15–20	20
20–25	16
> 25	8

gy is particularly important in younger men, in whom prostate cancer is more likely to be fatal. This strategy has been challenged for older men, however, because sensitivity is sacrificed for a small increase in specificity.

Race-specific serum PSA ranges have also been proposed, because healthy African Americans have mean serum PSA levels that are slightly higher than those of whites.[26] Serum PSA levels increase faster in men with prostate cancer than in men without the disease, but the use of this principle (so-called PSA velocity) in determining who should undergo biopsies is limited because of the normal variation in PSA levels.

Another strategy is determination of the ratio of the serum PSA to the volume of the prostate gland (so-called PSA density [PSAD]).[27] In general, patients with cancer have a higher PSAD. A major limitation with this approach has been the difficulty in objectively assessing prostate volume through transrectal ultrasonography (TRUS).

Determination of the free PSA (i.e., the percentage of PSA that is unbound to serum proteins) is also a potential means of distinguishing malignancy from benign hyperplasia.[28] For unclear reasons, PSA derived from malignant epithelial cells tends to bind more avidly to serum proteins. Thus, in men with an elevated serum PSA level, cancer is more likely to be present when the percentage of free PSA is low [*see Table 2*]. Because sensitivity and specificity vary with respect to each other, depending on the free PSA cutoff, the optimal cutoff value for free PSA is still under debate.

The insensitivity of PSA levels below 4.0 ng/ml is also an issue. In one large study, 15.2% of men with a PSA level of less than 4.0 ng/ml who underwent biopsy had prostate cancer; 14.9% of these cancers were high grade.[29] Whether it would be prudent to lower the PSA threshold for biopsy is controversial. Although the number of cancers detected would increase, the rate of overdiagnosis and overtreatment would increase as well.

Diagnosis

A prostate biopsy is generally performed when cancer is suspected because of an elevated serum PSA level, an abnormal DRE, or both. Biopsies are performed transrectally: a TRUS probe is inserted into the rectum to visualize the prostate during biopsy sampling. TRUS itself is neither an adequate screening test nor a means of reliably visualizing nonpalpable cancer; its major contribution is in ensuring the accurate spatial sampling of the prostate gland. TRUS also is helpful in the estimation of gland volume, information that may be useful in making decisions about treatment. Traditionally, biopsy samples have been taken in a sextant pattern (bilateral base, midgland, and apex). This approach often missed cancer, particularly in the apex (the portion nearer the anal verge) and, less frequently, in the base (the portion nearer the bladder). Increasing the number of samples per session improves cancer detection,[30,31] but at the risk of added morbidity from multiple samples and the increased possibility of detecting clinically insignificant cancer.

BIOPSY FINDINGS

The vast majority of prostate cancers are adenocarcinomas; small cell carcinomas and sarcomas are occasionally seen. Adenocarcinomas arise from the glandular epithelium of the prostate and are often multifocal. The diagnosis is often made on the basis of a limited amount of gland pathology because of the limitations of sampling the gland. The subtlest pathologic change associated with carcinoma is loss of the basal layer within the glandular epithelium. Invasion into the surrounding stromal tissue is common and makes the diagnosis easier.

HISTOLOGIC GRADING

The most commonly used grading system is the Gleason grading system, in which tumors are classified by the degree of disorganization of glandular structures. Tumors are graded from 1 (least malignant) to 5 (most malignant) on the basis of the architectural patterns in the examined tissue. The grades reflecting the two most common architectural patterns are then added together to create the Gleason score (e.g., 4 + 3 = 7). The Gleason score correlates with clinical prognosis and is therefore used in stratifying patients. However, the majority of tumors are classified as either Gleason 6 or 7, which limits the clinical utility of the Gleason score.

A condition known as prostate intraepithelial neoplasia (PIN), which represents a premalignant state,[32] is felt to predate true carcinoma and often coexists with carcinoma in the prostate gland. When biopsy reveals PIN but no actual cancer, further biopsies are warranted.

Staging

Staging in prostate cancer attempts to determine which cancers are organ confined (and thus curable with local therapy alone) and which are not organ confined. Prostate cancer has a propensity to spread to lymph nodes and bone. Clinically significant spread to visceral organs, such as the liver or lung, is unusual.

CLINICAL STAGING

The clinical stage is based on the extent of disease assessed by palpation (i.e., DRE). The Marshall Jewett classification (in which stages are denoted as A, B, C, or D) has largely been replaced with the TNM classification [*see Table 3*].

Clinical staging of prostate tumors distinguishes between localized (T1 and T2) tumors and locally advanced (T3 and T4) tumors. T1a and T1b prostate tumors (stage A tumors in the Marshall Jewett system) are detected by transurethral resection. These tumors, which probably originate in the transition zone of the prostate, are generally indolent. Currently, most of the prostate cancers that are detected are nonpalpable (T1c) cancers. Although T1c and T2 tumors generally behave in a similar fashion, their distinction from T3 and T4 tumors is critical because T3 and T4 tumors will rarely be cured by surgery or radiation therapy alone. Clinical staging is otherwise of limited value in judging curability and extent of disease and in determining appropriate treatment.

Table 3 Clinical Staging Definitions

Malignancy	*Stage*	*Characteristics*
Primary Tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Clinically inapparent tumor not palpable or visible by imaging
	T1a	Tumor incidental histologic finding in ≤ 5% of tissue resected
	T1b	Tumor incidental histologic finding in > 5% of tissue resected
	T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)
	T2	Palpable tumor confined within prostate*
	T2a	Tumor involves one lobe
	T2b	Tumor involves both lobes
	T3	Tumor extends through the prostatic capsule†
	T3a	Extracapsular extension (unilateral or bilateral)
	T3b	Tumor invades seminal vesicle(s)
	T4	Tumor is fixed or invades adjacent structures other than seminal vesicle, bladder neck, external sphincter, rectum levator muscle, and/or pelvic wall
Pathologic Primary Tumor (pT)	pT2‡	Organ confined
	pT2a	Unilateral
	pT2b	Bilateral
	pT3	Extraprostatic extension
	pT3a	Extraprostatic extension
	pT3b	Seminal vesicle infusion
	pT4	Invasion of bladder, rectum
Regional Lymph Node Metastasis	NX	Regional lymph node cannot be assessed
	N0	No regional lymph node metastasis
	N1	Metastasis in regional lymph node or nodes
Distant Metastasis§	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Nonregional lymph nodes
	M1b	Bone(s)
	M1c	Other site(s)

*A tumor that is found in one or both lobes by needle biopsy but is not palpable or reliably visible by imaging is classified as T1a.
†Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.
‡There is no pathologic T1 classification.
§When more than one site of metastasis is present, the most advanced category is used.

MULTIFACTORIAL STAGING

The most clinically useful means of stratifying patients according to prognosis is through multifactorial staging—that is, using the clinical stage, the serum PSA level, and the Gleason score together.[33] Combined-modality staging can determine whether a patient is at low, intermediate, or high risk of biochemical relapse (i.e., relapse as evidenced on PSA testing) after local therapy [*see Table 4*].[34] In addition, refinements have been made in stratifying patients by use of the proportion of biopsy samples that contain cancer.[35] Although such classifications have proved helpful in distinguishing patients with organ-confined cancer from those with non–organ-confined cancer, thus facilitating clinical decision-making, they have not allowed discrimination of indolent cancers (which do not need to be treated) from clinically relevant tumors.

Although the use of PSA measurement to detect and stage prostate cancer has declined, changes in PSA before diagnosis may have prognostic significance. In a recent study, time to death—from prostate cancer and from any cause—was significantly shorter in men whose PSA level increased by 2 ng/ml or more in the year before the diagnosis of prostate cancer, compared with men whose PSA levels increased at a lower rate; 10-year mortality was 15% in the former group and negligible in the latter.[36]

STAGING BASED ON IMAGING STUDIES

Currently, prostate cancer is almost always diagnosed in men who have no radiographic evidence of metastases; few men come to medical attention as a result of symptoms of metastatic disease, which, most frequently, is pain resulting from osteoblastic bone metastases. For that reason, radiographic and scintigraphic methods of staging are not useful for the vast majority of patients.[37] However, bone scans to assess skeletal involvement and computed tomographic scans or magnetic resonance imaging scans to assess regional lymph nodes may be useful in patients with prostate cancers whose serum PSA level is above 10 ng/ml, whose Gleason score is 8 to 10, or who have locally advanced cancer (T3 or T4). Endorectal coil MRI scans (erMRIs) offer better definition of the prostate gland than does TRUS but are useful in staging in only a small fraction of patients (i.e., those with a serum PSA level between 10 and 20 ng/ml, a Gleason score of less than 8, and more than 50% of biopsy cores positive). In such patients who appear clinically to have organ-confined disease, erMRI is 78% accurate in predicting extracapsular disease and 90% accurate in predicting seminal vesical involvement.[38] Scintigraphy with ProstaScint (indium-111 capromab pendetide), a radiolabeled murine monoclonal antibody to a prostate-specific membrane antigen, is also of limited value in initial staging.[39]

Table 4 Combined-Modality Staging Approach

Risk	*5-Year PSA Failure-Free Survival*	*Characteristics*
Low	> 85%	T1c, T2a *and* PSA ≤ 10 ng/ml *and* Gleason score ≤ 6
Intermediate	50%	T2b *or* PSA > 10 and ≤ 20 ng/ml *or* Gleason score = 7
High	33%	T2c *or* PSA > 20 ng/ml *or* Gleason score ≥ 8

Natural History of Untreated Prostate Cancer

Data regarding the outcome of patients who receive no therapy for their prostate cancer are available from a series of over 3,000 men identified in the Connecticut Tumor Registry who, after diagnosis, either chose not to be treated or were advised by their physicians to receive no treatment.[40] These patients were followed for a minimum of 15 years or until death. The two major determinants of death from prostate cancer were tumor grade and age at diagnosis. According to the study findings, men with prostate cancer whose Gleason scores are 7 or higher and who are younger than 74 years face significant prostate cancer mortality; conversely, men of all ages whose Gleason scores are 6 or lower are at minimal to modest risk of death from prostate cancer. This study resulted in two important observations: Gleason 7 tumors should be regarded as high-grade tumors (along with Gleason 8 to 10 tumors), and age at diagnosis appears to have little impact on cancer-specific mortality after 15 years in patients with low-grade or high-grade tumors. Age is more a determinant in men with moderately differentiated tumors.

Treatment of Localized Prostate Cancer

When prostate cancer is confined to the organ, surgery or radiation therapy is commonly used with great success. Reducing the morbidity associated with treatment remains a challenge in such patients, however. In men with non–organ-confined cancer, who very frequently harbor occult metastatic disease, surgery or radiation therapy provides benefits only with respect to local disease control.

A prospective trial in which patients with localized prostate cancer were randomized to undergo either radical prostatectomy or observation found no difference in overall survival between the two arms of the study over a relatively brief follow-up period of 6.2 years.[41] However, early indicators of benefit were seen with surgery—a reduction in cancer-specific mortality and in metastasis rate. Single-institution reports have alleged that different treatment modalities are effective in the management of early prostate cancer,[42-44] but comparative data are hard to obtain because of potential bias in patient selection. Information from pooled hospital-based datasets[45,46] or from population-based databases, such as the Surveillance, Epidemiology, and End Results (SEER) database,[47] suggest only modest short-term benefits, with those benefits observed only in high-grade tumors. The 10-year survival probabilities in these studies are similar to the nontreatment data from the Connecticut Tumor Registry, largely because of the excellent short-term prognosis for patients with untreated prostate cancer. It is therefore not surprising that in studies in which data from SEER and hospital-based treatment series were analyzed, the outcomes in patients receiving radical prostatectomy and external-beam radiation therapy—the most commonly used treatment modalities—were similar 10 years after treatment [*see Table 5*].[48,49]

In the absence of randomized studies showing a therapeutic superiority of surgery over radiation therapy, treatment decisions are largely made by patients themselves after physician consultation. A mixture of physicians' bias, patient priorities and fears regarding cancer, attitudes toward treatment-related side effects, and comorbidity comes into play.

RADICAL PROSTATECTOMY

In the United States, radical prostatectomy has been the standard treatment and may offer the greatest chance of cancer control for patients with organ-confined prostate cancer. The procedure is most commonly performed in a retropubic fashion, although a transperineal approach is sometimes used. The transperineal approach has the potential advantage of a shorter postoperative hospitalization, whereas the retropubic approach allows lymph node dissection, preservation of the nerves that control erectile function, and wider resection margins.

Table 5 10-Year Disease-Specific Survival (DSS) of Patients with Localized Prostate Cancer by Grade and Treatment

Grade	*Prostatectomy*		*Radiotherapy*		*Conservative*	
	N	*% DSS (95% CI)*	*N*	*% DSS (95% CI)*	*N*	*% DSS (95% CI)*
I	3,854	94 (91–95)	4,065	90 (87–92)	9,804	93 (91–94)
II	14,287	87 (85–89)	7,939	76 (72–79)	6,198	77 (74–80)
III	5,133	67 (62–71)	2,596	53 (47–58)	2,236	45 (40–51)

CI—confidence interval N—number of patients

RADIATION THERAPY

Computer-aided planning systems, such as CT simulation and so-called conformal three-dimensional planning (in which radiation conforms to the contours of the gland), allow radiation therapy to be administered with fewer side effects and at doses higher than the traditional 7,000 cGy. Brachytherapy (i.e., implantation of radioactive iodine 125 or palladium 103 seeds directly into the tumor) is a very popular alternative therapeutic strategy because of the relative ease of administration, the apparently favorable toxicity profile, and the promising cancer control rates at 5 to 10 years of follow-up.

The efficacy of radiation therapy remains a major concern. With external-beam radiation therapy, the dose applied (7,000 cGy) may be insufficient to eradicate all cancer. With brachytherapy, implant placement may leave so-called cold spots where cancer can persist. These concerns probably apply more to patients with intermediate-risk and high-risk prostate cancer, in which tumor volumes are on average higher, but these concerns are also relevant to low-risk patients, particularly younger men.

TREATMENT-RELATED SIDE EFFECTS

Radical prostatectomy can result in urinary incontinence and erectile dysfunction; the frequency and severity of these side effects are a subject of debate.[50,51] Reports of low frequencies of these side effects may reflect patient selection, better surgical expertise, or both, although inaccuracy in obtaining symptom data may be a more realistic explanation.[52,53] A review of the SEER database suggests that the rates of postoperative and late urinary complications in men who undergo radical prostatectomy are significantly lower when the procedure is performed in a high-volume hospital and by a surgeon who performs a high number of these procedures.[54]

Stress urinary incontinence is reported in 5% to 35% of patients after radical prostatectomy.[50] Erectile dysfunction occurs frequently after radical prostatectomy, rendering most patients impotent, even when the nerves that control erectile function are spared.[50,51] In selected series, however, potency was reportedly maintained in more than half of the patients.[52,53]

External-beam radiation therapy is generally well tolerated, but erectile dysfunction occurs in the majority of patients, and rectal injury resulting in altered bowel habits or minor rectal bleeding occurs in a minority of patients.[50] Insufficient data are available to make any assessment of the long-term sequelae of brachytherapy.

Comparison of the side effects of radical prostatectomy and external-beam radiation therapy has shown that men who undergo radical prostatectomy are more likely to have urinary incontinence or impotence (although significant declines in sexual function are seen with both treatments). On the other hand, men who receive external-beam radiation therapy are more likely to suffer changes in bowel function.[55,56] Because concern about particular side effects may vary with individual patients, this information may be useful in guiding treatment decisions.

TREATMENT SELECTION BY RISK OF RECURRENCE

Low-Risk Patients

Low-risk patients have a high likelihood of organ-confined cancer [*see Table 4*]. Treatment options include radical prostatectomy, brachytherapy, external-beam radiation therapy, or no treatment. Outcomes are generally excellent, regardless of therapy, in this subset of patients. Although radical prostatectomy remains the standard approach, nonrandomized data suggest equivalence among the treatment options for this subgroup.[49,57] A significant subset of patients with low-risk prostate cancer probably do not require treatment, but the accurate identification of such patients remains uncertain.

Intermediate-Risk Patients

Intermediate-risk patients usually have a higher cancer volume and a higher likelihood of occult metastatic disease. Radical prostatectomy can be offered to these patients, but many will require further therapy, either because of recurrent or persistent local cancer or because of metastatic cancer at distant sites, as indicated by recurrent or persistent PSA elevation after treatment. Nonetheless, surgery is curative in about 50% of these cases. Efforts at improving upon the results of surgery by reducing tumor volume through androgen ablation (i.e., chemical or surgical castration) before surgery have thus far been unsuccessful.[58-60] Whether external-beam radiation therapy can eradicate all tumor cells, even when organ confined, is not established. One strategy to address this concern has been to increase the dose of radiation by use of conformal radiation, which allows higher-intensity treatment without excess tissue damage.[61] Alternative approaches combine external-beam radiation therapy either with brachytherapy[62] or with the administration of protons (generated by a cyclotron).[63] Although these approaches appear promising, none have been evaluated in a randomized trial. Several randomized trials suggest that combining external-beam radiation therapy with androgen ablation (to shrink the prostate gland) in intermediate-risk patients improves cancer control or survival.[64-66] However, the optimal timing and duration of androgen ablation are still under investigation. One randomized study found that 6 months of androgen ablation, used concomitantly with radiation, provided a survival benefit in this patient population.[67]

High-Risk Patients

High-risk patients and those with locally advanced prostate cancer (T3 and T4) have the highest likelihood of occult metastatic disease. Local therapy alone is rarely curative, making the morbidity of radical prostatectomy difficult to justify. Many such patients are now treated with androgen ablation followed by external-beam radiation therapy, although even with this multimodality approach, long-term results are poor.

ADJUVANT THERAPY FOR LOCALIZED PROSTATE CANCER

Efforts to improve survival in high-risk cases include giving additional (adjuvant) treatment once local treatment has been completed. After surgery, radiation therapy may be offered to patients with such adverse pathologic findings as resection margins involved by tumor, capsular penetration, or seminal vesical involvement. No controlled studies have indicated whether this approach influences outcome. Androgen ablation has also been used after either surgery or radiation therapy. Three years of androgen-deprivation therapy resulted in a statistically significant increase in survival in a randomized European study of 415 men with locally advanced or high-grade prostate cancer that was treated with external beam radiation.[65] No studies have yet examined the role of adjuvant cytotoxic chemotherapy after local therapy.

Treatment of Advanced Prostate Cancer

The spectrum of advanced prostate cancer has changed dramatically since the late 1980s, largely because of the use of the

PSA test. Most cases are diagnosed earlier, and treatment failure is recognized sooner. As a result, patients with advanced prostate cancer now include many men who undergo surgery or radiation therapy and subsequently experience serologic progression (i.e., a rising serum PSA level). A few of these patients can be cured with further local treatment to the prostate, but most will ultimately require systemic therapy.

SALVAGE TREATMENT

Patients who undergo radical prostatectomy and who subsequently relapse, with detectable and rising serum PSA levels, can be successfully treated with radiation therapy in some cases. Factors that appear to predict curability in this setting include organ-confined prostate cancer at the time of initial treatment, longer time to disease recurrence (> 2 years for a rise in PSA level), and a serum PSA level less than 1 ng/ml at the time of salvage radiation therapy. Salvage radiation therapy can generally be given with minimal morbidity. In contrast, disease recurrence after initial radiation therapy poses a much more difficult problem because salvage radical prostatectomy is associated with a very high morbidity. If either salvage treatment is planned, it is appropriate to restage the cancer with bone scan, CT scan, MRI, and possibly scintigraphy with ProstaScint [*see* Staging, *above*].

ANDROGEN ABLATION

The standard initial treatment for patients with advanced prostate cancer is androgen ablation, a therapeutic strategy that involves either lowering the production of testosterone or blocking its binding to the androgen receptor. Prostate cancer cells require androgen for growth and possibly survival, so removal of androgen will result in cell dormancy or apoptosis. In turn, the serum PSA level generally decreases promptly and dramatically. For the vast majority of patients, symptoms from metastases will lessen or disappear. Radiographically, metastases may diminish or remain the same; complete radiographic responses are unusual. For asymptomatic patients, the only evidence of a response to androgen ablation is a decrease in the serum PSA level.

Androgen ablation is achieved by a variety of strategies. Castration or diminishing testosterone production can be achieved surgically (i.e., with orchiectomy, which removes the testosterone-secreting organs) or chemically (i.e., through use of luteinizing hormone–releasing hormone [LHRH] agonists, which diminish luteinizing hormone and thereby testosterone production by the testicles). The permanency of orchiectomy, as well as the emotional stigma associated with surgical castration, has made the use of LHRH agonists (e.g., leuprolide and goserelin) popular. These agents are administered either monthly or every 3 or 4 months. Other modalities include antiandrogens (e.g., flutamide, bicalutamide, and nilutamide), which are drugs that bind to the androgen receptor competitively. They have mostly been used in conjunction with chemical or surgical castration in an effort to provide maximal or combined androgen blockade. The utility of antiandrogens as sole agents is not completely established.

Androgen ablation is associated with significant side effects, including hot flashes, loss of libido, impotence, gain of adipose tissue, and loss of muscle and bone mass. Despite these side effects, most men tolerate androgen ablation reasonably well. Disabling hot flashes may respond to treatment with clonidine, venlafaxine, or gabapentin.[68]

Prostate cancer typically recurs after androgen ablation. A rise in the serum PSA level is generally the first sign of recurrence, usually predating other evidence of recurrence by months or sometimes years. The duration of response to androgen ablation is highly variable, reflecting the degree of androgen sensitivity of the tumor. In patients with overt metastatic disease, the duration of response is about 12 to 18 months; in patients without evidence of metastasis, the duration is much longer.

Estrogen (e.g., diethylstilbestrol) also lowers LH levels and thereby lowers testosterone levels, and it may have direct effects on prostate cancer cells. The use of estrogens was popular in the past but fell into disfavor because of such side effects as gynecomastia and thromboembolic phenomena.

Timing of Androgen Ablation

Is it better to start androgen ablation therapy along with primary treatment or better to wait until symptomatic metastatic disease appears? This question is controversial, because androgen ablation therapy is palliative rather than curative, and its effect on survival is uncertain.

In three randomized studies, early androgen ablation therapy slowed progression of disease and prolonged survival in patients who received primary therapy with either radiation or prostatectomy for locally advanced or metastatic prostate cancer.[65,69,70] Similarly, a meta-analysis of older studies found that early androgen suppression reduces disease progression and related complications and may slightly improve 10-year survival.[71]

Optimal Androgen-Deprivation Therapy

Many studies have helped define the optimal regimen or regimens of androgen-deprivation therapy. Randomized comparisons of monotherapies (i.e., orchiectomy, LHRH agonists, and estrogens) have shown that although these modalities have differing side effects, they appear to have an equivalent impact on survival.[72,73] The possible exception is antiandrogen monotherapy, which appears to be inferior to other modalities in patients with established metastases.

The adrenal androgens are relatively weaker than testosterone, and their role in supporting prostate cancer cell growth is uncertain. Nevertheless, regimens have been devised to suppress production of both testicular and adrenal androgens to provide maximal androgen deprivation. The concept of combined androgen blockade (CAB) was objectively assessed in a multi-institutional trial in which 603 men with metastatic prostate cancer were randomized to receive either leuprolide alone or leuprolide plus flutamide.[74] Compared with leuprolide alone, CAB resulted in a significant improvement in time to disease progression and median survival. However, a larger and more recent study, which enrolled 1,387 men with metastatic prostate cancer and compared orchiectomy alone with orchiectomy plus flutamide, found no difference in overall survival between the two groups.[75] Three meta-analyses on this topic have concluded that if CAB does benefit patients with established metastases, that benefit is extremely modest.

CHEMOTHERAPY

Chemotherapy has a clear role in patients with hormone-refractory prostate cancer. Two randomized trials of mitoxantrone plus a corticosteroid documented improvements in quality of life (albeit no improvement in survival) with the use of mitoxantrone.[76,77] These two studies led to the approval of mitoxantrone by the Food and Drug Administration for the treatment of hormone-refractory prostate cancer.

An important recent finding is that taxanes (i.e., paclitaxel and docetaxel) are active against prostate cancer. These drugs inhibit mitosis in prostate epithelial cells by interfering with microtubular assembly in the nucleus. Two randomized studies demonstrated longer survival for men treated with docetaxel than for those treated with mitoxantrone plus prednisone.[78,79] Docetaxel plus prednisone is now the standard chemotherapy for men with metastatic prostate cancer.

PALLIATION OF BONE PAIN

Because prostate cancer tends to spread to bone, bone pain is a major source of morbidity in patients with advanced disease. The mainstays of treatment for bone pain are analgesics (i.e., nonsteroidal anti-inflammatory drugs and narcotics) and external-beam radiation therapy. Radiation therapy is effective at reducing or eliminating pain at specific sites in over 90% of patients within 2 weeks of treatment. Radiopharmaceuticals such as strontium-89 and samarium-153–labeled ethylenediaminetetramethylenephosphonate (EDTMP) are sometimes useful in patients with multiple sites of pain. These injectable isotopes concentrate in osseous tissue. Pain relief usually occurs within a few weeks after treatment, although 15% of patients experience a flare in pain within the first 2 weeks. These agents are generally well tolerated, but progressive bone marrow suppression may occur with repeat dosing. Their mechanism of activity is uncertain, but pain relief in patients who receive these agents is rarely coupled with a decline in serum PSA levels.

Prevention of Prostate Cancer

Risk reduction and chemoprevention of prostate cancer are important objectives. The 5α-reductase inhibitor finasteride may interfere with the development or progression of prostate cancer. Currently approved for use in BPH, finasteride reduces the conversion of testosterone to dihydrotestosterone, a more potent androgen, and decreases prostate size [*see 10:XIII Benign Prostatic Hyperplasia*]. Although a large, double-blind, placebo-controlled trial (the Prostate Cancer Prevention Trial) demonstrated a 24.4% reduction in primary prostate cancer with finasteride, study patients who developed prostate cancer while taking finasteride were more likely to have higher-grade cancer.[80] This puzzling finding has stymied the use of finasteride as a preventive agent.

Selenium and vitamin E may lower the risk of prostate cancer. That possibility is being tested in the Selenium and Vitamin E Cancer Prevention Trial (SELECT), a randomized, prospective, double-blind study.[81] Along with high lycopene consumption [*see* Diet, *above*], high consumption of vegetables (particularly cruciferous vegetables)[82] and consumption of fish (especially fatty fish such as salmon)[83] may reduce the risk of prostate cancer. Large studies have been inconclusive on possible links between obesity and prostate cancer—but whether a link exists or not, reduction of excess weight is still indicated, given the many other health risks of obesity.[84]

X GYNECOLOGIC CANCER

Stephen A. Cannistra, m.d.

Epithelial Cancer of the Ovary

The ovary contains three distinct cell types: germ cells, stromal cells, and epithelial cells. All of these cell types can give rise to tumors that vary widely in their presentation, natural history, and treatment approach. Ovarian germ cell tumors are derived from the oocyte and often occur in women younger than 20 years. The typical presentation is pelvic pain, which is caused by rapid tumor growth. Ovarian stromal cell tumors are derived from supporting elements such as granulosa or theca cells, which are normally responsible for sex steroid production. Stromal cell tumors can occur at any age, although they often affect postmenopausal women. These tumors are characterized by their ability to secrete estradiol. The type of ovarian tumor that most commonly affects adult women, however, is derived from the epithelial cells that cover the ovarian surface. Epithelial ovarian cancer can be divided into four common histologic subtypes: papillary serous cystadenocarcinoma, endometrioid, clear cell, and mucinous [*see Table 1*].

This chapter focuses on the diagnosis and management of epithelial ovarian cancer, with special emphasis on increased survival resulting from the use of taxanes as first-line therapy. Unless otherwise stated, the term ovarian cancer refers to an invasive neoplasm of epithelial origin, as opposed to germ cell and stromal cell neoplasms.

epidemiology and risk factors

Epithelial ovarian cancer occurs at a mean age of 60 years in the United States and is the most lethal of gynecologic tract tumors. In approximately 70% of affected women, the tumor has spread beyond the pelvis by the time of diagnosis.[1] An estimated 25,400 new cases of ovarian cancer and approximately 14,300 deaths from the disease occurred in the United States in 2003.[2]

Temporary suppression of menstrual function is associated with a decreased risk of epithelial ovarian cancer. Thus, oral-contraceptive use (any history), pregnancy, and lactation are each associated with a significant reduction in risk.[1] Conversely, nulliparity is associated with an increased risk of ovarian cancer; it is not uncommon to diagnose this tumor during evaluation for and treatment of infertility. The use of talc has been associated with increased ovarian cancer risk, although this finding is somewhat controversial.[3,4] The association between the use of such fertility drugs as clomiphene citrate and increased risk of ovarian cancer is also controversial, with some studies suggesting a higher risk and others showing no increased risk.[5-7] Interpretation of these studies is confounded by the fact that nulliparity (and therefore perhaps infertility) itself is a risk factor for ovarian cancer.

A large population study confirmed nulliparous women are at a slightly increased risk for ovarian cancer; however, the risk may be higher in nulliparous women who have a family history of breast cancer or ovarian cancer in first-degree relatives [8] The most important risk factor for ovarian cancer is family history, with two or more affected first-degree relatives conferring an approximately 10-fold increased risk.[1] Two familial syndromes that are associated with an increased risk of ovarian cancer are the breast-ovarian cancer syndrome (involving mutations in either the *BRCA1* gene, located on chromosome 17q, or the *BRCA2* gene, located on chromosome 13q) and the Lynch syndrome II (usually involving mutations in the *MSHII* or *MLHI* gene).

Familial Ovarian Cancer

Breast-ovarian cancer syndrome A family history suggestive of a genetic predisposition for ovarian cancer may be found in as many as 10% of patients affected with the disease. The breast-ovarian cancer syndrome, as the name implies, occurs in families whose members may have breast cancer, ovarian cancer, or both.[9,10] Mutations in the *BRCA1* or *BRCA2* genes are responsible for this syndrome. BRCA1 and BRCA2 are nuclear proteins that associate with RAD51, a molecule responsible for maintaining genomic integrity.[11] Loss of heterozygosity for the *BRCA1* or *BRCA2* locus (meaning that only one of the two alleles remains, usually representing the mutated gene) is a common feature of tumors occurring in the setting of an inherited germline mutation. Whether loss of *BRCA1* or *BRCA2* function increases cancer risk by predisposing to genomic instability is currently being investigated.

Because the mutated *BRCA1* and *BRCA2* genes can be inherited from either parent, it is imperative to obtain a complete history from both sides of the family. In addition, there are subtle but important differences between the phenotype of *BRCA1* mutation carriers and the phenotype of *BRCA2* mutation carriers. *BRCA1* mutations are often associated with early onset breast cancers and an overall lifetime breast cancer risk of 50% to 80%. There may also be a slightly increased risk of colorectal and prostate cancer in *BRCA1* mutation carriers. The lifetime

Table 1 Common Histologic Types of Epithelial Ovarian Cancer

Histology	*Clinical Features*
Papillary serous cystadenocarcinoma	The most common type of epithelial ovarian cancer; may also be observed in primary peritoneal serous cancers; associated with psammoma bodies
Endometrioid	Histologically resembles endometrial cancer and is sometimes associated with endometriosis; tends to occur in slightly younger women and at an earlier stage than papillary serous carcinoma; may be associated with a separate endometrial (uterine) cancer in 15% of patients
Clear cell	Distinguished by cleared-out cytoplasm (due to glycogen) and hobnail nuclei; also may be associated with endometriosis; humorally mediated hypercalcemia may occur in rare instances; the most chemoresistant of all epithelial ovarian cancer histologies
Mucinous	The only histology not convincingly associated with *BRCA1* mutations; often associated with normal or only slightly elevated CA125 level; the presence of *Pseudomyxoma peritonei* and bilaterality should suggest an appendiceal primary tumor with metastases to the ovaries

ovarian cancer risk for *BRCA1* mutation carriers is 16% to 40%.[9,10] Some investigators have suggested that patients with ovarian cancer caused by the *BRCA1* mutation have a better prognosis than patients with the sporadic variety of ovarian cancer,[12,13] but this finding is not supported by other studies.[14] In addition to developing ovarian cancer, patients with the *BRCA1* mutation may develop primary peritoneal serous cancers, which are histologically identical to ovarian cancer and are presumed to represent malignant transformation of the peritoneal mesothelial surface.[15]

BRCA2 mutations are not as likely as *BRCA1* mutations to be associated with the early onset of breast cancer, although the lifetime risks for breast cancer are similar for the two mutations.[16,17] In addition, *BRCA2* mutations are associated with a higher risk of male breast cancer and possibly with a higher risk of pancreatic cancer. The ovarian cancer risk associated with *BRCA2* mutations is about 10%, which is lower than the risk associated with *BRCA1* mutations.[10]

Specific *BRCA1* and *BRCA2* mutations have been noted to occur with a higher than expected frequency in certain ethnic groups. It is thought that this phenomenon represents a founder effect, in which, over many generations of inbreeding, an ancestral gene has been selected. The best-studied group are Ashkenazi Jewish women of eastern European descent, in whom three distinct mutations occur with a relatively high frequency: the *BRCA1* 185 del AG mutation, the *BRCA1* 5382 ins C mutation, and the *BRCA2* 6174 del T mutation.[9] In healthy Ashkenazi Jewish women, the prevalence of these mutations is approximately 2.5%, and they are found in about 30% to 40% of early onset breast and ovarian cancers. It is important to note that these and other *BRCA1* and *BRCA2* mutations are not specific for Ashkenazi Jewish women and may occur in persons of other ethnic groups.

The value of screening patients who harbor germline mutations in *BRCA1* or *BRCA2* genes is controversial, although the strategy of screening with transvaginal ultrasonography and measurement of the CA125 level is under investigation.[18] Prophylactic oophorectomy after the completion of childbearing in high-risk women older than 35 years is a reasonable consideration, but the value of this procedure in prolonging survival is unproved.[19] Patients who consider prophylactic oophorectomy should be informed that it is still possible to develop primary peritoneal serous cancer at other sites in the abdominal cavity.[15,20]

Lynch syndrome II Lynch syndrome II, also known as hereditary nonpolyposis colon cancer (HNPCC), is characterized by a familial predisposition for ovarian, endometrial, and colon cancers. Affected women are often younger than 50 years.[21] Although ovarian cancer is a component of this entity, the HNPCC syndrome more frequently occurs simply as a cancer in the right side of the colon.[22] In this regard, a patient with ovarian cancer in the setting of HNPCC will probably describe a significant family history of colon cancer, without recalling anyone else in her family having had ovarian cancer. This genetic predisposition is the result of germline mutations in genes that encode proteins responsible for mismatch repair of DNA, including *MSH2* (on chromosome 2p), *MLH1* (on chromosome 3), *PMS1* (on chromosome 2), and *PMS2* (on chromosome 7).[21]

CLINICAL FEATURES

Early onset ovarian cancer that is restricted to the pelvis usually produces no signs or symptoms. Occasionally, a premenopausal woman with cancer limited to the ovary (stage I) [*see Table 2*] may present with a pelvic mass on routine physical examination or will come to medical attention because of intermittent pelvic pain caused by ovarian torsion. A postmenopausal woman with early onset ovarian cancer may have a palpable ovary, which is not a normal finding for a woman in this age group and raises suspicion of malignancy. Unfortunately, approximately 70% of women present with advanced disease that has extended beyond the pelvis to involve other areas such as the upper abdomen (stage III) and the pleural space (stage IV) [*see Table 2*]. In these cases, the tumor cells have shed from the primary ovarian mass and have spread throughout the peritoneal cavity, resulting in diffuse tumor nodules that involve the omentum, undersides of the diaphragm, and serosal surfaces of the abdominal cavity and bowel [*see Figure 1*]. Women with advanced disease often note a progressive increase in abdominal girth and bloating for several months before they are diagnosed. These symptoms are caused by malignant ascites. The tumor can spread via the lymphatics to involve the para-aortic lymph node chain, which is the primary drainage site for the ovaries (as with the testes). In rare instances, patients may present with inguinal adenopathy as the first sign of disease. A large omental tumor cake can cause early satiety and weight loss as a result of gastric compression; however, weight loss is more commonly offset by the development of ascites. Because of the nonspecific nature of the abdominal complaints, which are related to the presence of ascites and omental disease, many patients initially undergo an upper gastrointestinal tract evaluation for a possible ulcer before the true nature of the illness is recognized. Finally, ovarian

Table 2 FIGO Surgical Staging of Ovarian Cancer*

Stage I:	Tumor confined to the ovaries
Stage IA:	Limited to one ovary, without capsular spread, tumor rupture, positive peritoneal washings, or malignant ascites
Stage IB:	Bilateral ovarian involvement, without capsular spread, tumor rupture, positive washings, or malignant ascites
Stage IC:	Capsular spread, tumor rupture, positive washings, or malignant ascites
Stage II:	Tumor extends into the pelvis
Stage IIA:	Involvement of the uterus or fallopian tubes
Stage IIB:	Involvement of other pelvic organs (bladder, cul-de-sac implants, vagina, rectum)
Stage IIC:	Pelvic extension, plus findings as indicated for stage IC
Stage III:	Tumor extends to the upper abdomen or involves retroperitoneal lymph nodes
Stage IIIA:	Microscopic seeding outside of the true pelvis (e.g., serosa of the small bowel, undersides of diaphragm, or omental involvement)
Stage IIIB:	Gross implants about 2 cm before debulking
Stage IIIC:	Gross implants > 2 cm before debulking, or the presence of retroperitoneal lymph node involvement (usually para-aortic)
Stage IV:	Distant organ involvement, including pleural space (most common) or hepatic-splenic parenchyma (unusual)

*The staging system for ovarian cancer is established by the International Federation of Gynecology and Obstetrics (FIGO) and is based on the results obtained at the time of surgery.

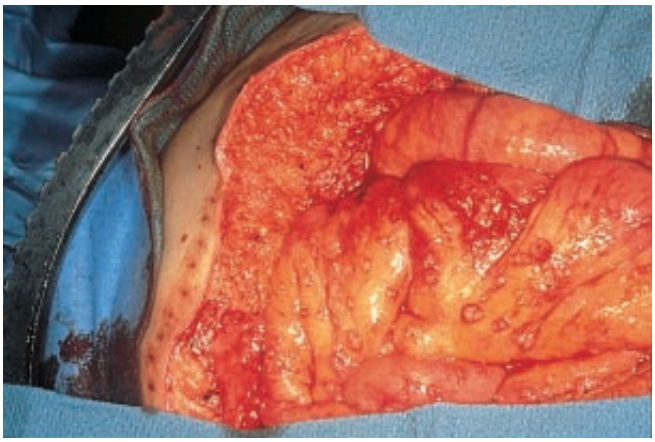

Figure 1 **Intraoperative appearance of stage III epithelial ovarian cancer. Multiple peritoneal implants are widely scattered throughout the upper abdomen in a patient with stage IIIC disease.**

cancer can sometimes be preceded by a paraneoplastic syndrome, such as cerebellar degeneration (which is often not reversible despite treatment of the tumor), migratory superficial thrombophlebitis and hypercoagulability (Trousseau syndrome), or the sign of Leser-Trélat (sudden appearance of multiple seborrheic keratoses).[1]

EVALUATION AND DIFFERENTIAL DIAGNOSIS

Women suspected of having an intra-abdominal malignancy such as ovarian cancer on the basis of findings of a pelvic mass, ascites, or both are often evaluated by transvaginal ultrasonography. A transvaginal approach is preferred for the performance of sonography because the ultrasound probe is closer to the ovaries, and the patient is not required to have a full bladder for adequate definition of pelvic anatomy.

Sonography is more sensitive than computed tomography for the detection of pelvic masses and is capable of yielding qualitative information about a mass that can help determine whether it is malignant. An ovarian mass composed of both solid and cystic components, especially if it is septated (multicystic) and echogenic (implying free-floating tumor debris), is referred to as complex and suggests a malignancy. Conversely, a so-called simple cyst is entirely fluid filled, is nonechogenic, and is not associated with a solid component. Simple cysts are usually benign.

If a complex mass is observed on a sonogram, the next step in the diagnostic evaluation is usually an exploratory laparotomy, which is required for tissue diagnosis, staging, and debulking. The performance of CT or paracentesis for preoperative confirmation of malignancy is not usually helpful once a complex mass has been discovered in a patient who is a good surgical candidate. Such a patient generally requires an operation for tissue diagnosis and tumor resection, regardless of the results of these additional studies. A tissue diagnosis (as opposed to cytologic evaluation) is often required for the distinction between primary ovarian cancer and tumors from other primary sites that have metastasized to the ovary. Metastatic involvement of the ovary is known as a Krukenberg tumor; it is often (but not always) bilateral and typically represents spread from an unsuspected gastric, colorectal, or breast cancer. Because early-stage ovarian cancer is potentially curable, it is especially important to proceed to surgical exploration in patients whose sonograms show only a pelvic mass and whose examination reveals no evidence of advanced disease. Such pelvic masses should generally not be diagnosed by percutaneous biopsy, because tumor dissemination may occur if the cyst is inadvertently ruptured.

There are occasional instances in which surgery is not required in the evaluation and management of a suspected intra-abdominal malignancy such as ovarian cancer. For instance, an elderly patient with a cytologically confirmed malignant pleural effusion containing a papillary carcinoma with psammoma bodies (concentric rings of calcification observed on microscopic evaluation) and obvious intra-abdominal disease on examination or sonogram probably has stage IV ovarian cancer (or primary peritoneal serous cancer, which is treated similarly). Because surgery is not without risk in the elderly population and because the benefits of surgical cytoreduction in the setting of stage IV disease are controversial, it is reasonable to forgo the procedure in such a patient and proceed directly with appropriate chemotherapy (see below). However, initial surgery may be appropriate in an elderly patient if imminent bowel obstruction is a concern. Also, a patient with disproportionate complaints of upper abdominal discomfort, left-sided supraclavicular adenopathy (Virchow node), blood in the stool, and iron deficiency anemia would be better served by upper endoscopy to exclude gastric cancer, which can metastasize to the ovaries and cause a Krukenberg tumor. Finally, patients with suspected ovarian cancer require a breast examination, because breast cancer can metastasize to the abdominal cavity, producing ascites and ovarian masses (a more likely presentation with lobular, as opposed to ductal, carcinoma of the breast).

Serum tumor markers such as CA125 and carcinoembryonic antigen (CEA) are generally not helpful in the differential diagnosis of a patient with presumed intra-abdominal malignancy. Although a very high CA125 value in the setting of a normal or slightly elevated CEA level is suggestive of ovarian cancer, most patients require surgery for definitive diagnosis of ovarian cancer and debulking. The CA125 level is a useful parameter for assessment of the response of ovarian cancer patients to chemotherapy and for detection of relapse.[23,24] However, measurement of the CA125 level by itself is not useful as a screening test; the CA125 level is elevated in only 50% of patients with early-stage disease and may be elevated in other cancers, as well as in nonmalignant conditions such as pregnancy and endometriosis. The strategy of both measuring the CA125 level and performing transvaginal sonography for screening has resulted in greater specificity, although its value in the early detection of ovarian cancer in the general population has not been proved and is under investigation as a screening tool in high-risk patients.[10]

STAGING AND SURGICAL MANAGEMENT

The staging system for ovarian cancer is derived from the International Federation of Gynecology and Obstetrics (FIGO) [*see Table 2*]. Early-stage disease is localized to one or both ovaries (stage I) or extends beyond the ovary to involve other pelvic structures (stage II). Advanced disease involves the upper abdomen or lymph nodes (stage III) or areas outside of the abdomen, such as a cytologically documented malignant pleural effusion (stage IV).

Exploratory laparotomy for evaluation of suspected ovarian cancer is typically performed with a vertical midline incision to provide adequate visualization of the upper abdomen. Peri-

toneal washings are obtained before removal of the ovarian mass to avoid contamination of the cytologic specimen with tumor cells inadvertently released by ovarian rupture during resection. If the suspicion of epithelial ovarian cancer is confirmed by frozen section, a bilateral salpingo-oophorectomy (BSO) and total abdominal hysterectomy (TAH) are usually performed, along with a partial omentectomy. Other sites of tumor involvement are carefully evaluated with palpation and biopsy of the undersides of the diaphragm, the serosal surfaces of the bowel, and the paracolic gutters. The para-aortic lymph nodes are typically assessed when information about lymph node status would change patient management or when precise surgical staging is required to determine eligibility for protocol therapy. Finally, an attempt is made to remove as much tumor as possible at the time of initial surgery (debulking) because patients with residual tumor measuring less than 1 cm in diameter are more likely to respond to chemotherapy and have an improved survival rate.[1] It is not known whether this is the result of an intrinsic therapeutic effect of debulking, as opposed to a selection phenomenon, whereby the ability to debulk identifies a patient population with more favorable biologic features. For patients whose tumor cannot be optimally debulked at the time of initial surgery, a repeat attempt may be considered after three cycles of chemotherapy have been administered. This approach is referred to as an interval cytoreductive procedure and was associated with an increase in the median duration of survival by approximately 6 months in a randomized trial performed by the European Organization for the Research and Treatment of Cancer (EORTC).[25]

POSTOPERATIVE TREATMENT

Early-Stage Disease (Stages I and II)

Some women with ovarian cancer have low-risk features that confer a 5-year survival rate of about 95%. Members of this low-risk group have stage IA or stage IB disease that is well or moderately well differentiated (i.e., grade I or II). These patients do not generally derive benefit from the use of postoperative adjuvant therapy.[26] In contrast, approximately 20% of women with early-stage disease have risk factors that are associated with an overall relapse rate of between 20% and 40%.[27,28] The risk factors include any or all of the following: involvement of the ovarian capsule, tumor rupture, tumor present in peritoneal washings, grade III histology, and stage II disease. Patients with early-stage disease who have any of these risk factors are commonly treated with postoperative adjuvant chemotherapy with a platinum-based regimen, because this class of agents provides effective treatment for patients with more advanced disease (see below). Adjuvant treatment of this high-risk group has been shown to improve the disease-free survival rate, although its effect on overall survival is still controversial.[27,28] More recent randomized data suggest that platinum-based adjuvant therapy may confer an overall survival advantage in high-risk, early stage disease, although the benefit appears to be restricted to those patients who were inadequately staged.[29] The overall 5-year survival rate for patients with high-risk, early-stage ovarian cancer who are treated with adjuvant chemotherapy is about 80%.

Advanced-Stage Disease (Stages III and IV)

Approximately 70% of patients with ovarian cancer have advanced disease that cannot be completely resected at the time of exploratory laparotomy. Eradication of residual disease in these patients generally requires some form of postoperative treatment, most often platinum-based chemotherapy. Postoperative therapy for advanced-stage ovarian cancer leads to long-term disease-free survival in 10% to 30% of patients, depending on the exact stage and residual disease status. For instance, a patient with stage IV, suboptimally debulked disease (residual nodules measuring more than 1 cm in diameter) has an expected long-term survival rate of less than 10% despite treatment with platinum-based chemotherapy, whereas a patient with stage III, optimally debulked disease has an approximately 30% chance of long-term survival.

The platinum analogues are the most effective agents in the treatment of epithelial ovarian cancer, with single-agent response rates in the range of 50% to 60%. Platinum compounds, such as carboplatin and cisplatin, exert their cytotoxic effects by inducing DNA damage, primarily through the formation of intrastrand cross-links. The taxanes, such as paclitaxel and docetaxel, are also highly active drugs, with single-agent response rates in newly diagnosed advanced disease of approximately 40%. Paclitaxel was originally isolated from the bark of the Pacific yew tree *Taxus brevifolia* and exerts its cytotoxic effects in part by binding to and stabilizing the tubulin polymer during mitotic spindle formation.[30] The mitotic spindle apparatus cannot readily dissociate in the presence of paclitaxel, resulting in M-phase arrest and subsequent cell death through apoptosis.[31] The distinct mechanisms of action of platinum compounds and taxanes suggest that when they are used in combination, they may act independently (i.e., there is no cross-resistance). In this regard, the activity of combined paclitaxel and cisplatin chemotherapy has been evaluated in two large randomized trials of patients with newly diagnosed ovarian cancer.[32,33] Compared with cyclophosphamide and cisplatin, paclitaxel and cisplatin demonstrated superior activity and led to statistically significant improvement in the overall survival rate. The combination of paclitaxel and carboplatin has been shown to be therapeutically equivalent to the original paclitaxel-cisplatin regimen but is associated with less emesis, neurotoxicity, and nephrotoxicity.[34,35] Paclitaxel and carboplatin are easier to administer on an outpatient basis because prehydration and posthydration are not required (cisplatin requires adequate hydration to prevent nephrotoxicity). For these reasons, the combination of paclitaxel (3-hour infusion) and carboplatin has become the standard regimen for the postoperative management of patients with advanced epithelial ovarian cancer. It is important to note that this chemotherapy is administered intravenously, although there are some investigators who believe that intraperitoneal (IP) administration of agents such as cisplatin may be beneficial.[36,37] The value of IP chemotherapy as first-line treatment of patients with optimally debulked, advanced disease is uncertain. Finally, it has been recently shown that administration of single-agent paclitaxel for 1 year is capable of prolonging median progression-free survival by 7 months in patients with advanced disease who achieve a clinical complete remission after first-line therapy.[38] Unfortunately, this strategy does not appear to prolong overall survival, and it is associated with side effects such as neuropathy and continued alopecia.

MANAGEMENT OF RELAPSE

The most common adverse prognostic factors for ovarian cancer are advanced-stage, high-grade, and suboptimally debulked disease [*see Table 3*].[1,39-45] These prognostic factors are

predictive of a poor response to chemotherapy and poor durability of complete remission. Thus, approximately 30% of patients with advanced disease have residual, active tumor after treatment with paclitaxel and carboplatin. Conversely, about 70% of newly diagnosed patients achieve a complete response to surgery followed by treatment with paclitaxel and carboplatin, although most of these women eventually experience relapse. Relapse of ovarian cancer is almost always incurable; it is often detected by the finding of an elevated CA125 level in the absence of signs, symptoms, or CT evidence of tumor.[1]

The goal of treatment of ovarian cancer relapse is palliation of symptoms. For patients with relapse detected only by the finding of an elevated CA125 level, there is no convincing evidence that second-line, cytotoxic chemotherapy improves survival rate; however, it can compromise quality of life at a time when patients are feeling well. In this situation, treatment with tamoxifen or an aromatose inhibitor is a reasonable consideration because this antiestrogen is well tolerated, is conveniently administered by mouth, and has a response rate of approximately 17% in patients experiencing relapse.[46,47] Cytotoxic chemotherapy is generally reserved for patients who progress through tamoxifen therapy or who are becoming symptomatic (often complaining of mild abdominal cramping) in the setting of CT findings such as peritoneal implants or ascites.[42,47] When chemotherapy becomes necessary, retreatment with either platinum compounds or taxanes is often a reasonable first step if the interval between the last chemotherapy regimen and relapse is longer than 6 months.[42,47] Recent data suggest that a combination of paclitaxel and a platinum compound may confer a survival advantage over single-agent platinum in patients with relapsed disease who are potentially platinum sensitive.[48] However, because of methodologic concerns, additional studies are required to confirm these findings. For cases of rapid relapse after completion of first-line therapy and cases of development of platinum-resistant disease, potentially useful second-line agents include liposomal doxorubicin, topotecan, gemcitabine, and etoposide.[47,49] For selected patients who experience a prolonged remission after first-line chemotherapy (i.e., remission lasting longer than 12 months) and who experience recurrence of localized, potentially resectable disease, a secondary cytoreductive procedure is sometimes considered before the institution of chemotherapy.[50] In patients experiencing relapse, this procedure is almost never curative, and the value of this approach has not been tested in a prospective, randomized trial. Although patients who undergo successful secondary cytoreduction tend to survive longer than those whose cancer cannot be resected, it is unclear whether the surgery itself confers the survival advantage or whether it is simply the fact that the patients who are selected to undergo cytoreduction have more indolent, chemoresponsive disease.

Table 3 Selected Adverse Prognostic Factors in Epithelial Ovarian Cancer

Advanced disease (stages III/IV)[1,39]
Suboptimal cytoreduction (> 1 cm residual)[1,39]
High grade[1,39]
Clear cell histology[1,39]
Older age (> 65 yr)[40]
Persistent CA125 elevation after three cycles of chemotherapy[41]
Rapid recurrence (within 6 mo of completing first-line therapy)[42]
p53 mutation[43]
Underexpression of the BAX protein (a death-promoting member of the BCL2 family)[44]
Amplification of the *HER-2/neu* gene (a member of the EGF tyrosine kinase receptor family)[45]

MANAGEMENT OF OTHER TYPES OF OVARIAN TUMORS

Borderline ovarian tumors, also known as tumors of low malignant potential, are epithelial tumors that show no histologic evidence of invasion and often appear at an early stage during patients' fourth or fifth decade of life. These tumors are generally associated with excellent survival rates (about 90% at 10 years).[51-55] Even advanced borderline tumors involving the upper abdomen may have a very indolent natural history, characterized by serial tumor recurrences that are managed by repeated surgical resection. In contrast to more typical invasive epithelial ovarian cancer, borderline tumors are generally not sensitive to chemotherapy, and there is no well-defined role for the use of postoperative adjuvant therapy.

Malignant ovarian germ cell tumors may be histologically classified as either dysgerminoma or nondysgerminoma. Dysgerminoma of the ovary is to women what testicular seminoma is to men; patients with dysgerminoma often present with stage I disease (although dysgerminoma may be bilateral in about 10% of cases).[56] Staging of this tumor ideally includes para-aortic lymph node dissection because dysgerminoma has a predilection for lymph node spread. After resection, dysgerminoma that is limited to the ovary (stage IA) is often managed by careful follow-up; assuming that adequate staging has been performed, postoperative adjuvant chemotherapy is not necessary. More advanced disease is usually treated with postoperative platinum-based chemotherapy containing bleomycin, etoposide, and cisplatin (BEP). Immature teratoma is a form of malignant ovarian germ cell tumor that is occasionally treated with surgery alone if the tumor is confined to the ovary and characterized as grade I or, sometimes, grade II.[57,58] Patients with stage I, grade III immature teratoma or with more advanced disease are often treated with BEP. Other types of malignant nondysgerminomas of the ovary (e.g., embryonal cell, endodermal sinus, and choriocarcinoma) generally require postoperative treatment with BEP, regardless of stage, in view of the high risk of recurrence.[59,60] Malignant ovarian germ cell tumors are often chemoresponsive and highly curable; therefore, to preserve fertility, the initial surgical management of these tumors is often a unilateral salpingo-oophorectomy (with staging) as opposed to a TAH/BSO.[61,62]

Finally, women with ovarian stromal neoplasms such as granulosa cell tumors may present with signs and symptoms related to estradiol production.[63,64] A young girl may develop precocious puberty, or a postmenopausal woman may develop breast tenderness or vaginal bleeding as a result of either endometrial proliferation or the presence of a separate uterine cancer caused by unopposed estrogen production by the granulosa cell tumor. Because of its highly vascular nature, a ruptured granulosa cell tumor may sometimes mimic an ectopic pregnancy, with hypotension and abdominal pain caused by intraperitoneal bleeding. Treatment of stromal cell ovarian tumors is primarily surgical; the role of adjuvant chemotherapy or whole abdominal radiotherapy for high-risk patients (i.e., with large primary tumors, capsular rupture, or advanced-stage disease) is undefined. Recurrence of ovarian stromal cell

tumors may occur many years after the original diagnosis, and patients therefore require long-term follow-up. Because these tumors often produce estradiol, inhibin, and müllerian inhibitory substance (MIS), these serum markers may prove to be valuable for postoperative surveillance.

Cancer of the Uterine Cervix

Invasive cervical cancer is uncommon in developed countries, partly because of the effectiveness of Papanicolaou (Pap) smear screening. Nevertheless, it is estimated that in the United States in 2003, cervical cancer affected 12,200 women and caused approximately 4,100 deaths.[2] Part of the success of Pap smear screening is due to the fact that this approach typically detects premalignant lesions, as opposed to invasive cancer. This unique feature makes it possible to eradicate precursor lesions before the development of frankly invasive cancers. In addition, the interval of time between the development of a precursor lesion and the occurrence of invasive disease may be several years, thus allowing many opportunities for the detection and eradication of premalignant disease. In developing countries, however, cervical cancer is a major cause of death in patients with gynecologic cancer; Pap smear screening on a routine basis is difficult because of a lack of resources and poor patient compliance.

EPIDEMIOLOGY AND RISK FACTORS

Cervical cancer is typically a disease of women in their fifth and sixth decades, whereas premalignant cervical lesions (see below) are often discovered in women younger than 40 years.[65] This rather large gap in the age distribution between precursor lesions and invasive cancer is indicative of a long latency period for malignant transformation. Infection with human papillomavirus (HPV)—most commonly, subtypes 16, 18, 31, 33, and 35—is largely responsible for the development of precursor lesions and subsequent transformation to invasive disease.[65-67] Not surprisingly, factors that predispose to transmission of this virus are associated with an increased risk of the development of cervical cancer. These high-risk factors are sexual intercourse at an early age, multiple male sexual partners, and male sexual partners who themselves have multiple partners.[65] A history of smoking also confers a higher risk. Immunosuppression associated with either an underlying lymphoproliferative disorder such as Hodgkin disease or immunosuppressive drugs used in the prevention of allograft rejection also confers a higher risk of cervical cancer.[68] In women with HIV infection, the immunosuppressive state associated with the infection increases the risk of development of cervical precursor lesions, although it is not clear whether the development of such lesions results in a higher incidence of invasive cervical disease.[69]

EARLY DETECTION OF PREINVASIVE DISEASE

The Pap smear detects cytologic changes that indicate the possible presence of precursor lesions that could give rise to invasive disease if not removed. Thus, the main role of this screening test is to identify patients who require further evaluation by a gynecologist and possible cervical biopsy. If a subsequent cervical biopsy reveals preinvasive disease, it may be appropriate to eradicate the lesion with conservative outpatient techniques, such as laser vaporization or the loop electric excision procedure (LEEP), or with more aggressive surgical techniques, such as cervical conization (also known as cone biopsy, in which a conical portion of cervix is removed along with a portion of the endocervical canal). Pap smear screening should begin when a female becomes sexually active or reaches 18 years of age and should continue annually for at least 3 years. If three or more annual Pap smear evaluations are negative and the patient's risk of cervical cancer is average, further testing can be performed at the physician's discretion, perhaps every 2 to 3 years, although the optimal frequency in this situation has not been established.[65] Continued annual Pap smears are reasonable for women at high risk of developing cervical cancer.

DIAGNOSIS

Cervical cancer is often asymptomatic and is commonly detected as a gross cervical lesion at the time of a routine pelvic examination. The presence of a grossly visible cervical lesion warrants biopsy, even if the Pap smear is normal. Occasionally, microscopic invasive disease is found during the evaluation of an abnormal Pap smear. It should be remembered, however, that abnormal Pap smears do not usually signify the presence of invasive disease but rather indicate the possibility of precursor lesions that could give rise to invasive disease if not removed. Some patients with cervical cancer present with vaginal discharge or postcoital bleeding. Patients with more advanced disease may present with lower extremity edema, caused by involvement of pelvic lymph nodes; such edema can be painful and can cause ureteral obstruction.

Biopsy of a grossly visible lesion or discovery of invasive cancer as part of the evaluation of an abnormal Pap smear may reveal squamous cell carcinoma, the most common histologic variant of cervical cancer. Adenocarcinoma is the second most common histologic finding; it is clinically similar to squamous cell carcinoma, with the exception of its propensity to be located within the endocervical canal and to sometimes display an endophytic growth pattern, which results in a barrel-shaped cervix. In rare instances, small cell carcinoma of the cervix is discovered on biopsy, usually in a young woman; small cell carcinoma of the cervix may be associated with rapid metastases and the syndrome of ectopic adrenocorticotropic hormone secretion.

STAGING

The FIGO staging system for cervical cancer is based entirely on clinical criteria. Stage I disease is limited to the cervix and may be either microscopic (stage IA) or grossly visible (stage IB). In stage II, the cancer has extended beyond the cervix, to involve either the upper two thirds of the vagina (stage IIA) or the parametrial tissue (stage IIB). Stage III disease is more locally extensive, involving the lower one third of the vagina (stage IIIA) or extending to the pelvic side wall or causing hydronephrosis (stage IIIB). Stage IV disease is the most advanced, representing either extensive infiltration of local pelvic structures (involvement of the bladder or rectal mucosa—stage IVA) or disease outside of the pelvis (stage IVB).

Accurate staging is necessary to help determine whether the disease is amenable to a surgical approach (appropriate for stages IA, IB, and IIA) or primary radiotherapy (appropriate for stages IIB, III, and IVA). To determine whether disease involves the parametrial tissue, it is often necessary to perform a pelvic examination with the patient under anesthesia. In addition, radiographic visualization of the ureters is often required to exclude hydronephrosis and to define the ureteral anatomy if a surgical approach is deemed appropriate. For more locally

advanced lesions, consideration of cystoscopy and proctoscopy is reasonable to exclude stage IVA disease. Finally, a chest x-ray is obtained to exclude hematogenous spread to the lungs, which is a common site of metastasis in this disease.

TREATMENT

Stage IA

Patients with stage IA squamous cell carcinoma that has extended to a depth of greater than 3 mm (stage IA2) or who have involvement of the lymphovascular space or surgical margins, as revealed by cone biopsy, are appropriate candidates for a radical hysterectomy with pelvic lymph node dissection. Radical hysterectomy is a procedure in which the uterine corpus and cervix are removed en bloc along with parametrial tissue, the ureterosacral ligaments, and a 2 to 3 cm cuff of vagina. This procedure is designed to remove lymphatic channels, which may harbor microscopic tumor cells. Pelvic lymph node dissection is typically performed as part of the radical hysterectomy procedure because the finding of metastatic disease within this nodal chain will alter postoperative treatment [*see* Special Management Considerations, *below*]. The ovaries are typically not removed; they are seldom the site of cervical cancer spread, although they may be transposed to the outside of the pelvis in the event that postoperative radiotherapy is required (see below). In contrast, a simple hysterectomy (removal of the uterus and cervix, leaving intact the other associated structures mentioned above) is a reasonable procedure for patients with stage IA cervical cancer with less than 3 mm of invasion and an absence of lymphatic channel or margin involvement on cone biopsy (stage IA1). Alternatively, selected patients with stage IA1 disease are sometimes treated with cervical conization only, especially if future childbearing is desired. The survival rate of patients with stage IA cervical cancer is about 95%.

Stages IB and IIA

Local disease that is technically resectable with tumor-free margins, such as stage IB or IIA disease [*see Figure 2*], is often treated with a radical hysterectomy and pelvic lymph node dissection. For patients with comorbid disease that precludes surgical resection, primary radiotherapy is an option that produces equivalent survival rates for patients with stage IB or IIA disease, although possible toxicities are vaginal stenosis, bladder and bowel enteritis, and cessation of ovarian function. The overall survival rate of patients with cervical cancer of stage IB or IIA is in the range of 80% to 90%.[65]

Stages IIB to IVA

Once the tumor involves the parametrial tissues and beyond, a surgical approach is not technically feasible, because the chance of obtaining tumor-free resection margins is very low. In the past, patients with this extent of disease progression were treated with primary radiotherapy consisting of external-beam pelvic radiation (to encompass the pelvic lymph nodes) followed by intracavitary treatment, which provides high local doses of radiation to control areas of tumor bulk. However, recent data suggest that these patients are best served by treatment with concomitant chemotherapy and radiation (see below). Intracavitary radiotherapy is typically provided by either cesium-137 or radium-226, which is temporarily inserted into the uterine cavity and vaginal fornices. A common reference point used in the assessment of total radiation dose is known as point A, which is located 2 cm lateral and 2 cm superior to the cervical os. An optimal target dose to point A is approximately 85 Gy delivered over 8 weeks (total external beam plus intracavity dose).

The overall survival rate of patients with disease at stages IIB to IVA treated with primary radiotherapy is about 30%; patients with stage IVA disease fare less well (about 10% survival), and patients with stage IIB disease have survival rates of about 70%.[65] Many patients with tumors in stages IIB to IVA experience local failure, suggesting that radiation by itself is often incapable of sterilizing the original site of bulk disease. In this regard, three large randomized studies have recently been performed to investigate the value of concomitant platinum-based chemotherapy and radiation in patients with cervical cancer at stages IIB to IVA.[70-72] The theoretical basis for this concept stems from in vitro observations that suggest that cisplatin can function as a radiosensitizer, presumably by virtue of inhibiting DNA repair. All three studies were performed in patients with disease at stages IIB to IVA without para-aortic lymph node involvement. The studies differed with respect to the type of chemotherapy used and inclusion of other high-risk patient subsets. Nevertheless, these studies convincingly demonstrated that platinum-based chemotherapy administered concomitantly with radiation can reduce the chance of relapse by 30% to 50% and can improve the survival rate of patients with locally advanced cervical cancer. In addition, the toxicity profile of platinum-based chemotherapy is acceptable, and treatment delays are infrequent. Although the optimal chemotherapy regimen has not been completely defined, it is reasonable to conclude that radiosensitization with single-agent cisplatin is a new standard with which other chemotherapy regimens will be compared in the treatment of patients with cervical cancer at stages IIB to IVA.

SPECIAL MANAGEMENT CONSIDERATIONS

Early-Stage Disease with High-Risk Features

Patients with disease at stages IA2, IB, or IIA are reasonable candidates for radical hysterectomy and pelvic lymph node dissection. However, the unanticipated discovery of disease in pelvic lymph nodes, parametria, or surgical resection margins places such patients at a higher risk of local relapse. In the past, these high-risk features indicated the need for postoperative external-beam radiotherapy to a pelvic field, which yields overall survival rates in the range of 40% to 60%. However, a recent randomized intergroup study conducted by the Southwest Oncology Group (SWOG) demonstrated that treatment with concomitant platinum-based chemotherapy and radiation produced a significant survival advantage.[73]

Bulky Stage IB Disease

Bulky stage IB tumors that are at least 4 cm or greater (stage IB2) have a high probability of local relapse if managed with radical hysterectomy. Patients with such tumors are reasonable candidates for primary radiotherapy and are treated similarly to those with more advanced local disease; the expected survival rate is about 70%. In an approach similar to that demonstrated in patients with disease at stages IIB to IVA, platinum-induced radiosensitization has recently been tested in a large randomized study involving 369 patients with stage IB2 disease.[74] Patients in this trial were randomized to receive pelvic

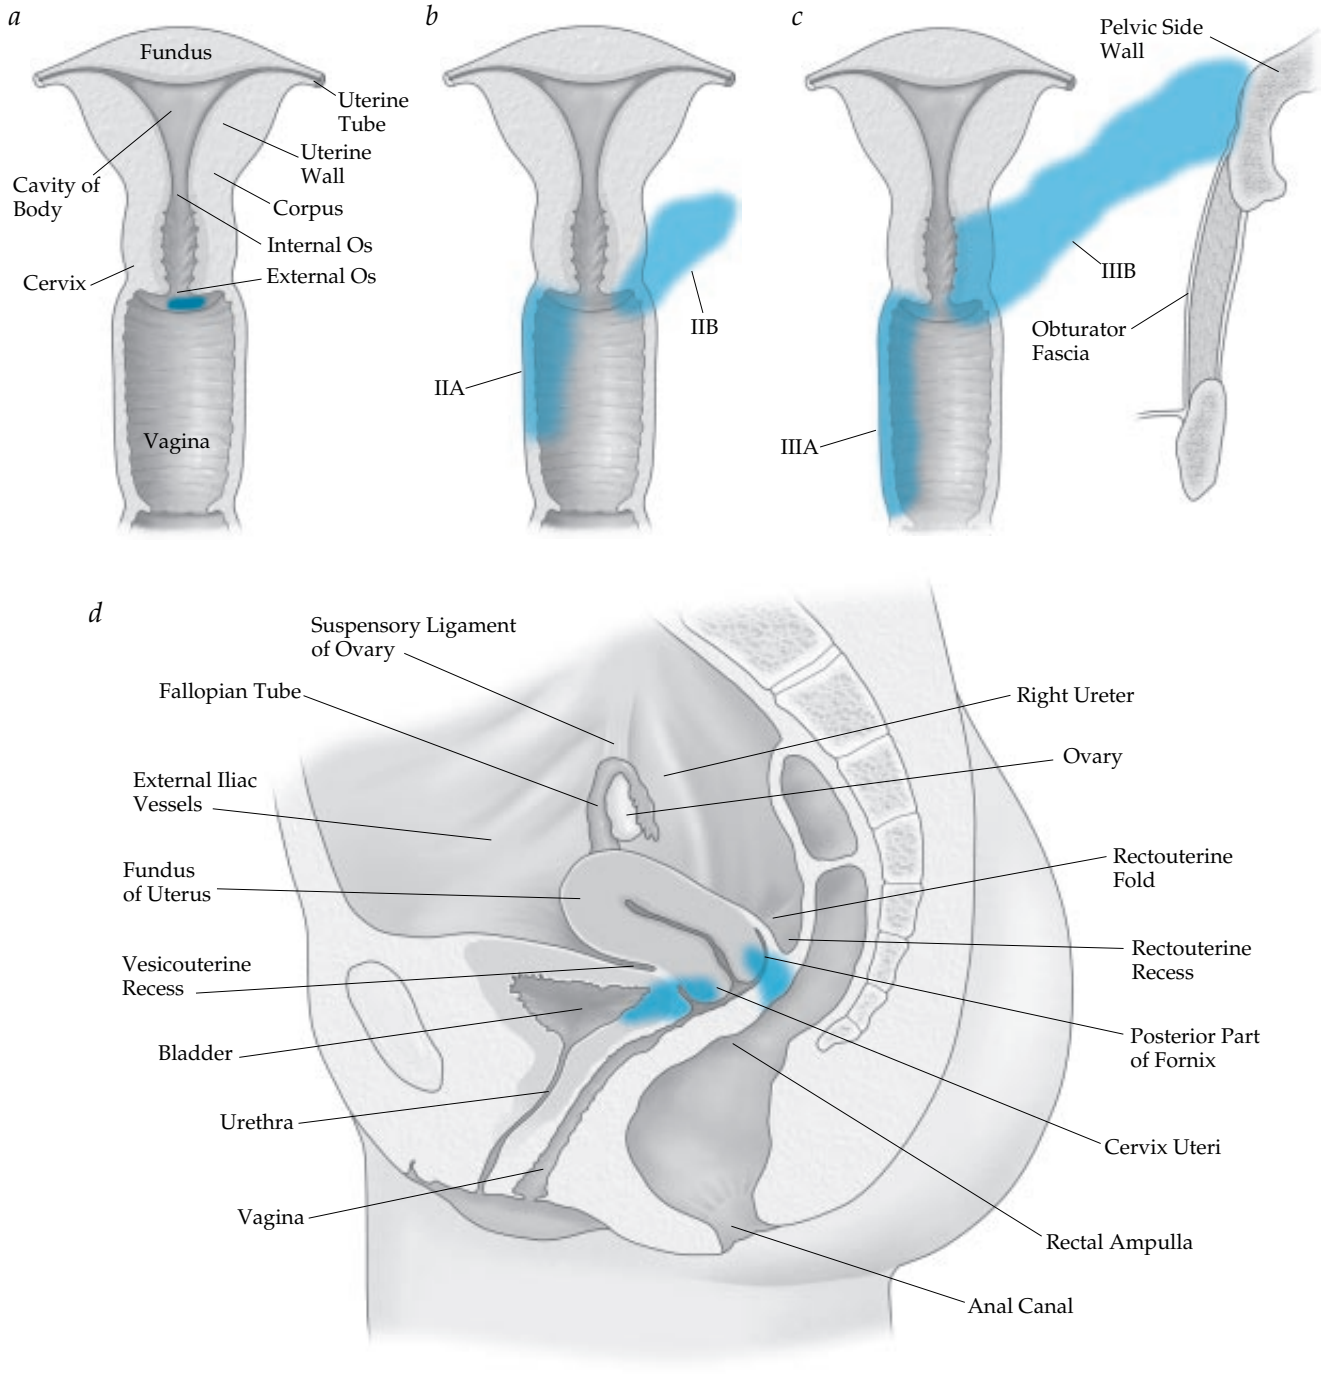

Figure 2 **International Federation of Gynecology and Obstetrics (FIGO) clinical staging of cervical cancer. (*a*) The clinical staging system for cervical cancer is defined by FIGO. Staging may include information obtained from an examination under anesthesia, an intravenous pyelogram, cystoscopy, and proctoscopy. The staging assignment for cervical cancer is determined on the basis of clinical assessment and does not change on the basis of information obtained at the time of surgery. Stage 1 disease is limited to the cervix. Stage IA disease is a microscopic lesion not exceeding 5 mm in depth from the basement membrane and no wider than 7 mm in lateral extent. Stage I is divided into stage IA1 (invasion ≤ 3 mm, no wider than 7 mm) and stage IA2 (invasion > 3 mm but ≤ 5 mm, and no wider than 7 mm). The Society of Gynecologic Oncologists (SGO) definition of microinvasion is a lesion with invasion ≤ 3 mm beneath the basement membrane, without evidence of lymphovascular space involvement. Stage IB lesions are often grossly visible tumors limited to the cervix, although they may also include microscopic lesions that are more extensive than stage IA. Stage IB1 are lesions ≤ 4 cm in diameter, and stage IB2 are lesions > 4 cm in diameter. (*b*) Stage II disease extends to the upper vagina or parametrium. Stage IIA tumors involve the upper two thirds of the vagina and are often amenable to surgical resection. In contrast, stage IIB lesions (i.e., lateral extension into the parametrium; the pelvis side wall is not involved), as well as lesions of stage III and IVA, are not technically resectable and require primary treatment with concomitant radiation and chemotherapy. (*c*) Stage IIIA disease involves the lower one third of the vagina, and stage IIIB involves lateral extension to the pelvic side wall or hydronephrosis. (*d*) Stage IVA disease is characterized by extensive locoregional involvement and has infiltrated the mucosa of the bladder or rectum. Stage IVB disease involves distant sites and is primarily treated with systemic chemotherapy, although pelvic radiotherapy may also be needed for local control.**

radiation with or without weekly cisplatin. All patients in both treatment groups subsequently underwent adjuvant hysterectomy, although it has been recently recognized that performance of surgery after primary radiotherapy confers no added survival advantage in this patient group. Weekly treatment with platinum reduced the risk of relapse and death by approximately 50% and conferred a statistically significant survival advantage (83% of patients who received cisplatin plus radiation were alive, compared with 74% of patients treated with radiation alone; $P = 0.008$). On the basis of this study, it is reasonable to consider concurrent chemoradiation with a platinum-based regimen for the primary management of patients with bulky stage I disease.

MANAGEMENT OF RELAPSE

Patients who are experiencing the relapse of cervical cancer may present with pelvic pain or bleeding caused by a pelvic mass, back pain caused by para-aortic adenopathy or bony metastasis, or shortness of breath and cough caused by pulmonary parenchymal disease. In rare instances, resection of the tumor along with the bladder and rectum (pelvic exenteration) may be considered if the recurrence is localized to the pelvis and does not involve the pelvic side walls or lymph nodes. Unfortunately, the chance is small that this procedure will be curative, and the morbidity is significant. A number of chemotherapy agents show modest results with this tumor; these agents include cisplatin, paclitaxel, ifosfamide, and vinorelbine.[65,75,76] Response rates for recurrent disease treated with single-agent cisplatin are generally about 20% and are typically observed for metastatic lesions located in sites outside of the pelvis. However, a recent study suggests that the response rate may be as high as 36% if cisplatin is combined with paclitaxel, although these data are preliminary.[77] Finally, it is important to note that patients with end-stage cervical cancer often develop renal failure as a result of bilateral hydronephrosis. Given the small chance of obtaining a meaningful response to chemotherapy, the quality of life of such patients may be best served by providing careful attention to fluid balance and pain control rather than by exposing the patient to chemotherapy-induced morbidity.

Cancer of the Endometrium (Uterine Cancer)

Cancer of the endometrium is a malignancy that begins in the inner, glandular lining (endometrium) of the uterus. Because it is usually associated with postmenopausal bleeding, the tumor is typically detected at an early stage, when it is highly curable. Although the uterus may be involved with other tumor types, such as primary uterine sarcomas, over 97% of uterine cancers are derived from the endometrium. This section is restricted to a discussion of the endometrioid histology of uterine cancer, which is the most common type of adenocarcinoma to affect the uterus.

EPIDEMIOLOGY AND RISK FACTORS

Endometrial cancer is the most frequent tumor of the gynecologic tract; it is estimated that in 2003 it affected 40,100 women and caused 6,800 deaths in the United States.[2]

Endometrial proliferation is estrogen dependent. Any factor associated with increased exposure to estrogen over time, especially if unopposed by the antiproliferative effects of progesterone, leads to an increased risk of endometrial cancer.[78] Obesity is one of the most common risk factors, an effect related to the peripheral conversion of androstenedione to estrone by aromatase present in fat cells. Early menarche, late menopause, chronic anovulation (e.g., polycystic ovary disease), and nulliparity are each associated with an increased risk as a result of either prolonged duration of estrogen exposure or absence of a progesterone effect (as is the case with chronic anovulation or nulliparity).[79] Malignancies such as granulose cell tumors of the ovary can secrete estradiol and are consequently associated with a synchronous uterine cancer in some women.[63] A synchronous uterine cancer (usually at an early stage and well differentiated) is sometimes found in association with a limited-stage endometrioid cancer of the ovary.[1] The two tumors most likely arise independently (i.e., they are clonally distinct) and tend to have a good prognosis.[80] Estrogen replacement therapy with unopposed estrogen (i.e., in the absence of progestin) is associated with a higher risk of uterine cancer development (usually well-differentiated tumors) and is not prescribed, unless the uterus has been surgically removed. Current replacement therapy entails daily administration of an estrogen and a progestin and is associated with a reduction in risk of uterine cancer development compared with matched control subjects.[79]

The use of tamoxifen, a drug traditionally thought of as an estrogen antagonist, is also associated with an increased uterine cancer risk.[81-83] This is in part caused by the tissue-specific action of tamoxifen, which has antagonistic effects on proliferation of breast epithelium but agonistic effects on bone mineral density, lipid metabolism, and endometrial proliferation. In a randomized trial conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP), tamoxifen (20 mg daily) was compared with placebo as adjuvant breast cancer therapy. The relative risk of endometrial cancer development after 5 years of tamoxifen use was 2.2; this is equivalent to an annual hazard rate of approximately two cases per 1,000 women.[84] It is important to note that most women who develop uterine cancer during tamoxifen therapy present with vaginal bleeding, have early-stage disease, and usually (but not always) have well-differentiated tumors. Furthermore, the benefits of tamoxifen in the adjuvant breast cancer setting far outweigh the small risk of uterine cancer development. Serial endometrial biopsy and ultrasonography in this patient population are associated with a high rate of false positive results; thus, their value as screening tools is controversial.[83] Currently, a reasonable approach for these patients is a routine pelvic examination and prompt evaluation of abnormal vaginal bleeding by endometrial biopsy. Finally, uterine cancer can be observed as part of the Lynch syndrome II.

CLINICAL FEATURES AND DIAGNOSTIC EVALUATION

All patients with postmenopausal vaginal bleeding require evaluation to exclude endometrial cancer, although the chance that endometrial cancer is the cause of the bleeding is age dependent. Postmenopausal bleeding in a 50-year-old woman is associated with a 9% chance of endometrial cancer, whereas the likelihood increases to 28% by age 70 and 60% by age 80.[79] A pelvic examination to exclude another cause of bleeding, such as cervical cancer, and an outpatient endometrial biopsy are common next steps in management. If uterine tissue is obtained through outpatient endometrial sampling, the chance of diagnosing endometrial cancer is excellent. If endometrial tissue is not obtained, a dilatation and curettage under general anesthesia is often required to obtain a sample suitable for fur-

Table 4 FIGO Surgical Staging of Endometrial Cancer*

Stage I: Tumor confined to the uterine corpus
- Stage IA: Limited to the endometrium (no myometrial invasion)
- Stage IB: Invading < 50% of myometrial thickness
- Stage IC: Invading > 50% of myometrial thickness

Stage II: Tumor extends into the uterine cervix
- Stage IIA: Endocervical gland involvement
- Stage IIB: Cervical stroma involvement

Stage III: More extensive locoregional disease
- Stage IIIA: Deep extension to uterine serosa or adnexal involvement, or both, or positive cytology
- Stage IIIB: Local extension into the vagina
- Stage IIIC: Retroperitoneal node involvement (pelvic or para-aortic)

Stage IV: Extensive locoregional disease or distant spread
- Stage IVA: Involvement of bladder or rectal mucosa
- Stage IVB: Distant disease, including involvement of the upper abdomen or hematogenous spread to organs outside of the abdominal cavity

*The staging system for endometrial cancer is established by the International Federation of Gynecology and Obstetrics (FIGO) and is based on the results obtained at the time of surgery. Although not specifically listed, assignment of grade is considered to be a formal part of stage designation for endometrial cancer. For example, the stage of a patient with a well-differentiated, superficial tumor would be stage IA, grade I. The stage of a patient with a high-grade, deep lesion extending out to the uterine serosa would be stage IIIA, grade III.

ther evaluation. In the setting of postmenopausal bleeding, transvaginal ultrasonography is sometimes performed to determine whether the endometrium is thickened and, therefore, possibly involved with cancer. A normal transvaginal ultrasound under these circumstances does not guarantee the absence of cancer, however, and a suggestive study will not change management in women who would require biopsy in any event.

STAGING AND SURGICAL MANAGEMENT

If the endometrial biopsy establishes the presence of cancer, surgery for definitive resection and staging is the next most common step in management. For patients who are not optimal surgical candidates, primary radiotherapy is an option that can produce long-term survival in selected patients. Surgery for uterine cancer entails performance of peritoneal washings, TAH/BSO, evaluation of pelvic and para-aortic lymph nodes (palpation and biopsy if indicated; see below), and omental biopsy. An assessment of the depth of uterine muscle (myometrial) invasion is made intraoperatively, along with frozen-section assessment of grade, as these two factors have independent predictive value for the presence of lymph node involvement.[85] Specifically, a patient with a superficial, noninvasive, grade I endometrioid uterine cancer has a negligible chance of having involvement of either pelvic or para-aortic nodes; in such patients, it may be acceptable to omit a formal biopsy of these lymph node chains. Conversely, the risk of nodal involvement increases to at least 20% in patients with high-grade lesions that are deeply invasive (greater than two thirds of the myometrial thickness). Under these circumstances, it is reasonable to consider obtaining a biopsy sample of at least the para-aortic lymph node chain so as to detect occult involvement that would require modifying the field of postoperative radiotherapy (see below).[86]

The FIGO staging system for uterine cancer is determined by the findings at surgery and histologic review [*see Table 4*]. Stage I disease is limited to the uterine corpus; stage II disease involves the uterus and cervix; stage III disease often involves

Table 5 Postoperative Management Considerations for Patients with Uterine Cancer (Endometrioid Histology)

*Stage**	*Possible Treatment Options*	*Comments*
IA, grade I or II	No further therapy	Long-term survival in over 90% of patients
IA, grade III	No further therapy	Risk of pelvic nodal involvement is low; benefit of pelvic XRT is controversial
IB, grade I or II	No further therapy, or vaginal apex brachytherapy	Benefit of vaginal apex brachytherapy for stage IB, grade I or II lesions is uncertain
IB, grade III	Pelvic XRT	Role of vaginal apex brachytherapy in addition to pelvic external-beam treatment is uncertain
IC	Pelvic XRT	Role of vaginal apex brachytherapy in addition to pelvic external-beam treatment is uncertain
II	Pelvic XRT ± vaginal apex brachytherapy	Cervical involvement is associated with a higher risk of vaginal apex recurrence
IIIA or B	Pelvic XRT or WAXRT	Pelvic XRT is considered for high-risk features, including deep myometrial invasion, grade III, or adnexal-vaginal involvement. If cancer is stage IIIA on the basis of positive peritoneal washings, risk of upper abdominal relapse is increased if the tumor extends to the uterine serosa or involves other pelvic structures (e.g., adnexa or parametria); in this case, consideration of WAXRT is reasonable; adjuvant chemotherapy in addition to XRT for treatment of high-risk stage III patients is sometimes considered, although its value is uncertain
IIIC	Pelvic and para-aortic XRT (if para-aortic nodes involved)	Morbidity of radiotherapy is increased through the use of a para-aortic field (increased nausea/myelosuppression); WAXRT is also a consideration if washings are positive
IV	Possible WAXRT; possible adjuvant chemotherapy	Risk of relapse is high with WAXRT; consideration of adjuvant chemotherapy is reasonable in view of activity of platinum-based regimens, although value is unproven; hormonal or cytotoxic chemotherapy is reasonable for distant disease

*Assumes complete surgical staging as described in text.
WAXRT—whole abdominal external-beam radiotherapy (XRT)

other adnexal structures, such as the ovaries, and may involve lymph nodes; and stage IV disease involves areas outside of the pelvis, such as the upper abdomen, or distant sites, such as lung or bone. Because the ovaries can be involved by endometrial cancer, it is important that a BSO be performed as part of routine surgical resection; this also removes a potential source of estrogen production in premenopausal women. In contrast to the staging systems for ovarian and cervical cancers, endometrial cancer staging incorporates the use of grade in its descriptions because of the independent prognostic relevance of this feature in predicting the likelihood of lymph node involvement.

PROGNOSIS AND POSTOPERATIVE TREATMENT

Approximately 80% of patients with endometrial cancer present with stage I disease and have a 5-year survival rate of greater than 80%. The 5-year survival rates of patients with stage II, III, and IV tumors are 73%, 52%, and 27%, respectively.[79] In addition to advanced stage, other adverse prognostic factors are deep myometrial invasion,[87] high grade,[87] race (African Americans have a lower rate of survival, stage for stage),[88] overexpression of the HER-2/neu protein (a member of the EGF [epidermal growth factor] receptor family of tyrosine kinases),[89] *p53* mutation,[90] and aneuploidy (having either more or less than the normal number of 46 chromosomes).[79] Postoperative pelvic radiotherapy is considered when certain high-risk features are present that confer an increased risk of local pelvic failure. These features include (1) deeply invasive, high-grade, early-stage lesions (e.g., stage IC, grade III), especially with lymphovascular involvement (LVI), as these features are associated with an approximately 20% risk of occult pelvic lymph node involvement, and (2) cervical involvement (i.e., stage II), which confers an increased risk of vaginal vault recurrence. When para-aortic lymph node involvement is documented (i.e., stage IIIC), the radiation field is often extended to encompass both the pelvic and the para-aortic lymph node chains. Whole abdominal radiotherapy is reserved for the management of positive peritoneal cytology in the setting of adverse local features, such as tumor extension to the uterine serosa or adnexal involvement (stage IIIA)[91]; under these circumstances, patients are at risk for relapse to occur in the upper abdomen.[92,93] The use of postoperative pelvic radiotherapy probably does not confer a survival advantage, although it significantly reduces the chance of local relapse, which can be highly morbid if associated with pain and bleeding. There is no proven survival advantage associated with the use of adjuvant hormone therapy (e.g., progestational agents) or chemotherapy,[94-97] although these modalities may be useful for the management of systemic relapse.[98] The postoperative management of patients with the common endometrioid variety of uterine cancer entails treatment that depends on the disease stage [*see Table 5*].

MANAGEMENT OF RELAPSED OR METASTATIC DISEASE

Patients who experience an isolated vaginal vault relapse have an approximately 30% long-term survival rate if managed with resection followed by radiotherapy, when the latter is technically possible, as determined on the basis of the patient's previous radiation exposure. For all other patients, the chance of long-term survival after relapse is very low, and the goal of treatment is palliation. Likely sites of recurrent disease are the parenchyma of the lung, bone, liver, and local pelvic and para-aortic nodes. For local disease (e.g., a painful bone metastasis or a vertebral metastasis causing cord compression), radiotherapy is a reasonable option. For more extensive systemic disease that is not associated with significant symptoms, a trial of progestational therapy (e.g., medroxyprogesterone acetate) is reasonable, although response rates are generally low (about 10% to 20%) and are related to the differentiation status of the tumor.[98] Grade I lesions, which tend to be estrogen and progesterone receptor positive, are most likely to respond, compared with poorly differentiated grade III tumors. For rapidly progressive, symptomatic recurrence, platinum-based chemotherapy is a reasonable next step. Combinations of doxorubicin and cisplatin are associated with response rates of approximately 40%,[99] and paclitaxel is also effective for recurrent disease.[100-102] The combination of paclitaxel and carboplatin has not been extensively tested but may prove to be a useful option, especially in view of the generally improved toxicity profile of carboplatin compared with cisplatin.[103] However, the increased myelosuppression associated with carboplatin may limit its usefulness in patients who have previously received pelvic radiotherapy.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XI LYMPHOMAS

Kieron Dunleavy, m.d.
Wyndham H. Wilson, m.d., ph.d.

Lymphoma is the sixth most common type of cancer in the United States, with an estimated incidence of over 62,000 cases annually.[1] The incidence of lymphoma has risen steadily over recent decades. Approximately 85% of lymphoma cases are non-Hodgkin lymphoma (NHL) and 15% are Hodgkin lymphoma.

Hodgkin Lymphoma

epidemiology and etiology

In the United States and Western Europe, Hodgkin lymphoma has a higher incidence in men than in women and occurs in a bimodal age distribution, with the greatest peak in the third decade and a lesser peak in the seventh decade. In developing countries, the disease is likewise more common in males, but the incidence peaks in the second decade.[2] Family members of patients with a history of Hodgkin lymphoma are at increased risk for the disease: the risk may be increased by a factor of 10 in same-sex siblings and by as much as a factor of 100 in identical twins.[3,4] There is significant human leukocyte antigen (HLA) concordance in affected family members. Specific HLA class II antigens are associated with an increased risk of Hodgkin lymphoma, and they may be associated with particular histologic subtypes of the disease.[5,6]

Epstein-Barr virus (EBV) infection is associated with Hodgkin lymphoma. There is an increased incidence of Hodgkin lymphoma in persons with a history of infectious mononucleosis. A prospective, controlled study found elevated EBV titers in patients before the diagnosis of Hodgkin lymphoma.[7,8] In addition, the EBV genome can be detected in the malignant cells of about 50% of patients with Hodgkin lymphoma.[9] The EBV genome is more commonly detected in Hodgkin lymphoma tissues from young children, in patients from developing countries, and in classic mixed cellularity–type Hodgkin lymphoma.

histologic classification

Although a variety of histologic classification schemes have been used for Hodgkin lymphoma in the past, the current World Health Organization (WHO) classification defines two biologically distinct types: classic and nodular lymphocyte predominant.[10] In turn, classic Hodgkin lymphoma comprises four subtypes: nodular sclerosis, mixed cellularity, lymphocyte rich, and lymphocyte depleted. Nodular sclerosis is the most common subtype, especially in patients younger than 40 years, followed by mixed cellularity. The subtype names describe the histologic milieu in which Reed-Sternberg cells and variants of these cells appear, as well as the extent of normal lymphocytic infiltration. Cytokines may play a role in the histologic milieu of Hodgkin lymphoma, which is characterized by plasma cells, eosinophils, neutrophils, lymphocytes, and, in the nodular sclerosis subtype, broad bands of collagen.

Immunohistochemistry is important both in the subclassification of Hodgkin lymphoma and in differentiating Hodgkin lymphoma from NHL. In classic Hodgkin lymphoma, the tumor cells are usually positive for CD30 (a marker of activated cells) and for CD15 (a monocyte-macrophage marker) and negative for CD45 and pan–B cell and pan–T cell antigens. In contrast, the tumor cells of nodular lymphocyte-predominant Hodgkin lymphoma subtype are negative for CD30 and CD15 but positive for CD20, BCL6, and CD45. Unfortunately, molecular investigation of the Reed-Sternberg cell and its morphologic variants has been hindered by the fact that they constitute only a small proportion of the total number of cells in Hodgkin lymphomas; inflammatory cells predominate.

biology

The neoplastic cell of Hodgkin lymphoma is almost always a B cell—either the Reed-Sternberg cell or one of its mononuclear variants [*see Figure 1*]. These malignant cells originate from germinal center B cells that have undergone a transforming event of some kind.[11] The critical transforming events associated with Hodgkin lymphoma have yet to be defined. However, mutations of the *IκBα* gene, causing upregulation of the nuclear factor–κB pathway, have been identified in both EBV-negative and EBV-positive Hodgkin lymphomas, and mutations in the *FAS* gene have also been identified; mutations of the *p53* gene have been found in a subset of EBV-negative cases.[12-14] The role of other genes in the etiology of Hodgkin lymphoma is under investigation, and the advent of microarray technology, which can generate distinct gene-expression signatures of different lymphomas, is enhancing oncologists' understanding of the molecular events integral to this disease. The very different appearance, presentation, and natural history of the histologic subtypes of Hodgkin lymphoma suggest variable pathways of lymphomagenesis, each involving a complex interaction between genetic factors, environmental factors, and the immune system of affected persons.

diagnosis

Clinical Features

The most common presenting feature of Hodgkin lymphoma is painless lymph node enlargement, usually of one or more lymph nodes above the diaphragm. Mediastinal lymphadenopathy is common at presentation, especially in patients 15 to 35 years of age with classic nodular sclerosis. Subdiaphragmatic involvement is more common with the classic mixed-cellularity subtype. Nodular lymphocyte-predominant Hodgkin lymphoma rarely involves the mediastinum or marrow. Occasionally, Hodgkin lymphoma presents as cough, chest discomfort, or superior vena cava syndrome.

Hodgkin lymphoma is characterized by the orderly spread from one lymph node region to contiguous nodal sites. The course of untreated Hodgkin lymphoma is highly variable. In many young patients, the disease can be quite indolent, with waxing-and-waning lymphadenopathy; in other patients, however, it may follow a more virulent course. The spleen and the lymph nodes in the celiac axis are often the first sites of subdiaphragmatic disease, which is found in 20% to 30% of patients with disease otherwise confined to the neck, axillae, or chest. Typically, the para-aortic and pelvic lymph nodes are the next to become involved. Hepatic and marrow disease are associated with splenic involvement. Contiguous intrathoracic disease of-

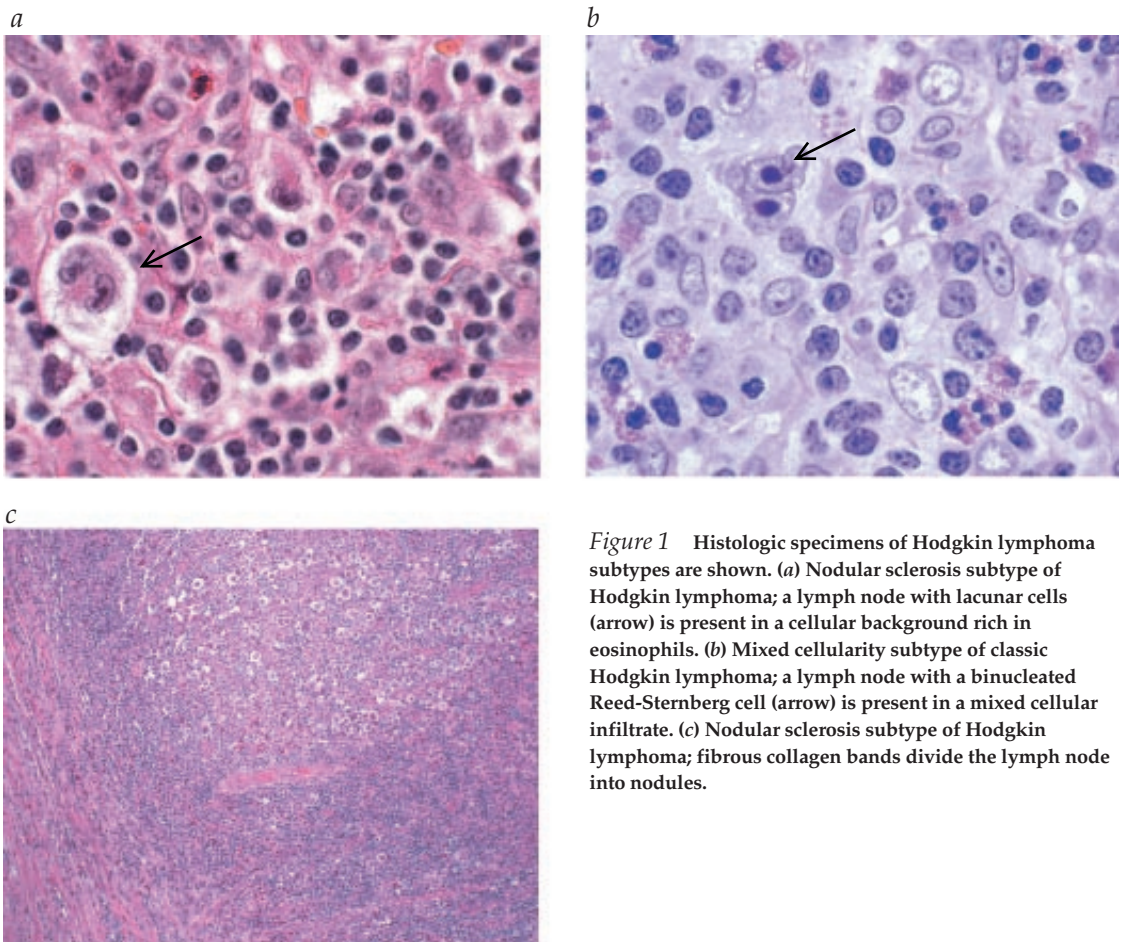

Figure 1 **Histologic specimens of Hodgkin lymphoma subtypes are shown. (*a*) Nodular sclerosis subtype of Hodgkin lymphoma; a lymph node with lacunar cells (arrow) is present in a cellular background rich in eosinophils. (*b*) Mixed cellularity subtype of classic Hodgkin lymphoma; a lymph node with a binucleated Reed-Sternberg cell (arrow) is present in a mixed cellular infiltrate. (*c*) Nodular sclerosis subtype of Hodgkin lymphoma; fibrous collagen bands divide the lymph node into nodules.**

ten occurs as a result of spread to the pulmonary parenchyma, pericardium, and chest wall from bulky mediastinal lymphadenopathy. Osseous lesions, which frequently appear osteoblastic on radiography, may develop by contiguous spread from enlarged lymph nodes or by hematogenous spread. Spinal cord compression may be caused by direct extension from enlarged nodes or by vertebral disease.

Some patients have prominent systemic symptoms known as B symptoms, which include drenching sweats at night, fever, and unexplained weight loss. Occasionally, patients experience Pel-Ebstein fevers, which are intermittent episodes of evening fevers that last for several days and alternate with afebrile periods. Total body pruritus, which is usually quite uncomfortable and refractory to antipruritic agents, may accompany Hodgkin lymphoma. A unique feature is pain at sites of lymphadenopathy immediately after ingestion of alcohol.

The clinical course of Hodgkin lymphoma differs according to histologic subtype, patient age, geography, and the integrity of the immune system. Nodular lymphocyte-predominant Hodgkin lymphoma follows a particularly indolent course: constitutional symptoms are rare and relapses are frequent but usually respond to therapy. In general, patients who are elderly, who live in developing countries, and who are infected with HIV are more likely to have widespread disease with systemic symptoms at diagnosis. The classic mixed-cellularity subtype is the most common variant observed in this group. Young-adult patients in the United States and Western Europe most often present with limited disease of the nodular sclerosis subtype.

History and Physical Examination

The history of current illness focuses on systemic symptoms, if any. The history should include questions regarding prior malignancy, chemotherapy or radiation treatment, immunosuppressive illness, or immunosuppressive therapy. Any family history of lymphoproliferative disorder should be elicited.

A detailed physical examination should include a careful assessment of all lymph node regions for extent of peripheral lymphadenopathy, as well as evaluation of the chest wall. Abdominal examination is performed to detect hepatosplenomegaly.

Laboratory Studies

The purpose of the diagnostic evaluation is to assess the extent (stage) of Hodgkin lymphoma, which determines prognosis and treatment. Toward this end, the single most useful diagnostic test for a patient with suspected lymphoma is a properly evaluated, technically adequate excisional lymph node biopsy. Optimal pathologic evaluation usually requires a whole lymph node.

Additional laboratory studies include a complete blood count; erythrocyte sedimentation rate (ESR); and serum chemistries, including the lactate dehydrogenase (LDH) level. The most common hematologic abnormality is normocytic, normochromic anemia, which is often found in patients with symptomatic, extensive disease. Cytopenias secondary to hypersplenism or marrow disease are rare. Modest elevations of alkaline phosphatase can occur in patients with limited disease; higher levels are associated with hepatic, osseous, or marrow involvement. Hypercalcemia is a rare paraneoplastic manifestation. The ESR

is commonly elevated in Hodgkin disease, and the degree of elevation has prognostic significance in patients with early-stage disease.

Imaging studies for the initial evaluation of Hodgkin lymphoma should include a screening chest radiograph and computed tomography of the chest, abdomen, and pelvis (with intravenous contrast if possible). CT is the gold-standard imaging modality. Positron emission tomography (PET) is an important adjunct to CT for initial staging. Its more important role is in the assessment of response to therapy by helping to distinguish active lymphoma from benign tissue in residual masses; in this setting, a positive PET scan is highly predictive of treatment failure.[15-17] PET findings, however, require careful interpretation, particularly with borderline specific uptake values. In general, patients with a positive PET scan after treatment should undergo biopsy to confirm the presence of active lymphoma.

One shortcoming of CT and other imaging modalities is a lack of reliability in diagnosing occult splenic and nodal disease. In one study, the overall accuracy of CT in detecting splenic disease was 58%.[18] Staging laparotomy, the only definitive modality for detecting occult splenic disease, was often included in the initial assessment of Hodgkin lymphoma in the past. Currently, its use is controversial; it is indicated only in patients for whom optimal management requires the assessment of occult splenic disease (i.e., patients for whom definitive radiotherapy is planned). Because chemotherapy is so commonly incorporated into the initial treatment of Hodgkin lymphoma, laparotomy is now rarely done. In one prospective study, laparotomy had no significant impact on survival or relapse rate in patients with a favorable prognosis who were randomized to staging with laparotomy or to clinical staging.[19] PET scanning, which may more accurately detect occult splenic disease in Hodgkin lymphoma, is very useful. Magnetic resonance imaging and isotope bone scanning are not routinely indicated in the initial assessment of Hodgkin lymphoma but may be useful in patients presenting with bone disease.

The incidence of marrow infiltration in Hodgkin lymphoma varies from series to series, with a range in adults of 2% to 32%.[20] In a review of 955 cases, the incidence of marrow involvement at diagnosis was 5.2%.[21] Despite its low yield, marrow biopsy is still recommended in all patients with newly diagnosed Hodgkin lymphoma.

Staging and Prognosis

The Ann Arbor staging system for Hodgkin lymphoma, developed over 30 years ago, continues to be used for the staging of NHL. A four-stage Cotswold modification, which accounts for such factors as bulky mediastinal disease, is currently used for staging Hodgkin lymphoma [*see Table 1*].[22]

Analysis of a large international dataset of patients with advanced Hodgkin lymphoma identified seven adverse factors, in addition to stage, that predicted outcome.[23] These are age greater than 45 years, stage IV disease, male sex, anemia, hypoalbuminemia, lymphopenia, and neutrophilia. The International Prognostic Score (IPS) incorporates these adverse factors and may be used to identify patients with poorer prognoses for more intensive therapies [*see Table 2*].

TREATMENT

An improved histopathologic classification, accurate staging, improved radiotherapy, and effective chemotherapeutic agents contribute to the high cure rate for Hodgkin lymphoma. For therapeutic success, care should be given by a multidisciplinary team with expertise in histopathology, diagnostic radiology, medical oncology, and radiation therapy.

Historically, radiation therapy was the preferred treatment for Hodgkin lymphoma, with chemotherapy reserved for advanced disease or radiotherapy failures. However, appreciation of the late effects of radiation therapy, including secondary malignancies and cardiac disease, has led to new approaches aimed at achieving high cure rates with minimal long-term toxicities.

Initial Therapy for Hodgkin Lymphoma, Stages I and II

Although stage of disease is the primary determinant of prognosis and therapy in Hodgkin lymphoma, the European Organization for Research and Treatment of Cancer (EORTC) has subdivided patients with early-stage (I and II) disease into favorable and unfavorable prognostic groups, on the basis of the presence (of at least one) or absence of the following adverse fac-

Table 1 Staging Classification of Lymphoma

*Stage**	*Ann Arbor Classification*	*Cotswold Modification*
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I_E)	Involvement of a single lymph node region or lymphoid structure
II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or with involvement of limited, contiguous extralymphatic organ or tissue (II_E)	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is considered a single site, whereas the hilar lymph nodes are considered bilaterally); the number of anatomic sites should be indicated by a subscript (e.g., II_3)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (III_S); a limited, contiguous extralymphatic organ or site (III_E); or both (III_{ES})	Involvement of lymph node regions on both sides of the diaphragm: III_1 (with or without involvement of splenic hilar, celiac, or portal nodes) and III_2 (with involvement of para-aortic, iliac, and mesenteric nodes)
IV	Multiple or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without lymphatic involvement	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used

*All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant fever (> 38.0° C [100.4° F]), night sweats, and unexplained weight loss exceeding 10% of normal body weight within previous 6 mo. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single diagnostic biopsy only. In the Ann Arbor classification, the term pathologic stage (PS) is used if a second biopsy of any kind has been obtained, whether negative or positive. In the Cotswold modification, the PS is determined by laparotomy; X designates bulky disease (widening of the mediastinum by more than one third or the presence of a nodal mass > 10 cm), and E designates involvement of a single extranodal site that is contiguous or proximal to the known nodal site.

Table 2 International Prognostic Score for Advanced Hodgkin Lymphoma[88]

*Prognostic Score**	*Frequency (%)*	*Progression-Free Survival at 5 Years (%)†*	*5-Year Survival (%)†*
0	7	84	89
1	22	77	90
2	29	67	81
3	23	60	78
4	12	51	61
≥ 5	7	42	56

*One point is given for the presence of each of the following prognostic factors: age > 45 yr, stage IV disease, male sex, albumin level < 4 g/dl, hemoglobin level < 10.5 g/dl, white blood cell count (WBC) ≥ 15,000/µl, and lymphocyte count < 600/µl or < 8% of WBC.
†Based on data from 5,141 patients.[23]

tors: large mediastinal mass, age 50 years or older, elevated ESR, and involvement of four or more lymph node regions.[24]

Early-stage favorable disease For decades, extended-field radiation therapy without chemotherapy was the treatment of choice for early-stage favorable disease. Although complete response rates were high, 25% to 30% of patients experienced relapse and required chemotherapy. Combined chemotherapy and radiation is favored by most groups; it results in superior cure rates, with potentially less long-term toxicity because of lower radiation doses.[15,25,26] A recommended combination consists of short-duration chemotherapy (e.g., two cycles of doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine [ABVD]) with radiation to the involved field (20 to 30 Gy).[26] For low-risk stage I neck disease, some groups still recommend radiotherapy alone.[27] Some advocate chemotherapy alone in early-stage favorable disease, but whether chemotherapy alone is equivalent to combination therapy is still under investigation.[28]

Early-stage unfavorable disease Combined-modality therapy (typically, four cycles of ABVD with 20 to 30 Gy of radiation to the involved field) is an accepted treatment for early-stage unfavorable disease. However, because early relapse occurs in 15% of patients who have received ABVD, more intensive chemotherapy regimens are under study, and the use of chemotherapy alone is increasing.[15]

Initial Therapy for Hodgkin Lymphoma, Stages III and IV

Combination chemotherapy is the treatment of choice for patients with advanced-stage disease. Although MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) was the first multiagent regimen to achieve a high cure rate in this group, ABVD is currently the standard of care. In randomized comparisons, ABVD was more effective than MOPP and less toxic than MOPP hybrids.[29,30] Patients usually receive two cycles of therapy after complete remission, for a minimum of six and a maximum of eight cycles.

Patients with advanced-stage Hodgkin lymphoma who are treated with ABVD have close to 70% event-free survival. Nevertheless, investigators are attempting to improve outcome with more intensive regimens, many of which contain etoposide, a very active agent in Hodgkin lymphoma. The Stanford V regimen, a brief intensive regimen of chemotherapy (mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, and prednisone) combined with consolidative radiation to bulky lymph node sites, has produced a progression-free survival of 89% with an overall survival of 96% at a median follow-up of 5.4 years.[31] However, a randomized study suggested that it is not superior to ABVD.[32] The German Hodgkin Lymphoma Study Group has compared BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) and increased-dose BEACOPP with the combination of COPP (cyclophosphamide, vincristine, procarbazine, and prednisone) and ABVD in patients with advanced Hodgkin lymphoma.[33] Radiation therapy, used for bulky disease or for residual disease after eight cycles of chemotherapy, was given to two thirds of patients. Although increased-dose BEACOPP had greater toxicity, it produced fewer induction failures and had a higher rate of freedom from treatment failure at 5 years and a better overall survival compared with COPP/ABVD. The advantage of increased-dose BEACOPP was greatest for patients with a poor prognosis, as defined by the IPS. Thus, although ABVD remains the standard for advanced-stage Hodgkin lymphoma, more intensive regimens may become standard for patients with poorer prognoses.

Initial Therapy in Nodular Lymphocyte-Predominant Hodgkin Lymphoma

This rare subtype of Hodgkin lymphoma behaves very differently from classic Hodgkin lymphoma and is biologically similar to low-grade B cell lymphoma. The 10-year survival for early-stage disease exceeds 80%, and the role of therapy for early-stage favorable disease is unclear. The EORTC recommends involved field radiation.[15] Patients with advanced-stage disease have an unfavorable prognosis and should probably be treated in the same way as patients with an unfavorable prognosis.[34] In a phase II trial, the anti-CD20 antibody rituximab produced a complete response rate of 46%, but follow-up was short; the long-term impact of this treatment requires further study.[35]

Relapsed or Refractory Hodgkin Lymphoma

In patients with early-stage disease who experience relapse after radiation alone, subsequent treatment with regimens such as ABVD results in relapse-free survival of up to 70% at 10 years.[36] Relapses after combination chemotherapy or combined-modality therapy present a greater challenge. If the duration of initial remission exceeds 12 months, retreatment with chemotherapy (either the same or a different combination) yields up to 50% relapse-free survival at 5 years.[37-39]

Patients who fail to achieve complete remission with initial chemotherapy or who experience relapse within 1 year after initial chemotherapy have the least favorable prognosis and a poor chance of long-term survival with standard-dose chemotherapy.[37,40,41] For both of these groups, high-dose chemotherapy with or without radiotherapy, followed by autologous hematopoietic stem cell transplantation, is a standard approach. Although few data on long-term outcome are available, early results demonstrate 5-year progression-free survival of up to 61%.[42]

A number of salvage regimens are active in relapsed Hodgkin lymphoma and may be used for disease control before autologous transplant. These include ESHAP (etoposide, methylprednisolone, high-dose cytarabine, and cisplatin), ICE (ifosfamide, carboplatin, and etoposide), and EPOCH (etoposide,

prednisone, vincristine, cyclophosphamide, and doxorubicin).[43-45] Relapse after transplantation presents a challenge. Low-dose, long-term treatment with agents such as vinblastine or gemcitabine may be used in such patients.[46,47]

Several experimental therapies for Hodgkin lymphoma are under investigation. These include monoclonal antibodies, radioimmunoconjugates, immunotherapy, tumor vaccines,[48,49] and allogeneic stem cell transplantation.[50]

Long-term Effects of Therapy

Because of the high cure rate of Hodgkin lymphoma, long-term toxicity of therapy is becoming increasingly important as the follow-up time for patients increases. The full toxicity profile of radiation is only now becoming apparent. The risk of several types of solid tumors is dramatically increased in patients who receive radiation therapy for Hodgkin lymphoma.[51,52] Patients who were treated when young are at greatest risk. In long-term survivors who received mediastinal radiation, clinically significant cardiovascular abnormalities also occur.[53] In addition, hypothyroidism is a frequently encountered late complication of radiotherapy.[54] Although the limited fields, lower doses, and improved techniques used in current radiation therapy are likely to ameliorate these toxicities, long-term follow-up is needed to confirm these benefits.

Late effects of chemotherapy include the development of leukemias and myelodysplasia in patients who have received alkylating agents such as nitrogen mustard and procarbazine in the MOPP regimen.[55] Sterility occurs in approximately 90% of men and 80% of women older than 25 years after treatment with a full course of MOPP; the incidence is lower in younger women.[56,57] In contrast, acute leukemia or myelodysplasia have rarely been reported in patients receiving ABVD, and the incidence of infertility is 10% to 20%.[58] The bleomycin in ABVD can produce long-term pulmonary toxicity.[59]

Non-Hodgkin Lymphoma

EPIDEMIOLOGY AND ETIOLOGY

NHL, with an estimated 54,370 new cases each year, accounts for 4% of all new cancer cases in the United States.[1] The incidence of NHL is higher in males and with increasing age. NHL is more common in Western countries, and different subtypes have particular geographic predilections. Over the past 20 years, the incidence of NHL has doubled in the United States.[60] Factors contributing to this trend include an increasing population at risk of AIDS-related lymphoma and an increase in the reporting and detection of lymphomas. However, these various factors account for only 50% of the observed increase; other reasons for the rise in incidence of NHL are unknown or poorly understood.[60,61] Environmental toxins are likely to be important etiologic factors.

NHL is also more commonly observed in patients with immunodeficiency states or autoimmune diseases and in patients receiving long-term immunosuppressive therapy.[60,62] EBV infection is involved in most of the lymphoproliferative diseases in these settings. Other associated viruses or pathogens, in addition to HIV, include human T cell lymphotropic virus type I (HTLV-I), hepatitis C virus, *Helicobacter pylori,* human herpesvirus type 8, *Borrelia burgdorferi,*[63-67] *Chlamydia psittaci,* and *Campylobacter jejuni*.[68,69]

HISTOLOGIC CLASSIFICATION

Various classification systems have been used for NHL, including Rappaport, Kiel, Working Formulation, and Revised European-American Classification of Lymphoid Neoplasms (REAL). The current WHO classification [*see Table 3*] evolved from an international collaboration of pathologists and clinicians and is based on insights into the molecular pathogenesis of lymphoma, including the identification of so-called hallmark genet-

Table 3 World Health Organization Classification of Hematopoietic Neoplasms[10]

B Cell Neoplasms	*T Cell and Natural Killer (NK) Cell Neoplasms*
Precursor B cell neoplasms	Precursor T cell neoplasms
Precursor B lymphoblastic leukemia/lymphoma	Precursor T lymphoblastic leukemia/lymphoma
	Blastic NK cell lymphoma
Mature B cell neoplasms	Mature T cell and NK cell neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma	Adult T cell leukemia/lymphoma
Lymphoplasmacytic lymphoma	Extranodal NK/T cell lymphoma, nasal type
Splenic marginal-zone lymphoma	Enteropathy-type T cell lymphoma
Extranodal marginal-zone B cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)	Hepatosplenic T cell lymphoma
Nodal marginal-zone B cell lymphoma	Subcutaneous panniculitis-like T cell lymphoma
Follicular lymphoma	Mycosis fungoides
Mantle cell lymphoma	Sézary syndrome
Diffuse large B cell lymphoma	Primary cutaneous anaplastic large cell lymphoma
Mediastinal (thymic) large B cell lymphoma	Peripheral T cell lymphoma, unspecified
Intravascular large B cell lymphoma	Angioimmunoblastic T cell lymphoma
Primary effusion lymphoma	Anaplastic large cell lymphoma
Burkitt lymphoma/leukemia	
B cell proliferations of uncertain malignant potential	
Lymphomatoid granulomatosis	
Posttransplant lymphoproliferative disorder, polymorphic

ic abnormalities. Hematologic malignancies are stratified according to their lineage or cell of origin (B cell or T cell/natural killer [NK] cell).[10] Further, within each lineage or category of cell of origin, malignancies are described and defined by morphologic features, immunophenotype, genotype, and clinical behavior.

The pathologic assessment of lymphoma is based on the histologic features of the neoplasm and the immunophenotype [*see Figure 2*]. Morphology alone is often inadequate for classification, because NHLs with immunophenotypic and molecular heterogeneity may have a similar morphologic appearance. Immunophenotyping provides valuable information for classifying lymphomas. T cells and B cells express different cluster of differentiation (CD) antigens, and these antigens change according to the degree of maturation. By using monoclonal antibodies directed against these cell surface antigens, immunophenotypic analysis can define a lymphoma's cell of origin—B cell or T cell—and stage of differentiation. In addition, immunohistochemistry can detect gene products that are hallmarks of specific lymphoma subtypes, such as bcl-2, a protein that inhibits apoptosis, and bcl-1, a protein that promotes progression through the cell cycle [*see Figure 3*]. Many of these cell surface markers correlate with outcome and prognosis.[70-72]

Molecular diagnosis is very useful when morphology and immunohistochemistry fail to establish a definitive diagnosis.[73] All lymphomas have abnormal genes, a number of which are associated with cellular proliferation or apoptosis. Gene abnormalities (usually translocations) interfere with lymphoid cellular growth and differentiation, thereby causing malignant transformation. Abnormalities often involve genes that code for immunoglobulin chains. Thus, surface light-chain immunoglobulin and T cell receptor gene rearrangement, which can be detected by immunohistochemistry or DNA hybridization, can be useful in the assessment and diagnosis of lymphoid malignancies.

BIOLOGY

Lymphomas are derived from B cells, T cells, or NK cells at various stages of differentiation. For example, precursor B and precursor T lymphoblastic lymphomas are neoplasms of early lymphocyte differentiation (lymphoblasts committed to B cell and T cell lineages, respectively). In contrast, follicular lymphoma is a neoplasm of more mature lymphocytes (germinal center B cells), as is peripheral T cell lymphoma.

Karyotypic abnormalities characterize the majority of B cell NHLs [*see Table 4*]. Among these are the t(14;18)(q32;q21) translocation with rearrangement of the *bcl-2* gene, which is present in 80% to 90% of follicular lymphomas.[74,75] Inhibition of apoptosis by bcl-2 appears to play an important role in the pathogenesis of lymphomas.[75] *bcl-2* overexpression is also present in diffuse large B cell lymphoma (DLBCL) but less frequently (24% to 55% in two studies), and it is usually not associated with a *bcl-2* translocation.[70,76] Virtually all cases of mantle cell lymphoma contain the t(11;14)(q13;q32) translocation; this leads to overexpression of the *cyclin-D1* gene, which promotes progression from the G1 to S stages of the cell cycle.[77] Burkitt lymphoma is associated with a *MYC* translocation, which most commonly results from a t(8;14) translocation.[10]

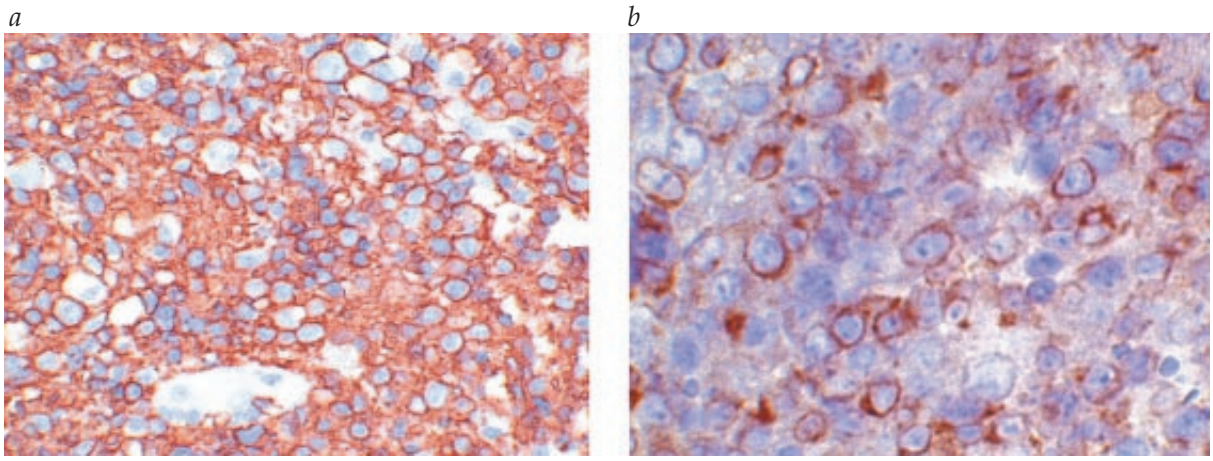

Figure 3 **Immunophenotypic analysis of a lymph node biopsy specimen from a patient with diffuse large B cell lymphoma shows that (*a*) large tumor cells express CD20 and (*b*) staining for the apoptosis-inhibiting protein bcl-2 is positive.**

Despite the increased precision in diagnosis made possible by advances in molecular techniques, response to therapy varies widely among specific lymphoma subtypes. In DLBCL, for example, only one third of patients are cured with CHOP (cyclophosphamide, hydroxydaunorubicin, vincristine, and prednisone), and about half are cured with rituximab-CHOP (R-CHOP) treatment.[78,79] This marked heterogeneity in therapeutic response implies that distinct diseases exist within a morphologic category. Molecular profiling has led to greater insights into the biologic diversity within morphologically defined categories of lymphoma.[80-82] RNA from a tumor sample can be analyzed by DNA microarrays, which can measure the expression of thousands of genes, thereby generating a distinct fingerprint of gene expression.

Table 4 Chromosomal Translocations in Non-Hodgkin Lymphoma[70-77,166-170]

*Lymphoma Subtype**	*Translocation*	*Percentage of Cases Affected*	*Proto-oncogene*	*Putative Function*	*Clinical Correlate*
Follicular center cell	t(14;18)(q32;q21)	80–90	*bcl-2*	Inhibits apoptosis	No association with prognosis
	17p13		*p53*	Confers resistance to chemotherapy	Large cell transformation and shorter time to disease progression
Small lymphocytic (CLL)	Trisomy 12	10–30	—	Loss of tumor suppressor function; associated with Ig-unmutated type	Advanced disease, atypical morphology, and resistant disease
	13q14	50	—	Putative tumor suppression gene unknown	Improved survival
	11q22-23	10–20	—	Unknown	Aggressive disease and worse prognosis
	17p13	6	*p53*	Confers resistance to chemotherapy	Shorter survival
Diffuse large B cell (DLBCL)	del(3)(q27)	35	*bcl-6*	Transcription factor for germinal center formation	Extranodal DLBCL; impact on treatment outcome controversial
	t(14;18)(q32;q21)	24–55	*bcl-2*	Inhibition of apoptosis	Poor prognosis
	17p13	20	*p53*	Confers resistance to chemotherapy	Poor prognosis
Mantle cell	t(11;14)(q13;q32)	—	*bcl-1/cyclin D1*	Cell cycle regulator; promotes G_1 to S progression	Seen in 70% of cases with cytogenetics and virtually 100% with FISH
	17p13	8	*p53*	Confers resistance to chemotherapy	Worse prognosis and blastic morphology
Burkitt	t(8;14)(q24;q32)	100	c-*myc*	Transcriptional activator regulating cell proliferation and growth	Present in 100% of cases; not entirely specific for Burkitt lymphoma
Marginal zone	t(11;18)(q21;q21)	60	*MLT-1*	Confers resistance to therapy through inhibition of apoptosis	Resistant to *Helicobacter*-eradication therapy
Anaplastic large cell	t(2;5)(p23;35)	50–80	*NPM/ALK*	Activates tyrosine kinase	Associated with a better prognosis

CLL—chronic lymphocytic leukemia FISH—fluorescence in situ hybridization

Clinical Features

A common presenting feature of NHL is painless peripheral lymphadenopathy. In contrast to Hodgkin lymphoma, mediastinal lymphadenopathy is uncommon at presentation. However, involvement of abdominal and pelvic nodes and extranodal sites is more frequent than with Hodgkin lymphoma. Extranodal disease can include any organ; the most common sites are the gastrointestinal tract, skin, and bone. Indolent lymphoma is typically characterized by waxing-and-waning lymphadenopathy, which can remain clinically quiescent over several years without therapy. In contrast, aggressive lymphoma is usually characterized by rapidly progressive lymphadenopathy that requires immediate therapy. Over a third of patients presenting with NHL have constitutional manifestations (so-called B symptoms), which include temperature higher than 38° C (100.4° F), unexplained loss of more than 10% of body weight, and night sweats; B symptoms are more common with aggressive subtypes. Marrow involvement is much more common in indolent lymphoma than in aggressive subtypes such as DLBCL.[79,83]

The clinical course of NHL depends on the histologic subtype, along with patient age and immune system status. Some histologic subtypes, such as Burkitt lymphoma and lymphoblastic lymphoma, are very aggressive, whereas follicular lymphoma is typically indolent. AIDS-related lymphomas, which are virtually always aggressive, are typically more advanced at presentation, with a high incidence of stage IV disease and a higher frequency of central nervous system involvement than similar lymphomas in HIV-negative patients.[84]

History and Physical Examination

Patients should be queried for systemic symptoms; any history of prior malignancy, chemotherapy or radiation treatment, and autoimmune or immunosuppressive illness; and any family history of malignancy. A history of infection with, or exposure to, pathogens such as HIV, hepatitis C virus, or HTLV-I should be sought. A detailed physical examination should include special attention to lymph node regions.

Laboratory Studies

The most important diagnostic test is a properly evaluated and technically adequate lymph node biopsy. Laboratory studies should include a complete blood count, serum chemistries (including LDH level), and HIV and hepatitis serologies. An elevated LDH has important prognostic implications for many lymphoma subtypes.[85] Potential etiologic pathogens or viruses suspected on the basis of the clinical evaluation should be investigated. Patients with chronic lymphatic leukemia or small lymphocytic lymphoma (SLL) should undergo serum protein electrophoresis with immunoglobulin quantification. Lymphoplas-

Table 5 Eastern Cooperative Oncology Group Performance Scale

Performance Status	*Definition*
0	Asymptomatic
1	Symptomatic but fully ambulatory
2	Symptomatic and in bed < 50% of the day
3	Symptomatic and in bed > 50% of the day
4	Bedridden

macytic lymphomas, such as Waldenström macroglobulinemia, are often associated with paraproteinemia. Monoclonal paraprotein can be monitored; immunoglobulin deficiency, which frequently accompanies these disease entities, can predispose to certain opportunistic infections.

Imaging studies should include a chest radiograph and CT of the chest, abdomen, and pelvis, with intravenous contrast if possible [*see Figures 4 and 5*]. The need for additional imaging studies, including MRI and PET scanning, depends on the clinical presentation and sites of disease. CT or MRI of the head is undertaken if CNS disease is strongly suspected [*see Figure 6*]. Certain aggressive histologic subtypes and clinical settings are associated with a higher risk of CNS disease.[86,87] Patients at high risk for CNS disease should undergo a lumbar puncture at diagnosis, with flow cytometric analysis of the cerebrospinal fluid in addition to cytologic evaluation.[87]

The incidence of marrow involvement in NHL varies according to histology but can approach 70% in indolent B cell lymphoma.[83] Consequently, marrow biopsy is a standard investigation at diagnosis.

Staging and Prognosis

The Ann Arbor staging system, originally designed for Hodgkin lymphoma, is now widely applied in the staging of NHL [*see Table 1*]. However, because of the tremendous heterogeneity of NHL and the lack of contiguous orderly spread from one lymph node region to another in these diseases, the Ann Arbor staging system is of limited prognostic value.

To identify prognostic factors in NHL, an international project correlated clinical variables and outcome in 2,031 patients with untreated aggressive lymphoma.[88] The following features were associated with a worse outcome: age greater than 60 years, Ann Arbor stage III or IV, elevated LDH, Eastern Oncology Group performance status of 2 or higher [*see Table 5*], and involvement of two or more extranodal sites. Project members created the International Prognostic Index (IPI) as a tool for predicting outcome. In the IPI, 1 point is allocated for each feature that is present. In the study cohort, 5-year survival proved to be directly related to the IPI score (survival of 73%, 51%, 43%, and 26% for scores of 0 to 1, 2, 3, and 4 to 5, respectively) [*see Table 6*].[88] Thus, the IPI is useful in predicting outcome for patients with aggressive lymphoma.

A validated clinical prognostic index is now available for patients with follicular lymphoma as well.[89] The Follicular Lymphoma International Prognostic Index (FLIPI), which is based on patient age, disease stage, serum LDH level, hemoglobin level, and number of nodal areas, has been found to reliably predict survival [*see Table 7*].

The clinical characteristics included in the IPI and FLIPI are probably surrogates for biologic features (see above). Expression of the proteins bcl-2, bcl-6, and MUM-1 has been evaluated and correlated with prognosis, particularly in DLBCL.[71,84,90-92] Several studies have identified bcl-2 positivity as a marker of poor outcome. A randomized study by a French group has validated the observation that the monoclonal antibody rituximab may overcome bcl-2–associated chemotherapy resistance in untreated DLBCL.[93,94]

Gene expression profiling is emerging as an important prognostic tool. In DLBCL, for example, morphologically identical tumors may show marked heterogeneity in gene expression. These genes can be classified into signatures associated with stages of differentiation.[95] On the basis of these signatures, DLBCL can be divided into two subtypes: DLBCL derived from a germinal center B cell, termed germinal center B cell–like (GCB) DLBCL; and DLBCL derived from a post–germinal center or activated B cell, termed activated B cell–like (ABC) DLBCL [*see Figure 7*].[96] Overall survival has proved to be significantly better in patients with the GCB subtype than in those with the ABC subtype (5-year survival of 60% versus 35%).[80] On the basis of these and other expression signatures, a molecular predictor of clinical outcome has been developed that can stratify patients with DLBCL into four prognostic quartiles [*see Figure 7*].[80]

The expression of six distinct genes has been found to be predictive of survival in DLBCL.[97] Gene expression profiling has also generated survival predictors in other NHLs, including follicular lymphoma, chronic lymphocytic leukemia (CLL), primary mediastinal B cell lymphoma, and mantle cell lymphoma.[81,82,98-100] Although molecular profiling is largely an experimental technique and is not widely available, it promises to improve pathologic diagnostic accuracy, predict outcome with

Table 6 International Prognostic Index for Aggressive Non-Hodgkin Lymphoma[88]

*IPI Score**	*Risk Group*	*CR Rate (%)*	*5-Year Overall Survival (%)*
0, 1	Low	87	73
2	Low intermediate	67	51
3	High intermediate	55	43
4, 5	High	44	26

*One point is given for the presence of each of the following characteristics: age > 60 yr, elevated serum LDH level, ECOG performance status ≥ 2, Ann Arbor stage III or IV, and more than two extranodal sites.

CR—complete response ECOG—Eastern Cooperative Oncology Group IPI—International Prognostic Index LDH—lactate dehydrogenase

Table 7 Follicular Lymphoma International Prognostic Index[89]

Risk Group	*Number of Factors**	*Distribution of Patients (%)*	*5-Year OS (SE)*	*10-Year OS (SE)*	*RR (95% CI)*
Low	0–1	36	90.6 (1.2)	70.7 (2.7)	1.0 (NA)

RR—relative risk of death SE—standard error

greater precision, and elucidate pathways of lymphomagenesis, thus identifying pertinent cellular targets and paving the way for more individualized therapy. Integration of immunostaining and gene microarray into large clinical trials, as well as evaluation of their prognostic value, should facilitate development of new and very useful prognostic models that may guide therapeutic choices.

TREATMENT

Indolent B Cell Lymphoma

Indolent lymphomas comprise several different subtypes, of which follicular lymphoma is the most common.[101] Although new and experimental therapies may offer the possibility of cure in the future, these lymphomas are considered incurable with conventional therapy.[102] Because these diseases are characterized by a waxing-and-waning course and patients can live for years, even without therapy, they are often managed with a "watch and wait" approach.[103] Indications for treatment include symptomatic or aggressive disease, bulky lymphadenopathy or cytopenias from marrow involvement, or hypersplenism.

Follicular lymphoma After DLBCL, follicular lymphoma is the second most prevalent histologic subtype, constituting 35% of NHLs in adults in the United States.[10] Patients typically are elderly and have disseminated disease at diagnosis. During the course of the illness, transformation from follicular to large cell lymphoma occurs in up to 35% of patients.[10] Median survival is approximately 10 years, and the clinical course is characterized by treatment response followed by disease progression.

Histologically, follicular lymphoma is categorized into grades 1, 2, and 3, according to the number of centroblasts per high-power field. Histologic grade correlates with prognosis: grades 1 and 2 are indolent, whereas grade 3A is aggressive but may be curable with systemic chemotherapy. Grade 3B is considered a variant of DLBCL for the purposes of treatment, and it is potentially curable.

Because follicular lymphomas of grades 1 and 2 are considered incurable, several differing approaches to therapy are reasonable. For selected patients with Ann Arbor stage I and II disease, deferred therapy is an acceptable option. In a study of early-stage follicular lymphoma, more than half the patients did not need treatment during 6 years of follow-up, and survival in untreated patients was comparable to that in a series of treated patients.[103]

Radiation alone has been evaluated in early-stage follicular lymphoma. No prospective, randomized trial has compared radiation with another treatment modality, but radiation alone in selected patients has produced 10-year disease-free survival rates of greater than 60%.[104] Fludarabine is a very effective drug in follicular lymphoma, with high response rates in both untreated and relapsed disease.[105] Alkylating agents such as cyclophosphamide and prednisone also achieve high response rates and can be combined with fludarabine.[106] Combined-modality therapy in early-stage disease also produces good response rates.

Rituximab, the monoclonal antibody against CD20, is very effective in follicular lymphoma, with response rates of up to 73% in untreated patients and 43% in patients with relapsed or refractory disease.[107,108] For patients who previously responded to rituximab, the response rate with retreatment is 40%.[109] Chemotherapy regimens such as CHOP or fludarabine with rituximab are highly active and may produce durable responses.[110,111] In a randomized study of CHOP with or without rituximab for treatment of follicular lymphoma, rituximab was associated with a significantly higher response rate and longer treatment benefit.[112] Rituximab also has a potential role in maintenance therapy, where it may improve progression-free survival, and in combination with systemic chemotherapy in the initial treatment of follicular lymphoma.[110,113] These results suggest that rituximab is likely to become a standard component of initial chemotherapy.

Radioimmunotherapy of follicular lymphoma involves the delivery of targeted radiotherapy to tumor tissue by conjugating an anti-CD20 antibody to either yttrium-90 or iodine-131. The anti-CD20 radioimmunoconjugates ibritumomab tiuxetan and tositumomab are approved for relapsed or refractory follicular lymphoma. In a randomized trial of relapsed and refractory follicular or transformed lymphoma, the overall response rate was better with ibritumomab tiuxetan than with rituximab (80% versus 56%).[114] Radioimmunotherapy is also being evaluated in combination with systemic chemotherapy.[115] In a study that used tositumomab as initial treatment for follicular lymphoma, 75% of patients had a complete response, and the median progression-free survival was 6.1 years.[116] The exact role of radioimmunotherapy in follicular lymphoma remains to be defined, but the results thus far are very promising.

Both autologous and allogeneic stem cell transplantation can induce durable remissions in follicular lymphoma, and allotransplant may be curable in selected patients.[117] Promising experimental approaches include the use of idiotype vaccine. These vaccines are prepared by isolating tumor-specific antigen—the idiotype protein—from the neoplasm and then conjugating and immunologically manipulating it in vitro. Idiotype vaccination has proved to be effective against several tumor types.[118] Two randomized studies of idiotype vaccination after chemotherapy in follicular lymphoma are under way.[119] Another experimental treatment modality in follicular lymphoma is

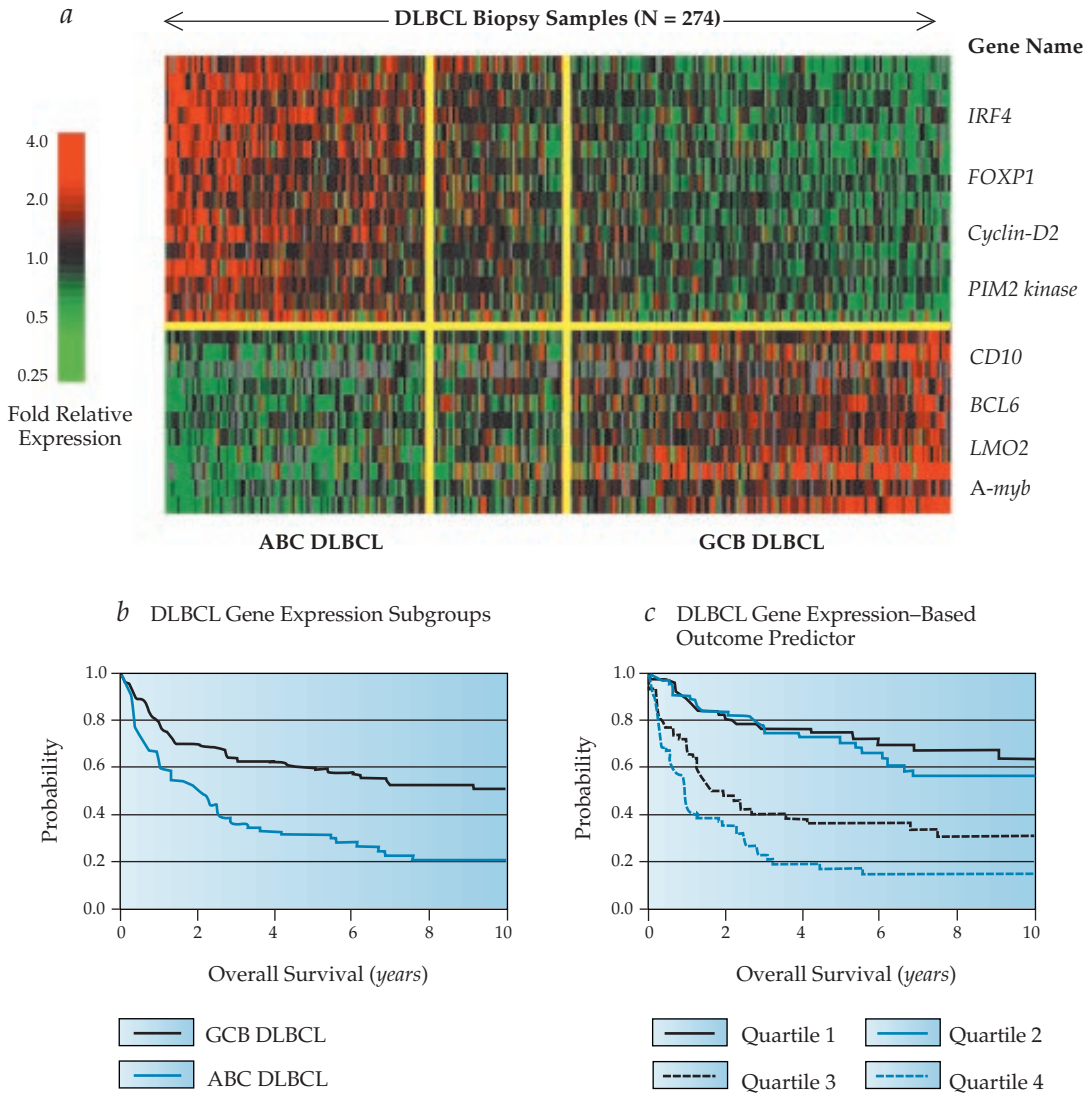

Figure 7 **Gene expression and development of a molecular predictor make it possible to diagnose disease subtypes in patients with diffuse large B cell lymphoma (DLBCL) after initial chemotherapy. (*a*) The expression levels of 27 genes from the subgroup predictor in 274 DLBCL samples are shown according to the color scale at the left. Eight named genes that showed increased expression in either the activated B cell (ABC) or the germinal center B cell (GCB) subgroups are shown at the right. (*b*) Kaplan-Meier estimates of overall survival are shown according to GCB or ABC DLBCL subtype; 5-year survival rates were 59% for patients with the GCB subtype and 31% for patients with the ABC subtype. (*c*) Kaplan-Meier estimates of overall survival according to the molecular outcome predictor are shown for each quartile. The 5-year survival rates were 73% for quartile 1, 71% for quartile 2, 36% for quartile 3, and 15% for quartile 4.**

bcl-2 antisense therapy, which putatively targets the bcl-2 oncoprotein.[120]

Small lymphocytic lymphoma and chronic lymphocytic leukemia SLL represents the solid tumor component of CLL; the two entities are considered to be biologically related [*see 12:XV Chronic Lymphoid Leukemias and Plasma Cell Disorders*]. Most patients are elderly. All patients with CLL have peripheral blood and marrow involvement at diagnosis, whereas SLL can be diagnosed in the absence of marrow or peripheral blood involvement. Treatment of CLL and SLL is similar to that of follicular lymphoma, with fludarabine and rituximab having important therapeutic roles.

Marginal-zone lymphoma Extranodal marginal-zone B cell lymphomas of mucosa-associated lymphoid tissue (MALT lymphoma) constitute 7% to 8% of all B cell lymphomas and a large proportion of primary gastric lymphomas.[10] They tend to be found in the gastrointestinal tract, salivary glands, thyroid gland, lungs, ocular adnexae, breast, and other extranodal sites. Most patients present with early-stage disease. A history of a chronic inflammatory disorder such as *Helicobacter*-associated chronic gastritis or Sjögren syndrome is common. In a small percentage of patients who have superficial, node-negative gastric MALT lymphomas, sustained remissions are possible after *Helicobacter* eradication with antibiotic therapy.[121] Otherwise, these tumors are sensitive to chemotherapy, rituximab, or radiothera-

py, alone or in combination; treatment of early-stage disease can result in long remissions.[122] MALT lymphomas tend to run an indolent course, remaining localized for long periods.

Splenic marginal-zone lymphoma, considered a separate entity in the WHO classification, involves the spleen, splenic hilar lymph nodes, marrow, and peripheral blood.[10] It characteristically has an indolent course and is classically treated with splenectomy; however, treatment with rituximab may ultimately replace this approach. Rituximab has been used in the treatment of extranodal marginal-zone lymphomas.[123] Nodal marginal-zone lymphoma is a rare, indolent, primary nodal B cell neoplasm that is considered the nodal counterpart of MALT lymphoma.

Aggressive B Cell Lymphomas

The aggressive B cell lymphomas include mantle cell lymphoma, DLBCL, Burkitt lymphoma, and lymphoblastic lymphoma. DLBCL is the most common aggressive B cell lymphoma, constituting approximately 30% to 40% of all adult NHLs in Western countries.[10] Both DLBCL and Burkitt lymphoma occur in the setting of HIV infection. Unlike indolent B cell lymphomas, the aggressive subtypes are, as their name implies, more rapidly progressive; and with the exception of mantle cell lymphoma, they are potentially curable. Hence, these tumors require expeditious evaluation and prompt, appropriate treatment.

Mantle cell lymphoma Mantle cell lymphoma is a B cell neoplasm that is composed of small to medium-size lymphoid cells with irregular nuclear outlines. It occurs at a median age of approximately 60 years and has a male predominance.[10] Most patients present with advanced-stage disease; the median survival is 3 years.[124] Morphologic variants of mantle cell lymphoma include two blastoid variants that are associated with a worse prognosis. The t(11;14) translocation occurs in almost all cases. Virtually all these tumors express cyclin-D1 (bcl-1), and a monoclonal antibody against cyclin-D1 is routinely used to confirm the diagnosis. Mantle cell lymphomas may respond to aggressive chemotherapy, but responses are generally short and the disease is considered incurable. Depending on the clinical circumstances, treatment strategies range from observation to aggressive treatment.

Although the overall response rate in mantle cell lymphoma is 89% with CHOP, the median overall survival is merely 37 months.[125] However, the hyper-CVAD regimen (hyperfractionated cyclophosphamide, doxorubicin, vincristine, and dexamethasone alternating with methotrexate and cytarabine) is effective, and adding rituximab enhances its effect.[126] In one study of untreated mantle cell lymphoma, DA-EPOCH-R (dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin-rituximab) produced a complete response rate of 93%.[127] Trials of high-dose chemotherapy with autologous stem cell transplantation or allogeneic transplantation are ongoing but to date have yielded variable results.[128] Hence, transplantation should currently be considered experimental for the treatment of mantle cell lymphoma. The proteasome inhibitor bortezomib has proved active in relapsed mantle cell lymphoma and may become an important therapeutic agent for mantle cell lymphoma.[129,130]

Diffuse large B cell lymphoma DLBCL is the most prevalent histologic subtype of NHL. Histologically, it consists of a diffuse proliferation of large neoplastic B cells. Although the median age at diagnosis is in the seventh decade, DLBCL affects children and adults of any age. Patients may present with nodal or extranodal disease and localized or disseminated disease. The most common extranodal site is the gastrointestinal tract, but any extranodal tissue can be affected. DLBCL can arise de novo or result from the histologic transformation of an indolent B cell lymphoma. Morphologic variants within the category of DLBCL include centroblastic, immunoblastic, T cell rich/histiocyte rich, and anaplastic.[10] DLBCL can arise in any organ. Thus, different clinical behaviors and natural histories are seen in certain subtypes, such as primary mediastinal B cell lymphoma, which arises in the mediastinum, or primary CNS lymphoma (see below).

Radiation alone is inadequate for the treatment of DLBCL, with high recurrence rates both locally and distally.[131] Hence, all stages of disease require at least systemic chemotherapy. For early-stage disease (I or II), whether chemotherapy alone is adequate remains somewhat controversial. The benefit of combined-modality treatment was demonstrated in a randomized study comparing full-course CHOP with limited-course CHOP plus involved-field radiation in early-stage aggressive lymphoma.[132] In this study, combined-modality treatment was associated with superior overall and progression-free survival rates of 82% and 77%, respectively. However, a follow-up analysis showed a convergence of the overall survival curves because of an increase in late systemic relapses in the combined-modality arm.[133] Furthermore, an Eastern Cooperative Oncology Group study showed no survival benefit for combined-modality treatment over chemotherapy alone.[134] These results suggest that involved-field radiation may not be necessary with the use of more effective systemic treatments, such as R-CHOP or ACVBP (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone).[79,135]

Some patients with early-stage primary mediastinal DLBCL (PMBCL), however, may require involved-field radiation after chemotherapy. In a study of 50 patients with untreated PMBCL who received MACOP-B (methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin) followed by radiation, 66% had a persistently positive gallium scan after chemotherapy alone, suggesting active disease.[136] However, treatment of PMBCL with other regimens that do not include involved-field radiation, such as ACVBP and DA-EPOCH, have yielded good results in PMBCL.[71,135] Furthermore, rituximab has improved the outcome in DLBCL.[79] Hence, it is reasonable to limit involved-field radiation to those patients with persistently positive PET scans after such treatments.

Advanced disease is treated with systemic chemotherapy. CHOP, developed in the 1970s, produces long-term remissions in approximately 35% of patients with DLBCL.[78] A number of newer regimens that improve on CHOP have been developed.[79,137-141] In a randomized trial, the addition of rituximab to CHOP resulted in a better response rate and survival in patients older than 60 years; thus, R-CHOP is emerging as the de facto standard for the treatment of DLBCL.[79] In poor-prognosis aggressive lymphoma, the regimen ACVBP improved event-free and overall survivals when compared with CHOP alone in patients older than 60 years.[138] The success of DA-EPOCH in untreated DLBCL led to the investigation of DA-EPOCH-R; this regimen has demonstrated progression-free and overall survival rates of approximately 80% at 2 years' median follow-up.[71,139] Unlike CHOP, DA-EPOCH appears to be effective in DLBCL with a high proliferative index.[71] Dose-dense CHOP

(given every 2 weeks) has been compared with CHOP given every 3 weeks, with or without the addition of etoposide (CHOP versus CHOEP), in young and elderly patients.[140,141] In young patients with aggressive lymphomas whose prognoses were good, survival was found to be better with CHOEP. In elderly patients, better results were seen with dose-dense CHOP than with CHOEP.

The initial treatment of aggressive DLBCL with high-dose chemotherapy and autologous transplantation continues to be studied but has not been definitively proved to be more effective than conventional chemotherapy.[142,143] One study showed that this approach provided better results than CHOP, but this conclusion is confounded by the study's inclusion of multiple lymphoma subtypes.[144] In addition, R-CHOP is now the standard for DLBCL, thus diminishing the value of studies that evaluate CHOP alone.

Treatment options for relapsed DLBCL include salvage chemotherapy and high-dose chemotherapy with autologous or allogeneic transplantation. For patients with a chemosensitive relapse who do not have marrow involvement, high-dose therapy and autologous transplant generally offer the best chance of response and remission.[142] With a higher percentage of current patients receiving regimens that are more effective than CHOP, the relative benefit of high-dose therapy will diminish, because current patients will have more resistant disease. Limited benefit can be obtained from conventional salvage regimens, and the choice between either salvage chemotherapy or high-dose therapy with autologous transplantation is influenced by a number of factors. Patients who experience relapse after an autologous transplantation may benefit from allogeneic transplantation.[145]

Primary central nervous system lymphoma Primary CNS lymphoma (PCNSL) is a rare lymphoma confined to the CNS; histologically, it is usually a DLBCL. Treatment of PCNSL is different from that of systemic NHL, because many of the chemotherapy agents used in the treatment of systemic NHL do not cross the blood-brain barrier. However, there may be a rationale for their use in patients in whom PCNSL disrupts this barrier. PCNSL is responsive to radiation, but responses tend to be short-lived and relapse rates high. Methotrexate is very effective in PCNSL, but when used alone, it produces a low median progression-free survival of only 12.8 months.[146] Methotrexate in combination with other chemotherapy agents is potentially curative, particularly in patients younger than 60 years, with an overall progression-free survival of 34% at 5 years.[147]

The role of consolidation radiotherapy after chemotherapy in PCNSL is controversial. Whole-brain radiation therapy is associated with significant neurotoxicity, particularly in elderly patients. Therefore, if results are equivalent with chemotherapy alone, radiation should be deferred until relapse. The Bonn group and others have reported good results with chemotherapy and deferred radiation.[148] This may become the standard approach for management of PCNSL in the future.[146,148]

Burkitt lymphoma Burkitt lymphoma is a highly aggressive lymphoma with three clinical settings: endemic, sporadic, and immunodeficiency related. Endemic Burkitt lymphoma occurs in young children in equatorial Africa; clinically, these patients often present with jaw and facial bone involvement. Sporadic Burkitt lymphoma, which is more commonly seen in children and young adults, often presents as abdominal disease or as other extranodal-site involvement. Immunodeficiency-related Burkitt lymphoma is usually seen in HIV-infected patients.

There are varying degrees of positivity for EBV infection with Burkitt lymphoma. All patients have a translocation of *MYC*.

Burkitt lymphoma is readily curable with systemic chemotherapy. Very intensive regimens that include intrathecal prophylactic therapy have traditionally been employed and continue to be the standard of care, despite significant toxicities.[149,150]

HIV-Related Lymphoma

For several reasons, including disordered immunosurveillance and chronic antigenic stimulation, the incidence of lymphoma is significantly increased in patients with HIV infection. Approximately 4% of patients with AIDS have NHL at the time of AIDS diagnosis. Although the incidence of all subtypes of lymphoma is increased in patients with HIV infection, the risk is increased 1,000-fold for Burkitt lymphoma and up to 400-fold for aggressive lymphoma.[135,151] Primary effusion lymphoma and plasmablastic lymphoma are almost exclusively seen in patients with HIV infection; both carry a very poor prognosis. Lymphomas are also observed with increased frequency after solid-organ transplantation; in certain autoimmune and inherited immunodeficiency syndromes; and with certain therapies, such as methotrexate.

Low-dose treatment strategies were standard in the early years of treating AIDS-related lymphomas, but highly active antiretroviral therapy (HAART) has improved survival and has thus allowed more aggressive treatment of lymphoma, with curative rather than palliative intent.[152] Systemic chemotherapy approaches for AIDS-related DLBCL and Burkitt lymphoma have included CHOP, but the efficacy of CHOP has been somewhat lower and its toxicity higher than in HIV-negative patients with similar lymphomas.[153] One major controversy in the treatment of AIDS-related lymphoma has been whether to suspend HAART during chemotherapy. HAART may enhance the toxicity of chemotherapy drugs, which may necessitate chemotherapy drug-dose reduction and thus compromise therapeutic efficacy. One approach is to suspend HAART during chemotherapy, with prompt resumption on completion of all cycles. The infusional regimen EPOCH, with HAART suspension, produced a 74% complete response rate and 72% overall survival at a median follow-up of 53 months.[89] These results were significantly superior to those for CHOP. The AIDS Malignancy Consortium is currently testing EPOCH in a randomized trial.

Epstein-Barr Virus–Associated Lymphoproliferative Disorders

Several lymphoproliferative disorders are associated with EBV infection. Posttransplant lymphoproliferative disorder (PTLD), which usually occurs after solid-organ transplantation, encompasses a broad spectrum of diseases with varying degrees of clinical aggressiveness. It is generally treated by withdrawal of chronic immunosuppression, but chemotherapy may be required for patients in whom PTLD behaves like an aggressive lymphoma or is resistant to immunosuppression withdrawal. Methotrexate-associated lymphoproliferative disorders can also be associated with EBV. Finally, lymphomatoid granulomatosis, a lymphoproliferative disorder involving extranodal sites, is EBV driven and is treated with interferon or chemotherapy, depending on the disease grade.[154]

Lymphoblastic Lymphoma

Precursor lymphoblastic lymphomas are cytologically identical to acute lymphoblastic leukemia. They are usually T cell lym-

phomas and are more common in adolescent boys or young men. Patients often present with a high white blood cell count and a large mediastinal mass. Treatment is with regimens that are appropriate for acute leukemia and that include CNS prophylaxis.

Mature T Cell and Natural Killer Cell Lymphomas

Lymphomas deriving from mature T cells and NK cells are uncommon, accounting for approximately 12% of all NHLs.[10] Their incidence varies significantly by geographic location, with an increased frequency in Asia. In lymphoma classifications that predated the current WHO classification, some of these lymphomas were considered unclassifiable or were not recognized. The natural history of mature T cell and NK cell lymphomas ranges from indolent to aggressive. Unfortunately, unlike aggressive B cell lymphomas, the majority of aggressive T/NK cell lymphomas are incurable. Important exceptions, however, include systemic anaplastic large cell lymphoma (ALCL), which is highly curable when it expresses the ALK fusion protein, and early-stage T/NK nasal angiocentric lymphoma (NAL), which is curable with high-dose radiation treatment.[155,156] Although a full description of these relatively rare diseases is beyond the scope of this chapter, several important subtypes are highlighted below.

Cutaneous T Cell Lymphomas

Cutaneous T cell lymphomas include mycosis fungoides, Sézary syndrome, primary cutaneous ALCL, and lymphomatoid papulosis. Mycosis fungoides presents in the skin with patches and plaques. The disease runs an indolent course and has a long natural history. General erythroderma may develop. Generalized disease dissemination is usually a late event in mycosis fungoides. A number of topical and local therapies, including ultraviolet radiation and skin electron-beam therapy, are very effective in mycosis fungoides. Systemic agents include the novel synthetic retinoid X receptor–selective retinoid bexarotene; the fusion toxin denileukin diftitox; and, experimentally, the histone deacetylase inhibitors.[157,158] Allogeneic transplantation has been investigated as a potentially curative treatment for advanced mycosis fungoides.[159]

Sézary syndrome consists of circulating neoplastic T cells, erythroderma, and lymphadenopathy. Unlike mycosis fungoides, Sézary syndrome is very aggressive.

Primary cutaneous ALCL affects the skin; this disease is distinct from systemic ALCL. In cases of localized skin involvement, skin-directed therapies are appropriate; extracutaneous disease requires more aggressive therapies. Lymphomatoid papulosis usually runs a benign clinical course and sometimes requires therapies such as low-dose methotrexate.

Anaplastic Large Cell Lymphoma

ALCL, a rare T cell lymphoma comprising 3% of all NHLs in adults, typically occurs in young men. ALCL is very curable; patients have a 70% long-term survival rate after systemic chemotherapy. The histologic hallmark of ALCL is CD30 positivity; in addition, most of these tumors express epithelial membrane antigen.[160] ALCL is associated with the t(2;5)(p23;q35) translocation, which results in the expression of the nucleophosmin anaplastic lymphoma kinase (ALK). ALK positivity, present in more than 50% of ALCLs, is associated with a better prognosis than ALK-negative disease.[155] ALK-positive ALCL often occurs in children or young adults. Most patients present with advanced disease and may have involvement of extranodal sites. ALCL responds very well to systemic chemotherapy, particularly if the disease is ALK positive.

Angioimmunoblastic T Cell Lymphoma

Angioimmunoblastic T cell lymphoma is a distinct type of peripheral T cell lymphoma that is associated with scattered EBV-positive B cells in biopsy specimens. Clinically, this disease is characterized by systemic symptoms, skin rash, organomegaly, hypergammaglobulinemia, and hemolytic anemia. Patients exhibit immunodeficiency and are particularly susceptible to infections. Angioimmunoblastic T cell lymphoma generally has an aggressive clinical course and is usually incurable with conventional chemotherapy.[161]

Peripheral T Cell Lymphoma, Unspecified

A large number of predominantly nodal T cell lymphomas are not included in other T cell lymphoma categories in the WHO classification. This group of lymphomas is very diverse, both morphologically and clinically. Patients generally have a poor long-term response to conventional chemotherapy, with a high rate of relapse and low rates of overall survival.[162] High-dose chemotherapy followed by autologous stem cell transplantation has been used with some success in patients with relapsed disease and offers some chance of long-term remission.[163,164] Early results with allogeneic transplantation in relapsed peripheral T cell lymphoma is promising, with some apparent graft versus lymphoma effect.[165]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XII ONCOLOGIC EMERGENCIES

Robert W. Carlson, m.d., f.a.c.p.

Malignant disease and its treatment may produce a variety of complications. Many of these complications are relatively specific to the disease (e.g., leukostasis in acute myeloid leukemia) or to a class of chemotherapeutic agents (e.g., chronic cardiomyopathy with the anthracyclines). However, life-threatening complications associated with malignancy are common to a variety of tumor types; in addition, many cytotoxic chemotherapeutic agents can produce potentially fatal toxicities, depending on the agent and its dosing schedule.

Cardiovascular Emergencies

pericardial disease and tamponade

Neoplastic pericardial disease is usually associated with advanced lung cancer, breast cancer, leukemia, or lymphoma, with pericardial involvement occurring either by direct extension or by spread via the mediastinal lymphatic vessels.[1,2] Pericardial disease with or without tamponade may also be caused by chemotherapeutic or radiotherapeutic toxicity. Patients who have neoplastic involvement of the visceral pericardium and those who receive mediastinal radiation therapy are at risk for effusive-constrictive pericarditis, a syndrome that is caused by pericardial effusion combined with constriction of the heart by the visceral pericardium. Patients who receive chemotherapy with anthracyclines or cyclophosphamide are also at risk for pericardial disease with tamponade, which may present as acute pericarditis or myocarditis syndromes. These syndromes occur primarily with very high dose chemotherapy regimens.

Diagnosis

The most common presenting symptoms of neoplastic pericardial disease with tamponade are progressive dyspnea, nonspecific chest discomfort, and cough.[1] Arterial blood pressure and heart sounds may be normal. Pericardial friction rubs frequently are not present. Although central venous pressure is always elevated in patients with tamponade, venous hypertension may be detected clinically in only about one half of cases because of anatomic variations in vasculature and body habitus and failure to observe venous pulsations.

A paradoxical pulse is the single most specific sign of pericardial tamponade. Because the signs and symptoms of pericardial tamponade in cancer patients are nonspecific, pericardial tamponade should be considered in any cancer patient who has dyspnea, nonspecific chest pain, elevations in jugular venous pressure, new and unexplained cardiomegaly on chest x-ray, or a paradoxical pulse.[3] Electrocardiography is usually not helpful in the diagnosis of malignant pericardial disease.

Echocardiography is the single most valuable noninvasive method of evaluating pericardial disease or tamponade in cancer patients. Pericardial effusions secondary to neoplastic disease usually are large and do not produce internal echoes. The presence of tamponade is indicated by early diastolic collapse of the right atrial or ventricular wall or by Doppler echocardiography–documented changes in the respiratory variation of blood flow velocity through the tricuspid or mitral valves.

Measurements of pericardial fluid pressure during pericardiocentesis may help differentiate pericardial tamponade from superior vena cava (SVC) syndrome. In tamponade, pericardial fluid pressure is elevated initially but returns to normal as the fluid is withdrawn, whereas in SVC syndrome, pericardial fluid pressure is normal and jugular venous pressure is unaffected by pericardiocentesis. In patients with effusive-constrictive pericarditis, pericardiocentesis produces only partial improvement of the hemodynamic abnormality.

Treatment

Treatment of pericardial tamponade includes pericardiocentesis, pericardial window formation, or pericardiectomy. Echocardiographically guided pericardiocentesis with concurrent catheterization of the right side of the heart allows for definitive diagnosis of cardiac tamponade, removal of pericardial fluid to relieve the tamponade, cytologic and microbiologic analysis of the fluid, and placement of an intrapericardial catheter to prevent fluid reaccumulation. Frequently, catheter drainage for several days results in a decreased rate of pericardial fluid collection and may provide definitive long-term benefit.[4] Intrapericardial instillation of bleomycin or tetracycline-doxycycline is a safe and effective method of sclerosing the pericardial space to prevent the recurrence of tamponade.[5,6] Patients in whom effusions rapidly recur may benefit from a pericardial window,[7] and those who have effusive-constrictive pericarditis may require partial pericardiectomy.[8]

Systemic chemotherapy or hormone therapy may be beneficial. Limited cardiac radiation therapy may also provide palliation, especially in patients with radiosensitive tumors. However, the survival of patients with cancer and secondary pericardial involvement is usually short because of the systemic nature of their disease [*see 1:XIII Diseases of the Pericardium, Cardiac Tumors, and Cardiac Trauma*].

superior vena cava syndrome

Extrinsic compression or intrinsic obstruction of the SVC [*see Figure 1*] may result in elevated venous pressures in the upper extremities, head, and neck and in increased intracranial pressure, soft tissue edema, venous distention, and venous collateral formation. Variations in the clinical presentation of SVC syndrome may occur if compression or obstruction involves a large upper mediastinal vein or a low cervical vein. The syndrome may develop rapidly over a period of days or slowly over a period of many months.

The most common cause of SVC syndrome is extrinsic compression of the thin-walled, low-pressure SVC by a malignant mediastinal mass, such as a bronchogenic carcinoma—especially small cell lung cancer [*see Figure 2*]—or non-Hodgkin lymphoma. Other malignant causes of SVC syndrome are thymic tumors, mediastinal germ cell tumors, and metastatic carcinoma. The differential diagnosis includes SVC thrombosis (especially in patients with central venous catheters), goiter, mediastinal fibrosis, tuberculous mediastinitis, histoplasmosis, and ascending aortic aneurysm.

In the past, SVC syndrome was considered an oncologic emergency that required the immediate initiation of mediastinal radiation therapy. Radiation therapy was thought to be neces-

sary for three reasons: to alleviate increased intracranial pressures because lung cancer was presumed to be the most likely diagnosis, and because it was erroneously believed that increased venous pressures would make diagnostic procedures hazardous. It is now recognized that in adults, SVC syndrome is usually not a true emergency and that a histologic diagnosis should be quickly established and treatment promptly initiated. Emergency treatment with endovascular stenting or mediastinal radiation therapy before a histologic diagnosis is established is warranted in children and in adults who have mental-status alteration, other life-threatening manifestations of increased intracranial pressure, cardiovascular collapse, or upper airway obstruction.

Diagnosis

SVC syndrome should be suspected in any patient who has a sensation of fullness in the face, plethora, dyspnea, facial swelling, distended neck veins, or venous collaterals in the neck or chest. In addition, many patients with SVC syndrome will acknowledge, if asked, that they have been sleeping fitfully and have been having nightmares. Headache, disturbance of vision, mental-status alteration, cough, and chest pain may also be present. In almost all patients with SVC syndrome, a chest x-ray demonstrates widening of the superior mediastinum, a right hilar or an upper lobe mass, or pleural effusion. Computed tomography of the chest is the single most useful diagnostic tool. It confirms the clinical diagnosis, localizes the abnormality, provides information regarding biopsy sites, and identifies coexisting thrombosis. The diagnosis of SVC syndrome should be assumed if the patient has clinical manifestations of the syndrome and there is radiographic evidence of mediastinal disease.

In a patient without a history of cancer, the evaluation should focus on identifing any abnormality for which a biopsy can be performed to provide a histologic diagnosis. Procedures include sputum cytology, fine-needle aspiration of pathologic lymphadenopathy, cytologic examination of pleural fluid, and bone marrow biopsy and aspiration. Because bronchogenic carcinoma is the most common cause of SVC syndrome, bronchoscopy is a high-yield procedure. Bronchoscopy can be performed safely in most patients with SVC syndrome. The combination of sputum cytology, bronchoscopy, and biopsy of palpable lymph nodes provides a definitive histologic diagnosis in approximately 70% of patients.[9] Although the safety of biopsy procedures in patients with SVC syndrome has been well established,[10] it is prudent to take biopsy samples from sites of disease outside the region of elevated venous pressures whenever possible.

Treatment

Treatment of SVC syndrome caused by a malignancy is evolving, with the increasing use of endovascular stents to rapidly reverse the hemodynamic abnormality followed by combination chemotherapy or radiation therapy to treat the underlying malignancy. Endovascular stenting provides rapid relief of symptoms and has a high success rate and low morbidity.[11-14] Combination chemotherapy is often effective as the primary therapy for SVC syndrome in patients with small cell lung cancer or lymphoma; in most patients, this treatment produces a positive disease response and improvement in the SVC syndrome.[15] Because there is increased risk of extravasation from veins with elevated pressure, chemotherapeutic agents should be infused into a vein in the lower extremity or a femoral vein. In patients with non–small cell lung cancer or other tumors that are relatively resistant to chemotherapy, endovascular stenting is generally followed with mediastinal radiation therapy.

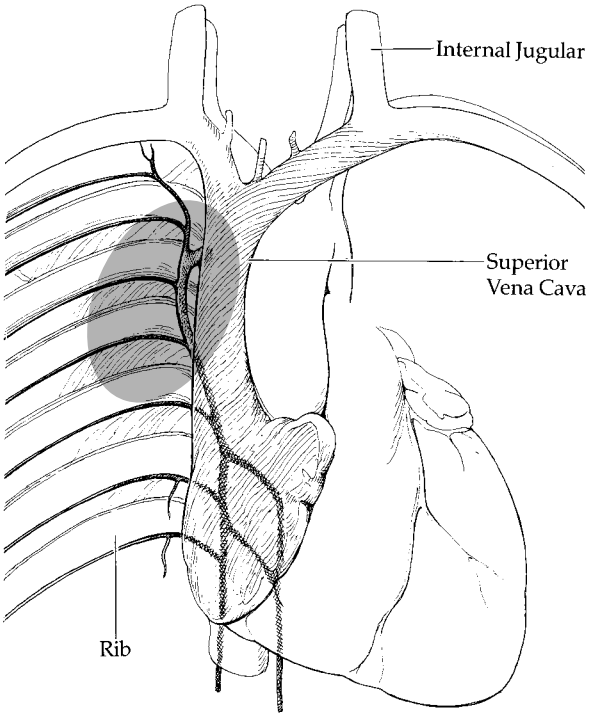

Figure 1 **Obstruction of the superior vena cava in patients with malignant disease is caused by compression of the thin-walled vessel by tumorous lymph nodes or by direct invasion of the wall of the vessel by the tumor. The shaded region represents the most common site of obstruction.**

SVC syndrome often results in SVC thrombosis, and thus, some clinicians routinely prescribe anticoagulants for these patients; however, except in patients with demonstrable thrombosis or endovascular stents in place, there are no convincing data to support routine use of these agents, and anticoagulation has been associated with a 10% fatality rate secondary to intracranial hemorrhage.[16] SVC thrombosis should be suspected in the rare patient who fails to respond to chemotherapy or radiation therapy. Treatment with anticoagulants or fibrinolytics is probably appropriate in patients with documented thrombosis. Patients with stridor or significant airway compromise should be treated with glucocorticoids. Endotracheal intubation should be considered for acute airway management.

In 10% to 20% of patients, SVC syndrome will recur after radiation therapy and chemotherapy. If the patient does not already have an intravascular stent, insertion of such a device will often provide palliation.[17] The overall prognosis in patients with SVC syndrome secondary to malignancy is determined by the malignancy, not by the presence of the syndrome per se.

Hematologic Emergencies

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) involves systemic activation of the coagulation process by tissue factor, impaired fibrinolysis, and deficiency in the physiologic anticoagu-

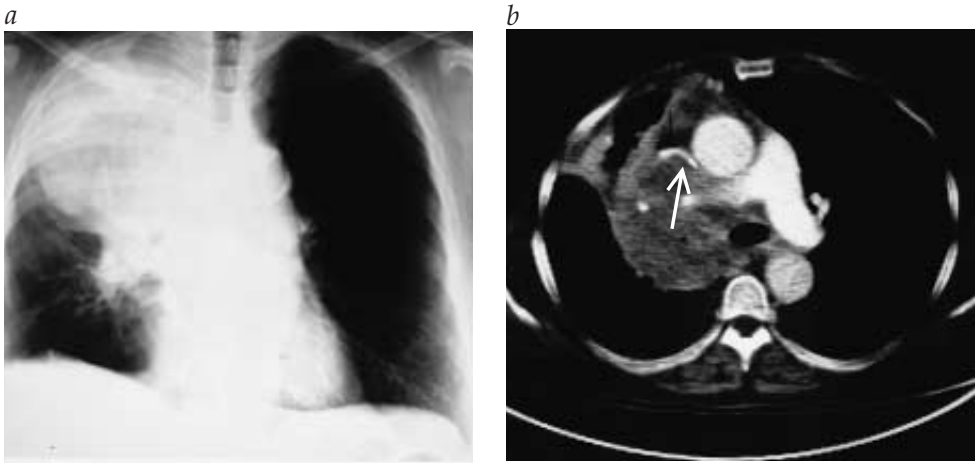

Figure 2 **(*a*) Shown is a chest x-ray of a patient with small cell lung cancer and superior vena cava syndrome. (*b*) Contrast-enhanced CT scan in the same patient is also shown.[103] Note that the thin-walled, contrast-enhanced superior vena cava is compressed by the tumor mass to a crescentic shape (arrow).**

lant system.[18,19] This leads to consumption of platelets and coagulation factors, which causes bleeding, and to deposition of fibrin, which causes microvascular thrombosis. In addition to malignancy, common causes of DIC include infection, obstetric complications, and trauma.[18] The fibrinolytic system usually is activated secondarily; it is rarely activated primarily (primary fibrinolysis) without associated DIC. Patients with malignancy often have asymptomatic abnormalities of the coagulation system. These abnormalities include increased levels of factor VIII, fibrinogen, and platelets or evidence of increased fibrinolysis, as measured by increased levels of fibrin monomer, fibrinopeptide A, and fibrin degradation products.[20] Patients with adenocarcinoma (especially of the pancreas or prostate) or promyelocytic leukemia are particularly at risk. DIC may be either acute or chronic, and the coagulopathy may vary in severity, ranging from difficult to detect—even in the laboratory—to a fulminant bleeding diathesis. Thromboembolic manifestations are common.

Chronic DIC

Low-grade chronic DIC occurs in most patients with disseminated malignancy. The body typically compensates well, and laboratory measurements of coagulation may be normal or near normal. Some patients with low-grade chronic DIC, however, experience deep vein thrombosis, Trousseau syndrome, nonbacterial thrombotic endocarditis, or embolism without bleeding.[20] Patients who have thrombosis and no evidence of bleeding should immediately be started on long-term anticoagulant therapy with heparin (either unfractionated or low-molecular-weight heparin). Warfarin provides inadequate protection against recurrent thrombosis in patients with chronic DIC.

Acute DIC

Diagnosis Patients with acute DIC usually have clinical evidence of consumption coagulopathy, a low platelet count, and activation of clotting factors, which cause prolongation of the prothrombin, partial thromboplastin, and thrombin times; and elevated levels of fibrin degradation products. Fibrinogen levels may be decreased because of consumption or may be normal or elevated as an acute-phase reactant despite consumption. Common signs of acute DIC include bleeding from surgical wounds, venipuncture sites, the nose, the mouth, and the gastrointestinal tract; ecchymoses; petechiae; purpura; and stroke. In patients with malignancy, simultaneous blood loss from three or more sites usually is an indication of life-threatening acute DIC. The bleeding associated with DIC may be fulminant and may cause shock, end-organ dysfunction, and death.

Treatment Treatment of acute DIC includes elimination of the underlying cause, such as infection or malignancy, whenever possible. DIC in patients with promyelocytic leukemia may resolve with treatment with all-*trans*-retinoic acid.[18,21-23] Replacement of consumed platelets and clotting factors usually is appropriate, and red cell transfusions should be given to patients who have significant blood loss. Despite evidence suggesting a role for supraphysiologic doses of antithrombin III, a randomized trial of high-dose antithrombin III in patients with severe sepsis did not document a reduction in mortality.[22,24,25] The use of heparin remains controversial.[19,23,24] Heparin may be valuable in inhibiting DIC and thereby in maintaining appropriate levels of clotting factors, but it carries a significant risk for increasing bleeding. When heparin is used, the lowest dosage of unfractionated heparin (300 to 500 U/hr) or low-molecular-weight heparin that maintains the platelet count (> 50,000 U/μl) and clotting factor level (a fibrinogen level > 150 mg/dl) should be given. In patients with primary fibrinolysis, treatment consists of the vigorous replacement of consumed clotting factors with cryoprecipitate or fresh frozen plasma. Early evidence suggests that the use of activated protein C may also be of benefit.[26]

BLEEDING WITH THROMBOCYTOPENIA

In patients with cancer, thrombocytopenia is most commonly caused by the underproduction of platelets secondary either to bone marrow infiltration by tumor or to the toxicity of chemotherapy or radiation therapy. Increased destruction of peripheral blood elements, as occurs in hypersplenism, DIC, and immune-mediated disorders, is also sometimes observed. In patients who are receiving myelosuppressive chemotherapy and in those with thrombocytopenia, the use of agents that inhibit platelet function (e.g., aspirin) should be specifically avoided.

Bleeding time increases when platelet counts fall below 100,000/μl, and the risk of spontaneous bleeding significantly increases when platelet counts fall below 10,000/μl.[27] The American Society of Clinical Oncology (ASCO) has developed guidelines for the use of prophylactic platelet transfusions.[28] In patients with leukemia, hematopoietic cell transplantation, or solid tumors, the ASCO guidelines recommend prophylactic platelet transfusions for chemotherapy-related thrombocytopenia at a platelet count threshold of 10,000/μl. Higher thresholds for

transfusion are appropriate for patients with hemorrhage, high fever, or coagulation abnormalities or when invasive procedures are anticipated. Alloimmunization may be reduced or prevented by the use of blood products leukoreduced by filtration. To prevent allosensitization, prophylactic platelet transfusions should not be performed in patients with increased destruction of peripheral blood elements.

Treatment of bleeding in patients with thrombocytopenia from underproduction of platelets consists of platelet and red cell transfusions and local control at the site of bleeding. Patients who become sensitized to transfused platelets may benefit from HLA-matched, single-donor platelet transfusions. Underlying DIC should also be considered and, if identified, should be treated as noted in the discussion of DIC (see above). In patients undergoing chemotherapy for solid tumors who are at high risk for thrombocytopenia, the use of recombinant human interleukin-11 (oprelvekin) has been shown to reduce thrombocytopenia and the need for platelet transfusions but is associated with substantial toxicity.[29,30]

THROMBOTIC MICROANGIOPATHY

Thrombotic microangiopathy is a rare syndrome that includes microangiopathic hemolytic anemia, thrombocytopenia, uremia, neurologic dysfunction, and fever. The syndrome may present as thrombotic thrombocytopenic purpura (TTP) or the hemolytic-uremic syndrome (HUS)[31]; TTP is typically diagnosed if neurologic symptoms predominate, whereas HUS is diagnosed if uremia predominates. Evidence suggests that TTP and HUS represent distinct histopathologic entities.[32] Both TTP and HUS involve the intravascular hemolysis of red cells. TTP is usually fatal if not treated. Thrombotic microangiopathy occurs in a variety of situations, including malignancy (e.g., adenocarcinomas and squamous cell carcinomas) and chemotherapy.

The diagnosis of thrombotic microangiography is suggested by anemia and the presence of schistocytes on peripheral blood smears. The severity of disease varies widely, ranging from minimal anemia with few schistocytes to profound anemia with rapid hemolysis and large numbers of schistocytes. The differential diagnosis includes sepsis with DIC; many patients also have associated DIC. Patients with gastric carcinoma are particularly at risk.

HUS may occur in patients who have no evidence of active disease. HUS is most commonly observed after chemotherapy with mitomycin but is also seen after treatment with bleomycin, cisplatin, dacarbazine, fluorouracil, lomustine, vinca alkaloids, gemcitabine, and high-dose chemotherapy with autologous stem cell support.[31,33] In one series, the syndrome developed in approximately 4% of mitomycin-treated patients.[33]

Mortality from thrombotic microangiopathy is high, and no consistently effective therapy is available. The mainstay of therapy is immediate plasma exchange with either fresh frozen plasma or cryosupernatant plasma.[31,34-36] Prolonged courses of plasma exchange of one calculated plasma volume a day may be required. The use of extracorporeal immunoadsorption of plasma has produced improvement in 45% of treated patients.[37] Other therapies that have been utilized in patients with refractory or recurrent thrombotic microangiopathy include vincristine, cyclophosphamide, cyclosporine, prednisone, and rituximab.[38-40]

FEVER AND NEUTROPENIA

Patients with cancer may experience transient or protracted periods of neutropenia related to the disease or its treatment. Patients with neutropenia (defined as counts of polymorphonuclear leukocytes plus bands of less than 500/μl) experience an increase in the frequency and severity of a variety of infections. The increased susceptibility to infection is related both to the level and to the duration of the neutropenia. Patients are at particular risk for life-threatening infection if neutropenia is profound (counts of polymorphonuclear leukocytes plus bands below 100/μl). Other factors that place patients with cancer at increased risk for infection include deficient phagocytic function secondary to cytotoxic therapy, the breakdown of skin and mucosal barriers secondary to chemotherapy, the presence of vascular access devices, and the high frequency of invasive procedures. Although some studies have demonstrated that patients with fever and neutropenia who are at low risk for infection may be managed in the outpatient setting, most patients should be managed in the hospital until further confirmatory studies are available.[41-43]

Prevention

The optimal dosages and schedules of antitumor chemotherapy for a number of malignancies produce neutropenia. Methods of minimizing infection in patients with protracted neutropenia include the maintenance of good hygiene, with aggressive treatment of abrasions and mucositis; careful hand washing by medical personnel between patient contacts; not placing fresh flowers or plants in the patient's room; the use of low-microbial diets; the use of prophylactic antibiotics; and the use of colony-stimulating factors. However, prophylactic antibiotic treatment is of limited usefulness, is expensive, and increases the risk of drug-resistant infection. In addition, granulocyte colony-stimulating factor (G-CSF) (e.g., filgrastim, pegfilgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF) can decrease the duration of chemotherapy-induced neutropenia [*see* Colony-Stimulating Factors, *below*].[44-47]

Diagnosis

In patients with neutropenia, serious infection should be presumed after a single temperature measurement of 38.3° C (101 °F) or higher or after recurrent temperature measurements of 38.0° C (100.4° F) or higher.[48] In a neutropenic patient, even life-threatening infections may not be apparent on initial evaluation. Localizing signs and symptoms of infection may be absent. When present, the manifestations of infection may be subtle because of an inadequate inflammatory response; repeated daily examinations are therefore essential. Physical examination should focus on common sites of infection, including the sinuses, ears, mouth, oropharynx, skin, chest, abdomen, perianal region, and catheter sites. Cultures should be obtained from the blood and urine; in patients undergoing long-term venous catheterization, blood cultures from each catheter lumen should be obtained at the same time as peripheral venous blood cultures. Cultures of sputum, the pharynx, stool, pleural or peritoneal fluid, cerebrospinal fluid, and catheter sites should be obtained if signs or symptoms of localizing infection are present. A chest radiograph should be obtained, although it may be normal in neutropenic patients who have pneumonia, because the development of an infiltrate requires the presence of neutrophils.

Despite careful and thorough evaluation, an infectious source is identified in only 30% to 40% of patients with fever and neutropenia. Gram-positive organisms are now the most commonly identified organisms, particularly in patients undergoing long-term catheterization; the most common organisms are *Staphylo-*

coccus epidermidis, *Streptococcus* species, and *S. aureus*. Gram-negative organisms, especially *Escherichia coli*, *Klebsiella* species, and *Pseudomonas aeruginosa*, are also commonly identified.[48] Neutropenic hosts also have increased susceptibility to fungal infection, most commonly with *Candida*, *Aspergillus,* and *Zygomycetes* species [*see 7:XXXVIII Mycotic Infections in the Compromised Host*].

Treatment

Antibiotic selection Antibiotic therapy in the neutropenic patient who has fever or other manifestation of infection should be initiated promptly and at full dosages (after adjustments are made for renal and hepatic function). If a specific infectious organism is identified, the antibiotic regimen should be modified to ensure coverage of that organism, ideally with two different antibiotics. However, the spectrum of coverage should not be narrowed. Neutropenic patients who have an identifiable source of infection should receive treatment for at least as long as nonneutropenic patients with a similar infection. In the absence of an identifiable source of infection, antibiotics should be continued until the patient has a granulocyte count of greater than 500/μl and has been afebrile for 48 hours or longer. The duration of antibiotic therapy in the patient with prolonged neutropenia who becomes promptly afebrile is controversial. One reasonable approach is to continue intravenous antibiotics in high-risk patients and to change to an oral antibiotic regimen in low-risk patients after 48 hours without fever (e.g., ciprofloxacin plus amoxicillin-clavulanate).[48]

The antimicrobial agents that are initially selected for patients with fever and neutropenia should provide broad-spectrum coverage against both gram-positive and gram-negative organisms (including *P. aeruginosa*) with consideration for the frequency of antibiotic resistance in the local population. A number of intravenous and oral antibiotic regimens are effective.[48-53] Reasonable dual combination regimens include an antipseudomonal aminoglycoside combined with either an antipseudomonal penicillin or an extended-spectrum antipseudomonal cephalosporin; ciprofloxacin plus an antipseudomonal penicillin; or a double β-lactam.[53] Alternatively, monotherapy with a broad-spectrum agent (e.g., a carbapenem or an extended-spectrum antipseudomonal cephalosporin) may be used[53] [*see 7:XIV Chemotherapy of Infection*]. The addition of vancomycin to the regimen should be considered in patients with a long-term vascular access device, in those with severe mucositis, and in patients at centers with high rates of methicillin-resistant *S. aureus* infection.[48,54] Randomized studies demonstrate that patients at low risk for infection may be treated effectively with oral antibiotics (ciprofloxacin plus amoxicillin–clavulanic acid).[55,56] Limited studies also suggest that carefully selected low-risk patients may be managed on an outpatient basis with oral or parenteral antibiotics.[41-43]

Secondary infection, antimicrobial resistance, or inadequate initial coverage commonly necessitates ongoing modification of the antimicrobial regimen.[57] To minimize toxicity, serum levels of the aminoglycosides and vancomycin should be monitored and the doses adjusted if necessary. Nephrotoxicity from aminoglycosides may be increased in the elderly and in patients who have been or are being treated with cisplatin or amphotericin B.

Neutropenic patients who have persistent fever despite receiving broad-spectrum antibiotics for 5 to 7 days or who experience recurrence of fever after an initial response to antibiotics should be considered for empirical antifungal therapy with liposomal or conventional amphotericin B.[57,58]

Indwelling catheters Patients with indwelling catheters who experience fever with or without neutropenia present special problems. Indwelling catheters are associated with infections of the exit site, the catheter tunnel, and the catheter lumen. A variety of organisms cause catheter-related infections, the most common of which is *S. epidermidis*. Catheter lumen–related or exit-site infections caused by *S. epidermidis* may be effectively treated by administering antibiotics through the catheter lumen without removing the catheter. In patients with fungal infections, however, the catheter should be removed. Infections of the subcutaneous catheter tunnel usually necessitate catheter removal regardless of the causative organism. Antibiotics should be rotated through each lumen of multilumen indwelling catheters to ensure eradication of all organisms.

Colony-stimulating factors Colony-stimulating factors are hematopoietic growth factors that stimulate the growth and maturation of committed bone marrow progenitor cells. Two of these colony-stimulating factors are currently available: G-CSF and GM-CSF. Treatment with G-CSF before neutropenia develops reduces the duration of the neutropenia and decreases the frequency of infectious episodes in patients who are receiving highly myelosuppressive cytotoxic chemotherapy. However, the high cost of G-CSF and GM-CSF precludes their prophylactic use except in patients who are receiving highly myelosuppressive therapy or in those who have a history of fever and neutropenia.[48] Prospective, randomized trials of both G-CSF and GM-CSF have demonstrated limited value in the treatment of fever and neutropenia. G-CSF and GM-CSF decrease the duration of neutropenia and hospitalization but not days with fever or mortality.[47,59-62]

FEVER AND ACTUAL OR FUNCTIONAL SPLENECTOMY

The spleen is an important organ in antibody production and in the destruction of nonopsonized or poorly opsonized bacteria. Patients who have undergone surgical splenectomy or who are functionally asplenic after splenic radiation therapy are at increased risk for infection with encapsulated bacteria, including *S. pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, group A streptococci, and *Capnocytophaga canimorsus*.[49] Such patients who become infected with these organisms may experience rapidly overwhelming sepsis. Therefore, asplenic or functionally asplenic patients should have in their possession antibiotics that are active against the encapsulated bacteria. Patients should start taking these antibiotics at the onset of any febrile illness and should promptly seek medical attention. The threshold for hospitalization should be low, and use of an antibiotic such as cefotaxime or ceftriaxone should be urgently initiated. Vancomycin should be considered if penicillin or cephalosporin resistance is locally common or is suspected.[63]

Metabolic Emergencies

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia of malignancy occurs in 10% to 20% of patients with cancer at some time during their illness and may range from a mildly increased calcium level in asymptomatic patients to a life-threatening emergency. Hypercalcemia is usually a manifestation of advanced disease and is observed in patients with hematologic malignancies, solid tumors without bone metastasis, and solid tumors with bone metastasis.[64]

Non–small cell lung cancer, breast cancer, head and neck cancer, renal cell cancer, myeloma, and T cell lymphoma are the tumors most commonly associated with hypercalcemia. Patients with breast cancer metastatic to bone may experience hypercalcemia during the initiation of treatment with estrogens, androgens, progestin, or antiestrogens.

Pathophysiology

Normal calcium homeostasis is a balance of intestinal absorption of calcium, bone resorption and formation, and renal excretion of calcium.[64] In healthy adults, bone resorption and formation are closely balanced, so that renal elimination of calcium is primarily determined by intestinal calcium absorption. Intestinal calcium absorption occurs both actively and passively. Active absorption of calcium is subject to saturation and is regulated primarily by 1,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$]. Other hormones, such as parathyroid hormone (PTH) and glucocorticoids, participate indirectly in regulation of the active intestinal absorption of calcium by modulating renal production of 1,25-$(OH)_2D_3$. Renal calcium reabsorption is increased by PTH.

Both trabecular bone and cortical bone undergo a dynamic process: bone resorption by osteoclasts, followed by bone formation mediated by osteoblasts. Bone resorption is stimulated by PTH and inhibited by calcitonin. Under normal conditions, the temporal and spatial balance of bone resorption and formation limits the ability of bone to participate in calcium regulation. The final pathway common to the mechanisms of hypercalcemia in malignancy is an uncoupling of the spatial and temporal balance of bone resorption and formation; as a result, bone resorption occurs more quickly than bone formation. Intestinal calcium absorption decreases, the extracellular volume contracts, and urinary excretion of calcium declines, producing hypercalcemia.

The uncoupling of bone resorption and formation is mediated by humoral factors released by tumors without bone metastasis and by paracrine factors released by metastatic deposits in bone. The humoral mediators that have direct effects on the uncoupling of bone include PTH-related protein (PTHrP), transforming growth factor–α (TGF-α), colony-stimulating factors, interleukin-1 (IL-1) and IL-6, tumor necrosis factor, and prostaglandins.[65,66]

PTHrP is a peptide that has homology to PTH at eight of 13 amino acids at the PTH receptor–binding domain. PTHrP is primarily associated with epithelium and is found in very high concentrations in milk. In humoral hypercalcemia of malignancy, PTHrP appears to activate the PTH receptor, which results in increased renal reabsorption of calcium and increased bone resorption. Unlike PTH, however, PTHrP does not stimulate new bone formation.[65-67]

A syndrome of increased levels of 1,25-$(OH)_2D_3$ may occur in patients with Hodgkin or non-Hodgkin lymphoma (especially patients with T cell lymphoma or leukemia who test positive for human T cell lymphotropic virus type I). In affected patients, elevations in the level of 1,25-$(OH)_2D_3$ result in increased intestinal absorption of calcium and increased bone resorption, leading to hypercalcemia.

Many patients with hypercalcemia of malignancy have widespread bone destruction secondary to metastatic lesions, a development that is especially common in patients with breast cancer and multiple myeloma. In these patients, local bone destruction appears to be the cause of the hypercalcemia. The metastatic cells either release directly or induce the surrounding normal cells to release paracrine factors such as TGF-α and prostaglandins, which uncouple bone resorption and bone formation by activating local osteoclasts.[65]

Hypercalcemia may arise in association with widespread osseous metastases, as occur with breast and prostate cancer; with the release of osteoclast-activating factor in such B cell malignancies as multiple myeloma and (less often) non-Hodgkin lymphoma; and with the release of a cytokine that interacts with the PTH receptor, as seen with any squamous cell carcinoma (e.g., cancer of the lung, cervix, anus, head and neck, and esophagus), renal cell carcinoma, or hepatocellular carcinoma. In patients with hepatocellular carcinoma, hypercalcemia may occur in the total absence of bony involvement; by contrast, in patients with breast or prostate cancer, hypercalcemia almost always occurs in the setting of bony involvement.

Diagnosis

Patients with hypercalcemia of malignancy have nonspecific symptoms. Early symptoms include polydipsia, polyuria, anorexia, fatigue, and constipation. Abdominal pain and bloating, nausea, and change in mental status are also seen. Late manifestations include coma and cardiac arrhythmia. Bone pain may or may not be present. Documentation of an elevated serum calcium level, either corrected serum calcium or ionized calcium, is required for diagnosis.

In the differential diagnosis of hypercalcemia of malignancy, the most common competing diagnosis is primary hyperparathyroidism. Primary hyperparathyroidism is associated with a slightly elevated serum calcium level (i.e., 11 to 12 mg/dl) and a decreased serum phosphate level (i.e., 2 to 3 mg/dl). In contrast, the hypercalcemia of malignancy is usually associated with a more dramatic increase in the serum calcium level (often to greater than 14 to 15 mg/dl) with a normal serum phosphate value. Immunoradiometric assays for intact PTH appear to distinguish between hypercalcemic patients with elevated PTH levels (hyperparathyroidism) and those with depressed PTH levels (hypercalcemia of malignancy).

Treatment

Hypercalcemia of malignancy is usually a manifestation of advanced cancer. In patients who have symptomatic hypercalcemia and for whom there are no effective anticancer treatment options, median survival is approximately 35 days; for patients with anticancer treatment options, median survival is less than 90 days.[68] For this reason, in patients for whom there are no anticancer treatment options, withholding active treatment of the hypercalcemia may be the most humane, compassionate, and appropriate course of action.[65] In the patient for whom effective anticancer therapy is available, treatment of the hypercalcemia is appropriate and includes volume and electrolyte repletion, inhibition of bone resorption, and treatment of the underlying malignancy.[69]

Extracellular volume deficits exist in all patients with symptomatic hypercalcemia of malignancy. The single most important and urgent therapeutic measure is the infusion of normal saline to correct the extracellular volume deficit, increase glomerular filtration rate (GFR), and, secondarily, increase renal calcium excretion. Hypokalemic metabolic alkalosis commonly is observed in patients with hypercalcemia of malignancy despite the coexisting decrease in GFR. Therefore, attention should also be directed to the correction of any coexisting potassium deficit, especially in patients who are taking digitalis preparations. Phosphate levels should be monitored, with oral phosphate

replacement as necessary. Care should be taken to maintain the calcium-phosphate product below 30 to 40.

Diuretics should not be used until the volume deficit has been fully corrected. Loop diuretics cause calciuresis and therefore may be effective in acutely decreasing calcium levels—but again, only after volume repletion. Thiazide diuretics decrease renal calcium excretion and should be specifically avoided.

The bisphosphonates offer an improved and simplified treatment of hypercalcemia of malignancy. The bisphosphonates have a high affinity for areas of high bone turnover, such as the areas of bony involvement with malignancy, where they block osteoclast attachment to bone matrix and osteoclast recruitment and differentiation.[65] Zoledronate (4 mg given in a 15-minute intravenous infusion) is the preferred bisphosphonate in the treatment of hypercalcemia of malignancy, with a complete response rate of 88% at day 10.[70] The toxic effects of the bisphosphonates include transient fever, local reactions at the infusion site, hypomagnesemia, hypophosphatemia, decreased renal function, and occasionally a flulike syndrome.

Other agents used in the second-line treatment of hypercalcemia of malignancy include the antineoplastic agent plicamycin, calcitonin, and glucocorticoids.

Immobilization leads to a rapid increase in bone resorption. Mobilization is therefore an important but frequently neglected component in the treatment of hypercalcemia of malignancy. Agents that increase calcium levels, such as thiazide diuretics, vitamin D, and lithium, should be discontinued. Except in the rare case of hypercalcemia of malignancy secondary to increased levels of $1,25\text{-}(OH)_2D_3$, intestinal absorption of calcium is depressed in patients with hypercalcemia of malignancy. Therefore, efforts to decrease intestinal absorption of calcium by dietary restriction are of limited therapeutic value.

Overall, a reasonable approach to the treatment of hypercalcemia of malignancy includes rapid saline rehydration, with correction of any coexisting electrolyte deficiency; inhibition of bone resorption with zoledronate; ambulation, if feasible; and active treatment of the underlying malignancy.

TUMOR LYSIS SYNDROME

Patients with a large tumor burden or rapidly proliferating tumors may experience a spontaneous or treatment-related tumor lysis syndrome that includes the rapid discharge of intracellular electrolytes and nucleic acids. The syndrome usually occurs within 6 to 72 hours after the initiation of therapy and is characterized by hyperkalemia, hyperuricemia, and hyperphosphatemia with secondary hypocalcemia. Tumor lysis syndrome is most often seen in patients with lymphoma or leukemia but also occurs in patients with a variety of solid tumors. A large tumor burden, a high growth fraction, an elevated pretreatment lactate dehydrogenase level, an elevated pretreatment uric acid level, or preexisting renal insufficiency increases the risk of tumor lysis syndrome. High levels of uric acid, xanthine, and phosphate may result in precipitation of these substances in the kidney. Renal sludging and acute renal insufficiency or failure further aggravates the metabolic abnormality.

The hyperkalemia associated with tumor lysis syndrome may be accentuated by associated renal insufficiency or renal failure and may cause electrocardiographic alterations and potentially fatal cardiac arrhythmia. The major manifestation of hyperphosphatemia is secondary hypocalcemia caused by precipitation of calcium phosphate in the soft tissues and the kidney. Hypocalcemia may lead to alterations in mental status, neuromuscular irritability, carpopedal spasm, and seizures.

Treatment

Anticipation and controlled management of tumor lysis are the keys to preventing the syndrome. Patients who are at risk should be hospitalized and fully hydrated, with ongoing diuresis before, during, and after treatment, and they should undergo frequent electrolyte monitoring. Diuresis minimizes the renal sludging caused by high urinary loads of uric acid, xanthine, and phosphate. Pretreatment with allopurinol blocks the conversion of hypoxanthine and xanthine to uric acid and minimizes the uric acid sludging in the kidney caused by xanthine crystals, but typically, it takes days to lower uric acid levels. Alkalinization of the urine with sodium bicarbonate infusion increases the solubility of urinary uric acid and decreases the risk of urate nephropathy but may increase risk of calcium phosphate precipitation. Recombinant urate oxidase (rasburicase) rapidly converts uric acid to allantoin, which is more soluble than uric acid and is readily cleared by the kidney.[71] Rasburicase rapidly lowers uric acid levels, and it has been approved by the Food and Drug Administration for the treatment of tumor lysis syndrome in children[71,72]; this agent appears to have similar activity in adults.[73,74] Thus, rasburicase should be considered an alternative to allopurinol in patients with very high uric acid levels or fulminant tumor lysis syndrome.

Patients at risk for tumor lysis syndrome should not receive supplemental potassium and should be monitored for development of hyperkalemia. Life-threatening hyperkalemia should be treated aggressively with diuresis, potassium-binding salts, and renal dialysis. Patients who have either symptomatic hypocalcemia or the electrocardiographic changes associated with hypocalcemia should be treated with an infusion of calcium gluconate. The hypocalcemia may persist beyond the period of observed hyperphosphatemia.

In its most severe form, tumor lysis syndrome may result in the rapid onset of profound and life-threatening fluid and electrolyte abnormalities and acute renal failure. The rapid lysis of tumor usually is iatrogenic and transient; therefore, aggressive supportive care is appropriate. Such care includes meticulous monitoring of fluid and electrolyte balances, cardiac monitoring, and hemodialysis as necessary.

Neurologic Emergencies

BRAIN METASTASIS

Intracranial metastasis occurs in 20% to 30% of patients with systemic cancer. The most common primary cancers that result in intracranial metastasis are lung cancer, breast cancer, GI cancer, genitourinary cancer, and melanoma. Most metastases are to the cortical-medullary junction, are associated with vasogenic edema, and occur with approximately equal frequency as a single metastasis or multiple metastases.

Diagnosis

Intracranial metastases compress the adjacent brain parenchyma and increase intracranial pressure. The increased intracranial pressure is associated with nonspecific symptoms, including headache that is frequently retro-orbital, nausea, and vomiting, all of which may be most severe in the morning. Cranial nerve abnormalities, including blurred vision, diplopia, and

visual-field defects, also are common. Finally, localized mass effects and edema may produce localized neurologic signs and symptoms, including motor and sensory abnormalities, dysphasia, ataxia, personality change, and seizures.

CT with contrast enhancement and magnetic resonance imaging with contrast enhancement are both relatively sensitive methods of diagnostic imaging in patients with suspected intracranial metastasis. Contrast-enhanced MRI is generally preferred, because it is more sensitive.

When multiple intraparenchymal metastases develop in a patient who has a known primary neoplasm, histologic diagnosis of the metastases usually is not warranted. However, intraparenchymal metastasis may be the presenting manifestation in some cases of neoplastic disease. In such cases, a focused evaluation for the primary tumor is appropriate, with special consideration of lung cancer, breast cancer, and melanoma. If the primary tumor is identified, it should be biopsied. Should no primary tumor be identified, biopsy of the intracranial disease is appropriate. Biopsy or excisional biopsy is particularly appropriate to help differentiate between a primary CNS tumor and a metastatic tumor in patients with no known primary malignancy who have a solitary intracranial lesion.

Treatment

Factors to consider when deciding on a treatment regimen for intracranial metastasis are the patient's age, whether the disease is controlled at other systemic sites, the patient's performance status, and the number of intraparenchymal metastases. The survival of patients with untreated intraparenchymal metastases is approximately 1 month.[75] Treatment usually provides substantial palliation and may prolong survival.

Glucocorticoids should be given to patients with newly diagnosed intraparenchymal metastases. In most patients, dexamethasone (4 to 16 mg/day in divided doses) lessens symptoms within hours to days.[76] Higher doses may improve the rates of response, but toxicity is also increased. The optimal duration of glucocorticoid administration is not known, but doses should be tapered gradually as therapy is completed.

Patients who have seizures should receive antiepileptic drugs. Erythema multiforme major (Stevens-Johnson syndrome) may occur in patients treated with phenytoin, cranial radiation therapy, and glucocorticoids.[77]

Randomized studies document the superiority of surgical resection followed by radiation therapy over the use of radiation therapy alone in the treatment of patients who have surgically resectable solitary intraparenchymal brain metastasis.[78,79] However, patients with uncontrolled systemic disease experience no benefit from the addition of initial surgery. Thus, patients who have a solitary brain metastasis and controlled systemic disease should undergo initial surgical resection when possible, followed by whole brain radiation therapy. Patients who have an unresectable solitary brain metastasis or uncontrolled systemic disease should undergo whole brain radiation therapy.

Whole brain radiation therapy provides substantial palliation and increased survival in patients who have multiple intraparenchymal metastases. A few studies have suggested that initial surgery provides some benefit in patients with multiple surgically resectable intraparenchymal metastases, but other studies have found no advantage.

Techniques now exist for the delivery of high doses of stereotactically directed ionizing radiation to defined tumor volumes with relative sparing of surrounding normal tissue.[80] These techniques have been used successfully to treat solitary and multiple brain metastases with or without whole brain radiation therapy.[81-85] In the primary treatment of intraparenchymal metastasis, the benefit of whole brain radiation therapy after stereotactically directed radiation therapy is still being defined.[81-85]

EPIDURAL SPINAL CORD COMPRESSION

Epidural compression of the spinal cord or cauda equina occurs in 5% to 10% of patients with malignancy. Patients with breast cancer, lung cancer, prostate cancer, lymphoma, renal carcinoma, or sarcoma are at particular risk. The site of epidural compression is thoracic in 70% of patients, lumbar in 20%, and cervical in 10%. More than 30% of patients experience multiple levels of epidural compression.

Pathophysiology

The epidural space lies between the dura mater of the spinal cord and the bony spinal canal. Mass lesions in the epidural space may cause injury to the spinal cord or cauda equina by direct mechanical distortion or by vascular compromise with edema and ischemia or infarction.

About 80% of epidural masses occur as the result of extension of metastasis from the bony spine, especially from the vertebral bodies. Involvement of the epidural space also may occur by extension through the intervertebral foramina by paravertebral adenopathy, particularly in lymphomas; or through the Batson venous plexus in patients with increased intra-abdominal pressure [*see Figure 3*].

Diagnosis

Because the prognosis for recovery of neurologic deficits from spinal cord compression is related to the duration and the severity of the deficits at the start of treatment, early diagnosis is crucial. More than 95% of patients with epidural compression caused by malignancy have pain, either local or radicular, both as the first symptom and at the time of diagnosis [*see Table 1*]. The pain is usually constant and progressive and increases with the Valsalva maneuver or straight leg raising. Unlike the pain of spinal disk disease, the pain of epidural compression typically is worsened by recumbency. Local vertebral tenderness to percussion often is present. Sensory loss in a distribution distal to the site of epidural compression is common and may be rapidly progressive, but this symptom is of limited value in localizing the level of compression. Hyperreflexia and Babinski reflexes may be seen with spinal cord compression above T10, whereas lesions below T10 that compress the conus or cauda equina produce hyporeflexia.

Weakness, usually bilateral and symmetrical, is present in more than 75% of patients at the time of diagnosis and may be rapidly progressive. Autonomic dysfunction of the bladder or bowels is a late sign of epidural compression. The duration, severity, and rapidity of onset of neurologic dysfunction before the initiation of treatment are strong predictors of whether neurologic function can be maintained or restored.[86-91]

Radiographs of the spine and radionuclide bone scans are usually abnormal in patients with epidural compression but are neither sensitive enough nor specific enough for definitive diagnosis or localization.[80] The current recommendation for the radiographic evaluation of patients with possible epidural compression is gadolinium-enhanced MRI of the entire spinal axis. Although myelography is sensitive and specific for detecting epidural compression, it is invasive; it may be uncomfortable for

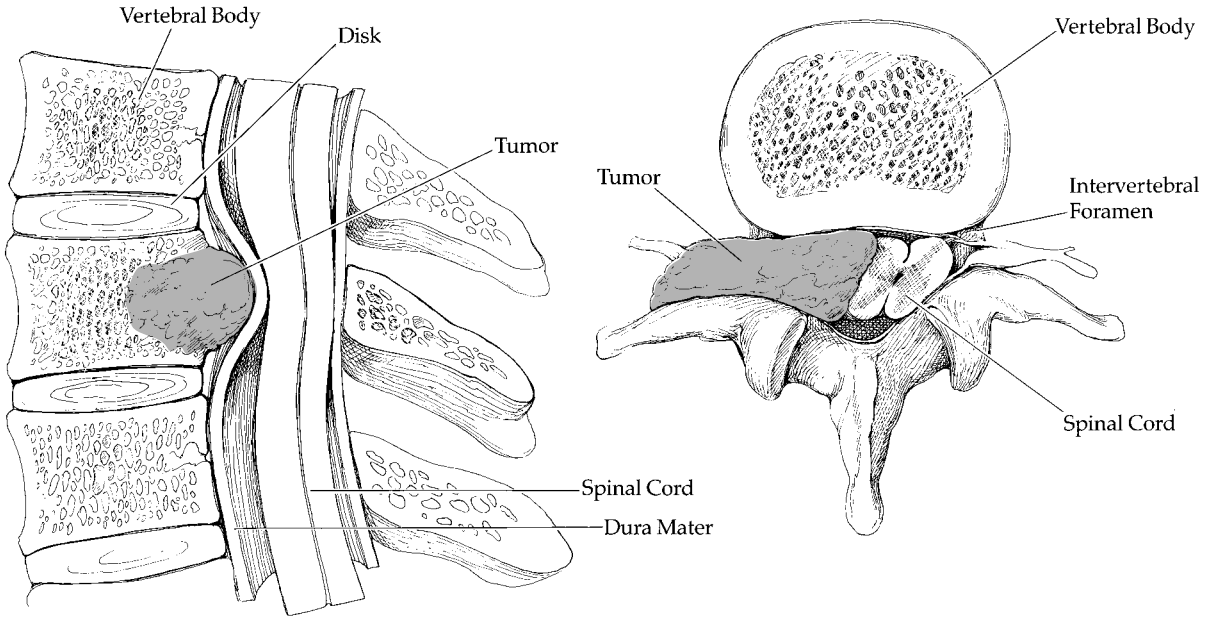

Figure 3 **Spinal cord compression as a complication of neoplastic disease can be caused by extension of a metastatic lesion located in a vertebral body (left, medial section) or by extension of a tumor through an intervertebral foramen (right, transverse section).**

the patient with severe bone pain; and radiologists experienced in its interpretation may not be available. MRI of the spine, especially with gadolinium enhancement, is highly sensitive, noninvasive, and more sensitive than myelography in detecting intramedullary metastasis. MRI of the spine should encompass the entire spinal axis and thus may be time consuming and resource intensive. CT of the spine should not be performed, because its ability to scan the entire spinal axis efficiently and its sensitivity in identifying epidural disease are inferior to those of gadolinium-enhanced MRI.

Treatment

Treatment of epidural cord compression should be initiated immediately, especially in patients with recent onset of neurologic dysfunction or whose neurologic dysfunction is progressive. Ideally, cancer patients with back pain should be evaluated and treated before neurologic dysfunction develops. Nonmalignant spinal disorders (e.g., osteomyelitis, tuberculosis) must be excluded.

The typical patient who has a known malignancy and epidural cord compression should receive immediate treatment with dexamethasone and local radiation therapy. An initial surgical approach is considered in patients who do not have a histologic diagnosis of malignancy, in patients who have an unstable bony spine, in patients whose symptoms progress during radiation therapy, or in patients whose symptoms progress after a maximally tolerated dose of radiation to the spinal cord. Dexamethasone provides pain relief for many patients and may decrease edema that is localized to the area of compression. One evidence-based guideline recommends 24 mg of dexamethasone every 6 hours.[92] Regardless of the dexamethasone dosage, it should be tapered to minimize toxicity.

Patients with known metastatic cancer sensitive to radiation and with documented spinal cord compression should undergo immediate radiation therapy to the level of epidural compression and to a margin of normal tissue above and below it, or they should have immediate anterior surgical resection of the area of metastatic tumor causing the cord compression followed by radiation therapy.[89,92,93] In a randomized clinical trial of immediate surgical resection followed by radiation therapy versus immediate radiation therapy without surgery in 101 patients with spinal cord compression,[93] patients treated with initial surgical resection had superior preservation of the ability to walk (126 days versus 35 days; $P = 0.006$) and of continence, but there was no difference in overall survival (129 days versus 100 days; $P = 0.08$). Spinal cord tolerance to radiation is related both to the fraction size and to the cumulative dose, and multiple dose and fractionation schedules have been used.[94,95] The frequent occurrence of multiple synchronous or metachronous levels of epidural compression necessitates careful planning to minimize the need for serial treatment of adjoining areas of the spine. With

Table 1 Signs and Symptoms Associated with Epidural Spinal Cord Compression[104]

Sign or Symptom	*First Symptom (%)*	*Symptoms at Diagnosis (%)*
Pain	96	96
Weakness	2	76
Autonomic dysfunction	0	57
Sensory loss	0	51
Ataxia	2	3
Herpes zoster	0	2
Flexor spasms	0	1

serial treatment, it is particularly difficult to match adjoining radiation therapy fields to avoid overlapping the fields.

A surgical approach to epidural compression may provide pain relief, halt the progression of the neurologic deficits, allow for stabilization of the spine, and provide a histologic diagnosis of malignancy in patients without a known primary tumor.[92,96] However, most patients with epidural compression have widespread disease and are at increased operative risk. Because the rate of local recurrence after surgery alone is high, local radiation therapy is still warranted. Aggressive surgery for epidural cord compression may produce encouraging results, especially when the spine is unstable, pathologic compression fracture has caused impingement of the cord by bone fragments, or the tumor is resistant to radiation therapy. However, most studies of surgery plus radiation therapy versus radiation therapy alone have not demonstrated meaningful differences in the return of neurologic function and survival.

INTRAMEDULLARY METASTASIS

Intramedullary spinal metastasis is unusual and occurs primarily in patients with lung cancer, breast cancer, colon cancer, or lymphoma. Presenting manifestations are similar to those of epidural spinal cord compression except that the associated motor weakness is commonly unilateral. Intramedullary metastasis must be distinguished from epidural cord compression, leptomeningeal metastasis, radiation myelopathy, primary intramedullary tumors, and necrotizing myelopathy. Myelography may reveal a fusiform swelling of the spinal cord, but myelographic results are frequently normal. High-resolution CT or MRI with gadolinium enhancement is superior to myelography in identifying intramedullary metastasis. Treatment is similar to that of epidural spinal cord compression.

LEPTOMENINGEAL METASTASIS

Leptomeningeal metastasis is uncommon. It is observed chiefly in patients with lung cancer, breast cancer, melanoma, or lymphoma.

Diagnosis

The signs and symptoms of leptomeningeal metastasis may be referable to the brain, cranial nerves, or spine.[97-99] In patients with malignancy, the presence of signs or symptoms that are referable to more than one location within the craniospinal axis always raises the possibility of leptomeningeal metastasis.[97-99] Headache, changes in mental status, ataxia, nausea, vomiting, diplopia, facial weakness, lower extremity weakness, paresthesia, reflex asymmetry, and spinal pain are particularly common. Results of cerebrospinal fluid examination are almost always abnormal, with elevated protein levels and positive cytology being the most common abnormalities. However, excluding leptomeningeal metastasis generally requires three lumbar punctures. Pleocytosis in the CSF may be seen as a manifestation of leptomeningeal involvement in patients with leukemia or lymphoma. Results of contrast-enhanced CT or gadolinium-enhanced MRI may be abnormal, but false negative results are common.[99]

Treatment

Systemic administration of chemotherapy usually results in very low levels of drug in the CSF. However, therapeutic levels of methotrexate, cytarabine, and thiotepa may be safely achieved in the CSF by lumbar puncture or by intraventricular instillation and provide substantial palliation.[99,100] The use of subcutaneous reservoirs attached to a catheter that is inserted into the lateral ventricle (Ommaya reservoir) is a safe and convenient method of delivering intrathecal chemotherapy and provides a uniform distribution of drug throughout the CSF in many patients.[101] A sustained-release formulation of cytarabine is commercially available. In one study comparing sustained-release cytarabine with methotrexate for intrathecal treatment of neoplastic meningitis, onset of neurologic progression was slower with cytarabine (given once every 14 days) than with methotrexate.[102] Radiation therapy may be administered to patients with leptomeningeal metastasis who have particularly severe symptoms, bulky disease, sites of involvement threatening neurologic function, or disease refractory to intrathecal chemotherapy.

The response to therapy for leptomeningeal metastasis is strongly dependent on the underlying tumor type, previous therapy, the extent of disease, and the presence or absence of blockage of CSF flow. Patients who have leptomeningeal involvement from leukemia, lymphoma, or breast cancer may experience substantial palliation and increased survival after prompt and aggressive therapy.[100]

As is the case with the other CNS emergencies, the extent of neurologic dysfunction when therapy is initiated predicts the degree of neurologic function that will be achieved after therapy. In general, however, patients with leptomeningeal metastasis have a poor prognosis.

XIII SARCOMAS OF SOFT TISSUE AND BONE

Haralambos Raftopoulos, m.d.
Karen H. Antman, m.d.

Sarcoma, which was distinguished from carcinoma (crablike tumors) during Hippocrates' era, is derived from the Greek root *sarc*, for "flesh." Most sarcomas develop in tissues of mesodermal embryologic origin and are thus related embryologically to leukemias and lymphomas. Neurosarcomas, peripheral neuroectodermal tumors, and probably Ewing sarcomas, however, arise from tissues of ectodermal embryologic origin.

Overview of Sarcomas

CLASSIFICATION

Sarcomas originating in bone are distinguished from those that occur in soft tissue. Soft tissue sarcomas, which can present in muscles, fat, tendons, synovial tissue, vessels, and nerves, are further subdivided into the classic soft tissue sarcomas of the trunk and extremities and into visceral sarcomas of the gastrointestinal tract[1] and gynecologic tract.[2] Miscellaneous sarcomas include Kaposi sarcoma (KS)[3] and mesotheliomas.

EPIDEMIOLOGY

Bone and soft tissue sarcomas currently represent 1% of adult malignancies and 15% of pediatric malignancies. In 2003, an estimated 10,700 persons in the United States will have developed sarcoma, and 5,200 will have died of the disease.[4]

The predominant histology of sarcoma varies with age [*see Table 1*]. Several histopathologic variants of sarcoma occur predominantly in persons older than 50 years (e.g., liposarcoma, malignant fibrous histiocytoma, and leiomyosarcoma). Embryonal rhabdomyosarcoma develops most frequently in small children (usually in the orbit) and in adolescents (often in the urinary tract).[5] Ewing sarcoma and synovial sarcoma typically develop in individuals between 15 and 30 years of age. Osteosarcoma has a biphasic pattern of incidence, most commonly presenting in adolescents and persons older than 50 years.[6,7] Chondrosarcoma occurs most frequently in persons in the sixth and seventh decades of life.

Whether males or females are primarily affected is dependent upon the histologic variant of the disease [*see Table 1*]. For example, 70% of patients with KS are men, as are 58% to 62% of patients with liposarcoma and embryonal rhabdomyosarcomas; however, 65% of leiomyosarcomas occur in women. Although the incidence of osteosarcoma by age in whites and that in nonwhites are virtually identical, Ewing sarcoma is predominantly a disease of whites.[6,8,9]

GENETIC FACTORS

Familial Sarcoma

Although sarcomas in the general population are rare, certain families have multiple members who are affected. In these families, the risk for sarcoma is increased. Germline *p53* mutations have been implicated in families in which childhood sarcomas, breast cancer, and other tumors (e.g., Li-Fraumeni syndrome) have occurred [*see Table 2*].[10-12]

Patients with neurofibromatosis have a 7% to 10% lifetime risk of developing a malignant sarcoma, most commonly a neurosarcoma or fibrosarcoma.[13,14] About half of all neurofibrosarcomas occur in patients with neurofibromatosis.

About 7% of children with familial retinoblastoma develop osteosarcoma,[15,16] both in radiation ports used for treatment of the initial retinoblastoma and in long bones that clearly are unaffected by the radiotherapy ports, thus suggesting a hereditary susceptibility to osteosarcoma. Sporadic osteosarcomas often carry a 13q chromosomal deletion associated with the lack of a retinoblastoma tumor suppressor gene (*RB*).

Persons with familial or sporadic osteochondromas or fibrous dysplasia of bone may develop osteosarcoma or chondrosarcoma in the preexisting lesion.[17,18]

Translocations Diagnostic of Sarcoma

Translocations involving chromosome 22 characterize both Ewing sarcoma and peripheral neuroectodermal tumors (PNETs). The most common translocation is between chromosome 11 and chromosome 22.[19] Variant translocations affecting t(21;22) and t(7;22) are also characteristic of Ewing sarcoma or PNET.[20]

Other sarcomas that have characteristic cytogenetic abnormalities include synovial sarcomas [t(X;18)],[21] alveolar rhabdomyosarcomas [t(2;13) and t(1;13)], and myxoid liposarcomas [t(12;16)].[22]

ETIOLOGY

Radiotherapy, chemotherapy, and exposure to certain chemicals have been identified as risk factors for the development of sarcoma. About 5% of sarcomas are associated with prior radiotherapy, generally delivered 4 to 20 years before the diagnosis of sarcoma.[23-25] Most radiation-associated sarcomas are osteosarcomas, but mixed mesodermal sarcomas of the uterus, mesotheliomas, angiosarcomas, and other soft tissue sarcomas have been reported. The risk of development of a secondary sarcoma after radiation exposure is substantially less than 1%, except for patients receiving radiation therapy for retinoblastoma or Ewing sarcoma and for radium-dial painters.[25] In a review of the Swedish Cancer Registry, Karlsson and colleagues determined an odds ratio of 2.4 for development of soft tissue sarcoma after breast cancer irradiation.[26] The incidence of angiosarcoma was strongly related to the presence of lymphedema (odds ratio, 9.5). It has been shown that sarcomas arising in radiation ports may be more resistant to chemotherapy. Alkylating agents (particularly melphalan, procarbazine, nitrosoureas, and chlorambucil) given for prior childhood malignancies are causally associated with development of sarcoma.[27]

Environmental or occupational exposures to certain chemicals have been established as risk factors for sarcoma. Asbestos clearly causes mesothelioma.[28] Polyvinyl chloride (plastic industries),[29] androgens, arsenic,[30] and iron overload (hemochromatosis) are associated with angiosarcoma of the liver. Exposure to dioxin (Agent Orange), chlorophenols, or agricultural herbicide has been linked to the development of soft tissue sarcomas in some studies.[31]

Immunosuppressed patients (e.g., renal transplantation patients and patients with AIDS, chronic lymphocytic leukemia,[32]

Table 1 Summary of Sarcomas

	Histologic Variant	Tissue of Origin	Common Age Distribution	Sex Distribution (male:female)	Comments
Soft Tissue Sarcomas	Liposarcoma	Fat	Fifth to seventh decades	3:2	Lesions may be multicentric; rarely arise from lipomas
	Fibrosarcoma	Fibrous tissue			
	Synovial sarcoma	Intramuscular tissue	Second to fourth decades	5:4	Lesions arise adjacent to joints; can be calcified; locally invasive; requires wide surgical margins
	Neurosarcoma and malignant schwannoma	Nerve sheaths	Unknown	Unknown	50% are associated with von Recklinghausen neurofibromatosis (NF1)
	Malignant fibrous histiocytoma (MFH)	Controversial	Fifth to seventh decades	2:1	Incidence decreasing; improved immunohistologic stains able to identify specific tissue markers in poorly differentiated tumors previously classified as MFH
	Peripheral neural ectodermal tumors (PNET)	Neural ectoderm	Unknown	Unknown	Similar to Ewing sarcoma in cytogenetics and treatment
	Leiomyosarcoma	Smooth muscle	Fifth and sixth decades	3:6	Lesions arise in uterus, large blood vessels, GI tract, and other smooth muscle; associated with Epstein-Barr virus
	Rhabdomyosarcoma	Striated muscle	First and second decades	6:4	Chemotherapy is established treatment; in children 4 yr of age or younger, it commonly presents in the orbit; in the early teens, it presents in the genitourinary and gynecologic tracts; in older adolescents, it presents most commonly in the extremities
	Angiosarcoma	Endothelium	Elderly men, young women		Most common primary cardiac malignancy; develops in edematous extremities (Stewart-Treves syndrome); in young women, it presents in the breast; in elderly men, in the scalp; associated with arsenic (insecticides) and vinyl chloride (plastics)
	Hemangioendothelioma	Endothelium	Fifth decade	5:5	Less aggressive than angiosarcoma
	Hemangiopericytoma	Vascular pericytes	Fifth decade		Lesions arise commonly in trunk and extremities but also intracranially
	Kaposi sarcoma (KS)	Endothelium	Differs with variant	7:3	Four variants: classic KS commonly affects elderly men of Mediterranean origin; lymphadenopathic KS affects children in endemic areas of Africa; KS occurring in transplant patients affects patients of various ages; KS occurring in AIDS patients most commonly affects men who have sex with men and affects patients of various ages; KS is associated with human herpesvirus type 8 (HHV-8)
	Mesothelioma	Mesothelium	Sixth and seventh decades	5:1	Associated with asbestos exposure
	Gastrointestinal stromal tumors	Interstitial cells of Cajal	Fourth to seventh decades		Responds to imatinib
Sarcomas of Bone	Osteosarcoma	Bone	Second and third decades; also > 50 yr	~2:1	Surgery and adjunct chemotherapy are established treatments; can be radiation associated; resistant to radiation therapy
	Ewing sarcoma	Bone	Second decade		Chemotherapy, radiation, and possibly surgery are established treatments; rare in nonwhites
	Chondrosarcoma	Cartilage	Sixth and seventh decades		Resistant to radiation and chemotherapy except for mesenchymal chondrosarcomas

or autoimmune hemolytic anemia) have a higher than normal risk of developing soft tissue sarcomas, particularly KS. A viral etiology of sarcoma is well documented in other species (murine, simian, and avian sarcoma viruses), and an infectious agent most likely plays a role in the etiology of two types of sarcoma in humans. In immunosuppressed patients, KS and leiomyosarcoma are associated with human herpesvirus type 8 (HHV-8)[33] and Epstein-Barr virus, respectively.[34,35]

Patients with Paget disease of bone have a 0.2% risk of developing osteosarcoma, particularly in families with Paget disease.[7,8,36] Fibrosarcomas have occasionally developed in scars of burns or major trauma, often after 30 years or more.

Sarcomas of Soft Tissue

Soft tissue sarcomas currently represent 1% of adult malignancies and 15% of pediatric malignancies.[4] Until recently, malignant fibrous histiocytoma (MFH) and leiomyosarcoma (LMS) were the most common diagnoses; however, the incidence of MFH and the incidence of LMS are declining as more specialized diagnostic methods (e.g., immunocytochemistry and virtually diagnostic translocations) lead to reclassification of these tumors into other subsets.[37] Most sarcomas of the GI tract previously thought to be LMS are now diagnosed as gastrointestinal stromal tumors (GISTs).

DIAGNOSIS

Clinical Manifestations

Patients with soft tissue sarcomas usually present with a painless, palpable mass on the extremities or the trunk. Forty percent of soft tissue sarcomas develop in the lower extremity, about 30% in the trunk and retroperitoneum, 15% in the upper extremities, and 15% in the head and neck. Intra-abdominal and retroperitoneal primary lesions may cause pain and weight loss from invasion or displacement of organs. The duration of symptoms before diagnosis ranges from a few weeks to decades, with a median of 1 to 3 months.

Preoperative Evaluation

Preoperative evaluation generally requires computed tomographic studies of the lungs and either a CT scan or magnetic resonance imaging of the primary lesion to establish extent of tumor involvement. Uptake in adjacent bone as evidenced on bone scan may suggest invasion or merely periosteal reaction to the tumor. An incisional biopsy for definitive diagnosis facilitates optimal management of the tumor and should be performed by the surgeon who will undertake the definitive surgical resection. The surgeon is supported by a sarcoma team that usually includes surgical, radiation, orthopedic, and medical oncologists, as well as a pathologist. The sarcoma team's involvement in the planning of the incisional biopsy reduces the risk of an improperly placed biopsy compromising the surgical resection or subsequent radiation.

GRADING AND STAGING

The American Joint Committee staging system for soft tissue sarcomas [*see Table 3*] is largely dependent on tumor size (< 5 cm or > 5 cm) and grade (low, intermediate, or highly aggressive). Stages I through III are based largely on grade, which is determined by the number of mitoses per 10 high-power fields, tumor size, and tumor depth [*see Table 3*].[38-40] The 5-year survival rates for soft tissue sarcomas arising in different anatomic sites are similar when corrected for grade, size, and depth, except for intra-abdominal and retroperitoneal tumors, which tend to be large and to invade vital organs, even if they are low grade.[41] Patients with low-grade, superficial tumors tend to have a good prognosis if the tumors are adequately resected. Even high-grade tumors are associated with a good prognosis if they are less than 5 cm in diameter.

Table 2 Familial Syndromes Associated with Increased Risk of Sarcoma

- Neurofibromatosis type 1 and type 2
- Hereditary retinoblastoma
- Li-Fraumeni syndrome
- Familial Paget disease of bone
- Multiple hereditary exostosis

Table 3 Staging of Soft Tissue Sarcomas*

Stage	*Characteristics*
Stage I	The tumor is low grade, < 5 cm in greatest diameter, and has not spread to lymph nodes or to other organs
Stage II	The tumor is high grade, < 5 cm and superficial, and has not spread to lymph nodes or to other organs
Stage III	The tumor is high grade, > 5 cm and deep, but has not spread to lymph nodes or to other organs
Stage IV	A tumor of any size or grade has spread to lymph nodes or other organs

*Staging system excludes Kaposi sarcoma, dermatofibrosarcoma, desmoid type of grade 1 fibrosarcoma, and sarcomas that begin in the dura mater (e.g., brain), parenchymatous organs, and hollow viscera.

PATHOPHYSIOLOGIC FINDINGS AND IMPLICATIONS FOR MANAGEMENT

The behavior and treatment of most of the histologic variants of soft tissue sarcoma are generally similar grade for grade. Exceptions include osteosarcomas, rhabdomyosarcomas, and Ewing sarcoma, which are treated routinely with multimodality therapy, including chemotherapy, and must be distinguished from other sarcomas. The treatment of mesothelioma and KS also differs from that of the classic sarcomas. Irrespective of the histologic variant of the tumor, the goals of treatment for all histologic variants are the same: (1) local and systemic control of the sarcoma; (2) preservation of the extremity or the vital organ, along with its function, when possible; and (3) maintenance of quality of life. Local control of a soft tissue sarcoma is generally achieved by surgical resection, which is often combined with radiotherapy [*see* Treatment of Soft Tissue Sarcomas, *below*].

Low-grade tumors push aside contiguous structures, whereas high-grade tumors invade adjacent organs and have large areas of necrosis. Soft tissue sarcomas grow along histologic planes and are usually pseudoencapsulated (i.e., microscopic projections of tumor extend beyond the apparent tumor capsule). Any excision that merely "shells out" the apparently encapsulated tumor generally leaves behind microscopic residual tumor and results in local regrowth in about 80% of cases.[40] Wide excision of 3 to 6 cm of normal tissue is thus required for local control if radiation is not planned. Pathologically documented uninvolved margins of 1 mm are acceptable to save a limb or vital organ if adequate doses of radiation can be given. Obtaining local control of intra-abdominal lesions, however, is complicated by the lesion's proximity to vital organs that cannot tolerate the high doses of radiation necessary for control of sarcoma.

HISTOLOGIC VARIANTS

Liposarcoma

Liposarcomas range from low-grade, well-differentiated myxoid lesions to high-grade, round-cell, and pleomorphic lesions. Most liposarcomas develop in the thigh or retroperitoneum, but they may be multicentric, particularly in the abdomen and the retroperitoneum. They rarely, if ever, arise from

benign lipomas. Up to 60% develop in men; patients are generally older than 50 years [*see Table 1*].[42,43]

Fibrosarcoma

Fibrosarcomas, which originate in intermuscular fibrous tissue, fascia tendons, and aponeuroses, range from borderline locally invasive fibromatosis and Dupuytren contracture to highly malignant sarcomas.

Synovial Sarcoma

Characteristically, synovial sarcoma presents as a mass adjacent to a joint and involving the joint's capsule, bursae, and tendon sheath but not the joint itself. The mass may be present for months to years before the diagnosis is made. On radiograph, one third of these lesions may contain fine stippled calcifications or even radiopaque tumor. Histologically, synovial sarcomas are monophasic (epithelial and spindle cell) or biphasic. Wide excision of synovial sarcomas is particularly important but difficult to achieve because of their proximity to large joints.

Synovial sarcoma develops predominantly in adolescents and young adults (median age, 27 years) and somewhat more frequently in men.[21,44-46] Ninety percent of synovial sarcomas contain a characteristic chromosomal translocation involving a nuclear transcription factor on chromosome 18 called SYT. Patients with the t(X;18) SYT-SSX2 translocation may have significantly better metastasis-free survival than patients with the t(X;18) SYT-SSX1 translocation.[21]

Neurosarcomas and Malignant Schwannomas

Neurosarcomas and malignant schwannomas, which constitute 5% of soft tissue sarcomas, arise from tissues of ectodermal embryologic origin. About half of these lesions develop in patients with von Recklinghausen neurofibromatosis, and biopsy should be performed promptly on any mass that suddenly enlarges or causes pain in these patients. Neurosarcomas tend to produce a large fusiform mass extending for some distance within the nerve sheath in the proximal extremity or trunk. Large surgical and radiotherapy margins are required to ensure local control.[13,14]

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) was previously the most common soft tissue sarcoma in patients older than 50 years [*see Table 1*],[3] but its incidence has fallen as better immunohistologic stains identify poorly differentiated fibrosarcomas and liposarcomas.[37,47] Twice as many men as women are affected by this disease. Lesions deep in muscle and in the abdomen often recur locally and metastasize, but histologically identical lesions in skin are associated with an excellent prognosis.[46,48] A rare inflammatory MFH variant may be accompanied by fever, a high sedimentation rate, and a neutrophilia or eosinophilia that results from a tumor-produced growth factor.[46] Inflammatory symptoms typically resolve if the tumor is resected. A myxoid variant grows more slowly than the typical MFH lesion but tends to recur locally, thus justifying wide local excision and radiotherapy or even amputation.[46-48]

Leiomyosarcoma

Leiomyosarcomas, which arise in smooth muscle, can develop in the extremities, the trunk, and the abdomen [*see Table 1*]. Leiomyosarcoma is the most common uterine sarcoma and until recently was considered the most common soft tissue sarcoma of the gastrointestinal tract; however, immunohistochemical stains suggest that most GI sarcomas are GISTs [*see* Gastrointestinal Stromal Tumors, *below*].

Patients with uterine leiomyosarcomas present with bleeding or pain.[49,50] Because fibroid tumors are common, sarcoma is often not suspected until the diagnosis is established by pathology. If the uterus is particularly large and a CT scan is obtained for better visualization, a tumor with large areas of necrosis may raise suspicion of sarcoma. Whether leiomyosarcomas of the uterus arise within existing fibroid tumors or develop de novo remains controversial, but most experts believe that no more than a small fraction of 1% of fibroids become malignant.

Leiomyosarcomas of the retroperitoneum and the vena cava occur most commonly in women and may grow rapidly during pregnancy. Tumors originating in other large veins affect women and men equally.[47,51,52]

Rhabdomyosarcomas

Embryonal rhabdomyosarcomas originate in striated muscle and occur most commonly in the orbit in small children and in the genitourinary tract in adolescents [*see Table 1*]. Alveolar rhabdomyosarcomas arise most commonly in the extremities of adolescents and young adults and carry a more serious prognosis.[5,53-55] Pleomorphic rhabdomyosarcomas are occasionally diagnosed, generally in older patients.

Angiosarcomas

Angiosarcomas include tumors previously called hemangiosarcoma, lymphangiosarcoma, and hemangioblastoma. Immunoperoxidase stains from these tumors suggest the same cell of origin.

Angiosarcomas, like other vascular lesions (e.g., benign angiomas), may produce microangiopathic hemolytic anemia (Kasabach-Merritt syndrome), presumably as a result of traumatic injury of red blood cells traversing the tumor bed.[56,57] Angiosarcomas most commonly present as multicentric scalp lesions in older men[58] and as lesions of edematous extremities, typically after mastectomy and lymph node dissection for breast cancer in women.[59] The remainder of the angiosarcomas develop in soft tissue and in the breast, liver, heart, and lungs.[30,57,60-64] Angiosarcomas of the breast occur in young and middle-aged women. Angiosarcomas of the liver arise in adults previously exposed to thorium dioxide (for angiography), arsenic (insecticides), and vinyl chloride (plastics). Angiosarcomas have also arisen in sites previously exposed to radiotherapy (e.g., for treatment of breast cancer, Hodgkin disease, and cervical cancer) and are the most common primary malignant tumors of the myocardium.

Angiosarcomas of the skin resemble bruises and may appear as a single lesion or in clusters. Angiosarcomas in deeper locations have the consistency of a sponge rather than being a distinct mass, and tumors infiltrate substantially beyond their apparent extent. Even well-differentiated angiosarcomas can be difficult to control locally because of their characteristic multifocality and extensive invasion. The prognosis is poor.

Hemangioendothelioma Hemangioendotheliomas are rare vascular tumors of intermediate malignancy (between benign hemangiomas and conventional angiosarcomas) that affect men and women about equally and rarely develop in childhood. A spindle cell variant occurs in younger, predominantly male, patients and principally involves the skin of the hand; it tends to be locally and regionally recurrent.[3]

Hemangiopericytoma Hemangiopericytoma is a malignancy of vascular pericytes (normally found adjacent to the blood vessel endothelium, which is the cell of origin for angiosarcomas and hemangioendotheliomas). Generally diagnosed in patients in their fifth decade of life,[65] 35% of lesions are found in the thigh and 25% in the retroperitoneum; the remaining 40% occur throughout the body. Large tumors can produce arterial venous shunting, bleeding, and even hypoglycemia. Intracranial hemangiopericytomas, formerly designated as angioblastic meningiomas, grow along the sinuses, recur locally, and may metastasize.[3]

Kaposi Sarcoma

Although Kaposi sarcoma is a vascular lesion, its distinct etiology and sensitivity both to radiation and to a wide variety of chemotherapeutic agents distinguish it from other soft tissue sarcomas. Four variants of KS have been identified: classic, transplant associated, lymphadenopathic, and AIDS-KS.

Classification The classic variant presents as multiple blue-red flat skin lesions that indolently progress to nodules and plaques on the lower legs. This variant presents most commonly in elderly men, particularly those of Mediterranean origin. A second variant occurs in patients who receive organ transplants. KS develops an average of 16 months after transplantation. Transplant-associated KS develops most commonly in men, particularly if either the recipient or the organ donor is of Mediterranean extraction. A third aggressive variant is a lymphadenopathic KS that occurs in young children and is endemic to some areas of Africa.

The fourth variant is an aggressive epidemic KS that occurs in AIDS patients. This variant is 20 times more common in men who acquire HIV by sexual contact with men than in those who acquire it by parenteral means.The percentage of AIDS patients with KS ranges from 1% in men with hemophilia to 21% in men who have sex with men.[66] The incidence of KS in men with AIDS in the United States decreased from 40% in 1981 to less than 20% in 1992,[3,67,68] and it is expected to continue to decline with more effective antiretroviral combination therapy.[67]

In 1993, Chang and colleagues identified in an AIDS-KS skin lesion DNA fragments of a previously unrecognized herpesvirus that has alternatively been called Kaposi sarcoma–associated herpesvirus (KSHV) and human herpesvirus type 8 (HHV-8).[33] Over 95% of KS lesions, regardless of source or clinical subtype, have been found to be KSHV-associated. Immunosuppression of the host appears to be an important cofactor in the clinical expression of KS.[3]

KSHV, together with Epstein-Barr virus (EBV), belongs to the gamma herpesviruses.[3] Gamma herpesviruses cause tumors, particularly lymphoproliferative disorders and lymphomas, in humans and animals [*see Table 4*]. KSHV infection rates parallel the global incidence of KS, with low rates in the United States, Europe, and Asia; intermediate rates in Mediterranean countries; and high rates (> 50%) in some locations in Central Africa (e.g., Uganda, Zambia, and South Africa).[69]

Independent of their HIV serostatus, men who have sex with men have a higher rate of KS than the general male population and can have antibodies associated with KS in rates approaching 40%.[70,71]

Diagnosis Clinical manifestations of KS may differ with the variants of the disease. In classic KS, faint reddish-purple macules or patches appear on the feet. HIV-associated KS presents most commonly as cutaneous lesions but also may appear in the oral mucosa or lymph nodes. In contrast to classic KS lesions, HIV-associated KS lesions often begin on the upper body (i.e., face, trunk, or arms). Skin biopsy should be obtained in patients with suspected KS. The histopathologies of all KS variants are similar: spindle-shaped cells in the dermis, with extravasated red blood cells present in slits between irregular vascular spaces [*see 2:X Malignant Cutaneous Tumors*].

Table 4 Herpesviruses Found in Human and Nonhuman Hosts

Gamma herpesviruses	Rhadinovirus Epstein-Barr virus Equine herpesvirus type 2 Herpesvirus saimiri Kaposi sarcoma–associated herpesvirus Lymphocryptovirus
Alpha herpesviruses	Herpes simplex virus type 1 Herpes simplex virus type 2 Equine herpesvirus type 1 Pseudorabies virus Varicella-zoster virus
Beta herpesviruses	Human cytomegalovirus Human herpesvirus type 6 Human herpesvirus type 7

Peripheral Neuroectodermal Tumors and Extraosseus Ewing Sarcoma

Peripheral neuroectodermal tumors (PNETs) and Ewing sarcoma of bone and soft tissue have similar cytogenetic mutations [*see* Translocations Diagnostic of Sarcomas, *above*]. PNETs and extraosseus Ewing sarcomas present as masses most commonly in soft tissue of the chest wall and extremities. They are generally treated with resection, radiation, and chemotherapy in regimens used for Ewing sarcoma of bone [*see* Sarcomas of Bone and Cartilage, Ewing Sarcoma, *below*].

Gastrointestinal Stromal Tumors

GISTs occur predominantly in middle-aged patients but may rarely occur in younger individuals. Approximately 70% of GISTs occur in the stomach, 20% in the small intestine, and less than 10% in the esophagus, colon, and rectum. Survival correlates with tumor location (i.e., patients with GISTs located in the esophagus and stomach survive longer than those with tumors located in the small bowel). Age, mitotic index, and size less than 5 cm are also independent prognostic factors.

Classification Until 1990, most gastrointestinal sarcomas were thought to be leiomyosarcomas because they histologically resembled smooth muscle. However, clinical oncologists observed that GI leiomyosarcomas had a distinctly lower response rate to standard doxorubicin-based chemotherapy than did leiomyosarcomas of the uterus, trunk, and extremities. Subsequent immunocytochemical studies showed that GI sarcomas frequently lacked muscle markers that were typical of leiomyosarcomas found at other anatomic sites. The subset without muscle or Schwann cell (S-100) markers were eventually termed GISTs. These tumors almost universally expressed CD117 (c-*kit*) and often CD34, which are also expressed on hematopoietic progenitor cells.

Genetic factors Most GISTs express c-*kit*, a growth factor receptor with tyrosine kinase activity. c-*kit* is a proto-oncogene located on the long arm of chromosome 4 (4q11-q12) that encodes a transmembrane tyrosine kinase receptor. Its ligand is a stem cell factor. c-*kit* regulates normal hematopoiesis, as well as migration of germ cells, and is also expressed in normal human mast cells, immature myeloid cells, melanocytes, epithelial breast cells, and interstitial cells of Cajal (the gastrointestinal pacemaker cells). Interstitial cells of Cajal have immunohistochemical profiles similar to those of GISTs (i.e., c-*kit* and CD34 positive; desmin and S-100 negative) and thus are currently thought to be the cell of origin of GISTs.

c-*kit* mutations[72] in the juxtamembrane domain of GISTs include in-frame deletions and point mutations in exon 11 in approximately 60% of cases.[73] Mutations in most of the remaining cases involve exon 13 and exon 9. The mutated receptor is activated constitutively without its ligand, driving neoplastic transformation.

Diagnosis The most common symptoms of GIST at initial presentation are abdominal pain and gastrointestinal bleeding. CT and MRI scans may suggest the diagnosis and define the extent of the lesion. Diagnosis is typically confirmed histologically. The Carney triad includes the diagnosis of gastric stromal tumors (formerly called epithelioid leiomyosarcoma), functioning extra-adrenal paragangliomas, and pulmonary hamartomas (chondromas).[74-76] Patients with one or two components of the triad should be evaluated for the other components. Pulmonary lesions detected on radiographs may be either metastases or benign hamartomas; biopsy must be performed before chemotherapy is administered for presumed metastatic disease.[3]

Mesothelioma

The annual incidence of mesothelioma is not known with certainty. Mesotheliomas are difficult to diagnose, even by expert pathologists. Because cancer deaths are coded by primary site of the neoplasm (primary neoplasms of pleura and peritoneum) and not by histologic diagnosis (mesothelioma), data from death certificates are unreliable for estimating disease frequency despite the rapid progression to fatal outcome that is typical of malignant mesothelioma. A reasonable estimate is that about 2,000 new cases of mesothelioma occur annually in the United States (range, 1,000 to > 3,000 cases).[77] Reported rates have increased in the past decade, perhaps by as much as 50%.[78] In the United States, mesothelioma is approximately threefold to fivefold more common in men than in women.[78-80]

Etiology Persons at high risk for mesothelioma are those exposed to the processing and commercial uses of asbestos. The mineral is mined, milled, and used in a wide range of industrial and commercial products, including insulation, textiles, heat protectors, filters, and construction materials (e.g., spackling, roofing, siding, and floor and ceiling tiles).[80] Workers who are exposed to high levels of asbestos include miners, millers, producers of asbestos products, and laborers who install plumbing, boilers, and heating equipment. Workers who may not handle asbestos directly but are in proximity to others working with the material (e.g., carpenters, electricians, and welders) are also at risk.

Malignant mesothelioma is rarely curable; therefore, screening of asbestos workers for mesothelioma is inappropriate.[81] However, smoking greatly increases the risk of lung cancer (but not mesothelioma) in asbestos workers, and smoking cessation efforts are needed in this high-risk group.[81,82] A detailed exposure history should emphasize the period 20 to 50 years before diagnosis and should include possible household-contact exposure. Brief exposures may be long forgotten, and asbestos exposure can be documented in about 30% to 70% of patients with mesothelioma.[77]

Malignant pleural mesothelioma most commonly develops in the fifth to seventh decades of life (median age, 60 years). A significant proportion of patients with mesothelioma in whom the diagnosis was made between 20 and 40 years of age report household or neighborhood asbestos exposure during childhood. Children who present with the disease generally have no apparent asbestos exposure.[80]

Diagnosis Dyspnea, chest pain, or both prompt patients to seek medical attention. Physical examination is remarkable for dullness at one lung base, and chest x-rays typically reveal a large, freely movable unilateral pleural effusion. Occasionally, patients are asymptomatic, and the pleural effusion is found incidentally on chest x-ray. Sixty percent of patients have right-sided lesions, and fewer than 5% have bilateral involvement at the time of diagnosis.

A CT or MRI scan of the chest to assess the extent of disease is indicated if any treatment is contemplated. Loss of lung volume is evident early on CT. In advanced disease, scoliosis with contracture of the ipsilateral hemithorax is visible even on chest x-ray. Despite a history of asbestos contact in 50% to 70% of patients, pleural plaques or interstitial fibrosis is apparent on chest x-ray in only about 20% of patients; however, pleural calcifications are evident on CT scan in nearly 50% of patients and at autopsy in 87%.

Initial misdiagnosis is common, and pathologic opinion appears particularly diverse in cases in which litigation is involved. Special immunoperoxidase staining has made the diagnosis of mesothelioma more reliable. Because a substantial percentage of mesotheliomas develop in patients with no known asbestos exposure and because other malignancies are common in asbestos workers, asbestos exposure alone should not influence the diagnosis of mesothelioma.

TREATMENT OF SOFT TISSUE SARCOMAS

Patients with possible sarcoma should be referred to an institution with an experienced sarcoma service. If preoperative evaluation reveals no evidence of metastasis on chest CT, the goal of treatment is the control of local disease. Primary therapy for most relatively small localized soft tissue sarcomas (except for rhabdomyosarcoma and Kaposi sarcoma) is surgery. Wide excision (3 to 6 cm of pathologically documented normal tissue) is optimal to avoid the need for radiotherapy, particularly for abdominal or low-grade lesions. Careful pathologic examination of the margins is essential to document adequate resection and identify any involved margins that require further resection. If lesions are deep or adjacent to a major nerve, visceral organ, or bone, surgical margins may be necessarily narrow (e.g., 1 mm or less) or even involved in tumor. When pathologic margins are small (< 3 to 6 cm), radiation may be used to decrease the risk of local failure. Adequate radiotherapy (6,600 cGy or more) can usually be delivered to lesions located in the extremities; however, the risk of radiation damage to visceral organs generally precludes these doses for treatment of tumors located in the retroperitoneum or abdomen. Low-grade lesions, if ade-

Table 5 Meta-analysis of Doxorubicin-Based Adjuvant Chemotherapy for Localized Resectable Soft Tissue Sarcoma*

	Hazard Rate	*P-Value*	*Absolute Benefit at 10 Years (%)*
Local recurrence-free intervals	0.73	0.016	6 (from 75 to 81)
Distant recurrence-free intervals	0.70	0.0003	10 (from 60 to 70)
Overall survival	0.89	0.12	4 (from 50 to 54)

*The findings are based on 14 randomized trials involving 1,568 patients.

quately resected, are generally curable; thus, wide surgical margins are especially important to ensure local control. Very large lesions are often initially treated with radiation and chemotherapy to facilitate ultimate resection.

Superficial trunk lesions are frequently resectable with wide margins. For extremity lesions, a combined modality of conservative (often limb-sparing) surgery and radiotherapy may achieve local control without increasing the risk of locoregional recurrence.[83-85] The current standard of limb-sparing surgery combined with radiotherapy or radical resection (often amputation), as practiced at experienced centers, has improved local control from approximately 20% in 1950 to 90% or higher today.[83] Local control rates remain 50% to 75% for trunk lesions but only 30% to 50% for primary retroperitoneal lesions.[86-91] Many primary retroperitoneal and head and neck lesions involve vital structures and are unresectable at presentation.

Adjuvant Chemotherapy

Adjuvant chemotherapy is standard practice for the treatment of rhabdomyosarcomas, osteosarcomas, and Ewing sarcomas, but it remains controversial for other adult soft tissue sarcomas. Nevertheless, most experts agree that the risks of adjuvant chemotherapy are not warranted for low-grade lesions (given their low probability of metastatic spread) and for lesions less than 5 cm, even if high grade, because of their excellent prognosis.

Initial pilot studies investigating the effectiveness of adjuvant chemotherapy in adult soft tissue sarcomas reported significant survival benefit compared to survival reported in historical control subjects. However, subsequent randomized studies found that survival with no adjuvant chemotherapy to be higher than previously reported. Because surgical resection of recurrent local disease and even pulmonary metastases is sometimes curative, disease-free survival may be a less meaningful end point than overall survival.

A meta-analysis of individual patient data from all randomized doxorubicin-based adjuvant trials in patients with sarcoma included data from 1,568 patients [*see Table 5*]. Adjuvant chemotherapy improved the time to local and distant recurrence-free survival (hazard ratios, 0.73 and 0.70; $P = 0.016$ and 0.0003, respectively). However, overall survival in the group receiving chemotherapy showed only a 4% advantage and a hazard ratio of 0.89 ($P = 0.12$).[92] Adjuvant trials of doxorubicin and ifosfamide regimens have produced mixed results.[93,94]

Therapy for Advanced Soft Tissue Sarcomas

Resection Resection of subpleural metastases in carefully selected patients results in disease-free survival in about 20% of patients.[95-97] Patients with a disease-free interval longer than 12 months, fewer than five nodules, and a tumor doubling time of more than 20 days have the best prognosis. In one large study, the median disease-free survival for all patients undergoing repeat resections was 42.8 months, with an estimated 5-year survival of 36%.[96] Prolonged survival was associated with fewer than three nodules at the time of the second resection. A combined-modality approach (chemotherapy before resection) has yet to be evaluated in a randomized trial.

Single-agent chemotherapy Single-agent chemotherapy is generally chosen for palliation, particularly in older patients and in those with low-grade lesions. Doxorubicin is the most active single agent in soft tissue sarcomas, with a response rate of 15% to 35% in various studies.[98-100]

A dose-response relationship has been observed for doxorubicin in randomized trials.[101-103] Dose rates of 60 to 70 mg/m^2 every 3 weeks are generally superior to dose rates of 50 mg/m^2 or less.

Dacarbazine has a single-agent response rate of about 16% for most sarcomas and response rates of up to 44% when used in combination with doxorubicin in the treatment of leiomyosarcomas.[104,105] Nausea, which is a common side effect, may be improved by continuous infusion administration.[106]

Ifosfamide, an analogue of cyclophosphamide, is effective against sarcoma alone or in combination with doxorubicin.[107,108] Mesna must be administered in conjunction with ifosfamide to prevent bladder injury.

Combination chemotherapy Combination chemotherapy is generally used (1) for patients for whom a response would facilitate curative resection of a primary lesion and (2) for patients with unresectable or metastatic sarcoma. Combination chemotherapy is also used as palliation, particularly in patients younger than 50 years who have high-grade lesions. A combination of doxorubicin and ifosfamide produces response rates of 17% to 25%.[98,109,110] The median survival for patients with unresectable or metastatic sarcoma is 12 months, with no significant differences in survival.

Treatment of Nonclassic Soft Tissue Sarcomas

Rhabdomyosarcomas Children with rhabdomyosarcoma are generally treated with multiagent chemotherapy in regimens combining vincristine, actinomycin, and either cyclophosphamide or ifosfamide.[5,53-55] Doxorubicin-based regimens are generally used in adults.[111] Lymph node metastases occur more commonly than in other sarcomas. Although children with metastatic disease sometimes can be cured, the prognosis in adults is poor despite excellent responses to primary aggressive chemotherapy.[111] Chemotherapy is followed by resection of residual rhabdomyosarcoma and radiation therapy.

Kaposi sarcoma Lesions of the classic variant of KS generally respond to resection, radiotherapy, or low doses of vinblastine, doxorubicin, or interferon alfa.[111] Secondary tumors, espe-

cially lymphomas, are common. Transplantation-associated KS may be controlled by modification or cessation of immunosuppression therapy. Although HIV-associated KS responds to radiation therapy and chemotherapy, the response is less durable than in classic KS. HIV-positive patients with KS lesions involving limited areas of the skin or oral mucosa are often most easily treated with radiation. Advanced or visceral disease may be treated with cytotoxic chemotherapy using doxorubicin, vinblastine, or paclitaxel in single-agent or combination regimens; interferon alfa is usually used as a single agent.[111]

Mesothelioma No therapy for mesothelioma is considered standard. Cure is elusive even with resection, radiation, and combination chemotherapy.[112,113] Tumor volume shrinkage of at least 50% is achieved in 15% to 25% of selected patients treated with gemcitabine- and cisplatin-based regimens.[114,115]

Gastrointestinal Stromal Tumors

Treatment of GIST has changed dramatically with improved understanding of its biology. Complete en bloc surgical resection, when possible, remains the cornerstone of curative therapy. Recurrent or metastatic disease carries a poor prognosis because of GIST resistance to chemotherapy and radiotherapy.

Imatinib is an oral, relatively specific inhibitor of three tyrosine kinase receptors: (1) the protein produced by the Philadelphia chromosome translocation of chronic myelogenous leukemia, (2) the mutated c-*kit* receptor in GISTs, and (3) the platelet-derived growth factor receptor.[116] In a European trial evaluating doses of imatinib ranging from 300 to 1,000 mg orally daily, tumor growth was inhibited in 32 of 36 patients, and in 19 patients tumor volume decreased more than 50%.[117] In a study in the United States, 36 patients with unresectable or metastatic GIST were randomized to receive either 400 or 600 mg of imatinib daily; of these, 19 (54%) had a partial response of at least a 50% decrease in the size of the lesion; no advantage was shown for either dose. Disease progression occurred in four patients (11%).[118] In the European dose-escalation study, nausea and vomiting, edema, and dyspnea precluded administration of doses of more than 500 mg twice daily. The most common side effects (generally resolving after the first 8 weeks) were nausea and vomiting, rash, edema (particularly periorbital), and conjunctivitis (rarely with bleeding sclera). Myelosuppression was infrequent, although anemia did occur. Intratumoral and gastrointestinal bleeding developed in fewer than 5% of patients.

Sarcomas of Bone and Cartilage

Sarcomas are the second most common primary tumor of bone, after myeloma. The most common sarcomas of bone are osteosarcoma, Ewing sarcoma, and chondrosarcoma. Bone sarcomas currently represent 1% of adult malignancies and 15% of pediatric malignancies. In 2003, an estimated 4,000 persons in the United States will have developed sarcoma of bone, and 2,000 will have died of this disease.[4]

Primary malignant lesions of bone (arising de novo) and secondary malignancies (arising from a prior benign tumor) must be distinguished from the vastly more common metastases to bone. Radiographs of a lesion can help distinguish benign from malignant lesions and often suggest the histologic origin of the tumor. Osteosarcoma characteristically produces irregular cortical surfaces, whereas Ewing sarcoma has a layered appearance like that of an onion skin.

OSTEOSARCOMA

Osteosarcoma, defined as a primary malignancy that produces osteoid, is the most common sarcoma of bone. The incidence ratio of men to women is 1.5:1 to 2:1. The age distribution is bimodal, with the first peak in the second and third decades of life and the second in the sixth decade.[6] Osteosarcoma classically arises in growth plates (i.e., around the epiphyses) of long bones during the adolescent growth spurt.

Osteosarcoma in older adults often develops in previously irradiated sites or in existing benign bone lesions, such as pagetoid bone, solitary osteochondromas, or multiple enchondromatosis (Ollier disease). The risk of sarcoma is 0.2% in patients with Paget disease. Axial lesions are more common in adults than in children, occurring in fewer than 10% of pediatric patients but in 30% to 50% of adult patients. Extraosseous presentations are rare and occur in older adults.

Diagnosis

Clinical manifestations Patients with osteosarcoma present with severe pain of relatively short duration, often after a sports injury. Osteosarcoma may present as an obvious firm-to-hard mass covered by stretched, shiny skin, with prominent vascular markings, or may be evident only on radiograph. Multicentric osteosarcomas have developed in watch-dial painters who are subject to chronic radium ingestion and occasionally in persons without risk factors, most commonly in children younger than 10 years.

Imaging studies Radiographs and CT scans reveal osteolysis [*see Figure 1*], periosteal new bone formation, and late cortical destruction. Periosteal elevation may produce the classic Codman triangle on radiograph. Radiologically, the differential diagnosis includes osteochondroma and myositis ossificans.

Pathology Superficial, low-grade juxtacortical or parosteal osteosarcomas constitute only 3% to 4% of osteosarcomas, arise equally in males and females, and tend to affect adults with no prior risk factors. Low-grade osteosarcomas typically present in the third and fourth decades of life, whereas high-grade osteosarcomas appear in the second decade. Grossly, these bulky tumors encircle the cortex of bone (generally, the distal femur and, less commonly, the proximal humerus).

Staging Evaluation

Staging evaluation includes radiographs and CT scans of the primary lesion and the lungs, which is the most likely site of metastases. Bone scans generally reveal intense uptake in the lesion and may detect additional lesions more proximal than the dominant lesion in the same bone (so-called skip lesions), metastases to other bones, or multicentric primary tumors; pulmonary uptake suggests lung metastases. Levels of alkaline phosphatase at diagnosis, which are generally elevated except in very undifferentiated lesions, correlate with prognosis, and elevated values after amputation predict residual or relapsing disease.[119]

Patients in whom osteosarcoma is possible should be referred to an institution with an experienced sarcoma service. Expert multimodal consultation is essential before biopsy. Incisional biopsy should be performed by the surgeon who will do the definitive resection, because an improperly placed biopsy, particularly of proximal tibial lesions, may render limb-sparing surgery impossible and significantly compromise local control.

Figure 1 **Radiography reveals osteosarcoma in a 62-year-old man with Paget disease of bone. The patient had pain associated with a soft tissue mass in the area of the greater trochanter of the left femur. Note the destruction of the cortex by the osteosarcoma in pagetic bone. The position of the original cortex is indicated by the arrows.**

If the radiologic picture is virtually diagnostic, a fine-needle biopsy may be adequate to confirm the clinical diagnosis.

Treatment

Adjuvant chemotherapy On the basis of two small, randomized trials in which combination regimens were compared with observation, doxorubicin- and cisplatin-based adjuvant chemotherapy is the established treatment for osteosarcoma. The Pediatric Oncology Group and UCLA studies showed a significantly improved 2-year disease-free survival; the UCLA study also demonstrated a significantly prolonged overall survival.[120,121] The optimal combination of agents and schedule has not yet been established. Of six randomized trials evaluating high-dose methotrexate, one demonstrated an advantage for high-dose over standard-dose methotrexate, whereas five showed no advantage for high-dose methotrexate.[122,123] In a study by the European Osteosarcoma Intergroup, short intensive chemotherapy using doxorubicin and cisplatin was compared with a complex multiagent protocol in patients with operable osteosarcoma. Progression-free survival at 5 years was 44% in both groups, and the two groups had comparable overall survival.[124,125] In a follow-up study, the addition of ifosfamide did not appear to improve these results.[126]

Preoperative chemotherapy Preoperative chemotherapy has many theoretical advantages over postoperative adjuvant chemotherapy.

Early systemic treatment may more effectively eradicate microscopic metastatic deposits. The response to preoperative chemotherapy can be evaluated histologically, and the regimen can be modified if the response is suboptimal. Patients receiving preoperative chemotherapy whose resected tumor specimen is more than 90% necrotic may have a significantly higher survival rate than patients receiving only postoperative chemotherapy.[127] Patients who have less than 90% necrosis in the resected tumor after preoperative chemotherapy may have increased disease-free survival if switched to other effective agents postoperatively. Because resolution of tumor vascularity on angiography appears to correlate with histologic necrosis, monitoring angiographic findings may maximize tumor response to chemotherapy before surgery.[128]

Preoperative chemotherapy may facilitate limb-sparing surgery, preservation of muscle groups, and limb function. The delay in surgery also allows procurement of a correctly sized internal prosthesis for replacement of excised bone. However, patients receiving preoperative chemotherapy must be regularly evaluated and should undergo prompt resection if the tumor increases in size during chemotherapy.

Radiotherapy Osteosarcoma tends to be markedly radioresistant. Radiotherapy alone has not been shown to improve the rate of successful limb-sparing surgery or decrease the risk of local recurrence in tumors with close or positive surgical margins. However, in a randomized, controlled trial, higher doses of radiotherapy (given preoperatively with intra-arterial doxorubicin) significantly increased the rate of local complications.[120]

Surgical treatment Either amputation or limb-sparing surgery may be appropriate as long as lesions are widely excised with several centimeters of pathologically documented uninvolved margins. Lesions with a significant soft tissue component or neurovascular involvement generally necessitate amputation. Osteosarcomas arising in sites of prior Paget disease or irradiation tend to be vascular and centrally located and thus are difficult to resect for cure.

Although functional results after limb-sparing procedures are excellent in 60% to 75% of patients, relapse or complications from treatment may later necessitate amputation. In appropriately selected patients, local control rates (i.e., 90% to 97%) and survival rates for limb-sparing procedures are similar to those for amputation.[120,128] Limb-sparing resection tends to be more successful for upper-extremity lesions than for lower-extremity lesions because upper-extremity lesions are associated with fewer complications from weight bearing and dependent edema. In children, an internal prosthesis whose length can be adjusted as the child grows can reduce limb-length disparity. Fractures remain an important complication in active individuals, and thus, amputations are actually preferable for individuals who wish to pursue contact sports.[120]

Treatment of metastatic disease Relapses tend to occur in the first 2 years after completion of primary therapy. Major prognostic variables include grade and invasion through the bone cortex to involve soft tissue. Metastases most frequently develop in lung and, less commonly, in bone. Patients who have already received adjuvant chemotherapy may respond to the same drugs if metastases develop more than 6 months after the last adjuvant treatment. Between 20% and 40% of selected patients with five or fewer pulmonary lesions and a disease-free interval of more than 12 months can be cured with combination chemotherapy and surgical resection.

CHONDROSARCOMA

Chondrosarcoma, which represents about 20% of bone sarcomas, is the most common bone sarcoma after osteosarcoma. Extraosseous chondrosarcomas arising in soft tissue are rare.[129] Primary chondrosarcomas occur in previously normal bone; secondary chondrosarcomas arise in prior benign lesions, generally

enchondromas.[130] Chondrosarcomas in patients with multiple enchondromatosis (Ollier disease) are generally low grade, whereas chondrosarcomas associated with soft tissue hemangiomas (Maffucci disease) are frequently high grade. Chondrosarcoma represents about 10% of radiation-associated sarcomas and may arise in pagetoid bone.

The incidence of chondrosarcomas increases steadily with age.[6] The most common sites of involvement are the pelvis (31%), femur (21%), shoulder (13%), face (9%), and ribs (9%).[6] Lesions can be painless but tend to be painful if they grow rapidly.

Diagnosis

On radiograph, central chondrosarcomas appear as popcorn-shaped calcifications. Peripheral chondrosarcomas may appear as long, slightly calcified spicules radiating from the cortex to a flattened outer surface; there may be little cortical or medullary involvement and a faint Codman triangle caused by a disruption of the smooth periosteal surface. Bone scans generally demonstrate intense uptake in the lesion.

Chondrosarcomas are defined as malignant stromal tumors of bone that produce cartilage but no osteoid. Histologically, the tumors have the appearance of cartilage with malignant chondrocytes. Low histologic grade is less reliable than patient age, site of origin, lesion size, and radiographic appearance in determining biologic behavior.

Mesenchymal chondrosarcoma is a histologic variant that tends to arise in the ribs, mandible, maxilla, skull, and extraosseous sites; it is characterized by a small round cell histologic component and has some sensitivity to chemotherapy.

Treatment

Chondrosarcomas, which are relatively resistant to both radiotherapy and chemotherapy, must be adequately resected at the time of initial diagnosis. Aggressive resection is particularly appropriate for eminently curable low-grade chondrosarcomas. Local recurrences tend to increase with histologic aggressiveness.

EWING SARCOMA

Ewing sarcoma constitutes 10% to 14% of primary malignant bone tumors in whites but is rare in other races.[8] The peak incidence occurs between 10 and 25 years of age (range, 2 to 65 years), and the risk in men is twice that in women [*see Table 1*].[6] Ewing sarcoma and osteosarcoma occur in the same sex and age groups, but they can usually be distinguished radiographically and histologically.[5]

Diagnosis

Patients with Ewing sarcoma present with fever, weight loss, malaise, poorly localized bone pain, and a rapidly enlarging mass. Leukocytosis, fever, and an elevated erythrocyte sedimentation rate mimic osteomyelitis. The most common sites of involvement are femur (27%), pelvis (18%), and tibia and fibula (17%).[6] Diagnosis of pelvic Ewing sarcoma is frequently delayed because pain is poorly localized and the mass is not clinically apparent.

Histologically, Ewing sarcoma on reticulin stain appears as clusters of small blue cells bordered by fibrous septa (in contrast to lymphoma cells, which have no septa).[83] Cytogenetics generally reveal the t(11;22) translocation, which is identical to that found in PNETs, suggesting a possible neurogenic origin of Ewing sarcoma.[19]

Radiographically, Ewing sarcoma forms a fusiform enlargement of the long bones, with onion-skin layering of the periosteum and central mottling (so-called cracked-ice appearance). A pulmonary CT scan, bone scan, and marrow aspirate and biopsy are necessary for staging.

Clinically detectable metastases are present in about one third of patients at diagnosis. The most frequent sites of metastasis are the lung, bone, and marrow. Vertebral metastases commonly lead to spinal cord compression. Ewing sarcoma results in 90% mortality in patients who undergo surgical resection alone, which suggests that systemic disease may be present in a substantially higher percentage of patients than those who have detectable metastases at presentation.

Treatment

Initial treatment consists of a multiagent chemotherapy regimen of doxorubicin, vincristine, and cyclophosphamide, alternating with etoposide and ifosfamide administered before and during radiotherapy to the involved bone.[111,131] Radiotherapy concentrating on the primary lesion, if begun during the fourth or fifth cycle of chemotherapy, controls local disease in 70% of patients and provides good functional results. Because of a high risk of local failure and secondary radiation-associated osteosarcomas, expendable bones (e.g., rib, tibia) are often resected, particularly if biopsy after radiotherapy and chemotherapy reveals residual viable tumor.

Survival rates correlate inversely with age (i.e., 70% for patients younger than 10 years and 46% for those older than 16 years).[132] Lower survival rates are associated with primary lesions of the pelvis, humerus, and rib; high levels of lactate dehydrogenase; and extensive soft tissue involvement. One third of pediatric patients with metastases are cured by current therapy, but few adults with metastases survive.

OTHER BONE SARCOMAS

Fibrosarcoma, chordoma, angiosarcomas, and MFHs of bone are usually treated with resection. Radiation to the site of the lesion and adjuvant chemotherapy with doxorubicin and either cisplatin or ifosfamide may also be used.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter. Drugs discussed in this chapter do not have FDA approval for use in the treatment of sarcoma.

XIV BLADDER, RENAL, AND TESTICULAR CANCER

Derek Raghavan, m.d., ph.d.

Cancer of the Bladder

Bladder cancer accounts for more than 90% of urinary tract malignancies. It is the sixth most common cancer in the United States, with 50,000 new cases a year, and it causes over 10,000 deaths a year. The management of this disease has become a paradigm of the approach to solid tumor malignancy,[1] because bladder cancer exhibits stem cell function (with the ability to differentiate along different histologic pathways); is associated with expression of several common oncogenes; and responds to surgery, radiation, and chemotherapy.

Epidemiology and Etiology

The incidence of bladder cancer increases with age and is fourfold higher in men than in women. The disease is seen more often in whites than in African or Asian populations. The incidence is higher in urban areas, suggesting a possible role of environmental factors in carcinogenesis. Cigarette smoking is the primary risk factor, with a confirmed dose- and time-response relationship for both sexes.[2] Occupational exposure to carcinogenic compounds found in dye, rubber, paint, plastics, metal, and motor vehicle exhaust significantly raises the risk of bladder cancer. Other established risk factors include chronic infection of the lower urinary tract, history of external-beam radiation to the pelvis, long-term indwelling urinary catheter, the use of cyclophosphamide, high-fat diet, and low daily fluid intake. In the Mediterranean basin, schistosomiasis is still the main causative agent and is classically associated with squamous cell carcinoma.

More than 90% of bladder cancers are transitional cell carcinomas. The less common cell types are squamous cell carcinoma, adenocarcinoma, and small cell carcinoma; rare histologic types such as sarcoma, lymphoma, and melanoma comprise less than 1% of cases.[3] Although the histogenesis is not fully understood, bladder cancer appears to originate from a stem cell tumor[4] and, therefore, has the capacity to evolve different histologic patterns that are intermixed; for example, dominant transitional cell carcinoma may coexist with squamous and squamoid differentiation. Bladder cancer is often associated with a field defect of the urinary mucosa, implying an antecedent level of precancerous change that can affect multiple sites, with the result that the entire lining of the urinary tract may be at risk for developing malignancy.

Pathobiology

Pathologically, bladder cancer is categorized as superficial or invasive [*see Figure 1*]. Superficial bladder cancer, which constitutes about 80% of incident cases, is restricted to the level of the bladder mucosa and lamina propria. The seminal event in the development of superficial bladder cancer appears to be a loss of heterozygosity of chromosome 9 (i.e., that there is a potential oncogene located at that site).[5] Superficial bladder cancer is usually associated with a high level of histologic differentiation and with long patient survival.

Invasive bladder tumors are those that penetrate beyond the lamina propria. They are aggressive and tend to metastasize early. About 20% of patients have invasive cancer at presentation, although some superficial tumors recur as invasive disease. The

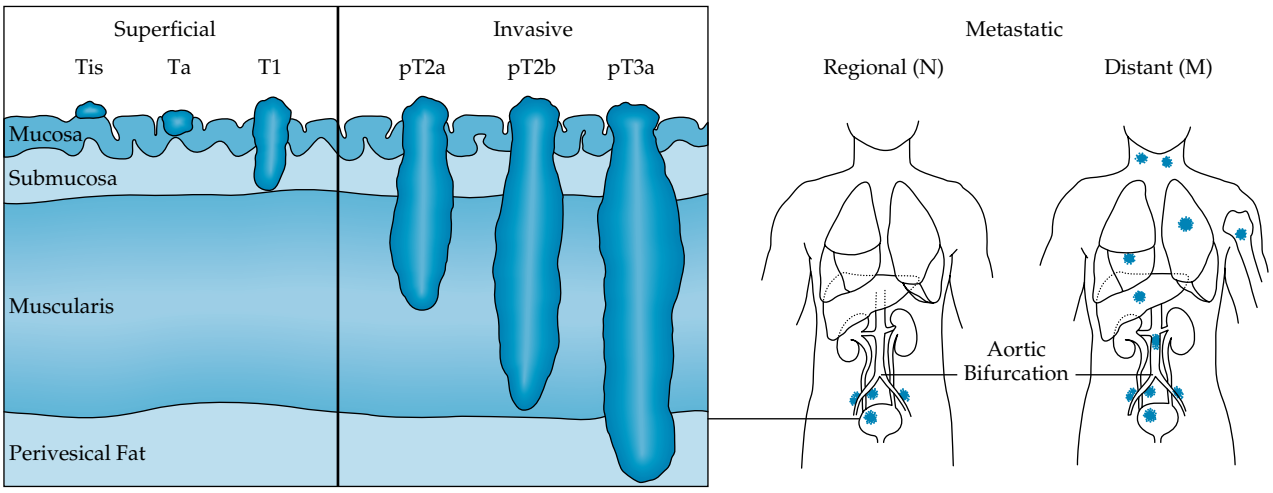

Figure 1 **Carcinoma of the bladder can be staged according to the depth of penetration of the tumor into the bladder wall and, for advanced disease, by the location of metastases. Superficial disease comprises noninvasive papillary carcinoma (Ta); carcinoma in situ, or so-called flat tumor (Tis); and tumors that extend only into the submucosa (stage T1). Invasive disease is characterized by extension past the submucosa. Invasion into the muscle layer is designated stage T2: pT2a denotes tumor that invades superficial muscle (the inner half); and pT2b, tumor that invades deep muscle (the outer half). Stage T3 tumors are those that invade perivesical fat: pT3a tumors are microscopic, and pT3b tumors are macroscopic (i.e., there is an extravesical mass). Stage T4 tumor invades adjacent organs: T4a invades the prostate, uterus, or vagina; and T4b invades the pelvic or abdominal wall. Metastatic disease represents spread to regional lymph nodes (i.e., those below the aortic bifurcation [stages N1 through N3]); involvement of lymph nodes above the aortic bifurcation, or involvement of any bone or soft tissue (stage M1).**

most important prognostic factor is the depth of tumor invasion (stage). T2 tumors, which extend into the muscularis propria, carry a better prognosis than T3 and T4 tumors, which extend beyond the muscularis propria. The level of differentiation (grade) is also an important factor. Unfortunately, most invasive tumors are high grade. Vascular or lymphatic invasion predicts an increased risk of soft tissue invasion and of distant metastasis. Other adverse prognostic factors include the absence of expression of blood group antigens on the tumor cell surface, DNA ploidy, expression of epidermal growth factor receptor (EGFR), and presence of mutations of the *p53* suppressor gene. Poorer prognosis has also been correlated with expression of other genes, including *p16*, *p21*, and *Rb;* these genes may work in concert with *p53* to regulate tumor growth.[6]

DIAGNOSIS

Clinical Findings

Most bladder cancers present as gross or microscopic hematuria that is painless and occurs suddenly or intermittently.[7] Urinary frequency, nocturia, and urgency can be the result of bladder wall irritation or volume loss from space-occupying lesions and are often misdiagnosed as chronic interstitial cystitis. Abdominal discomfort, flank pain, pelvic pain, altered bowel habit, or a palpable mass can occasionally be the first clinical evidence of invasive bladder cancer. Obstruction of the ureteral orifice with subsequent hydronephrosis and renal insufficiency may occur with an invasive tumor, although these tumors can remain clinically silent until locally advanced. Rarely, pneumaturia will suggest the presence of a fistula to the bowel.

Invasive bladder cancer may extend locally into the prostate, seminal vesicles, rectum, uterus or vagina, sacral vertebra, and the retroperitoneal soft tissue. It spreads via lymphatics and blood vessels to distant lymph nodes, the lungs, the liver, skin, peritoneum, and bones[1] and may even cause brain metastases or carcinomatous meningitis.[8] Depending on the practice setting, 5% to 20% of all patients with bladder cancer present with symptoms from metastatic lesions. Constitutional symptoms may occur with disseminated disease, but clinical paraneoplastic syndromes are relatively rare in transitional cell cancers.

Laboratory Findings

Routine urinalysis in patients with bladder cancer will usually show hematuria, the degree of which does not correlate with the extent of the lesion. Intravenous urography may reveal an intravesical filling defect and also provides anatomic information about the urinary tract, such as the presence of hydronephrosis or hydroureter. Ultrasound is sometimes used to assess the bladder wall and to evaluate the kidneys and ureters. Urine cytology is a convenient and inexpensive method to obtain a tissue diagnosis and has a specificity and sensitivity of 80% in grade III tumors, but it has a relatively low sensitivity for grade I or II tumors (about 10% and 50%, respectively). It has been suggested that flow cytometric studies of urine specimens may reveal occult tumors via the demonstration of aneuploidy. Direct visualization and biopsy of the tumor is usually achieved by cystoscopy, which has been facilitated in recent years by the introduction of flexible instrumentation.

Staging

The staging process for bladder cancer requires a thorough history and physical examination, along with laboratory studies that include a complete blood count and tests of hepatic and renal function. Renal function may be compromised by factors that caused the cancer, such as analgesic nephropathy, or by obstruction of renal outflow by the tumor mass. Occasionally, a patient will have a markedly elevated leukocyte count secondary to the production of granulocyte colony-stimulating factor (G-CSF) by the bladder cancer. A chest x-ray should be obtained in all patients. In some centers, CT scan of the chest is routinely performed instead of initial chest x-ray as part of routine staging. A CT scan of the abdomen and pelvis allows the assessment of lymphadenopathy and other organ involvement, although the yield of pelvic CT is relatively low. Radionuclide bone scans may be used for staging, but the yield in asymptomatic patients with normal serum alkaline phosphatase levels is low. MRI scanning may be helpful in defining the extent of abdominal or pelvic disease, especially in a patient with renal dysfunction who is not suitable for contrast-enhanced CT scanning. The role of positron emission tomography (PET) scanning has not yet been clearly defined in bladder cancer, although it is clear that false negative results limit utility.

It seems likely that in the future, more sophisticated molecular studies will become routine in the diagnosis and management of bladder cancer. For example, mutation of the *p53* gene appears to be an important predictor of outcome in invasive bladder cancer.[9] It is also clear that expression of the *Rb* gene, *p16*, *p21*, the epidermal growth factor receptor, thrombospondin-1, multidrug-resistance phenotype, and glutathione may be predictive of natural history or of response to therapy,[6,9-12] and it seems likely that these assays will become a part of a routine staging protocol.

MANAGEMENT

Superficial Bladder Cancer

For superficial papillary bladder cancer, the initial treatment is careful and thorough endoscopic resection of the tumor or tumors.[13] In patients at high risk for recurrence, bacillus Calmette Guérin (BCG) may be infused into the bladder through a urinary catheter as an adjuvant to transurethral resection. A common schedule is weekly administration for 6 weeks followed by monthly doses for 6 to 12 months, although the optimal approach has not been defined. The mechanism of action is incompletely understood, but it appears to be based on local immunologic response. Although there is great variability of published data, intravesical BCG appears to prevent recurrence in up to 30% of cases and delays recurrence in around 50%, compared with patients who do not receive adjuvant therapy.

Side effects of intravesical BCG include dysuria, frequency, hematuria, and a flulike syndrome. More significantly, because BCG is an attenuated mycobacterium, it can produce local, regional, and systemic infections. Granulomatous infections can occur at extravesical sites, including the prostate, epididymis, testes, kidney, liver, and lungs. BCG sepsis is the most serious complication and can be life-threatening. Systemic involvement (so-called BCGosis) is treated with triple-antibiotic antituberculous therapy for 6 months.

Cytotoxic agents can also be used for intravesical treatment, although the superiority of BCG to such agents has been demonstrated in randomized clinical trials.[13] Agents that may have a role for patients who refuse cystectomy after BCG failure include doxorubicin, thiotepa, and mitomycin-C. Because of their high molecular weight, doxorubicin and mitomycin-C have a lesser tendency to be absorbed systemically from the bladder than

Table 1 Studies of Chemotherapy plus Radiation in Invasive Bladder Cancer

Series	*Number of Patients*	*Clinical T Stage*	*Chemotherapeutic Regimen*	*Bladder Preservation (%)*	*Overall Survival*	*Median Follow-up (months)*
Coppin[18]	42	T2-T4	Cisplatin	Not reported	61% at 2yr	50

Sauer[135]	67	T1-T4	Carboplatin	84	66% at 3 yr	Not available
Tester[136]	46	T2-T4	Cisplatin	83	66% at 3 yr	36

does thiotepa, which is a small molecule. Clinical trials are in progress to assess the utility of some of the newer cytotoxic agents, such as the taxanes and gemcitabine, for intravesical chemotherapy. These agents are relatively large molecules, so significant systemic absorption seems unlikely.

Invasive Bladder Cancer

In North America and Europe, cystectomy is the standard treatment for organ-confined invasive bladder cancer.[14] Radical cystectomy involves the en bloc removal of the anterior pelvic organs, which include the bladder, prostate, and seminal vesicles in men and the bladder, urethra, uterus, ovaries, and vaginal cuff in women.[14,15] Bilateral pelvic lymph node dissection is often performed. The ureters are reconnected to an intestinal conduit as a urinary diversion. Traditionally, the conduit has been fashioned to drain into an external collecting bag attached to the abdominal wall. However, continent reservoirs such as the Koch pouch (using the ileum) and the Indiana and T pouches (using other segments of bowel) have become popular, because they afford greater degrees of continence and a return to more normal lifestyles. These procedures involve the creation of an internal conduit with an antireflux mechanism that is either brought to the abdominal wall or sutured to the urethra, thus allowing patients to self-catheterize or void in the normal position, which greatly improves their self-image and increases their acceptance of the procedure.

When performed in routine clinical practice, radical cystectomy results in 60% to 75% 5-year survival rates in patients with T2 disease and 20% to 40% survival in those with T3 or T4 disease. Centers of excellence have reported superior long-term results, with 10-year survival as high as 85% for patients with organ-confined disease.[15]

For patients with localized invasive disease who are not surgical candidates, radiation is the alternative definitive therapy in North America, although it should be noted that radical radiotherapy is the standard definitive treatment in some British, Canadian, and European centers.[16,17] To date, there have been no well-designed, randomized studies comparing radiation with surgery in patients with similar characteristics.

A relatively standard radiotherapy regimen is more than 65 to 70 Gy given over 6 to 7 weeks, with the major component of dosage focused on the tumor and surrounding areas, as defined by CT scanning in the prone position. Toxicities of radiation include dermatitis, proctitis that is occasionally complicated by bleeding and obstruction, cystitis or bladder fibrosis, impotence, incontinence, and development of secondary malignancies in the region surrounding the radiation field.

Combined-modality approaches, incorporating systemic chemotherapy with definitive local modalities, have been studied extensively in the past few years in the hope of sparing the bladder or improving overall survival.[1] The rationale is that systemic chemotherapy may reduce the extent of local tumor while controlling occult metastases. Trials of concurrent chemotherapy and radiation have suggested that a high rate of bladder preservation is possible with this approach, compared with radiation alone [*see Table 1*].[18] However, the one reported randomized trial did not show a statistically significant survival benefit, although it did not have sufficient statistical power to assess survival. When chemoradiation fails with local progression or relapse, salvage surgery becomes extremely difficult because of the formation of dense adhesions.

It is clear that neoadjuvant chemotherapy can often reduce the local tumor volume within the bladder, and complete remission is sometimes achieved. However, most randomized trials of neoadjuvant systemic chemotherapy followed by definitive radiotherapy or cystectomy have shown no significant survival benefit from the combined modality approaches [*see Table 2*].[19-21] It should be noted that combination chemotherapy has been more effective, and the North American Intergroup study of the combination of methotrexate-vinblastine-doxorubicin (Adriamycin)-cisplatin (MVAC) plus cystectomy versus cystectomy alone showed a statistically significant survival benefit.

Chemotherapy administered after radical cystectomy for patients with lymph node involvement may improve disease-free survival [*see Table 2*].[22,23] However, in the extant trials, which have been flawed by poor design and inadequate sample size, overall improvement in survival has not been demonstrated with statistical significance. These flaws have been addressed in a large international randomized trial that is currently under way.

Metastatic Bladder Cancer

Chemotherapy is the treatment of choice for patients with metastatic bladder cancer. The first major step in the modern era of chemotherapy was the development of MVAC by Sternberg and colleagues.[24] Several series demonstrated median survival of about 12 months in patients with advanced and metastatic bladder cancer treated with this regimen. At the time of the completion of that trial, median survival without chemotherapy was only 4 to 6 months.[1] A landmark study conducted by an international consortium compared the MVAC regimen to cisplatin alone.[25] The MVAC regimen produced a response rate of 39% with median survival of 12.5 months, which was statistically superior to the response rate of 12% and median survival of 8 months in the group that received cisplatin alone. The survival benefit persisted after a minimum follow-up of 6 years, although

the vast majority of patients in both randomization arms had died by that time.[26] The clear limitations of the MVAC regimen that were evident from this analysis opened the way for investigation of novel agents.[27]

Novel cytotoxic agents are being actively studied; and in recent years, single-agent therapy with paclitaxel, gemcitabine, docetaxel, or ifosfamide has been shown to produce response rates between 20% and 30% [*see Figure 2*]. The combination of these agents with other standard or investigational drugs has resulted in response rates of 50% to 80%, with apparently less toxicity than the conventional-combination MVAC regimen.[28-30]

A phase III trial comparing the regimen of gemcitabine and cisplatin with the MVAC regimen has been completed.[31] Although it was not designed to be an equivalence trial, this study suggests that there is no great difference in survival between the gemcitabine-cisplatin regimen and the MVAC regimen but does suggest that the gemcitabine-cisplatin combination is substantially less toxic. As a consequence, an international consortium (the International Intergroup) is now comparing gemcitabine-cisplatin with gemcitabine-cisplatin-paclitaxel for patients with previously untreated metastatic transitional cell carcinomas. These investigators have indicated that it is probably time to leave the MVAC regimen behind as the standard of care.

Of particular importance, there is emerging evidence that stage migration has occurred in the management of advanced bladder cancer (presumably because of increased use of chemotherapy for patients with asymptomatic or small volume metastatic disease detected by postoperative screening techniques, such as CT, MRI, and PET scans). At Memorial Sloan-Kettering Cancer Center, the initial experience with the MVAC regimen in the 1980s produced a median survival of about 12 months,[24] whereas recent data from that institution showed a median survival of 18 months with a variant of MVAC that has a relatively minor dose escalation. This should be borne in mind when considering the utility of novel combinations, such as the ITP regimen (ifosfamide, paclitaxel, and cisplatin), which also yields a median survival of about 18 months. Before novel regimens are accepted into routine clinical practice, their safety and efficacy should be defined in randomized trials against accepted current standards.

In addition to chemotherapy, novel agents that target cell regulatory proteins may have application to the management of bladder cancer. Clinical trials are currently assessing the efficacy of agents that modulate the function of EGFR and other tyrosine kinase inhibitors. These agents are being tested both as monotherapy and in combination with chemotherapy. The ability to

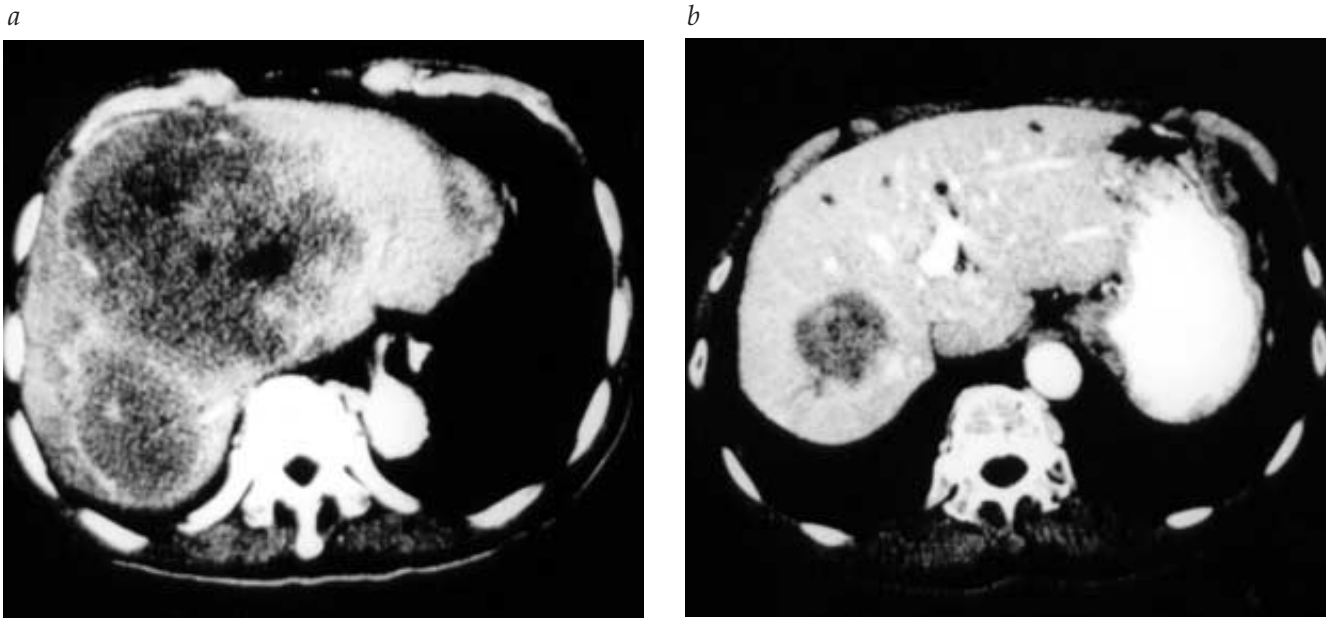

Figure 2 **CT scans of a patient with hepatic metastases from bladder cancer before (*a*) and after (*b*) treatment with gemcitabine-cisplatin.**

identify expression of the *HER-2/neu* oncogene, EGFR, and other molecular predictors of response to treatment may allow tailoring of more specific therapeutic strategies.

Cancer of the Kidney

Renal neoplasms are uncommon, accounting for 3% of all adult malignancies in Western society. The majority of these cancers are renal cell carcinomas (RCC), although other rare tumors of the kidney have been described, including transitional cell carcinomas, sarcomas, adult Wilms tumors, peripheral neuroectodermal tumors, lymphomas, and germ cell tumors.[32,33] It should not be forgotten that tumors can metastasize to the kidney, commonly from lung, breast, and gastrointestinal tract malignancies. Transitional carcinomas occur predominantly in the renal pelvis and are managed in similar fashion to transitional cell carcinomas that arise in the bladder and other sites.

EPIDEMIOLOGY AND ETIOLOGY

RCC affects 30,600 people in the United States annually, and the incidence is steadily rising, with more than 10,000 related deaths occurring each year.[34] This disease usually presents during the fifth to seventh decades of life, with a median age at diagnosis of 60 years. The incidence in men is twice that in women. RCC occurs in all ethnic groups, with no racial predilection. Most RCCs occur sporadically, but about 4% of cases present in an inherited pattern. Such familial renal cancers include von Hippel–Lindau (VHL) disease[35] and familial papillary renal cell cancers. Approximately 1.6% of RCCs are part of the autosomal dominant VHL disease, which is also characterized by retinal and central nervous system hemangioblastoma, pheochromocytoma, and pancreatic cyst. Compared with sporadic cases, RCCs in the VHL syndrome tend to be multifocal and bilateral and appear at a younger age. RCC and malignant angiomyolipoma are also associated with tuberous sclerosis complex, an autosomal dominant disorder of unknown etiology characterized by seizures, mental retardation, and hamartomas.

The true etiology of RCC remains largely undefined.[34] Documented associations include smoking, diet, obesity, and hypertension. The relationship between RCC and the use of antihypertensive agents remains controversial. Patients with autosomal dominant or recessive polycystic kidney disease are not at higher risk than the general population. However a threefold to sixfold higher incidence of RCC has been found in patients undergoing long-term dialysis and in renal transplant recipients, presumably because of the development of acquired cystic kidney disease. Occupational exposure to chemicals appears to have little consistent significance, although a range of different occupations has been implicated in isolated case-control studies.

The isolation of the *VHL* gene in 1993 on chromosome 3p25 was a critical step in the understanding of the molecular genetics of renal cell carcinoma.[35] Subsequently, the gene was found to encode for a tumor suppressor protein that prevents the formation of a transcriptional elongation complex and inhibits the transcription of certain target genes in cell proliferation. At the molecular level, both copies of the *VHL* gene must be inactivated for tumors to develop; therefore, the first mutation in the *VHL* gene is inherited in the germline, and inactivation of the remaining wild-type allele occurs as a somatic event. Inactivation of the *VHL* gene could also be responsible for the nonhereditary forms of RCC, given that somatic mutation of the *VHL* gene has been found in 75% to 80% of sporadic RCC cases. To date, the *VHL* gene does not appear to be involved in the development of papillary renal carcinomas.

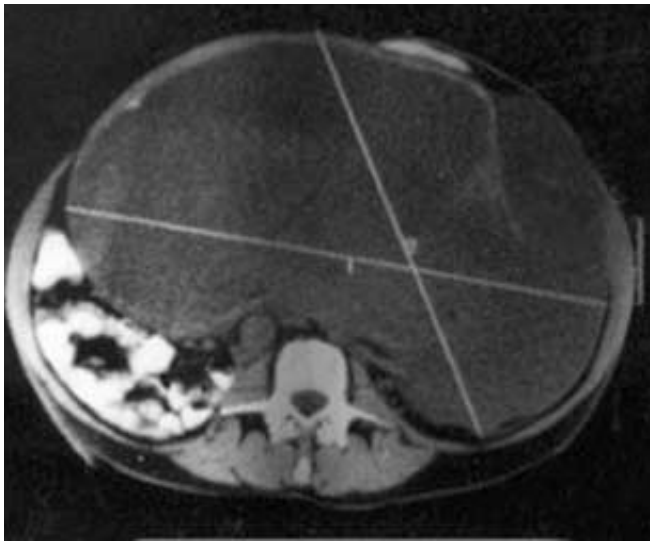

Figure 3 **Renal cell carcinoma. Figure shows a huge primary renal cell carcinoma that occupied a substantial part of the abdominal cavity but that was surgically resected without tumor spillage.**

PATHOBIOLOGY

Recent immunohistochemical studies suggest that RCCs may arise from the proximal convoluted tubular cells. Grossly, the tumors are often well demarcated, round masses protruding from the cortex. RCCs of the clear cell type are usually yellow because of high lipid content. On cross section, areas of necrosis, cystic degeneration, hemorrhage, and calcification are commonly present.[36] Histologically, RCCs are classified into five types: clear cell (75% to 85% of cases), chromophilic (12% to 14%), chromophobic (5%), oncocytic (2% to 4%), and collecting duct (1%).

DIAGNOSIS

Clinical and Laboratory Findings

With the increasing application of ultrasound and CT scans to the diagnosis of nonspecific abdominal symptoms and other conditions, 20% to 30% of RCCs are discovered incidentally as small tumors in a clinically asymptomatic stage. The classic triad of hematuria, flank pain, and a palpable mass has become a less common presentation and usually portends an unfavorable outcome.[37] However, presentation of one or two of these three symptoms is common: about 70% of patients have gross or microscopic hematuria, and 50% have abdominal or flank pain. By contrast, only 40% have a palpable mass. Constitutional symptoms (e.g., fever, night sweats, anorexia, and weight loss) are common. Exfoliative cytology of the urine may indicate the presence of carcinoma cells. Initial blood tests may reveal elevation of serum creatinine or uric acid levels; in more advanced disease, increased serum alkaline phosphatase concentrations or manifestations of paraneoplastic syndromes (see below) may be found.

Because the renal bed is a clinically silent area, some tumors are huge at first presentation [*see Figure 3*]. For the same reason, only 40% of patients have disease confined to the kidney at diagnosis, and nearly one quarter of patients present with symptoms of metastatic lesions. As the tumor grows, it may extend into and

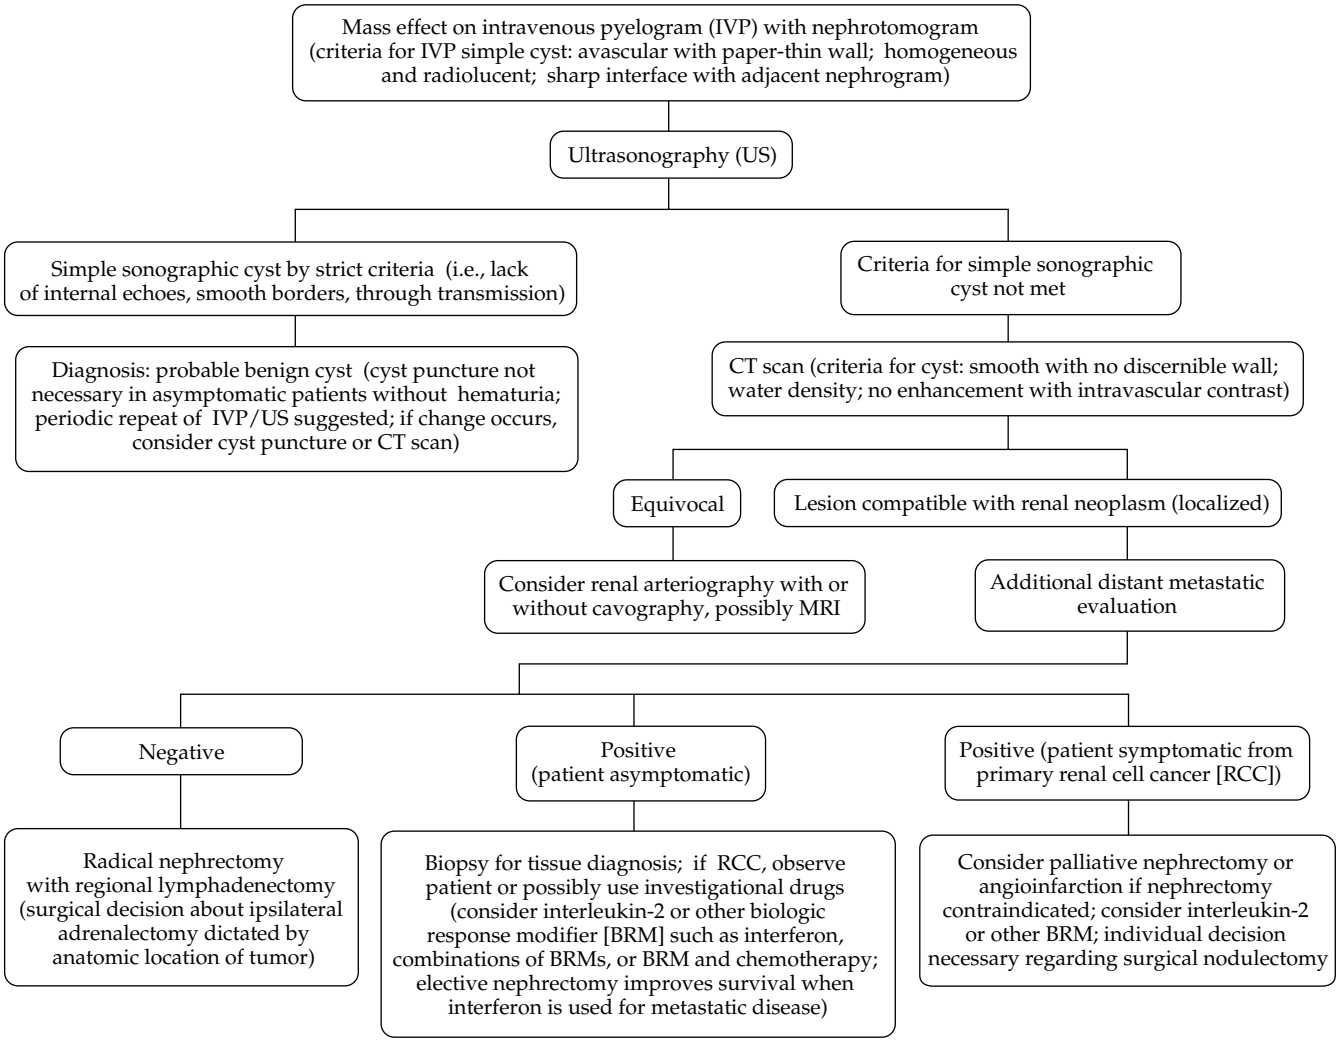

Figure 4 **Algorithm for the diagnostic evaluation of a renal mass.**

invade surrounding structures, such as the perinephric fat, posterior abdominal wall, inferior vena cava, ureter, adrenal gland, spleen, liver, or pancreas.[38] Hypertension may develop if the tumor compresses the renal parenchymal vasculature, causing increased renin production. Metastatic spread occurs via either the blood or the lymphatics. Common sites of distant metastasis include the lungs, lymph nodes, liver, bone, and brain, although metastatic lesions have been described in virtually every organ of the body.

Paraneoplastic syndromes are relatively common features in RCC, the most notable ones being hypercalcemia and erythrocytosis—from the ectopic secretion of parathyroid hormone (PTH)–like immunoreactive protein and erythropoietin, respectively. Anemia is often present. Hyponatremia from inappropriate secretion of antidiuretic hormone (ADH) and Cushing syndrome from ectopic production of adrenocorticotropic hormone (ACTH) also occur occasionally. Hypercoagulable states presenting as venous thrombosis or pulmonary embolism have been described. Other rare paraneoplastic syndromes that have been reported include amyloidosis, nonmetastatic hepatic dysfunction, limbic encephalitis, erythema gyratum repens, myopathy, and polymyalgia rheumatica.

Imaging Studies

In a patient with symptoms or signs that suggest a renal malignancy, the initial demonstration of a mass lesion is usually achieved with an intravenous pyelogram (IVP) or ultrasonography [*see Figure 4*]. An IVP may differentiate between renal cysts and malignant lesions and may reveal complications such as ureteral obstruction and hydronephrosis. Ultrasonography is a convenient method of evaluating a suspicious renal mass and is especially useful in differentiating between solid lesions and cystic lesions. When combined with an IVP, ultrasonography differentiates benign cysts from solid masses with an accuracy of more than 90%. It can also be used to evaluate the size of the contralateral kidney and to rule out obstruction and hydronephrosis, but it is not reliable for assessment of the renal vein, intrahepatic inferior vena cava, and retroperitoneal lymph nodes.

CT scanning is the technique of choice for diagnosis and staging. Performed with intravenous contrast, CT accurately defines the renal topographic anatomy, the size and location of the tumor, and the relationship of tumor to the surrounding vessels (renal vein and inferior vena cava). It also evaluates possible extracapsular spread, involvement of blood vessels or regional lymph nodes, and invasion of adjacent organs such as the

adrenals, spleen, pancreas, and liver. However, CT is less sensitive in detecting lesions smaller than 2 cm or tumor extension to the perinephric fat. Furthermore, its utility is reduced in patients in renal failure because intravenous contrast cannot be used safely in such cases. MRI may be superior to CT in detecting tumors that are less than 2 cm in diameter, in detecting extracapsular extension of tumor, and in delineating local anatomy. However, because of its expense and limited availability, MRI is often reserved for patients with known contraindications to iodine contrast or for when CT results are equivocal. The role of PET scanning has not been defined in this disease. Because 70% to 80% of RCCs are hypervascular, angiography is sometimes used to depict the lesion and provide a vascular map for the surgeon. Angiography is expensive and invasive and, therefore, should be used only for tumors in a solitary kidney, for vascular mapping before surgery, or for tumors in which angioinfarction is planned.

Staging

Staging of RCC is extremely important but sometimes difficult. The staging process should include a detailed history and physical examination, basic hematologic and biochemical studies, and a chest roentgenogram. A chest CT scan is sometimes necessary to rule out occult pulmonary and mediastinal metastasis. A bone scan should be obtained to rule out skeletal metastasis, although the yield is particularly low in asymptomatic patients with normal blood levels of alkaline phosphatase. Imaging of the brain with CT or MRI should be done in patients who have neurologic symptoms or signs. Fine-needle aspiration (FNA) of the tumor is usually not necessary, because if the FNA result is normal, the lesion will still need to be excised, given the possibility of a false negative result. On the other hand, if there is apparent extrarenal involvement of tumor, a CT-guided or ultrasound-guided biopsy of the primary lesion may be indicated if definitive surgical resection is not planned.

Tumor staging follows the standard TNM system and is predicated on the extent of the primary tumor (T), involvement of lymph nodes (N), and presence or absence of metastases (M).[39] Traditionally, T1 tumors have been defined as those limited to the kidney, with a diameter of 7 cm or less; T2 tumors, those limited to the kidney but greater than 7 cm in diameter; T3 tumors, those extending into major veins or invading adrenal or perinephric tissues but not beyond the Gerota fascia; and T4 tumors, those extending beyond the Gerota fascia. A recent modification of the staging classification divides T1 tumors into T1a (tumors 4 cm or less in diameter) and T1b (tumors greater than 4 cm in diameter), on the basis of reports showing lower 5- to 10-year survival for patients with larger T1 tumors.[39]

The pathologic stage of RCC is the most important prognostic factor. Stage I or II (tumor confined within the kidney capsule) is associated with a 5-year survival of 50% to 85%; stage III (tumor invading the renal vein, inferior vena cava, or regional lymph nodes), with 15% to 35% survival; and stage IV (T4 or N2 or metastatic disease), with 0% to 15% survival. It is still generally held that asymptomatic patients have a better prognosis than those with significant tumor-related symptoms, and normal performance status (i.e., 0) is being incorporated into many current prognostic algorithms as a favorable determinant. Important adverse prognostic factors include microscopic vascular invasion, high nuclear grade, and aneuploid DNA content. Mathematical models are being developed to incorporate these prognostic determinants into a single, predictive algorithm for individual patients,[40] but these algorithms have not yet been incorporated into standard practice internationally and still require extramural validation.

Non–clear cell histology has been investigated as a prognostic determinant but has proved difficult to assess because of the relatively small numbers of cases and the heterogeneity of histologic types (including chromophobe, collecting duct, and papillary carcinomas). However, a recent study suggests that this histologic grouping is associated with resistance to systemic therapy and poor survival, compared with the more common clear cell variants.[41] Similarly, Zisman and colleagues[42] have assessed the prognostic implications of the so-called unclassified RCC variant, comparing 29 cases of unclassified histology against a series of 264 clear cell cancers. This study also showed a more aggressive biologic behavior and worse clinical outcome, but it did suggest that immunotherapy in addition to nephrectomy may lead to an improved outcome, compared with nephrectomy alone or no active treatment. By contrast, another variant of renal malignancy, the so-called oncocytoma, characterized by dense infiltration of mitochondria within the cytoplasm, rarely metastasizes, and outcome is excellent with surgical management alone.

MANAGEMENT

Stages I, II, and III Renal Cell Carcinoma

The standard treatment for RCC in stages I through III is surgical resection. The conventional procedure is radical nephrectomy, which involves the en bloc removal of Gerota fascia with its contents and, usually, ipsilateral adrenalectomy.[43] Regional lymph nodes are resected during surgery. However, in patients with bilateral tumors, tumors in a solitary kidney, or a poorly functioning contralateral kidney, nephron-sparing surgery (partial nephrectomy or enucleation) may be considered. Recent studies have shown that for tumors 4 cm or less in size, nephron-sparing surgery provides the same rate of survival as radical nephrectomy.[44-46] However, nephron-sparing surgery does carry some risk of postoperative complications, such as hemorrhage and fistula formation, so the selection of candidates is important. In some centers, laparoscopic nephrectomy is being performed routinely for lesions of 4 to 5 cm or less, irrespective of whether nephron preservation is planned. Proponents suggest that this approach produces less morbidity because the scar is smaller and there is less disruption of the abdominal contents. Caution must also be exercised in case selection, to reduce the risk of inadequate or incomplete tumor clearance. Preoperative or postoperative radiation therapy does not reduce local recurrence or increase survival.

Stage IV Renal Cell Carcinoma

The outcome for patients with metastatic stage IV RCC is generally very poor, because RCCs are usually resistant to chemotherapy.[38] Most older clinical studies have shown response rates below 6%. Continuous infusion of floxuridine has reportedly produced response rates between 14% and 27%, although the responses are usually partial and short-lived. Investigators at the University of Chicago have published provocative data suggesting that the combination of weekly gemcitabine plus continuous-infusion fluorouracil (5-FU) may yield sustained remissions in up to 10% of cases,[47] but these data remain to be confirmed. In many cases of reported remission, the existence of true metastatic disease had not been confirmed histologically before the use of chemotherapy. This is important, because

granulomatous reactions may be found in the lungs and lymph nodes of patients with purportedly metastatic RCCs.

Surgical intervention is recommended in patients with solitary metastatic lesions that are resectable. Radiation therapy can be used to palliate symptoms from metastases to the bone or brain or from those causing spinal cord compression.

Spontaneous regression of metastatic RCC lesions has been reported in the literature, with an incidence rate of 0.8% to 3%. This has been reported for metastatic sites, including the brain, bone, regional and distant lymph nodes, liver, and, most commonly, the lungs. Complete and durable disappearance of tumors has been documented. The mechanism for this phenomenon is unknown, but it has been attributed to immunologic factors associated with reduction of tumor bulk. In many instances, spontaneous regression has occurred in supposed metastases that have not been confirmed by biopsy, and it is possible that these may have been reactive granulomata. Many of the so-called spontaneous regressions have followed surgical removal of the primary tumor, but in view of the relative rarity of this phenomenon, nephrectomy should not be routinely recommended in patients with stage IV RCC for the sole purpose of achieving spontaneous regression. Rather, nephrectomy should be considered for palliation of local symptoms such as pain and hematuria.

In a recent multicenter study of patients with advanced RCC, nephrectomy plus systemic immunotherapy with interferon was found to provide a statistically significant survival benefit over immunotherapy alone (12 months versus 8.5 months).[48] Although this difference is not very large, the order of magnitude is similar to the difference between MVAC and single-agent cisplatin in the Intergroup Advanced Bladder Cancer Study,[25] a trial that led to the establishment of MVAC as a standard of care. In addition, the tails of the survival curves were statistically different. However, critics have suggested that the results of the nephrectomy-plus-immunotherapy arm are equivalent to those reported in trials of single-modality therapy in Europe and that caution should be used in interpreting these data at this early stage. Such criticism is reasonable, but the fact is that this was a well-constructed, randomized trial with a comparison reflecting randomized cohorts. As such, this trial was less likely to be subject to the various selection biases of historical or nonrandomized comparisons. Consequently, it seems reasonable to view the combination of nephrectomy and immunotherapy as a new standard of care. However, it is not yet clear whether this applies to combinations that involve interleukin-2 (IL-2) and other, more novel cytokines.

IL-2 works through the activation of cytotoxic T cell subgroups and stimulation of cytokine release. A multicenter trial of IL-2 in patients with metastatic RCC showed therapeutic benefit (complete response rate, 4%; partial response rate, 8%; median duration of response, 23 months) but also displayed substantial toxicity, mainly from a capillary leak syndrome, which can cause cardiovascular ischemia, renal failure, and shock. Supportive measures such as use of vasopressors and intensive care unit monitoring are often needed.[49] Interferon alfa has been reported to be effective, with an overall response rate of 12%, although complete responses are less common.[50] A recent randomized study comparing IL-2 alone, interferon alfa alone, and the two agents together found a significantly higher response rate in the combination group (18.6%, versus 6.5% for IL-2 and 7.5% for interferon alfa).[50] Event-free survival at 1 year was also higher in the combination group, although there was no difference in overall survival.[50] However, other studies using similar combinations have failed to show any benefit over IL-2 used alone.[51] In general, it is believed that improved outcomes appear to be associated with the use of cytokines,[52] although most of the available data appear to be subject to the limitations of major case selection bias.

Immunologic factors seem to influence long-term survival in patients with advanced RCC. On the basis of studies showing that allogeneic stem-cell transplantation can induce curative graft-versus-leukemia reactions in some hematologic malignancies, transplantation of nonmyeloablative allogeneic peripheral blood stem cells has been used in advanced RCC, with some success.[53] Very heavy case selection occurs in the application of such strategies, however, and graft versus host disease (GVHD) is a very significant problem.[54]

Germ Cell Tumors of the Testis

The management of metastatic testicular germ cell tumors has become one of the paradigms of cancer treatment, reflecting progress in the development of chemotherapy and an improved understanding of the principles of tumor biology and of the importance of multidisciplinary management. An increased understanding of risk factors has allowed oncologists to tailor treatment to the level of risk. Because it has been determined that some treatment strategies are associated with significant late effects, modifications of the standard treatment regimens are cautiously being explored in an effort to reduce these late effects.

EPIDEMIOLOGY AND ETIOLOGY

Testicular cancer appears to be increasing in frequency in Western society. At the beginning of the 20th century, about two to three new cases per 100,000 males were identified each year. At present, the annual incidence appears to be approximately five to seven new cases per 100,000 males. This illness is found predominantly in white men and is uncommon in black and Asian populations. The etiology is unknown, although specific associations have been identified with testicular maldescent, infertility, family history of testicular cancer, carcinoma in situ (or atypical germ cells), the presence of a specific abnormality of the short arm of chromosome 12, and multiple atypical nevi.[55-61]

PATHOGENESIS

Most germ cell tumors arise from tissues derived from primordial cells that originate within the genital ridges and that usually migrate in the midline to the testicles. Less frequently, these cells migrate to the retroperitoneum, mediastinum, and pineal region; these are the source of extragonadal germ cell tumors. Two major groups of tumors, seminomas and nonseminomatous germ cell tumors (NSGCTs), form at these sites; the two groups arise from a common origin.[55,56] In the testicles, the tumors arise from precursor cells, atypical germ cells, or carcinoma in situ.[57] Less than 5% of testicular cancers consist of lymphomas and other non–germ cell tumors.[55,62] The different development pathways of these tumors are of particular importance with regard to late relapse (see below).

The most common type of seminoma, the classic variant, consists of uniform round or polygonal cells with abundant cytoplasm and a centrally placed nucleolus.[55] Less commonly, spermatocytic and anaplastic variants have been described, although it should be noted that the anaplastic variant sometimes represents a misdiagnosed NSGCT.[63] About 30% of seminomas include syncytiotrophoblastic giant cells; these may produce a

marker protein, human chorionic gonadotropin (hCG). A subgroup of seminomas has been identified that morphologically resemble a solid variant of yolk-sac carcinoma, with a worse prognosis than other seminomas when treated with conventional radiotherapy or standard chemotherapy regimens.[63] New biochemical determinants of outcome identified in studies of the human genome may explain the differences in the natural history of these tumors—for example, aberrations of expression of c-*kit* or other genes that regulate the cell cycle.

NSGCTs have several histologic subtypes: embryonal carcinoma, mature and immature teratoma, endodermal sinus tumor, and choriocarcinoma.[55] Many NSGCTs include several of these elements: histologic analysis may show undifferentiated cancer; trophoblastic tissue; and varying components of cartilage, glandular tissue, or hair.[55,56] Some elements of NSGCT may produce hCG, whereas endodermal sinus tumor classically produces α-fetoprotein (AFP). Embryonal carcinoma may also produce AFP. The presence of AFP in the circulation signifies that a tumor has nonseminomatous elements, even if the primary tumor has been diagnosed as a pure seminoma, and this constitutes an indication to treat the patient for nonseminomatous germ cell malignancy.

Testicular seminomas and NSGCT have many features in common, including age at presentation; an orderly pattern of spread from the testis to the surrounding supportive tissues or up the spermatic cord to regional and distant lymphatic channels and, sometimes, to visceral sites via blood-borne metastasis; and the elaboration of tumor markers. [55,56] Both have a characteristic marker on the short arm of chromosome 12[58,59] and are associated with testicular maldescent, carcinoma in situ of the testis,[60] and an unexplained association with the syndrome of multiple atypical nevi.[60] Both histologic patterns have been linked to a susceptibility gene localized to Xq27,[61] and tumors of both types are highly sensitive to chemotherapy.[64,65]

There are also important differences between testicular seminomas and NSGCTs. With seminoma, the age range at presentation is older, the prevalence of subsequent second primary tumors is slightly higher, and the patterns of metastasis are different. Seminomas have marked radiosensitivity, whereas NSGCTs have marked radioresistance. The c-*kit* ligand is expressed more heavily on seminomas than on NSGCTs.[66,67] It was thought that seminomas would be more sensitive than NSGCTs to treatment with modulators of these ligands, such as imatinib mesylate (Gleevec), but this does not seem to be true of the currently available modulators. Extragonadal seminomas (dysgerminomas) are sensitive to chemotherapy or radiotherapy and are relatively easily cured. In contrast, extragonadal NSGCTs have much higher relapse rates and have cure rates that are far inferior to their testicular counterparts.[68-70] The reasons for these differences are unknown, given that testicular and extragonadal tumors share virtually identical histologies and etiologic associations and have similar patterns of spread.

DIAGNOSIS

Clinical Findings

Primary testicular cancer commonly presents as a painless enlargement of the testis, often noted on self-examination.[71] (Despite popular advocacy of testicular self-examination [TSE], however, there are no randomized trial data to prove that TSE programs improve testicular cancer survival.) There may be local pain, which is often associated with hemorrhage within the tumor.[72] Occasionally, a large tumor will drag on the spermatic cord, causing referred pain in the region of the flank; therefore, this symptom does not necessarily indicate the presence of retroperitoneal lymph node metastases. Unless the patient has previously undergone surgery for testicular maldescent or has had scrotal violation as part of the initial approach to the primary tumor (a cardinal error of management), it is uncommon for inguinal lymph nodes to be involved. Lymphatic drainage of the testis is classically to the nodes at the level of the ipsilateral renal hilum,[73] although contralateral spread will sometimes occur unexpectedly.

The symptoms of metastatic germ cell tumors are protean and depend on the sites of involvement.[74,75] Most commonly, the retroperitoneal lymph nodes are involved early, which can result in lumbar backache or in central or lower abdominal pain. Occasionally, renal colic occurs from ureteral obstruction by advanced lymph node metastases. Pulmonary metastases may be asymptomatic or, if extensive, may be associated with dyspnea, cough, hemoptysis, or chest pain. Brain metastases, although uncommon, may present as headache, confusion, dementia, or focal neurologic syndromes and, occasionally, may be detected in the routine staging workup.[76,77] Liver and bone involvement, although seen frequently in the past, are now distinctly uncommon at presentation but may be associated with relapse. When these features are seen at presentation, choriocarcinoma should be considered to be the most likely histologic subtype. Seminoma will occasionally metastasize to bone, however.

Germ cell tumors may be associated with nonspecific or constitutional symptoms, including weakness, sweats, fevers, malaise, and asthenia, especially in the case of advanced disease. Gynecomastia may signal the presence of testicular cancer and is often associated with raised circulating levels of hCG; curiously, this condition sometimes occurs after the completion of therapy and reflects only changes in the hormonal milieu and does not necessarily signal a relapse.

The presentation of extragonadal germ cell tumors is similar to that of gonadal tumors but is more heavily influenced by the site of origin. For example, pineal germ cell tumors may be associated with headache, confusion, visual changes, strokelike syndromes, and other neurologic presentations that reflect the site of intracranial involvement.[68] The presentation of retroperitoneal germ cell tumors is identical to that of testicular tumors with retroperitoneal metastases, but retroperitoneal germ cell tumors do not have an obvious testicular primary tumor. Mediastinal germ cell tumors are commonly associated with dyspnea, cough, hemoptysis, chest or back pain, and, occasionally, superior vena cava syndrome. Mediastinal NSGCT is commonly associated with metastases at presentation, and the symptoms will reflect the sites of involvement.

Laboratory Tests

Imaging techniques are used both in the initial assessment of the extent of disease and serially (along with repeated physical examination) to monitor efficacy of treatment. Plain radiographs and CT scanning constitute the standard modalities; CT has almost completely replaced lymphangiography.[78] MRI scans are superior to CT for the study of brain metastases. Although there is preliminary evidence that PET scanning with labeled fluorodeoxyglucose may be useful in assessing for residual viable cancer after chemotherapy for germ cell tumors, this technology has not yet secured a defined place in management because of conflicting reports regarding specificity and sensitivity.[79,80]

Table 3 Stage Classification of Testicular Cancer

Clinical Involvement	*Classification System*		
	Royal Marsden[65]*	*Conventional United States*	*AJCC 2002[39]*
Testis only	I	A	I
Abdominal nodes	II	B	IIA-IIC
Mediastinum/ supradiaphragmatic	III	C	IIIA
Visceral metastases	IV	C	IIIA-C

*The Royal Marsden system also contains subclassifications (A, B, C), which depend on the extent of disease.
AJCC—American Joint Commission on Cancer

The circulating tumor markers AFP and hCG should be measured as part of the initial diagnostic workup and in the monitoring of therapy. The first specimens should be obtained before primary surgery. AFP has a normal half-life in the circulation of 5 to 7 days, and hCG has a half-life of 24 to 36 hours.[81] When levels of a circulating marker fail to decline according to normal half-life gradients after orchiectomy, this suggests continuing release of the marker into the blood by occult metastatic disease. Such cases require further investigation and treatment.[82] In patients with metastatic disease, the absolute levels of tumor markers in the blood constitute independent prognostic determinants (see below). During chemotherapy, the release of markers from dying cancer cells may result in a transient elevation of blood levels, after which they will decline according to normal half-life gradients. Thus, serial measurements should be taken to determine whether the patient is responding adequately to treatment. If these repeated measurements are not taken during chemotherapy, marker release will not be identified and the calculation of tumor marker half-life will be incorrect, suggesting a prolonged tumor-marker decline and incorrectly implying the presence of resistant disease.

Another important, but nonspecific, tumor marker is lactate dehydrogenase (LDH). Although LDH levels are elevated in many conditions, both benign and malignant, levels 10 or more times higher than the upper limit of normal are associated with a significantly worse outcome with standard chemotherapy (see below).

Staging

The extent of germ cell cancer is classified by standard staging systems. The staging regimen includes both noninvasive imaging methods and, in some cases of NSGCT, retroperitoneal lymph node dissection. In recent years, the European and United States classifications for testicular cancer have become quite similar [*see Table 3*].

MANAGEMENT

Stage I or A Disease

One of the most controversial issues in the management of germ cell tumors is the treatment of patients without evidence of metastatic disease (stage I or A disease).[83] Traditionally, stage I seminomas were treated with inguinal orchiectomy and adjuvant radiotherapy (originally with doses of around 35 to 40 Gy; later, with 25 to 30 Gy). With this approach, cure rates approached 90% to 95%, especially after the introduction of CT scanning and gallium scanning as part of the diagnostic workup. Today, many institutions use active surveillance, an approach involving close observation after inguinal orchiectomy, with serial measurement of tumor markers and repeated CT scans. Although this approach was initially developed for NSGCT, recent studies have suggested that it may have safe application to the management of seminomas, if it is implemented meticulously.[84,85]

Traditionally, stage I (A) NSGCT has been managed with inguinal orchiectomy, followed by a radical retroperitoneal lymph node dissection (RPLND). This has led to cure in more than 90% of cases and has even cured some patients with histologic evidence of lymphatic micrometastases without the need for chemotherapy. If extensive lymph node metastasis is identified at surgery, chemotherapy is usually required to achieve cure. The major disadvantage of this surgical approach has been the risk of surgical complications, including perioperative pain, pulmonary emboli, accumulations of lymphatic fluid, and hemorrhage. Of particular concern to men in the reproductive years is incompetent ejaculation secondary to transection of retroperitoneal nerves; such patients can achieve orgasm, but the interrupted nerve pathways preclude successful ejaculation of semen.

The potential for recurrence of stage I testicular cancer is indicated by adverse prognostic factors, including local extension to spermatic cord and surrounding structures, undifferentiated histology (embryonal carcinoma), and lymphatic-vascular invasion.[82,86] In addition, failure of tumor markers to normalize appropriately is associated with an increased risk of relapse[82] and constitutes an indication for chemotherapy. Choriocarcinoma has been suggested as an adverse prognostic determinant, but multivariate analysis has failed to support this because of both small case numbers and the significant association with other factors, such as cord involvement and failure of hCG to normalize.

Adjuvant radiotherapy does not increase survival after orchiectomy for stage I NSGCT[65,87] and is therefore no longer used. Instead, at many centers orchiectomy for stage I NSGCT is now followed with active surveillance rather than radiotherapy.[85,88] This approach, predicated on the high cure rates for good-risk metastatic disease, requires a meticulous initial diagnostic workup, with the exclusion of patients with established lymph node or visceral, small-volume metastases. For patients without major risk factors and with confirmed normal results on imaging studies, the relapse rate after orchiectomy alone is less than 25%. Thus, active surveillance should spare 75% of patients from unnecessary adjuvant therapy (RPLND or radiotherapy).[89] The trade-off is that because the risk of relapse is higher with surveillance than after RPLND, fewer patients undergo extensive abdominal surgery but, in exchange, more patients need subsequent chemotherapy.[83]

The most important risk associated with active surveillance involves lack of compliance, either through patients who do not adhere to the follow-up schedules or through physicians who are inexperienced and insufficiently familiar with the requirements of a rigorous program of follow-up. In either instance, patients who experience recurrences may present with far-advanced disease, with a lower potential for cure.

There is no single follow-up schedule that can be considered optimal.[90] However, the successful approaches all include meticulous initial diagnosis and workup and a structured approach to

routine follow-up, with serial assessment of clinical status and tumor markers and repeated chest radiographs and CT scans [*see Table 4*]. Over time, less frequent CT scans are performed, but frequent tumor-marker measurements and chest x-rays remain necessary. In centers with clinicians who are experienced in the conduct of surveillance programs and where a clear policy of patient selection and follow-up has been defined, cure rates of 90% to 95% or greater have been reported with active surveillance.[83] Occasionally, patients have relapses that prove intractable to therapy, and rarely, patients develop chemotherapy-related complications, such as leukemia.[91,92] Nevertheless, cure rates with adjuvant RPLND or radiotherapy protocols also are not 100%, so active surveillance remains a reasonable option. In choosing between active surveillance and adjuvant therapy, it is important for the clinician to explain the various options in detail and to involve the patient in the decision.

The appropriate management of stage I disease in patients with adverse risk factors is also controversial. Adjuvant chemotherapy after orchiectomy can prevent early relapse in patients who have locally extensive tumors with involvement of spermatic cord and other high-risk factors.[93] However, in patients who would not have suffered relapses, this approach results in unnecessary exposure to the toxicity of chemotherapy. Given that up to 50% of patients with high-risk stage I disease do not have relapses,[59,82,90] close observation may be a reasonable approach in the hands of an experienced practitioner. Another appropriate option is RPLND, which can define lymph node involvement, thus identifying patients who are likely to require chemotherapy. The drawback of RPLND is that some patients without evidence of retroperitoneal lymph node metastasis experience relapse in the lungs or other visceral sites. Ideally, a patient with high-risk stage I testicular cancer should be referred to a center of excellence for a second opinion before a final management plan is determined.

Lymph Node Metastases of 5 cm or Less in Diameter

In patients with seminoma who have evidence of small-volume lymph node involvement (stage IIA or IIB; stage B), treatment is usually with radiotherapy to the ipsilateral lymph nodes in the pelvis, with extension to the para-aortic chain (including the involved nodes).[94] Although there has been a recent tendency toward dose reduction to a level of 25 Gy, many clinicians use a more traditional dose of 30 to 35 Gy to ensure local tumor control. There is clear evidence that prophylactic mediastinal lymph node irradiation does not improve outcome and may, in fact, compromise subsequent chemotherapy, should that be needed. The preliminary experience with doses of 20 to 25 Gy suggests no increase in the pattern of early relapse, but longer follow-up is required to determine whether these lower doses are truly safe.

In NSGCT, the optimal management of early stage II disease is controversial. There is general agreement that radiotherapy has no role. However, the advocates for RPLND believe that surgery offers both diagnosis and definitive treatment; they cite surgical cure rates of up to 50%, particularly in patients with only microscopic evidence of lymph node involvement.[95] With this approach, chemotherapy can be used for salvage in most cases of relapse.[96] In many centers, adjuvant chemotherapy is administered routinely for patients with more than three to five nodes containing tumor.

The alternative approach is to offer first-line cytotoxic chemotherapy to such patients on the basis of cure rates approaching 100% for patients with small-volume metastases limited to the retroperitoneal nodes. The disadvantages of each approach are the morbidity from surgery and, with chemotherapy, the acute toxicity and the potential for late complications. No randomized trial has compared surgery with chemotherapy for small-volume stage II (B) disease. A randomized trial of adjuvant chemotherapy versus observation with salvage chemotherapy at the time of relapse in patients with stage II NSGCT showed no statistically significant difference in outcome.[97] Given the lack of data supporting any one approach, the choice of treatment is usually determined by the biases of the clinician and the preferences of the patient.

Another controversial issue is the management of patients with marker-only disease (i.e., without evidence of specific lymph node or other metastases but with persistent elevation of serum marker levels after orchiectomy). RPLND may reveal occult lymphatic involvement in some cases, achieving cure in up to half of these; however, 50% of the patients who undergo

Table 4 Active Surveillance Schedules for Stage A (or I) Nonseminomatous Germ Cell Tumors[138,139]

Year after Inguinal Orchiectomy	*Test*	*Annual Schedule (Number of Tests) by Institution*				
		Royal Marsden Hospital	*Memorial Sloan-Kettering*	*University of Southern California*	*Charing Cross Hospital*	*Princess Margaret Hospital*
1	H&P	12	12	8-12	12	12
	Tumor markers	12	12	8-12	25	12

	Chest x-ray/CT scans of abdomen and pelvis	2?/0	3,2/2	2–3/1–2	2–3	3,2/0

Note: More frequent follow-up and CT scans are indicated for patients with seminoma after 3 yr because of the risk for late relapse.
*Indicated if abnormality detected on chest x-ray.
†Chest CT scan repeated if baseline scan is abnormal.
H&P—history and physical examination

surgery will eventually require chemotherapy. As with small-volume nodal metastases, the cure rates with cytotoxic chemotherapy are close to 100%, although there is a risk of additional late toxicity compared with surgery alone.

Advanced Lymph Node Involvement and Distant Metastases

For patients with lymph node metastases measuring more than 5 cm in diameter (stage IIC or stage C disease) and for those with visceral metastases (e.g., lung, liver, bone), the treatment of choice is systemic chemotherapy.[96,98] The early combination of cisplatin, vinblastine, and bleomycin (the PVB regimen) produced cures in up to 70% of cases.[64,65] Subsequently, a less toxic regimen, in which vinblastine was replaced by etoposide, was tested and shown to be equivalent to the PVB regimen.

Certain prognostic features identify patients who are likely to experience inferior outcomes with standard cisplatin-based chemotherapy and, instead, require more intensive front-line chemotherapeutic regimens.[99-101] Adverse prognostic factors include greatly elevated serum tumor marker levels,[96,99,100,102,103] the volume of disease,[100,101] the number of pulmonary metastases,[102,103] and certain sites of involvement.[96,100,102,103] In the last instance, metastatic disease in the brain, liver, and possibly bone is associated with a worse prognosis with standard PVB therapy.[103]At the Memorial Sloan-Kettering Cancer Center, a numerical algorithm for attribution of prognosis, predicated on tumor marker levels and extent of disease,[99] has been used to identify patients requiring specific dose-intensive treatment strategies.[104]

Although most systems classify these tumors into similar prognostic groups, comparing results was difficult in the past because of subtle differences in classifications that nevertheless had substantial effects on the results of treatment.[105] As a result, an international collaboration led to a common system of classification to ensure uniform reporting of treatment results [*see Table 5*].[106] This classification, based on a cumulative experience with 5,202 NSGCTs and 660 seminomas in 10 countries, includes three prognostic groupings that are based on 5-year survival: good (91% 5-year survival), intermediate (79%), and poor (48%). However, it must be emphasized that cure is possible in patients with tumors in the worst-prognosis group; even patients with brain metastases may be cured by aggressive multimodality treatment.[76,77]

For patients with good- or intermediate-risk disease, replacement of vinblastine with etoposide in combination chemotherapy (PEB chemotherapy) has reduced acute toxicity without lowering high cure rates.[107] However, recent studies have shown occasional cases of acute leukemia in patients who have received etoposide-containing regimens, so this strategy will require further reassessment. Deletion of bleomycin in an attempt to reduce toxicity has resulted in lower cure rates[108-110] and has been abandoned in most centers. However, investigators at the Memorial Sloan-Kettering Cancer Center believe that bleomycin can be safely omitted, provided that the dose of etoposide is maintained at 500 mg/m^2.[111]

Three cycles of PEB chemotherapy have been shown to be equivalent to four cycles with respect to cure rate and are associated with less toxicity.[112] In the study demonstrating this equivalence, however, the patient numbers were not large enough to exclude a substantial difference in survival for patients with intermediate-prognosis disease. It will be important to maintain caution in the development of new trials that have the reduction of side effects of therapy as a primary end point, because there is the risk that ameliorating toxicity will be achieved at the price of reducing cure rates, as was found with bleomycin. In addition, randomized trials have shown that cure rates are reduced if cisplatin is replaced by carboplatin in combination-chemotherapy schedules for germ cell tumors.[113]

Table 5 International Germ Cell Tumor Group Classification of Metastatic Disease

*Criteria for Poor Risk Nonseminomatous Germ Cell Tumors**
Mediastinal primary site
Serum α-fetoprotein (AFP) level > 10,000 ng/ml
Serum human chorionic gonadotropin (HCG) level > 50,000 ng/ml
Serum lactate dehydrogenase (LDH) level > 10 times the upper limit of normal
Presence of nonpulmonary visceral metastases

*No seminomas are classified as poor risk.

Poor-Risk and Previously Treated Metastatic Germ Cell Tumors

Early studies of poor-risk metastatic disease were confounded by differences in systems of risk classification. For example, it was initially reported that a high-dose combination of cisplatin, etoposide, vinblastine, and bleomycin (PVeBV) yielded unsurpassed objective response rates and apparently increased survival in patients with so-called poor-risk disease. However, a randomized trial comparing this regimen with a standard-dose regimen failed to show any evidence of a significant benefit from PVeBV; these investigators suggested that the original difference in outcomes related to differences in risk attribution.[114]

Several recent reports have suggested that high-dose therapy with autologous bone marrow transfusion or peripheral stem cell support may improve outcome in patients with truly poor-risk disease (consistent with the international consensus classification)—in particular, those who have experienced relapses of germ cell tumors after initial chemotherapy and those with mediastinal NSGCT.[38,115-117] However, more extensive information is required from randomized clinical trials before a definitive statement on this topic can be made. At present, the North American Intergroup is conducting a study in which patients with poor-risk metastatic disease are randomly allocated to treatment with a standardized PEB regimen or to a similar regimen followed by high-dose therapy with autologous rescue.

One approach to poor-risk disease involves rapid cycling, dose-intense therapy (within the conventional dose range), with alternating delivery of cisplatin-vincristine-methotrexate-bleomycin (POMB regimen) and actinomycin D–cyclophosphamide-etoposide (ACE).[118] At Charing Cross Hospital, long-term survival with POMB/ACE treatment was recorded in 75% of poor-risk cases. The value of this regimen remains controversial, however.[118,119] Recently, the novel cytotoxic agents paclitaxel[120] and gemcitabine[121,122] have demonstrated activity in previously treated patients. The utility of these agents is currently being defined in a series of phase II and phase III clinical trials that are not yet complete. There are no final data reflecting their activity in previously untreated cases, but there may be an objective single-agent response rate of up to 20% in patients who have previously received cisplatin-containing regimens, depending on whether they have secured initial remissions in response to first-line cis-

Table 6 Late Toxicity of Treatment for Testis Cancer

Second malignancies	Leukemia Melanoma and dysplastic nevi Other solid tumors

platin-containing regimens. These novel agents have been incorporated into combination regimens. For example, treatment with paclitaxel, ifosfamide, and cisplatin has produced an objective response rate of 77% in patients with relapses of germ cell tumors.[52] In heavily treated patients, the combination of paclitaxel and gemcitabine has yielded a response rate of 20%, with occasional long-term survival.[123] It is likely that these agents will form the basis of many future trials, especially trials that focus on poor-risk previously untreated cases.

Investigational protocols have been developed that incorporate some of the concepts enumerated above—for example, rapid cycling of dose-intense regimens of paclitaxel-ifosfamide and carboplatin-etoposide, which appear to yield sustained remission beyond 30 months in around 50% of patients with an unfavorable prognosis for salvage response.[52] Although there is no uniform classification of unfavorable prognosis for salvage treatment, a reasonable approach has been proposed by investigators at the Memorial Sloan-Kettering Cancer Center, which includes extragonadal primary site, progressive disease after an incomplete response to first-line platinum therapy, or poor response or lack of response to prior treatment with cisplatin plus ifosfamide-containing conventional-dose therapy.

Similar data have been reported by Rick and colleagues,[124] with a 30% long-term survival in patients who have experienced relapses or whose cancers have been refractory to treatment with cisplatin-based regimens. In this study, conventional-dose salvage therapy with cisplatin, ifosfamide, and paclitaxel was followed by one cycle of high-dose chemotherapy with thiotepa, carboplatin, and etoposide. In most of these studies, the impact of case-selection bias and improved supportive care versus that of high-dose therapy have not been clearly defined.

Treatment of Patients with Late Relapse

Late failure of treatment—that is, failure that occurs well beyond the period usually expected for relapse—is an issue of increasing concern. Centers that manage large numbers of patients with germ cell tumors are beginning to occasionally see patients with relapse after more than 10 years, characterized by malignant teratoma or the evolution of non–germ cell elements associated with germ cell tumors (including adenocarcinoma, soft tissue sarcoma, or neuroendocrine carcinomas). These cases are proving to be difficult to treat effectively and are associated with a high mortality. As yet, there is no defined optimal approach to treatment. At the University of Southern California, our management generally depends on the histology of the late relapse. Our management is usually multidisciplinary, and it particularly involves the combination of cytoreductive surgery and potentially non–cross-resistant chemotherapy. Gemcitabine and the taxanes appear to be quite active in this context, especially for adenocarcinomas that arise from germ cell tumors, and ifosfamide-based regimens seem to be effective against tumors with sarcomatous differentiation. Because optimal management of late relapses has not yet been defined, we believe that such cases should be treated in tertiary referral centers.

TOXICITY OF CHEMOTHERAPY

The acute toxicity of chemotherapy has been well defined and includes nausea and vomiting, myelosuppression, alopecia, allergic phenomena, pneumonitis, infection, anorexia, and a range of relatively uncommon complications.[125,126] Most of these effects can be controlled by modern supportive techniques [*see 12:IV Principles of Cancer Treatment*].

The long-term or delayed side effects of treatment are now becoming increasingly recognized, especially because the medical community has become used to the concept of germ cell tumors as a curable entity and because the focus is now shifting to the avoidable costs of such cure [*see Table 6*]. Of particular concern is an apparent increase in the prevalence of cardiovascular and cerebrovascular diseases, hypercholesterolemia, and a range of subtle metabolic abnormalities after cisplatin-based chemotherapy.[127-129] Perhaps more sinister is the prevalence of second malignancies, including leukemia, soft tissue sarcoma, malignant melanoma, and other solid tumors.[125,130,131]

Given that some of these delayed effects have been identified in patients 5 to 10 years after treatment, it is possible that the reported prevalence figures are low and will increase with the duration of follow-up or that other unsuspected problems will emerge. For that reason, it is essential for careful and focused follow-up to be continued in such cases, despite the efforts of many health maintenance organizations to reduce structured follow-up by specialists by returning the care of these patients to primary care physicians.

The author has received research grant support from Eli Lilly and Company, Bristol-Myers Squibb Co., and Aventis Pharmaceuticals, Inc., and has acted as a consultant for these companies.

XV CHRONIC LYMPHOID LEUKEMIAS AND PLASMA CELL DISORDERS

Bruce D. Cheson, m.d.

The chronic lymphoid leukemias are a group of relatively indolent clonal lymphoid disorders, primarily of B cell lineage, that includes chronic lymphocytic leukemia (CLL), prolymphocytic leukemia (PLL), hairy-cell leukemia (HCL), and the leukemic phase of non-Hodgkin lymphoma (NHL).

The plasma cell dyscrasias are characterized by an accumulation of malignant plasma cells in the bone marrow, bone, or soft tissues. The name reflects the finding on bone biopsy of multiple tumors of plasma cells, rather than a single discrete mass. These diseases include multiple myeloma (MM), extramedullary plasmacytoma, and amyloidosis. Waldenström macroglobulinemia, characterized by IgM gammopathy, lymphadenopathy, and hepatosplenomegaly, was formerly included with these disorders but is now more appropriately classified as a lymphoplasmacytic, indolent non-Hodgkin lymphoma.[1]

Chronic Lymphocytic Leukemia

EPIDEMIOLOGY

CLL is the most common form of leukemia in adults in Western countries. The annual incidence of this disease appears to be decreasing in the United States, from 10,000 new cases a year a decade ago to an estimated 7,300 in 1998.[2] This decline may reflect, in part, a more appropriate classification of other lymphoid malignancies previously misdiagnosed as CLL. The median age at diagnosis is 62 years, with only 10% to 15% of cases diagnosed before age 50. CLL appears to be more common in males than in females and more common in Jewish people of Russian or Eastern European ancestry than in the general population. It occurs with similar frequency in blacks and whites. CLL is uncommon in Japan, China, and other Asian countries.

ETIOLOGY

The etiology of CLL is unknown, and there are no known causative risk factors. Studies have indicated no relationship between chemical exposure, ionizing radiation, and drug intake and the development of CLL.[3-5] Families with multiple cases of CLL have been reported, and there have been several sets of affected twins, with an increased frequency of lymphoproliferative disorders in first-degree relatives of CLL patients.[6] Spouses of patients with CLL who themselves have CLL have also been reported.[6]

PATHOGENESIS

CLL is a clonal expansion of mature-appearing lymphocytes. Although the morphologies of normal and CLL B cells are similar, there are marked molecular and immunologic differences between the two cell populations. Both CLL and normal cells express B-lineage antigens (e.g., CD19 and CD20); however, CLL cells also express activation antigens (e.g., CD23) and CD5.

$CD5^+$ B cells are not unique to CLL; they can also be found in small numbers in the germinal center of normal lymph nodes and in the peripheral blood. The early transforming events are unknown; however, CLL cells are thought to be anergic B cells with a defect in apoptosis. Nevertheless, there are numerous functional, immunologic, and molecular differences between the CLL B cell and the benign $CD5^+$ B cell.[7,8]

Cytogenetics

Acquired cytogenetic abnormalities can be detected in approximately 50% of patients with CLL by use of conventional banding techniques[9]; these abnormalities are more frequent in the advanced stages of the disease. However, more sensitive assays, such as fluorescence in situ hybridization (FISH), have revealed defects in more than 80% of cases,[10] with deletions of 13q detected in more than half of cases, deletions of 11q detected in 15% to 20% of cases, and trisomy 12 detected in 15% to 20% of cases. More than a third of patients have complex abnormalities.

Molecular Biology

No single genetic aberrancy has been implicated in the pathogenesis of CLL. However, CLL cells are characterized by a defect in apoptosis, or programmed cell death. Overexpression of the *bcl-2* gene is present in more than 70% of cases, even in the absence of the t(14;18) chromosome rearrangement.[11] The ratio of the antiapoptotic gene *bcl-2* to the proapoptotic gene *BAX* is increased in CLL cells, which favors cell survival. Deletions involving 13q34 have been identified in as many as 70% of cases by conventional cytogenetics; this defect, previously thought to be at the site of the retinoblastoma suppressor gene, has since been shown to be telomeric to that region.[12] This region of loss contains a novel suppressor gene called *DBM* (disrupted in B cell malignancy). There is an apparent correlation between the antiapoptotic protein Mcl-1 and resistance to chemotherapy.[13]

DIAGNOSIS OF CHRONIC LYMPHOCYTIC LEUKEMIA

Clinical Presentation

Patients with CLL are generally asymptomatic at presentation, and the diagnosis is often made incidentally when lymphocytosis is noted at the time of a routine evaluation. The results of physical examination are normal in 20% to 30% of patients at initial presentation, and lymphadenopathy, hepatosplenomegaly, or both are present in 40% to 50% of patients. However, as the disease progresses, generalized adenopathy and splenomegaly become common features.

Infections are a frequent complication and may be recurrent, with the most common pathogens being *Staphylococcus, Streptococcus,* other bacteria that require opsonization, and the herpesvirus.

As many as 20% of patients with CLL may have a positive result on the Coombs antiglobulin test, although clinical hemolysis is apparent in only half of those patients. The frequency of immune thrombocytopenia appears to be about 2%.

Pure red cell aplasia occurs in fewer than 5% of cases of CLL. Treatment options include corticosteroids, cyclosporine with or without concurrent corticosteroids, and systemic chemotherapy for CLL.[14]

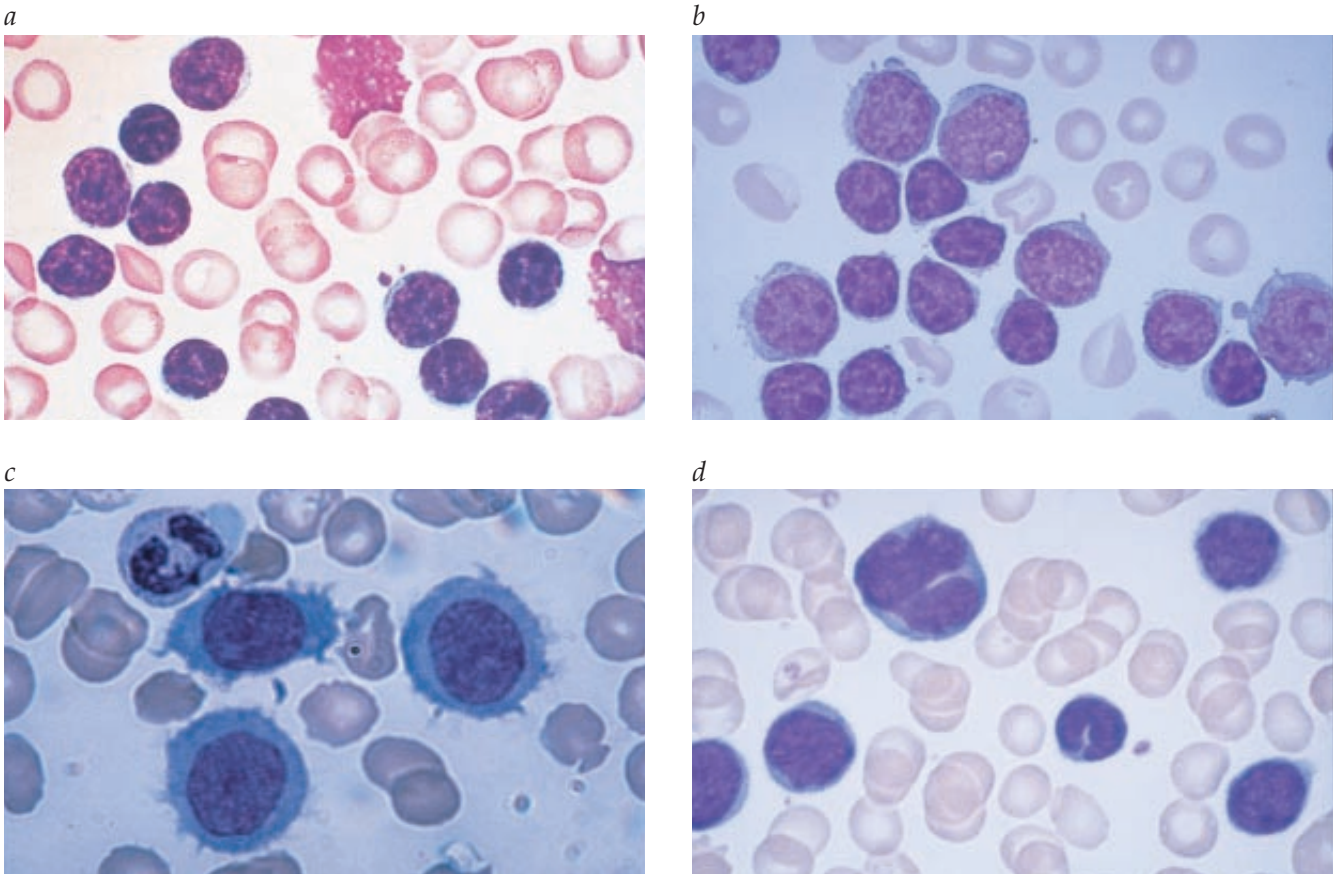

Figure 1 **Chronic lymphocytic leukemia (*a*), prolymphocytic leukemia (*b*), hairy-cell leukemia (*c*), and mantle cell lymphoma (*d*).**

Laboratory Findings

The diagnosis of CLL should be considered if there is a sustained increase in the number of small, mature-appearing lymphocytes (i.e., to > 5,000/μl) circulating in the peripheral blood and if this increase is unexplained by other medical conditions. The bone marrow aspirate and biopsy reveal infiltration by at least 30% lymphocytes. Evaluation of the bone marrow is rarely required to confirm the diagnosis of CLL, but it does provide important prognostic information and is needed to assess response to therapy.[15]

Immunophenotyping helps distinguish CLL from other chronic lymphoid leukemias, such as PLL, HCL and HCL variant, NHL in a leukemic phase (e.g., lymphoplasmacytic lymphomas; marginal-zone NHL, including splenic lymphoma with villous lymphocytes; and mantle cell NHL), and plasma cell leukemia [*see Figure 1 and Table 1*].[1,15] CLL lymphocytes are monoclonal B cells that express low levels of surface immunoglobulins and the CD5 antigen along with normal B cell antigens CD19, CD20, and CD23. Mantle cell NHL, another major $CD5^+$ B cell disorder, can be distinguished from CLL by its strong expression of surface immunoglobulin, a lack of CD23, and expression of cyclin D1.

STAGING AND PROGNOSTIC FACTORS

CLL is a clinically heterogeneous disorder; some patients live for decades without requiring treatment, whereas others die within months after diagnosis. The first staging system to be widely adopted was the five-stage Rai classification [*see Table 2*].[16] This system was subsequently simplified to three levels of risk (four stages): low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV). In some parts of Europe, the Binet classification is more often used[17] [*see Table 3*]. Although the Binet system fails to identify Rai stage 0 patients, the two systems nevertheless have similar predictive value. Between 60% and 70% of patients with CLL present in a low- or intermediate-risk group.

Although CLL tends to occur in patients older than 60 years, 10% to 15% of patients are younger than 50 years. Stage for stage, younger patients have a median survival comparable to that of older patients when corrected for non–CLL-related causes of death.[18]

Table 1 Chronic Lymphoid Leukemias

Leukemia	*Morphology*	*Immunophenotype*
Chronic lymphocytic leukemia	Small, compact nucleus; no visible nucleoli; homogeneous cells	sIg faint, $CD19^+$, $CD23^+$, $CD5^+$, $CD103^-$, $CD10^-$
Prolymphocytic leukemia	Larger, prominent nucleoli; mixed population	sIg^+, $CD19^+$, $CD20^+$, $CD23^{+/-}$, $CD103^-$, $CD10^-$
Hairy-cell leukemia	Filamentous projections	sIg^+, $CD19^+$, $CD20^+$, $CD23^-$, $CD5^-$, $CD103^+$, $CD10^-$
Mantle cell lymphoma	Small to medium cells; cleaved nuclei	sIg^+, $CD19^+$, $CD20^+$, $CD23^-$, $CD5^-$, $CD103^-$, $CD10^-$

sIg—surface immunoglobulin

Table 2 The Modified Rai Staging System for Chronic Lymphocytic Leukemia

Rai Stages	*Three-Stage System*	*Clinical Features*	*Median Survival (Years)*
0	Low risk	Lymphocytosis in blood and marrow only	> 10
I and II	Intermediate risk	Lymphocytosis + lymphadenopathy + splenomegaly ± hepatomegaly	7
III and IV	High risk	Lymphocytosis + anemia + thrombocytopenia	1.5

Prognostic factors include male sex, black race, poor performance status, and older age.[19] More predictive than the absolute number of circulating lymphocytes is the lymphocyte doubling time.[20] Serum β_2-microglobulin, soluble CD23,[21,22] and soluble interleukin-2 (IL-2) receptors[23] are also predictive of outcome.

Simple cytogenetic abnormalities are associated with a longer survival than complex cytogenetic abnormalities. Patients with 14q abnormalities have a particularly poor survival, whereas the outlook for those with 13q abnormalities appears to be similar to that for patients with a normal karyotype. Patients with abnormalities of 11q tend to have adenopathy that is out of proportion to the lymphocyte count; these patients have a poor prognosis.[9] Cytogenetic studies are not recommended as part of the routine evaluation of the patient with CLL, because they are expensive, are difficult to perform, and, most important, do not yet direct treatment decisions.

The ratio of bcl-2 proteins to BAX proteins in CLL cells favors bcl-2 and correlates with clinical resistance to chemotherapy and clinical outcome.[24,25] *p53* deletions are predictive of a poor response to therapy with fludarabine or pentostatin.[26]

Patients whose cells have high levels of CD38 expression and unmutated Ig genes have a significantly poorer outcome. This suggests that there may be two distinct types of CLL.[27,28]

CLINICAL COURSE AND COMPLICATIONS

Progressive Conditions

In approximately 10% to 15% of patients with CLL, a more aggressive lymphoproliferative disease develops, most commonly Richter syndrome, which is an aggressive large cell lymphoma that occurs in about 5% of patients with CLL.[29] Patients characteristically present with increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, progressive anemia, and thrombocytopenia with a rapid rise in the peripheral blood lymphocyte count. Patients with Richter syndrome respond poorly to systemic therapy, and they have a short survival.

The second most common transformation is PLL. Others include acute lymphocytic leukemia, plasma cell leukemia, MM, and Hodgkin disease.

Secondary Malignancies

Secondary malignancies appear to occur with increased frequency in patients with CLL and are related both to the immune defects associated with this disease and to the consequences of therapy. These disorders primarily involve the skin, prostate, and gastrointestinal tract.[30-33]

Immune Abnormalities

A spectrum of immune defects has been reported in CLL. CLL B cells produce reduced amounts of normal immunoglobulins in response to antigenic stimuli. In addition, there are quantitative and qualitative abnormalities of normal B cells, T cells, and natural-killer cells; a reduction in the number and function of normal T cells; and impaired complement activation.[34]

THERAPY FOR CHRONIC LYMPHOCYTIC LEUKEMIA

The prognosis of patients with CLL is related to the stage of the disease. Patients with early stage disease may live a normal life span, although some may experience disease progression and die of their disease. These two groups may be distinguished by CD38 expression and mutation status of the *Ih* heavy-chain genes.[27,28] The outlook for patients with advanced disease may be improving as a result of newer treatments. Because currently available therapies are not curative, the appropriate time to initiate therapy is important. There is no survival advantage for patients with early stage disease who are treated at diagnosis. The French Cooperative Group on CLL conducted two studies of patients with Binet stage A disease. In the first trial, patients were randomized to receive either daily oral chlorambucil therapy or to undergo observation. In the second trial, patients received either intermittent chlorambucil plus prednisone or no initial treatment. Neither study detected an advantage of early intervention; moreover, in the first trial, there was a greater number of fatal, secondary solid tumors,[33] presumably related to the use of chlorambucil.

Therapy should be initiated only when indicated by one or more disease-related symptoms (e.g., fevers, chills, weight loss, or pronounced fatigue); progressive bone marrow failure with anemia, thrombocytopenia, or both; autoimmune anemia or thrombocytopenia that is unresponsive to other therapies (e.g., corticosteroids); massive or progressive hepatosplenomegaly or lymphadenopathy; or recurrent infections. Although there is no absolute number of lymphocytes that can be used as a benchmark to initiate therapy, a rapid lymphocyte doubling time (< 6 months) may support the decision to treat.[20]

Single Agents

The standard agent for CLL has been chlorambucil. When this drug is administered either at a dosage of 6 to 14 mg orally daily for 4 to 8 weeks or in higher-dose, intermittent pulses of 20 mg/m^2 orally every 3 weeks or 30 to 40 mg/m^2 once a month, disease regression in lymph nodes, liver, and spleen and normalization of blood counts occur in about half of previously un-

Table 3 The Binet Staging System for Chronic Lymphocytic Leukemia

Binet Stages	*Clinical Features*	*Median Survival (Years)*
A	Fewer than 3 areas of clinical lymphadenopathy; no anemia or thrombocytopenia	12
B	Three or more involved node areas; no anemia or thrombocytopenia	7
C	Hemoglobin ≤ 10 g/dl and/or platelets < 100,000 µl	2

treated patients. However, complete remissions are rare.[35] Cyclophosphamide appears to have activity similar to that of chlorambucil but is generally used only when chlorambucil is poorly tolerated.

Corticosteroids are less active than alkylating agents in CLL and should be reserved for patients with autoimmune complications because of the risks of bacterial, viral, and fungal infections; diabetes; and osteoporosis.

Purine Analogues

Fludarabine Fludarabine has been shown to be the most active agent in the treatment of CLL. Fludarabine was initially studied in patients who either did not respond to alkylating agents or experienced relapse during therapy with the agents.[36-39] Because of difficulties in comparing various treatment results, the National Cancer Institute–sponsored Working Group on CLL[15] standardized eligibility, response, and toxicity criteria. With the use of these guidelines, complete clinical and hematologic remissions were achieved in 3% to 13% of patients, with an overall response rate of 40% to 50%. Results varied with factors such as patient age, stage, and performance status. The median time to progression was about 18 months for patients whose conditions were refractory to alkylating agents and 17 months for patients who experienced relapse after having previously responded to therapy; the median survival was 29 months for the patients who experienced relapse and 9 months for the patients whose conditions were refractory.

When fludarabine is used as the initial treatment, the complete-response rate is about 30%, and the overall response rate is 70%.[35,40,41] Randomized trials have demonstrated higher response rates and longer time to disease progression with fludarabine than with alkylating agents and anthracycline, although a survival advantage is not yet apparent.[35,40] The median time to disease progression in untreated patients is approximately 32 months; the median survival is longer than 5 years. Fludarabine is an effective front-line option for CLL and has now replaced alkylating agents as the preferred initial therapy for most patients with CLL.[35]

When fludarabine is used in accordance with the currently recommended regimen of 25 mg/m^2 I.V. for 5 consecutive days once a month, the major toxicities encountered are moderate myelosuppression and severe immunosuppression, with occasional neurotoxicity, particularly at higher than recommended doses.[42,43] Autoimmune hemolysis and thrombocytopenia have also been reported.[44,45] These conditions generally respond to therapy with corticosteroids. If these conditions are unresponsive to corticosteroids, alternative approaches include use of high-dose intravenous immunoglobulin, splenectomy, or rituximab.[45,46] Lymphocyte counts, particularly CD4$^+$ T cell counts, decrease within weeks and do not return to normal for a year or longer after treatment has been discontinued.[41,43] The use of prophylactic antibiotics is not recommended in most patients, because it would be impossible to cover the broad spectrum of potential pathogens, the use of additional drugs is costly, and there is an increased potential for toxicity.[47]

Other agents Both cladribine and 2′-deoxycoformycin (pentostatin) are active in CLL but are less commonly used than fludarabine because of their relatively lower response rates, less durable remissions, and greater expense.[48,49]

Combination Chemotherapy

The most frequently used combination chemotherapy regimens in CLL are chlorambucil and prednisone (CP) and cyclophosphamide, vincristine, and prednisone (CVP). Reported response rates with CP and CVP in previously untreated patients with advanced-stage disease vary from less than 10% to over 60%, depending to a large extent on the criteria used for determining response. It is uncommon to achieve disappearance of evidence of disease. The median survival is less than 2 years.[50,51]

Combination therapy is not clearly superior to single-agent therapy. Early studies, including studies involving small numbers of cases, suggest that prednisone may increase the response rate to chlorambucil but does not prolong survival.[50] More intensive regimens, such as CHOP (cyclophosphamide, doxorubucin [hydroxydaunomycin], vincristine [Oncovin], and prednisone), are not clearly better than less intensive ones.[51-53] Combinations of fludarabine and cyclophosphamide are currently being compared with fludarabine alone.[54,55]

TREATMENT OF RELAPSED/REFRACTORY DISEASE

Standard Approaches

Patients with an asymptomatic recurrence are generally not treated until therapy is indicated by use of the same criteria as for front-line therapy, with palliative intent. Fludarabine is the standard salvage agent for patients who have not responded to alkylating agents. Patients whose conditions are refractory to fludarabine have a low likelihood of responding to alkylating agents.

High-Dose Therapy with Stem Cell Support

The experience with allogeneic bone marrow transplantation (BMT) in CLL is limited, in part because the median age of patients at the time of diagnosis is over 60 years.[56-58] About half of the patients who undergo BMT may remain disease free for prolonged periods; however, it is unclear whether they are cured. Unfortunately, the treatment-related mortality is 25% to 50%. Submyeloablative transplantation appears to be effective in CLL; when compared with standard allogeneic BMT, it is associated with a reduction in the rate of acute graft versus host disease (GVHD), but it is associated with significant chronic GVHD. Longer follow-up is required to determine whether there is durable clinical benefit.[59,60]

Autologous stem cell transplantation has a questionable role for patients with CLL.[58,61]

Biologic Therapy

Responses to interferon alfa tend to be brief, and interferon alfa has no influence on outcome. The CAMPATH anti-CD52 monoclonal antibody has recently been approved for use in relapsed and refractory CLL, based on a 33% response rate and acceptable toxicity.[62-64] The anti-CD20 antibody C2B8 (rituximab), which has considerable activity in follicular lymphomas, does not appear to have major activity when used as monotherapy at standard doses; however, preliminary data suggest higher response rates when rituximab is used in more intensive regimens or when it is combined with fludarabine.[65-70] These approaches are being evaluated in clinical trials.

Supportive Care

Myeloid growth factors Whether myeloid growth factors can protect against chemotherapy-induced myelosuppression has not been demonstrated, and their use is not part of standard practice.

Intravenous immunoglobulins The majority of patients with CLL experience hypogammaglobulinemia, which is more common in the advanced stages of CLL and which worsens as the disease progresses. Historically, the most common pathogens in CLL have been those that require opsonization before being killed. Unfortunately, high-dose intravenous immunoglobulins fail to protect patients from severe bacterial, viral, or fungal infections. They have no influence on overall survival and are not cost-effective.[71,72] This therapy should be reserved for patients with documented, repeated bacterial infections.

Erythropoietin Anemia in CLL is not the consequence of deficient production of erythropoietin but, more commonly, is the consequence of bone marrow replacement, splenic sequestration, or hemolysis. Nevertheless, erythropoietin may reduce transfusion requirements in selected patients, and a trial of this agent can be considered in anemic CLL patients who have no other obvious correctable cause of anemia.[73]

Splenectomy

Splenectomy may play an important role in the palliative treatment of patients with CLL who have not benefited from systemic treatment.[46] Thrombocytopenia responds in varying degrees to splenectomy in almost all patients. When this procedure is performed by an experienced surgeon, related mortality is under 10%.

Prolymphocytic Leukemia

Most cases of PLL arise de novo; nevertheless, PLL represents the most common form of aggressive transformation in patients with CLL. Patients may present with clinical deterioration, often with a wastinglike disorder. Compared with patients whose PLL has evolved from CLL, those with de novo PLL tend to be older (in their 70s and beyond) than those with transformed disease (in their 60s); have a more marked lymphocytosis; have massive, rather than moderate, splenomegaly; and generally do not have prominent lymphadenopathy. The peripheral blood smear often reveals a dual population of cells, some being characteristic small lymphocytes of CLL and others being larger cells with prominent nucleoli. The phenotype of de novo PLL differs from that of CLL in that de novo PLL has stronger CD79b and weaker CD5. In patients with primary PLL, the t(6;12) chromosome rearrangement has been reported. *p53* abnormalities, which occur in more than 50% of patients, may result in resistance to chemotherapy.

Promising preliminary results have been published regarding the use of purine analogues[74] and the CAMPATH monoclonal antibody[75] for the treatment of PLL.

Hairy-Cell Leukemia

HCL is an uncommon B cell malignancy that occurs in about 500 new patients each year in the United States. The disease most often occurs in older persons, with a high male-to-female ratio.

DIAGNOSIS

Clinical Presentation

Patients with HCL are occasionally asymptomatic at presentation, but more often, they present with symptoms of impaired bone marrow production, such as infections, bleeding, and weakness. In rare cases, patients experience a vasculitis-like disorder. The physical examination is notable for splenomegaly that is often massive and accompanied by hepatomegaly; less commonly, lymphadenopathy occurs with splenomegaly.

Laboratory Findings

Laboratory evaluation reveals pancytopenia, which raises the possibility of aplastic anemia, acute leukemia, myelodysplastic syndrome, or HCL. A bone marrow biopsy may be required to make the diagnosis, because the aspirate is often packed with hairy cells; fibrosis is also present. The malignant cells are of B cell origin, expressing CD19, CD20, and the monocyte antigen CD11c. Perhaps the most specific marker is Bly-7 (CD103).

TREATMENT

HCL is generally an indolent disorder, and 10% of patients may never require treatment. Therapy is indicated if there is massive or progressive splenomegaly, worsening blood counts, recurrent infections, more than 20,000 hairy cells/μl of peripheral blood, or bulky lymphadenopathy. Until about 1983, splenectomy was the standard approach to HCL because it improves symptoms related to splenomegaly and, in the majority of cases, improves the peripheral blood counts; however, this procedure does not affect the disease itself. Splenectomy is now less often performed because of the availability of effective systemic therapies. Interferon alfa was the first agent to achieve meaningful responses in patients with HCL. Most patients experience clinical and hematologic improvement; however, in only 10% of these patients is the response complete, and the disease invariably recurs after therapy is discontinued.

The purine analogues have revolutionized the treatment of patients with HCL. In a North American trial, previously untreated patients with HCL were randomized to receive either interferon alfa or pentostatin; the complete response rate was approximately 11% for patients given interferon alfa, compared with 76% for patients given pentostatin, with a significant advantage to pentostatin in the durability of response.[76] Cladribine induces responses in 80% to more than 90% of patients, with 65% to 85% having complete remissions.[77] Only 25% to 35% of patients experience relapse after prolonged follow-up. In many cases, relapse is characterized only by an increase in bone marrow hairy cells, with no indication for treatment. Most patients who experience relapse and again require treatment achieve a second durable response. Results with pentostatin and cladribine are equivalent; the choice of which agent to use is based on physician preference. Rituximab and an anti-CD22 immunotoxin have been reported to be active in cases involving nucleoside analogue failures.[78,79]

Multiple Myeloma

EPIDEMIOLOGY

MM is uncommon in persons younger than 40 years; the incidence increases rapidly after age 50. Men and women are equally affected. Although blacks are affected more commonly than whites, the outcomes in the two groups are similar, stage for stage.[80] Approximately 14,000 new cases were projected for 2001 in the United States.[2] No apparent correlation has been identified between MM and socioeconomic status. The incidence of this disease is apparently lower in Chinese and other Asians. The etiology of MM is

unclear. Exposure to ionizing radiation, paints and solvents, and pesticides has been implicated but never firmly established.

PATHOGENESIS

MM is characterized by an accumulation of plasma cells in the bone marrow and, less often, soft tissues or visceral organs. The malignant cell is not the mature plasma cell but a cell that occurs earlier in B cell development, after the rearrangement of the heavy-chain genes. These cells express a distinct variety of adhesion molecules (e.g., CD11b),[81] which may permit the circulating B cells to attach to nonmalignant stromal cells in the bone marrow that produce cytokines capable of supporting myeloma cell growth, such as IL-6. IL-6 acts as both an autocrine and a paracrine growth factor in MM, thereby both stimulating cell growth and preventing apoptosis. A role in pathogenesis has been suggested for a herpesvirus (Kaposi sarcoma–associated herpesvirus or herpes simplex virus–8).[82]

Cytogenetic analyses have been difficult to perform in MM. However, recent studies using FISH have demonstrated aneuploidy in about 70% of cases.[83] The most frequent abnormalities involve chromosomes 13 ($13q^-$) and 14 ($14q^+$). These defects may result in impaired apoptosis and subsequent resistance to therapy. Mutations of *p53* have been identified in patients who experience MM relapse; mutations appear to correlate with poor outcome.

IMMUNOLOGY

MM is characterized by the overproduction of a monoclonal immunoglobulin. The frequency of the various immunoglobulin types of MM parallels the serum concentrations of those Igs: IgG in 60% to 70%, IgA in 20%, and light chain in only 15%; few cases of IgD and IgE have been reported, and approximately 1% of patients are nonsecretors. A secondary finding is depressed levels of normal residual immunoglobulins.

Bence Jones proteins (urinary light chains) are detected in the urine with antisera against light chains but without an anti–heavy-chain component.

DIAGNOSIS

The diagnosis of MM is often made incidentally when an increased serum protein concentration is detected on routine evaluation or in the evaluation of anemia, renal dysfunction, or asymptomatic hypercalcemia.

Monoclonal Gammopathy of Undetermined Significance

Monoclonal gammopathy of undetermined significance (MGUS) occurs in about 1% of the general population and 3% of otherwise healthy persons older than 70 years; IgG is most commonly increased. Features of MM that distinguish it from MGUS include greater concentrations of serum and urine M proteins, increased percentage of bone marrow plasma cells, a higher plasma cell labeling index, the presence of lytic bone lesions, and the presence of circulating plasma cells in the peripheral blood. After prolonged follow-up, four groups of patients with MGUS can be identified: (1) those with a contained monoclonal gammopathy (19%); (2) those whose serum immunoglobulin level increases to more than 3 g/dl but who do not require any therapy (10%); (3) those who die without developing MM or another related disease (47%); and (4) those in whom MM, amyloidosis, macroglobulinemia, or another lymphoproliferative disorder develops (24%, two thirds of which are MM). Progression to a malignancy occurs at 8 to 10 years. Unfortunately, there are no laboratory studies that reliably predict which patients with MGUS will progress to MM.

Table 4 Sites of Involvement with Plasma Cell Dyscrasias

Sites	*Disorders*
Skull	Lytic lesions
Soft tissues	Plasmacytoma
Bone marrow	Anemia
	Thrombocytopenia
	Neutropenia
Nerves	Peripheral neuropathy
	Spinal cord compression
Tongue	Amyloid
Heart	Amyloid
Bone	Compression fractures
	Osteopenia
	Lytic lesions
Kidneys	Proteinuria
	Amyloid
	Renal failure
Long bones	Fractures

Clinical Presentation

The diagnosis of MM requires at least one of the following major criteria: plasmacytoma; bone marrow with at least 30% plasma cells; and M protein on serum electrophoresis showing levels of IgG greater than 3.5 g/dl, IgA greater than 2.0 g/dl, or urine light-chain excretion greater than 1 g/24 hr. One or more of the following minor criteria are also required: bone marrow plasmacytosis greater than 10%; M protein in serum or urine but less than the levels listed above under major criteria; lytic bone lesions; and decreased residual immunoglobulins.

MM can affect many organs, including the bones, kidneys, nerves, heart, and liver [*see Table 4*].

Plasmacytomas Plasmacytomas are solid tumors consisting of plasma cells that may occur in soft tissues (extramedullary plasmacytomas); they may present as palpable masses but more commonly present as spinal cord compression. These tumors may be cured with local radiation therapy. Patients with plasmacytomas that occur in bone may initially respond to radiation therapy, but half will experience progression to overt MM, two thirds within 3 years after diagnosis. Persistence of the presence of M protein after radiation therapy is associated with an increased likelihood of evolution to MM.

Bone disease Bone disease is one of the most common and diagnostic features of MM. Although lytic bone lesions are most typical [*see Figure 2*], osteopenia is the most common form of bone disease in myeloma. Osteosclerotic disease has also been reported. Increased osteoclast activity is notable in the affected bones and is believed to be related to so-called osteoclast activating factor, which is a manifestation of the effects of tumor necrosis factor, IL-1, and IL-6.

Radiation therapy for painful bone lesions in a patient with newly diagnosed MM should be deferred if possible until the effectiveness of systemic therapy can be assessed, because radiation therapy may impair the ability to administer adequate doses of chemotherapy. Exceptions include spinal cord compression and potential fractures in weight-bearing bones that require im-

mediate intervention. For patients in relapse, local radiation therapy can provide substantial palliative benefit.

Vertebral compression fractures during the course of systemic therapy should not be the sole reason for use of radiation therapy, because these lesions are often the result of osteopenia; they do not necessarily represent disease progression and are generally not responsive to radiation.

Pamidronate is a second-generation bisphosphonate that has been studied in a placebo-controlled clinical trial in previously untreated patients and patients in relapse with stage III MM.[84] The drug provided significant protection against skeletal complications (measured by time to first skeletal event), appeared to improve quality of life, and possibly provides a survival advantage.[85] As a result, the current recommendation is to administer bisphosphonates to all patients with evidence of bone involvement, although some clinicians recommend this agent for all patients with MM.

Anemia Anemia occurs in most patients with MM, especially as the disease progresses. Anemia is a consequence of bone marrow replacement, renal failure, and chronic disease. In patients with MM who have inappropriately low serum levels of erythropoietin, erythropoietin may reduce red cell transfusion requirements.[86]

Hypercalcemia About 10% to 20% of patients with MM present with hypercalcemia. Serum calcium levels, corrected for albumin, can be used to identify patients at risk for symptoms related to hypercalcemia. Paraproteins may occasionally bind calcium, resulting in a falsely high calcium level; therefore, a free (ionized) calcium determination should be obtained in the asymptomatic patient with an elevated serum calcium level.

Previously untreated patients who either are asymptomatic or have only mild symptoms related to their mild or moderate hypercalcemia should be treated with systemic chemotherapy, including corticosteroids. Patients with high serum calcium levels or symptoms, such as lethargy, confusion, and constipation, should receive hydration with saline diuresis. Bisphosphonates are useful as a means of reducing the serum calcium concentration, as are mithramycin and calcitonin.

Figure 2 **Radiograph showing lytic bone lesions of the skull.**

Renal insufficiency Renal insufficiency is common in MM and may result from a variety of mechanisms. The tubules may become obstructed by myeloma protein (myeloma kidney), or the kidneys may be infiltrated by amyloid protein. The increased risk of infections creates a predisposition to pyelonephritis. Other causes include hypercalcemia, urate nephropathy, nephrotic syndrome, hyperviscosity, infiltration of the kidneys by plasma cells, and obstructive uropathy. Patients with suspected MM and abnormal renal function should be kept well hydrated and should not be subjected to dehydrating procedures such as a computed tomographic scan with contrast or an intravenous pyelogram, which can precipitate acute renal failure in the patient with occult renal impairment. Plasmapheresis may alleviate acute renal failure. Dialysis and even renal transplantation have been used successfully.

Hyperviscosity Signs and symptoms of hyperviscosity, such as shortness of breath, confusion, and chest pain, are uncommon in patients with IgG MM but may occur in patients with extremely high serum protein concentrations. Hyperviscosity occurs more often in patients with IgA MM because of greater polymerization of the paraprotein. Management should be directed at treating the underlying MM. Plasmapheresis may be considered if a rapid decrease in the paraprotein is required to alleviate symptoms.

Infectious diseases Patients with myeloma are at increased risk for life-threatening bacterial infections, even in the presence of normal numbers of circulating granulocytes. This abnormality is related to impaired synthesis of normal immunoglobulins and defective complement activation. Early in the course of their disease, patients are more likely to become infected with encapsulated organisms that require opsonization (e.g., *Streptococcus pneumoniae, Haemophilus influenzae,* and *Staphylococcus*), whereas the use of chemotherapy increases the likelihood of gram-negative infections.

Polyvalent pneumococcal vaccine is unlikely to be effective, because patients respond poorly to bacterial antigens, and other bactericidal defects are not corrected by vaccination. Neither intravenous immunoglobulins nor prophylactic antibiotics are cost-effective or uniformly protective and should be reserved for patients with documented, recurrent bacterial infections.

Neurologic symptoms Epidermal cord compression is a common presentation in patients with plasmacytoma; it is an oncologic emergency requiring decompression and radiation therapy. Paraproteinemias may be associated with other neurologic symptoms, such as POEMS syndrome. POEMS is the acronym for a collection of findings that include polyneuropathy (generally sensorimotor), organomegaly (e.g., hepatomegaly), endocrinopathy (e.g., diabetes, amenorrhea, and gynecomastia), M protein, and skin changes (e.g., hyperpigmentation). Other associated features include lymphadenopathy and osteosclerotic bone lesions.

STAGING AND PROGNOSTIC FACTORS

Once the diagnosis of MM has been made, the initial evaluation should include a complete blood count, as well as a bone

marrow aspiration and biopsy. Serum electrophoresis and quantitative immunoglobulins determine the concentration of paraprotein, which correlates with tumor mass, and an immunoelectrophoresis defines the immunoglobulin subtype. A urine electrophoresis will detect urinary light chains, if present. A radiographic bone survey is performed to identify sites of involvement and potential fractures. Radionuclide bone scans are of little value in assessing MM.

The clinical pictures of the subtypes of MM vary somewhat. For example, patients who secrete only light chains often present with progressive renal failure, initially without overt myeloma. Patients with IgD myeloma have a more aggressive clinical course characterized by a high frequency of renal failure, plasmacytomas, and amyloidosis and have a shorter survival than patients with IgG MM despite having low paraprotein concentrations.[87] IgE myeloma, which is rare, appears to be accompanied by an increased frequency of plasma cell leukemia.

Patients have most often been staged according to the classification of Durie and Salmon[88] [*see Table 5*], which correlates well with tumor mass and prognosis. Stage is determined by the level of M protein, the number of lytic bone lesions, hemoglobin concentration, and serum calcium (corrected for albumin). Patients are further subdivided into classes A and B on the basis of the serum creatinine level.

The median survival is approximately 5 years for patients with stage IA disease but 15 months for patients with IIIA MM. However, this staging system is not uniformly reliable in predicting outcome and is being replaced by more biologically relevant markers, notably the β_2-microglobulin, plasma cell labeling index, and cytogenetic abnormalities, as well as lactate dehydrogenase, Ki-67, serum levels of IL-6, C-reactive protein, and the presence of circulating plasma cells.[83,89-93] Cytogenetics are not part of standard evaluation, because such testing is expensive and does not influence therapy. Magnetic resonance imaging may prove to be valuable in the evaluation of bone marrow involvement and as a prognostic indicator.[94]

THERAPY FOR MULTIPLE MYELOMA

Indications for Treatment

A small proportion of patients are classified as having smoldering MM on the basis of the following features: M protein in serum less than 3.0 g/dl, less than 10% plasma cell infiltration in the bone marrow, no anemia, normal serum calcium and creatinine levels, no lytic bone lesions, and a low plasma cell labeling index. These patients may remain stable for several years without treatment.

Treatment of stage I and II MM should be considered for patients with progressive disease, which includes an increasing M protein level in the serum, urine, or both; decreasing serum hemoglobin level; progressive bone marrow failure with neutropenia, thrombocytopenia, or both; increasing serum calcium, creatinine, or uric acid concentrations; multiple lytic bone lesions; bone pain; recurrent infections; and extramedullary plasmacytoma. Those patients with stage III disease are generally symptomatic or have other hematologic or chemical abnormalities at presentation that warrant therapy. There are no known prophylactic therapies that can reduce the risk of developing MM.

Patients with MGUS require regular monitoring of serum immunoglobulin levels.

Table 5 Staging System for Multiple Myeloma

Stage I	
All of the following:	
Hemoglobin	> 10 g/dl
Serum calcium	< 12 mg/dl
Normal bone structure or solitary plasmacytoma on radiographs	
Low M component	
IgG	< 5 g/dl
IgA	< 3 g/dl
Urine light chains	< 4 g/24 hr
Stage II	
Fitting neither stage I nor stage III	
Stage III	
One or more of the following:	
Hemoglobin	< 8.5 g/dl
Serum calcium	>12 mg/dl
Advanced lytic bone lesions	
Hyper M component	
IgG	> 7 g/dl
IgA	> 5 g/dl
Urinary light-chain excretion	> 12 g/24 hr
Subclassification	
A: serum creatinine	< 2.0 mg/dl
B: serum creatinine	≥ 2.0 mg/dl

Standard Therapy

Once it has been decided that treatment is indicated, there are limited effective therapeutic options. Agents for use as monotherapy primarily include corticosteroids, alkylating agents, and interferon alfa. Melphalan with prednisone (MP) is most often used because of higher response rates when the two drugs are administered together. MP is generally administered every 3 to 4 weeks for 6 to 9 months, with treatment subsequently continued if a response is ongoing. Most often, the paraprotein concentration decreases to a stable value (plateau phase); continuing therapy beyond this point does not prolong survival but increases complications (e.g., infections). Other alkylating agents are also active but have no advantage over melphalan. Additional drugs used to treat MM patients, such as anthracyclines, have limited effectiveness when used as single agents.

Corticosteroids (either prednisone or dexamethasone) may decrease the M protein in as many as 40% of previously untreated patients and in 20% to 40% of patients who have not responded to primary treatment. Steroids also offer a treatment option for elderly patients and for those with impaired performance status.

Clinical response often results in a reduction in bone pain and normalization of the serum creatinine, calcium, and hemoglobin levels. The median survival of patients with MM who undergo treatment with melphalan and prednisone is 2.5 to 3 years; only 5% to 10% of patients survive 10 or more years.

Combination chemotherapy regimens (e.g., vincristine, carmustine, melphalan, cyclophosphamide, and prednisone; vincristine, carmustine, doxorubicin, and prednisone; or vincristine, cyclophosphamide, doxorubicin, and prednisone) have not been shown to be more efficacious than MP. The VAD (vincristine, doxorubicin [Adriamycin], and dexamethasone) regimen as initial therapy is less toxic to the stem cell population than MP and may be preferable for patients who are being con-

sidered for autologous stem cell transplantation. Interferon alfa has been the most widely studied of the biologic agents. Interferon alfa has activity as a single agent, but whether it adds to the effect of chemotherapy during induction or as a maintenance therapy is controversial. Most published trials and meta-analyses have failed to demonstrate a role for interferon alfa. Considering the associated toxicities and expense of the agent and its limited clinical benefit, interferon alfa cannot be recommended as a standard component of MM therapy. Use of corticosteroids as maintenance therapy after chemotherapy may prolong survival.

Relapsed/Refractory Disease

Relapse after a response to initial treatment of MM is universal. Further response to MP is less frequent and of shorter duration than after initial treatment, and therapy may be associated with more myelosuppression. The standard salvage regimen is VAD—a 4-day continuous infusion of vincristine and doxorubicin through an indwelling catheter and oral dexamethasone for 4 days, repeated on days 9 and 17 of each 21- to 28-day cycle. Responses are achieved in a third of resistant patients and in almost half of relapsed patients.

Stem cell transplantation Allogeneic BMT has not been widely used in MM, because patients tend to be elderly. BMT induces complete remissions in 40% to 50% of patients, and 25% to 30% remain alive after approximately 7 years. However, relapses may occur after several years, raising the question of whether any patients are actually cured. Because of the high rate of treatment-related morbidity and mortality, BMT is generally reserved for younger patients (< 50 years) with unresponsive or progressive disease. Submyeloablative transplantation is an encouraging new approach to the treatment of patients with MM.

Initial studies of high-dose chemotherapy and autologous stem cell transplantation were conducted in relapsed and refractory cases of MM. The frequency of response and the duration of response can be predicted by the serum lactate dehydrogenase level, β_2-microglobulin level, performance status, age (> 50 years), and responsiveness to previous therapy. For good-risk patients (i.e., those with no poor-risk factors or just one), the complete response rate is 20%, with a median relapse-free survival of 1.5 years and an overall survival of 3.5 years. With two or three poor-risk factors, the results are substantially worse, with a median relapse-free survival of 7 months and an overall survival of 20 months. With four or more poor-risk factors, the median duration of response is 3 months, with an overall survival of 5 months.

Recently, patients received this treatment earlier in the course of their disease. In a French study,[95] previously untreated patients younger than 65 years received either standard-dose chemotherapy or high-dose chemotherapy with autologous stem cell transplantation. There was an 81% response rate in the high-dose arm of the study, including 22% complete remissions and 16% very good partial remissions, compared with 57%, 5%, and 9%, respectively, in the standard-dose arm. These differences were highly significant. However, the 6-year event-free survival in the transplant arm was only 24%. A large North American randomized trial has been completed, and when the results are available, they should better characterize the role of high-dose chemotherapy with autologous or allogeneic stem cell support.

Thalidomide has emerged as an active agent for the treatment of MM, with responses in more than 30% of heavily pretreated patients. Its role in this disease is being more clearly defined.[96]

Waldenström Macroglobulinemia

Waldenström macroglobulinemia (WM) was formerly considered to be related to MM because of the presence of a paraproteinemia and infiltration of the bone marrow and other organs by plasmacytoid lymphocytes. However, several clinical features of WM are more similar to those of indolent non-Hodgkin lymphoma. In the World Health Organization Classification, WM is appropriately classified as a lymphoplasmacytic lymphoma.[97] About 1,500 persons are diagnosed with WM each year in the United States, making WM only 10% to 20% as common as MM. The median age at diagnosis is 65 years. The median survival from the time of diagnosis is about 5 years.

The diagnosis of WM is made on the basis of the presence of an IgM paraprotein and depressed levels of uninvolved immunoglobulins (i.e., IgG and IgA), with or without lymphadenopathy or hepatosplenomegaly. The bone marrow is generally infiltrated by at least 30% lymphoplasmacytoid lymphocytes. Clinical and laboratory features of WM include hyperviscosity, anemia, polyneuropathy, amyloidosis, renal abnormalities, skin deposits, and gastrointestinal involvement that leads to malabsorption and diarrhea.

Treatment of WM is directed at the complications related to the presence of either IgM or non-Hodgkin lymphoma. If patients are not symptomatic from the increase in IgM, a period of careful observation may be appropriate. If the IgM results in symptoms, treatment may involve plasmapheresis for hyperviscosity, transfusions for anemia, or treatment of hemolysis with steroids or rituximab. The lymphoma is managed as any other case of indolent non-Hodgkin lymphoma, with an alkylating agent, a purine analogue (e.g., fludarabine or cladribine), or a biologic therapy such as rituximab. Thalidomide has limited activity against this disorder.

Amyloidosis

Amyloidosis is characterized by the deposition of amyloid fibrils in various tissues.[98] Amyloidosis may occur either secondary to a chronic inflammatory condition (amyloid A, or AA) or as a primary condition (amyloid light chain–related, or AL) in the setting of a B cell malignancy. In AL, the fibrils are made up of fragments of light chains of immunoglobulins, with a clonal proliferation of bone marrow plasma cells, and Bence Jones proteinuria is present. The incidence of primary amyloidosis in the United States is 5.1 to 12.8 cases per million person-years. This disease primarily involves the heart in 90% of patients and also affects the liver, spleen, kidneys, tongue, and nervous system. The diagnosis is made by a biopsy of the affected organ or a urine sample stained with Congo red.

The treatment of amyloid AL is directed at both the affected organ and the underlying disease. Few drugs are active against amyloidosis. A randomized trial in which MP was compared with colchicine showed longer survival in patients who received the MP regimen.[99] Median survival is 18 months. High-dose therapy with stem cell support has no clear benefit.[100]

XVI ACUTE LEUKEMIA

Richard A. Larson, m.d.

The acute leukemias are characterized by aberrant differentiation and proliferation of malignantly transformed hematopoietic progenitor cells. These cells accumulate within the bone marrow and, once a substantial burden of leukemia cells is present, lead to suppression of the growth and differentiation of normal blood cells. Symptoms result from varying degrees of anemia, neutropenia, and thrombocytopenia or from infiltration into tissues. Although virtually any organ system may become involved once leukemia cells enter the peripheral blood, the most common sites detected clinically are the lymph nodes, liver, spleen, central nervous system, and skin.

The first recognition of leukemia as a distinctive entity is usually accorded independently to Virchow in Berlin and Bennett in Scotland in 1845. In 1847, Virchow coined the term leukemia (from the Greek *leuk*, white cells, and *emia*, in the blood) to replace "weisshäme," a German term. Leukemic disorders are currently classified by their presumed cell of origin. Acute myeloid leukemia (AML) results from the malignant transformation of a bone marrow (myeloid) progenitor cell or stem cell, which is the normal precursor for granulocytes, erythrocytes, and megakaryocytes.[1] Acute lymphoblastic leukemia (ALL) is a malignant disease of early precursor cells of the B cell and T cell lymphocytic lineages. Myelodysplastic syndrome (MDS) is any one of a heterogeneous group of malignant hematologic disorders that often involve all three myeloid cell lineages and probably arise from a very primitive or totipotential stem cell.[2] MDS combines bone marrow failure with many features of a chronic or so-called smoldering leukemia that can evolve into AML.

Epidemiology

Although leukemia can occur at any age, its incidence is strongly related to increasing age. Across the entire age spectrum, ALL and AML are nearly equal in overall incidence, but ALL predominates in children, whereas AML accounts for the majority of cases in adults. The median age at diagnosis of AML is about 60 years. The peak incidence of ALL occurs at ages 3 to 5 years, and childhood cases are distinctly different from ALL in adults. Although the median age for adults with ALL who are entered into clinical trials is 35 to 40 years, it is very likely that older patients are underrepresented in these reports. There are marked differences between the various subtypes of leukemia that occur in children, young adults, and older adults. MDS is rarely observed in adults younger than 50 years and becomes increasingly common in older age groups. There are many biologic and clinical similarities between MDS and the more common subtypes of AML that are seen in older adults, and some patients with AML may have disease that evolved from an unrecognized myelodysplastic syndrome.

Acute leukemia is more common in whites than blacks at all ages.[3] Jews are more commonly affected than non-Jews, but it is unclear whether this disparity is the result of genetic or environmental factors. Acute leukemia is more common in men than in women. This difference is caused in part by a higher incidence in young boys and older men. Factors such as occupational and environmental exposure may account for some gender disparity.

Geographic variations in incidence are likely related to a number of factors, including socioeconomics, ethnicity, and an urban or rural setting, and may account for the higher frequency reported in industrialized countries and urban areas. Some cytogenetic abnormalities have been reported more frequently in certain countries.

Etiology

Although the cause of acute leukemia in humans is unknown, a variety of hereditary and environmental factors appear to play an etiologic role. The pathogenesis of acute leukemia involves complex interactions between host susceptibility, chromosomal damage secondary to physical or chemical exposure, and possibly the incorporation of genetic information transmitted virally into susceptible progenitor cells.[4] Much of the evidence is indirect and has been inferred from epidemiologic studies. Investigators have relied heavily on animal models of leukemogenesis. In certain nonhuman species, for instance, exposure to an agent such as ionizing radiation or a chemical carcinogen increases the incidence of leukemia.

Characteristic leukemic disorders can be generated in animal models by transfecting fusion genes such as *bcr-abl* into germ cells. The *bcr-abl* fusion gene results from the translocation or juxtaposition of the *abl* gene from chromosome 9 with the *bcr* gene on chromosome 22. This novel fusion gene produces a protein that is not present in normal cells. The t(9;22) gives rise to an abnormal chromosome 22 that is called the Philadelphia chromosome (Ph). This rearrangement is found in about one third of adults with ALL, as well as in all patients with chronic myeloid leukemia (CML).

RADIATION

The leukemogenic potential of ionizing radiation has been well recognized for a number of years. Leukemias associated with radiation generally derive from the myeloid lineage but often have trilineage features characteristic of multipotential stem cells. Much of the epidemiologic evidence emanates from observations after human exposures to radiation from nuclear explosions, from therapeutic or diagnostic radiation sources, and from occupational radiation sources. After the atomic-bomb attacks on Hiroshima and Nagasaki, exposed survivors experienced a marked increase in the incidence of both acute and chronic leukemia.[5] The chance of leukemia developing in a person was related to the intensity of the person's radiation exposure, with relatively little risk observed in those exposed to less than 100 cGy.[6]

Patients who were treated with external-beam irradiation for ankylosing spondylitis or menorrhagia or with radioactive phosphorus (^{32}P) for polycythemia vera have experienced an increased incidence of acute leukemia.[7,8] The risk of therapy-related AML (t-AML) after the use of radiation therapy alone to treat Hodgkin disease or breast cancer appears low.[9] Current use of diagnostic x-ray imaging does not appear to result in any increased leukemia risk to patients. However, fetal exposure to intrauterine x-rays increases the risk of subsequent childhood leukemia.[10]

The risk of leukemia developing in persons exposed to radia-

tion at their workplace was documented in early studies of women employed as radium wristwatch dial painters and by the increased incidence of leukemia in radiologists during the early part of the 20th century.[11,12] Current radiation protection practices appear to have markedly diminished this risk.

CHEMICALS

There are substantial epidemiologic data linking the development of acute leukemia to either therapeutic or industrial chemicals. Exposure to alkylating agents such as melphalan or nitrogen mustard is associated with the development of t-AML, after a latency of 5 to 7 years.[9] This disease is characterized by pancytopenia, trilineage myelodysplasia, and complex cytogenetic abnormalities, most often involving losses of part or all of chromosomes 5 or 7. t-AML is a well-recognized complication resulting from treatment of Hodgkin disease, multiple myeloma, and ovarian cancer.[13] The risk is greater in patients receiving both chemotherapy and radiotherapy. Another subtype of t-AML has been observed in patients treated for certain hematologic and solid neoplasms with the epipodophyllotoxin drugs etoposide and teniposide and has also been observed with other agents that inhibit topoisomerase II activity, such as doxorubicin.[9,14] This leukemia has a much shorter latency, often only 1 to 2 years, and a more acute presentation, with a high leukocyte count, monoblastic morphology, and usually a cytogenetic abnormality of the long arm of chromosome 11 at band q23. The *MLL* (mixed lineage leukemia) gene at this locus is frequently rearranged.[15]

In the early part of the 20th century, acute leukemia was noted in workers exposed to benzene. For example, the incidence of acute leukemia in Turkish cobblers with long-term exposure to benzene was two to three times greater than the incidence of acute leukemia in the general population.[16] With the advent of stronger occupational safety laws, benzene-associated leukemia has nearly disappeared in Western countries but is still present in developing countries.[17]

VIRUSES

A number of viruses are known to cause acute leukemia in several nonhuman species. The potential role of viruses in human leukemogenesis has been explored for decades. There are no conclusive data that any of the common types of acute leukemia in humans have a viral origin. The Epstein-Barr virus (EBV) genome is present in the majority of Burkitt leukemia/lymphoma cells. Adult T cell leukemia, an uncommon form of human leukemia that is largely restricted to southern Japan and the Caribbean, is closely linked to infection by a leukemogenic virus, human T cell lymphotropic virus type I (HTLV-I).[18] However, most persons who express antibodies to this virus never exhibit evidence of malignancy.

HEREDITY AND GENETICS

Observations of the increased incidence of acute leukemia in members of certain families with high susceptibility, the high frequency of concordant leukemia in monozygotic twins, and the association of acute leukemia in persons with genetic disorders have established that hereditary factors play a role in the development of leukemia.[4] In identical twins, if one twin has leukemia, the other is also at risk for leukemia, often before 8 years of age.[19] The disease usually develops in the second twin within a year of the first twin's diagnosis. Nonidentical siblings of those affected by leukemia have a lesser risk, but the risk is still greater than that observed in the general population.[20] Molecular evidence of the *MLL-AF4* fusion gene has been detected in newborns who later developed ALL with t(4;11) during infancy or childhood.

The incidence of both AML and ALL is increased in patients with Down syndrome, a disease characterized by trisomy 21 resulting from chromosomal nondisjunction. Approximately 5% to 10% of childhood AML occurs in children with Down syndrome. Their prognosis is more favorable than that for children of the same age with AML but without Down syndrome.[21] Further evidence of the relation between leukemia and chromosomal abnormalities is the increased incidence in patients with Bloom syndrome and Fanconi anemia. Both disorders are hereditary conditions characterized by increased chromosomal breakage. Other genetic conditions not normally associated with chromosomal abnormalities, such as ataxia telangiectasia and congenital agammaglobulinemia, are associated with acute leukemia. The deficiencies of cellular and humoral immunity that mark these conditions may increase susceptibility to the development of leukemia.

Morphologic Classification of Leukemia

The traditional classification of the acute leukemias has relied on morphologic description, reflecting the predominant cell type present within the bone marrow population and relating that cell to its normal hematopoietic counterpart. In 1976, the French-American-British (FAB) group of hematopathologists established a subclassification system for the acute leukemias that separated AML and ALL into distinct disorders.[22] This system was based solely on light-microscopic evaluation of routinely stained blood and marrow smears, supplemented by a limited number of cytochemical procedures. Because of its ease of use

Table 1 World Health Organization Classification of Acute Myeloid Leukemia

- AML with recurrent genetic abnormalities
  - AML with t(8;21)(q22;q22); *AML/ETO*
  - AML with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(q22;p13); *CBFβ/MYH11*
  - Acute promyelocytic leukemia with t(15;17)(q22;q12); *PML/RARα* and variants
  - AML with 11q23 (*MLL*) abnormalities
- AML with multilineage dysplasia
  - Following MDS or MDS/myeloproliferative disorder
  - Without antecedent MDS
- t-AML and t-MDS
  - Alkylating agent–related
  - Topoisomerase type II inhibitor–related
  - Other types
- AML not otherwise categorized
  - AML minimally differentiated
  - AML without maturation
  - AML with maturation
  - Acute myelomonocytic leukemia
  - Acute monoblastic and monocytic leukemia
  - Acute erythroid leukemia
  - Acute megakaryoblastic leukemia
  - Acute basophilic leukemia
  - Acute panmyelosis with myelofibrosis
  - Myeloid sarcoma

Table 2 French-American-British (FAB) Classification of Acute Myeloid Leukemia

FAB Classification	*Subtype*	*Morphologic and Cytochemical Features*	*Cytogenetics*	*Frequency (%)*
M0	Minimally differentiated acute myeloblastic leukemia	Large, agranular myeloblasts, sometimes resembling lymphoblasts of FAB subtype L2; stain negative for myeloperoxidase and Sudan black; express CD13 or CD33 antigens on cell surface	—	2–3
M1	Acute myeloblastic leukemia without maturation	Large, poorly differentiated myeloblasts represent 90% or more of the nonerythroid cells; at least 3% of the myeloblasts stain positive for myeloperoxidase	—	20
M2	Acute myeloblastic leukemia with maturation	Between 30% and 89% of the nonerythroid cells are myeloblasts having abundant cytoplasm with moderate to many granules; Auer rods are often visible	t(8;21)(q22;q22)	25–30
M3	Acute promyelocytic leukemia (APL)	Leukemia cells usually contain heavy azurophilic granulation; nuclear size varies greatly; nuclei are often bilobed or kidney shaped; some cells contain bundles of Auer rods; leukemia cells stain strongly positive for myeloperoxidase; usually HLA-DR negative; there is a microgranular variant (M3V)	t(15;17)(q22;q11-12); t(11;17)	8–15
M4	Acute myelomonocytic leukemia (AMMoL)	Myeloblasts constitute over 30% of the nonerythroid cells, but total granulocytic precursors do not exceed 80%; monocytic cells account for > 20% of the nonerythroid cells; nonspecific esterase and chloroacetate stains are often positive; Auer rods may be present	—	20–25
M4Eo	AMMoL with abnormal eosinophils	Myelomonoblasts plus morphologically and cytochemically abnormal eosinophils	inv(16)(p13;q22); t(16;16)(p13;q22)	5
M5	Acute monoblastic leukemia (AMoL)	Monoblasts, promonocytes, or monocytes constitute 80% or more of the nonerythroid cells; in one subtype (M5A), 80% or more of all the monocytic cells are monoblasts; in the well-differentiated subtype (M5B), less than 80% are monoblasts; α-naphthyl acetate positivity is extinguished by NaF	t(9;11)(p22;q23); t(11q23)	10
M6	Acute erythroleukemia (AEL)	Greater than 50% of the nucleated marrow cells are erythroid; erythroblasts are usually strongly PAS positive; myeloblasts represent 30% or more of the nonerythroid cells	—	5
M7	Acute megakaryoblastic leukemia (AMegaL)	Large and small megakaryoblasts with high nuclear/cytoplasm ratio; cytoplasm is pale and agranular; standard cytochemical stains are not definitive; platelet peroxidase and platelet-specific antibodies are often positive	t(1;22)(p13;q13)	1–2

and applicability when comparing treatment results among institutions, this system has been widely adopted. In addition, the FAB system was shown to have independent prognostic significance regarding survival. The system was revised in 1985 to provide clarification and extend to new diagnostic techniques.[23] Most recently, a committee of the World Health Organization (WHO) described a comprehensive classification scheme that utilizes morphology, immunophenotyping, etiology, and cytogenetics and more clearly distinguishes between AML, MDS, and chronic myeloproliferative disorders [*see Table 1*].[24]

ACUTE MYELOID LEUKEMIA

The blast cells of patients with AML are most often larger than lymphoblasts and display a greater heterogeneity in size and shape. AML blasts have abundant cytoplasm and often contain cytoplasmic granules. Auer rods, azurophilic crystalline-like accumulations of abnormal lysosomal granules visible in the cytoplasm with Wright staining, are detected in about 10% of patients with AML.

A diagnosis of AML is now established when 20% or more of all the nucleated marrow cells are blast cells.[24] The FAB group defined eight variants of AML [*see Table 2*], including three types with predominantly granulocytic differentiation (M1, M2, and M3), two with at least 20% monocytic precursors (M4 and M5), one with a high proportion of erythroblasts (M6), and a more recently recognized and rarely occurring variant with predominance of megakaryoblasts (M7).[23] In addition, the FAB group described a form of AML with minimal myeloid differentiation, designated M0, which cannot be diagnosed solely on morphologic or cytochemical grounds but requires the added use of immunohistochemical staining.[25] These cases express myeloid antigens on the blast cell surface but lack myeloperoxidase reactivity.

MYELODYSPLASTIC SYNDROME

MDS is any one of a heterogeneous group of hematopoietic stem cell disorders characterized by cytologic dysplasia in the bone marrow and blood and by various combinations of anemia, neutropenia, and thrombocytopenia.[2,24,26] These disorders have in common the progressive evolution of a monoclonal population of hematopoietic cells, usually involving multiple lineages, generally with accompanying suppression of normal hematopoiesis. The natural history of these syndromes varies widely, ranging from chronic anemias with a low propensity for leukemic conversion to syndromes with severe hematologic disturbances and a high risk of progression to AML. The examination of well-prepared peripheral blood smears, bone marrow aspirate smears, and bone marrow biopsy specimens can usually confirm the diagnosis of MDS. The marrow should be at least normocellular for the patient's age, and cytologic evaluation of the blood and aspirate smear should show dysplasia in at least one cell line. It should be emphasized that these abnormalities

are not specific to MDS but can be seen in a variety of other inherited and acquired hematologic disorders. Care must be taken to exclude these other processes before making a diagnosis of MDS.

A variety of terms, including preleukemia, smoldering or subacute leukemia, dysmyelopoietic syndrome, and myelodysplasia, have all been used to describe MDS. There is considerable evidence that these disorders are clonal and neoplastic from their earliest detection. Thus, the term preleukemia seems inappropriate, because it implies a premalignant condition. Rather, these disorders are better considered as a chronic or smoldering leukemia. Unfortunately, our diagnostic abilities and nomenclature are not yet adequate to discriminate between clinically distinct subsets within these syndromes, with rare exceptions. There are considerable overlaps with other morphologically determined diseases, particularly those categorized as chronic myeloproliferative disorders (CMPDs). Whereas differentiation of hematopoiesis is qualitatively unimpaired in CMPDs, at least in their early stages, MDS is characterized chiefly by impaired differentiation. Thus, one can speculate that MDS results from alterations of genes that control transcription and cellular differentiation rather than those that regulate cell proliferation or survival.

In 1982, the FAB group attempted to standardize the classification of MDS patients by use of criteria based on cytology and the number of blast cells in the marrow and peripheral blood.[26] Later, another important subset was described: refractory cytopenia with multilineage dysplasia (RCMD).[27] The WHO classification for MDS is now widely accepted [*see Table 3*].[24] In some patients, there is a natural progression of disease between categories as cellular maturation becomes more arrested and blast cells accumulate. In other patients, however, the diagnostic category does not change during the patient's lifespan.

Increased use of cytogenetic analysis and the development of new techniques for assessing clonality are proving useful not only for diagnosis but also for providing insights into pathogenesis and patterns of responsiveness to growth factors and possible differentiation-inducing agents.[28-30] Considerable data suggest that MDS results from combined defects of both stroma and hematopoietic stem cells. Several clinical syndromes that may have a more predictable natural history can now be defined. For example, a deletion of the long arm of chromosome 5 can be detected in some older patients, especially women, with a macrocytic, refractory anemia (RA). The platelet count is typically normal or elevated. The bone marrow picture in the RA with $5q^-$ syndrome is characterized by the presence of monolobulated and bilobulated micromegakaryocytes. Two thirds of these patients have RA or RA with ringed sideroblasts (RARS), and the remainder has RAEB (RA with excess of blasts). In those patients who have a del(5q) as their sole cytogenetic abnormality, MDS tends to follow a more benign course, although progression to AML may occur.[30] Although MDS is not commonly seen in patients younger than 50 years, there are two distinct pediatric syndromes of importance: juvenile chronic myelomonocytic leukemia and the monosomy 7 syndrome.

ACUTE LYMPHOBLASTIC LEUKEMIA

The FAB classification system described three subtypes of ALL (L1, L2, and L3), defined by individual cytologic features such as cell size, nuclear chromatin pattern, nuclear shape, nucleoli, and amount of basophilia in the cytoplasm.[31] The subtype L1 accounts for over 80% of the ALL cases in children and consists of predominantly small cells, up to twice the diameter of a small lymphocyte. The majority of adult cases of ALL are of subtype L2. These cells are larger than cells in L1 and are often heterogeneous in size. This distinction, however, is often arbitrary and provides little guidance for the management of individual patients. Consequently, it has been abandoned. The

Table 3 World Health Organization Classification of Primary Myelodysplastic Syndrome (MDS)

	Subtype	*Peripheral Blood*	*Bone Marrow*
RA	Refractory anemia	< 1% blasts; reticulocytopenia; macrocytic or normochromic/normocytic	Usually erythroid hyperplasia with dyserythropoiesis; < 5% blasts
RA del(5q)	RA with isolated del(5q)	Anemia; < 5% blasts	< 5% blasts; isolated del(5q); no Auer rods
RARS	RA with ringed sideroblasts	No blasts; dimorphic red cell morphology	As in RA, but sideroblasts ≥ 15% of erythroid precursors
RCMD	Refractory cytopenia with multilineage dysplasia	< 1% blasts; cytopenia; multilineage dysplasia; no Auer rods	< 5% blasts; multilineage dysplasia (≥ 10% of cells in ≥ two myeloid cell lines)
RCMD-RS	Refractory cytopenia with multilineage dysplasia and ringed sideroblasts	< 1% blasts; cytopenia; multilineage dysplasia; no Auer rods	< 5% blasts; multilineage dysplasia (≥ 10% of cells in ≥ two myeloid cell lines); ≥ 15% ringed sideroblasts
RAEB-1	RA with excess of blasts–1	< 5% blasts; cytopenias in two or three cell lines; no Auer rods	5%–9% blasts; unilineage or multilineage dyspoiesis
RAEB-2	RA with excess of blasts–2	5%–19% blasts; cytopenias in two or three cell lines; may have Auer rods	10%–19% blasts; unilineage or multilineage dyspoiesis
MDS-U	MDS-unclassified	< 1% blasts; cytopenias	< 5% blasts; unilineage dysplasia; no Auer rods
CMMoL	Chronic myelomonocytic leukemia	< 20% blasts or promonocytes; > 1×10^9/l monocytes; dysplasia in ≥ one myeloid lineage	< 20% blasts or promonocytes; no *BCR/ABL* fusion gene
Atypical CML	Atypical chronic myeloid leukemia	Neutrophilic leukocytosis; prominent dysgranulopoiesis; basophils < 2%	< 20% blasts; no *BCR/ABL* fusion gene; hypercellular

WHO classification recognizes only precursor B cell and precursor T cell subgroups.[24] The least common form of ALL, seen in approximately 3% to 4% of both children and adults, is termed L3. In this subtype, the cells are morphologically identical to the neoplastic cells in Burkitt lymphoma. It is important to recognize L3 because initial treatment of this variant is markedly different from the treatment of other subtypes of ALL. In L3, the cells are large and uniform, with finely stippled chromatin and regular nuclear shape. Nucleoli are often prominent. Cytoplasm is moderately abundant and deeply basophilic.

Cytochemical evaluations of blast cells in ALL reveal characteristic patterns. By definition, stains for lysosomal enzymes such as myeloperoxidase or the Sudan black reaction must be negative to support a diagnosis of ALL. The periodic acid–Schiff reaction will reveal clumpy positivity caused by glycogen in ALL blasts (except L3, which reacts negatively) but is a poor discriminator of cell lineage because many AML cells will also react positively. Chloroacetate esterase and lysozyme stains are negative in ALL, but α-naphthyl acetate esterase may be positive in T lymphoblasts. ALL blast cells contain the enzyme terminal deoxynucleotidyl transferase (TdT), which, when present in the great majority of cells, is a fairly reliable marker for ALL. L3 leukemia cells often stain positively with oil red O because of the neutral lipid within the cytoplasmic vacuoles.

Immunophenotyping of Acute Leukemia

Morphologic examination of blood or bone marrow smears sometimes fails to provide an unequivocal diagnosis. However, identification of various differentiation antigens on the surface of the abnormal cells by flow cytometry studies can rapidly provide this critical information.[32]

ACUTE MYELOID LEUKEMIA

As yet, no AML-specific surface antigens have been identified. Rather, AML cells often coexpress antigens on the cell surface that are not normally coexpressed by their normal myeloid counterparts.[33] Efforts to correlate immunologic phenotyping with the FAB classification of AML or with clinical outcome have in general been imprecise. However, the expression of certain antigens, such as CD34, an early stem cell marker, may carry important prognostic information.[34] In addition, CD33, which is expressed on most myeloblasts, has become an important target for monoclonal antibody–directed therapy.

ACUTE LYMPHOBLASTIC LEUKEMIA

Approximately 80% of cases of ALL arise from the B cell lineage and express B cell differentiation antigens (CD19, CD20, or both) and have undergone heavy-chain and light-chain immunoglobulin gene rearrangement.[35] The leukemia cells in many of these cases also express the common ALL antigen, or CALLA, which is designated CD10. Lymphoblasts from patients with progenitor B cell ALL do not express CD10. CD10-bearing cells can be further divided on the basis of the presence of cytoplasmic μ heavy-chain immunoglobulin (cμ). Most cases of ALL do not express cμ on their blast cells and are termed progenitor-B ALL (if CD10-negative) or common ALL (if CD10-positive). Approximately 20% of CD10-positive cases express cμ and are designated pre-B ALL. Although the immunoglobulin genes are always clonally rearranged in B-lineage ALL, surface immunoglobulin expression occurs in only 2% to 5% of ALL cases. These disorders are termed mature B cell ALL or Burkitt-type ALL and typically display the FAB L3 morphology.

Between 15% and 20% of ALL cases arise from the T cell lineage.[32,35] These cells express T cell antigens such as CD2, CD5, and CD7. CD10 may also be present, but CD19 and CD20 are not. In the majority of cases, one or more of the T cell receptor genes are rearranged. Further subclassification of T cell ALL into early, intermediate, and mature thymocyte types is based on the expression of various T cell differentiation antigens.

Some antigens normally present only on myeloid cells can be expressed by malignant lymphoblasts of B or T cell origin. This disorder is called myeloid antigen–positive ALL.[35,36] A small percentage of ALL cases lack either B cell or T cell features and are termed acute undifferentiated leukemia.

HYBRID LEUKEMIAS

Application of immunophenotyping and molecular probes has uncovered cases in which leukemia cells display characteristics of myeloid and lymphoid cells. In such instances, a single neoplastic cell may coexpress features of distinct lineages (biphenotypic), or two distinct subpopulations of leukemia cells may express either myeloid or lymphoid features separately (bilineal). Various theories have been put forward to explain the occurrence of these hybrid leukemias. One hypothesis, termed lineage infidelity, states that the leukemia cell displays aberrant gene expression by virtue of its neoplastic transformation. Another theory, lineage promiscuity, proposes that normally differentiating cells may express characteristics of more than one distinct lineage and that the leukemia cell is merely reflecting that particular phase in a cell's development. Finally, a theory termed lineage switching proposes that in some cases leukemia is a malignancy of a pluripotent stem cell capable of differentiation along either a myeloid or a lymphoid lineage. Thus, any individual case may express one or both phenotypes. The prognostic significance of such lineage infidelity is uncertain, but these patients often have poor outcomes regardless of whether AML or ALL therapies are used.

Cytogenetics

Cytogenetic abnormalities occur commonly in the acute leukemias and are often used to identify and define the malignant hematopoietic clone.[15] Since the application of chromosome banding techniques in the early 1970s, cytogenetic analysis has provided the most clinically useful approach to subclassifying the acute leukemias. Particular nonrandom chromosomal abnormalities correlate with specific morphologic subtypes and clinical profiles.[15,37-39] These cytogenetic abnormalities are somatic (rather than germline) mutations that frequently result from translocations of chromosomal DNA, resulting in new (abnormal) protein products from the resultant fusion genes. It is assumed that the protein products from these fusion genes are responsible for the cellular dysregulation that leads to the malignant state. Such recurring chromosomal abnormalities are critical in determining therapeutic strategy and have provided important independent information regarding response to therapy and overall prognosis [*see Tables 4 and 5*].

Cytogenetic analysis has furthered our understanding of leukemogenesis.[15] Careful analyses of the chromosomal breakpoints associated with leukemia-specific cytogenetic abnormalities have permitted identification of a number of genes that appear to play an integral role in leukemogenesis.[40,41] The chromosomal location of a large number of these so-called oncogenes

Table 4 Cytogenetic Subsets in Acute Myeloid Leukemia, Treatment, and Outcomes

Karyotype	*Complete Remission Rate*	*Remission Duration*	*Treatment Approach*
t(8;21)(q22;q22)	High	Long	Standard induction with cytarabine and an anthracycline; intensive consolidation with several courses of high-dose cytarabine
inv(16)(p13;q22) or t(16;16)(p13;q22)	High	Long	Standard induction with cytarabine and an anthracycline; intensive consolidation with several courses of high-dose cytarabine
t(15;17)(q22;q11-12)	High	Long	All-*trans*-retinoic acid together with an anthracycline; arsenic trioxide to treat relapse

del(5q), +13, +8, -7, inv 3, del(12p), t(9;22), other t(11q23), or complex abnormalities	Low	Short	New induction regimens, including use of growth factors during or after chemotherapy, or modulators of drug resistance; perform stem cell transplantation in first complete remission

has been identified. The functions of these oncogenes are being investigated, but many are involved in intracellular signaling pathways and the control of cellular proliferation and differentiation. Structural chromosomal changes may lead to activation or perturbation of oncogene expression resulting in disturbance of cellular regulation and eventually malignant transformation. Deletions or loss of DNA may eliminate genes that have tumor suppressor functions.

General Principles of Therapy

The goal of remission induction chemotherapy is the rapid restoration of normal bone marrow function. The term complete remission (CR) is reserved for patients who have full recovery of normal peripheral blood counts and bone marrow cellularity with less than 5% residual blast cells [*see Table 6*]. Induction therapy aims to reduce the total-body leukemia cell population from approximately 10^{12} cells to below the cytologically detectable level of about 10^{9} cells. The leukemia cells in some patients have high levels of primary drug resistance and will be refractory to courses of remission induction chemotherapy. It is assumed, however, that even in CR a substantial burden of leukemia cells persists undetected, leading to relapse within a few weeks or months if no further therapy is administered. Postinduction or remission consolidation therapy, usually comprising several additional courses of chemotherapy, is designed to eradicate residual leukemia, allowing the possibility of cure. Multiple chemotherapy drugs in high doses are typically used to prevent emergence of resistant subclones and to limit cumulative and overlapping toxicities. Lower doses of prolonged remission maintenance therapy lasting 1 to 3 years have been used with some success in ALL, but this adjunctive therapy has uncertain value in AML.

Complications of cytotoxic therapy include tumor lysis syndrome with urate nephropathy and electrolyte imbalance (hyperkalemia, hypocalcemia, and hyperphosphatemia), gastrointestinal injury (mucositis and diarrhea), thrombocytopenic bleeding, and neutropenic infections. Prophylactic measures and supportive care are critically important during the treatment period. Patients must receive adequate intravenous hydration. Hyperuricemia responds rapidly to rasburicase. Allopurinol, parenteral hydration, and alkalinization of the urine reduce the likelihood of uric acid precipitation in the renal tubules. Blood products are transfused to maintain a platelet count greater than 10,000/μl in a nonbleeding patient and a hematocrit greater than 25%. Broad-spectrum antibiotics are be-

Table 6 Terminology Used in Leukemia Treatment

Term	*Definition*
Remission induction therapy	Initial chemotherapy treatment aimed at achieving a complete remission (CR)
Remission consolidation (intensification) therapy	Postremission therapy aimed at destroying clinically occult disease
Maintenance (continuation) therapy	Lower dose of chemotherapy aimed at preventing reemergence of leukemia
CR	Disappearance of leukemia after treatment, with full regeneration of normal hematopoiesis
Cytogenetic (or molecular) CR	Inability to detect residual leukemia by use of genetic methods
Minimal residual disease	Persistent leukemia, not detectable by light microscopy
Refractory disease	Leukemia that does not enter CR
Relapsed disease	Clinically overt recurrence of leukemia after CR
Immunophenotype	Pattern of expression of cell surface or cytoplasmic markers
Cytogenetics	Analysis of chromosomes in metaphase cells for additions, losses, or rearrangements
Multidrug resistance	Biologic feature that protects cells from certain classes of chemotherapy drugs through different membrane mechanisms
Stem cell transplantation	Transfusion of hematopoietic stem cells from the patient (autologous) or a normal donor (allogeneic) after high-dose chemoradiotherapy

gun empirically whenever the temperature exceeds 38.5° C (101.3° F) in a neutropenic patient (neutrophils < 500/μl), and antifungal therapy is added for persistently febrile patients.

Myeloablative therapy followed by transplantation of bone marrow or hematopoietic stem cells (SCT) using an HLA-identical sibling donor is an established treatment modality in acute leukemia and is indicated for suitable high-risk patients in first remission or for any young or middle-aged patient in first relapse or second remission.[42] Allogeneic SCT (alloSCT) has two therapeutic components. Intensive myeloablative therapy is used to eradicate all tumor cells, if possible. Secondly, T cells in the donor marrow can produce a graft versus leukemia immune response that can destroy remaining leukemia cells; this effect has been correlated with improved disease-free survival. Unfortunately, this beneficial immune response is closely associated with acute and chronic graft versus host disease (GVHD), a major cause of morbidity and mortality after alloSCT. GVHD can be reduced by T cell depletion from the donor marrow but only at the cost of increased rates of graft failure and leukemia relapse. Because the risk of treatment-related mortality increases with age, most centers restrict SCT to patients younger than 60 years. The use of alloSCT is also limited in part by donor availability. A patient has only a 25% to 30% chance that a sibling will have inherited the identical HLA alleles.

Autologous SCT allows the use of myeloablative therapy in the absence of an allogeneic marrow donor as well as in older patients.[43] The appropriate role for this treatment modality is controversial. Treatment-related morbidity and mortality (< 5%) are relatively low, thus allowing its use in older patients, but relapse rates are high, and overall outcomes are not clearly better than in patients who receive intensive but nonablative therapy. Peripheral blood stem cell transplantation appears to be as good as, if not better than, SCT and is being used more frequently in the treatment of hematologic cancer. A recent study indicated that peripheral stem cells restore blood counts faster than marrow cells without increasing the risk of GVHD.[44]

Acute Myeloid Leukemia

DIAGNOSIS

Clinical Features

Typically, antecedent symptoms such as fatigue are brief in patients with AML. About one third of patients will present with bruising or hemorrhage. One quarter of patients will have a serious infection involving the lungs, soft tissues, or skin. Splenomegaly and hepatomegaly are not common, occurring in less than 25% of patients. Lymphadenopathy is even less common. Gingival hypertrophy or skin infiltration by leukemia (called leukemia cutis) occurs in 50% of patients with monocytic leukemia. Patients with acute promyelocytic leukemia (APL) frequently present with more severe bleeding from disseminated intravascular coagulation.

The leukocyte count is elevated above the normal range in 50% of AML patients. Counts above 100,000/μl are reported in fewer than 10% of patients, but these patients may have severe CNS effects or respiratory distress from leukostasis; emergency leukapheresis and chemotherapy may be lifesaving. The peripheral blood contains some leukemic blast cells in 85% to 90% of cases. The absolute neutrophil count is almost always depressed in AML and is less than 1,500/μl in 50% of patients at diagnosis. A moderate degree of anemia is common, and the platelet count is typically less than 100,000/μl and often less than 20,000/μl.

Mild to moderate elevations of serum uric acid levels are common and typically reflect increased cell turnover. The serum lactate dehydrogenase (LDH) level may be elevated but not as commonly as in ALL. Muramidase (lysozyme) is elevated in the serum or urine of patients with acute myelomonocytic or monoblastic leukemia and may contribute to renal dysfunction.

AML is not limited to the bone marrow and peripheral blood. Abnormalities in one or more organ systems may result from leukemia cell infiltration or metabolic complications related to leukemia. Rarely, a patient with AML develops a solid mass of leukemia cells called a granulocytic or myeloid sarcoma (chloroma). The skin and bones (particularly the sternum, ribs, and orbit) are most commonly involved, but myeloid sarcomas can occur in any organ. Respiratory distress in patients with AML is most often caused by infection. However, patients with very high numbers of circulating blast cells (> 100,000/μl) may experience severe dyspnea and hypoxemia because of leukostasis within the pulmonary vasculature. Cardiac dysfunction, including murmurs, heart failure, and dysrhythmias, is most often secondary to anemia.

Retinal hemorrhages are most often caused by thrombocytopenia. However, patients with extreme hyperleukocytosis may develop so-called cotton-wool spots as a result of retinal ischemia. Frank CNS involvement and cranial neuropathies are unusual at the time of initial diagnosis of AML.

Cytogenetic Abnormalities

Clonal chromosomal abnormalities can be detected in most cases of AML.[1,15] These abnormalities include gains or losses of whole chromosomes or losses of the long (q) or short (p) arms of chromosomes (deletions), as well as a variety of structural re-

arrangements (translocations, inversions, or insertions).

It is strongly recommended that cytogenetic analysis be performed before initiation of therapy on every newly diagnosed patient because studies of the prognostic significance of recurring cytogenetic abnormalities in AML have yielded consistently similar results.[1,38] Cytogenetic characterization has become the strongest predictor of both response to therapy and remission duration.[37] Thus, in many centers, plans for postremission therapy rely heavily on cytogenetic analysis at diagnosis [*see Table 3*].

Cytogenetic data have been used to map chromosomal breakpoints at a molecular level, allowing the use of probes for fluorescence in situ hybridization (FISH) and of primers for reverse transcriptase polymerase chain reaction (RT-PCR) methods for the detection of tumor cells. FISH and RT-PCR can detect molecular genetic rearrangements not visible when examining chromosome bands by conventional methods. However, both of the newer methods test only for specific, defined genetic mutations and cannot be used initially for general screening or for a comprehensive evaluation. FISH analysis is more sensitive than conventional karyotype analysis and can be performed on both metaphase and interphase cells. The morphology of the positive cells can be determined concurrently, and the proportional involvement by leukemia of all of the hematopoietic cells can be evaluated.

RT-PCR is the most sensitive method for detecting occult leukemia cells (about 1 in 10^5 cells). Newer methods are quantitative, and the clinical significance of a positive result after treatment is being investigated. A positive assay confirms the presence of cells with the specific genetic abnormality but does not necessarily indicate the neoplastic growth potential of these cells. For example, a positive RT-PCR assay after treatment appears to predict leukemia relapse reliably in patients with APL and a t(15;17), but not in patients with AML-M2 and a t(8;21).[45,46]

TREATMENT

Remission Induction Therapy

The most common remission induction regimen used for patients with AML is cytarabine given by continuous intravenous infusion daily for 7 days plus daunorubicin given daily for 3 days (the 7 + 3 regimen). Depending on age and patient selection, 50% to 80% of patients achieve CR.[47,48] The outcome in general has not been improved by the substitution of other anthracyclines such as idarubicin or mitoxantrone for daunorubicin, by increasing the dose of cytarabine, or by adding a third or fourth cytotoxic drug.

Postremission Therapy

Additional chemotherapy after a successful remission induction is mandatory to cure AML. The median disease-free survival for patients who receive no additional therapy is only about 4 months. When several courses of consolidation chemotherapy are given, survival at 4 years is 40% to 50% for young and middle-aged adults. For patients younger than 60 years, consolidation therapy results in significantly longer survival than maintenance therapy alone.[47-49] For consolidation, the same induction chemotherapy may be repeated for one or more cycles, with or without dose intensification, or non–cross-resistant drugs can be used. There is increasing evidence that high-dose cytarabine (HiDAC) provides the best survival for good- and intermediate-prognosis patients.[50-52]

Maintenance therapy with relatively nonmyelosuppressive doses of cytotoxic drugs has no proven benefit in the management of AML. Currently, clinical trials are testing the benefit of immunomodulatory therapies such as interleukin-2 for AML patients in remission.

Most studies reporting on allogeneic or autologous SCT for AML patients in first CR are nonrandomized, and many are retrospective.[53] Considerable selection bias is generated by the delay between remission induction and transplantation and by the entry requirements for good performance status for most trials. Prospective, randomized studies comparing intensive consolidation chemotherapy with SCT have failed to show a clear survival advantage[54-57] [*see Table 7*].

Treatment of Patients with Relapsed or Refractory AML

A limited number of agents are effective in the treatment of AML, and management of patients with resistant or relapsed disease is difficult. Patients with long initial remissions (> 1 year) have a 50% to 60% reinduction rate with daunorubicin and cytarabine or with HiDAC, but the duration of the second remission is usually shorter than that of the first. Gemtuzumab ozogamicin, an anti-CD33 immunoconjugate, is active as a single agent in relapsed AML.[58] SCT should be considered for any patient who has undergone relapse after an intensive initial treatment program.

ACUTE PROMYELOCYTIC LEUKEMIA

APL (FAB M3) is a biologically distinct disease with characteristic clinical, morphologic, and cytogenetic features.[45,59,60] It constitutes about 8% to 15% of cases of AML. The malignant cells have a t(15;17) that juxtaposes the *RARα* gene on chromosome 17 with the *PML* gene on chromosome 15. Disseminated intravascular coagulation at presentation or soon after the initiation of cytotoxic chemotherapy can cause pulmonary or cerebrovascular hemorrhage in up to 40% of patients and is associated with a high mortality. The cytoplasmic granules in the leukemic blasts contain factors with procoagulant as well as fibrinolytic activity.[61]

All-*trans*-retinoic acid (ATRA, or tretinoin) was first used in the treatment of APL in China in 1986 and has proved to be a highly effective remission-induction agent.[59,60] ATRA accelerates the terminal differentiation of malignant promyelocytes to mature neutrophils, leading to apoptosis and CR without bone marrow hypoplasia. This effect is a unique consequence of the rearranged *PML/RARα* gene resulting from the t(15;17) that defines APL.[45] ATRA induction therapy produces CR rates of 80% to 95% in both previously untreated patients and patients in relapse. The best results have been obtained when ATRA was combined with daunorubicin and cytarabine or with idarubicin alone.[59,62] Arsenic trioxide is an effective treatment for patients with relapsed APL.[63]

ATRA does not have the usual toxicities associated with cytotoxic chemotherapy. Intrinsic drug toxicity is generally minor. ATRA is neither immunosuppressive nor myelosuppressive. However, two serious and specific complications may occur with ATRA treatment of APL.[64] In 25% to 40% of patients, the so-called retinoic acid syndrome develops within 2 to 21 days after initiation of treatment and is characterized by fever, peripheral edema, pulmonary infiltrates and respiratory distress, hypotension, renal and hepatic dysfunction, and serositis leading to pleural and pericardial effusions. The syndrome is possibly the result of the infiltration of tissue by maturing malignant promyelocytes and the systemic effects of cytokine release. Ear-

ly recognition and aggressive treatment with dexamethasone has been effective. Hyperleukocytosis occurs in up to 50% of patients treated with ATRA and is probably secondary to the induction of cellular maturation.

Management of the coagulopathy associated with APL may be difficult and should be done expectantly.[59] Coagulation parameters, including fibrinogen, D-dimer, and platelet levels, should be monitored closely. Platelet transfusions and cryoprecipitate or fresh frozen plasma are used to maintain the fibrinogen level above 100 mg/dl and the platelet count above 20,000/μl. The role of heparin is controversial; a continuous low-dose infusion (5 to 10 U/kg/hr) has been reported to be effective at stopping the consumption of clotting factors. Inhibitors of fibrinolysis should be considered only for life-threatening hemorrhage. The coagulopathy of APL typically improves rapidly after treatment with ATRA is begun.

MYELODYSPLASTIC SYNDROME

No specific, uniformly effective therapy currently exists for MDS. Clinical prognostic factors, including bone marrow morphology and cytogenetics, should be evaluated at diagnosis.[30] A period of observation with close follow-up of serial blood counts is recommended for initial management, and a second bone marrow examination after several months is useful to assess the rapidity of disease progression.

RA and RARS often follow a clinically indolent course; patients may need no treatment for variable lengths of time. However, patients who are severely anemic (hemoglobin < 7 to 8 g/dl) should receive red blood cell (RBC) transfusions. Washed RBC units are rarely necessary. Commonly, the recurrence of fatigue or angina is a more useful indicator of the need for the next RBC transfusion than any particular hemoglobin level. Transfusion requirements increase as MDS progress, and iron overload and hemochromatosis may occur.

Prophylactic platelet transfusions are not routinely administered to thrombocytopenic patients with MDS who are not bleeding, because of the expense, inconvenience, and risk of alloimmunization. This risk increases with the frequency of platelet transfusion and may limit future treatment options. Platelet support should be reserved for treatment of acute hemorrhage or for prophylaxis before surgery. MDS patients with thrombocytopenia should be carefully instructed to avoid aspirin-containing products and other nonsteroidal anti-inflammatory agents, which interfere with platelet function.

Infections are a common problem in patients with MDS and can be life-threatening. The utility of vaccines (pneumococcal, influenza, and hepatitis B) should not be overlooked. Fever, localized infections, or even general malaise should be carefully evaluated in patients who have both quantitative and functional neutropenia. Prompt institution of broad-spectrum antibiotic therapy while trying to locate the source of infection is critical; therapy should be continued for 7 to 10 days even in the absence of an obvious source of infection or positive blood cultures. If a neutropenic patient fails to respond to antibacterial agents or has repeated episodes of fever in the absence of an obvious source, a fungal infection should be suspected, and treatment with amphotericin B, fluconazole, or itraconazole should be initiated.

The role of cytotoxic drugs in the treatment of MDS is uncertain for the majority of patients but should be considered for younger and healthier patients with more aggressive forms of disease, such as those with RCMD, RAEB, and therapy-related MDS (t-MDS). In general, cytotoxic therapy with standard regimens used in the treatment of AML (e.g., containing daunorubicin and standard or high doses of cytarabine) has had limited success in extending survival for the majority of MDS patients. This poor outcome is not surprising, for a number of reasons: (1) most MDS patients are elderly and tolerate aggressive treatment poorly, (2) the number of normal hematopoietic stem cells available to regenerate the marrow after therapy-induced hypoplasia is probably reduced, and (3) the majority of effective antileukemia drugs may be relatively ineffective in the low proliferative states seen in MDS because these drugs act primarily during cell division. For these reasons, intensive chemotherapy has been associated with CR rates of only 10% to 40%, with duration of remissions generally lasting less than 1 year. The toxicity of the therapy and the prolonged marrow hypoplasia and cytopenia that it produces may actually shorten the lives of older patients. It is therefore important to direct this treatment option primarily to younger MDS patients, who are better able to tolerate it.

Allogeneic SCT has been tested as curative therapy in the small group of MDS patients who are younger than 60 years (approximately 10% to 20% of all MDS patients) and for whom a histocompatible donor is available.[65] Approximately 45% of patients who undergo transplantation have disease-free survival. Patients with favorable or intermediate cytogenetic factors have better outcomes than those with poor risk factors. These data suggest that appropriately chosen patients can probably be cured with SCT.

Because the vast majority of patients with MDS are not candidates for SCT and because the outcome with conventional cytotoxic therapy has generally been poor, attention has been focused on a variety of agents that can induce differentiation of acute leukemia cell lines in vitro, slowing proliferation and restoring apparently normal maturation and function. Several such so-called differentiating agents (e.g., low-dose cytarabine, azacitidine, thalidomide, amifostine, and growth factors) have been tested in clinical trials of MDS.[66-69] Clinical trials have not demonstrated any benefit from the long-term administration of myeloid colony-stimulating factors (such as granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage CSF [GM-CSF]), although they may have a role as a short-term adjunct with antibiotics in the treatment of infections. Erythropoietin therapy has been beneficial only for anemic patients with inappropriately low endogenous erythropoietin levels in the blood.

TREATMENT OF OLDER PATIENTS WITH ACUTE MYELOID LEUKEMIA

Two factors combine to explain in large part the poor outcome of older patients with leukemia.[70] Most evident is the inability of many of these patients to withstand the rigors of intensive chemotherapy and its expected complications. Patients with age-related chronic cardiac, pulmonary, or renal disorders suffer greater acute toxicity from chemotherapy. Older patients may also have less bone marrow regenerative capacity, even after successful leukemia cytoreduction. Inability to tolerate long periods of pancytopenia and malnutrition and the nephrotoxicity of aminoglycosides or amphotericin remain major barriers to successful treatment.

Less obvious is the fact that the genetic mutations most often associated with treatment failure in young patients (e.g., abnormalities of chromosome 5 or 7 in AML or t(9;22) in ALL) are more common in older patients. Conversely, all of the so-called favorable cytogenetic abnormalities, such as t(8;21), t(15;17), and inv(16) in AML, are more common in younger adults and are responsible in part for the better disease-free survival of young and middle-aged adults.[15,37] The multidrug-resistant phenotype that results in part from the overexpression of the P-glycoprotein responsible for drug efflux from AML cells is also more common in older patients.[71]

MDS is more resistant to therapy and is also more common in older patients. Many cases of AML with dysplasia in older patients have presumably evolved through a myelodysplastic phase. MDS is characterized by the stepwise accumulation of genetic abnormalities, analogous to the evolution of new chromosomal abnormalities that occurs as chronic myeloid leukemia accelerates into the terminal blast phase. The multidrug-resistant phenotype may also emerge during this evolutionary process. At the same time, normal hematopoiesis is increasingly inhibited, and the normal stem cell compartment may be lost. The net result is ineffective hematopoiesis and dysfunctional blood cells. By the time AML emerges, these patients often have infections from pathogenic flora; in addition, these patients often experience recurrent bleeding episodes, and they are often dependent on transfusions. The outcome after chemotherapy in these patients has been poor.

Primum Non Nocere

Not every patient benefits from intensive chemotherapy; this is particularly true of older patients. Well-meaning attempts to induce remission may actually shorten survival. Patients unlikely to survive treatment can be identified by their poor performance status or comorbid disorders. Case series from large referral institutions suggest that 25% to 50% of AML patients older than 60 years are not offered remission-induction chemotherapy.

In a few older patients with acute leukemia (determined by the usual quantitative criteria of > 20% bone marrow blast cells), the disease has a much more smoldering course, especially when the patients have had MDS. These patients suffer from bone marrow failure and pancytopenia more than from hyperleukocytosis. Their survival may be equally long and their quality of life better if transfusion support and antibiotics are used rather than intensive chemotherapy. This finding may be particularly true for patients with hypoplastic AML.

Otherwise healthy, older patients with acute leukemia, especially those with favorable cytogenetic features, should be offered curative chemotherapy. With a standard 7 + 3 regimen of cytarabine and an anthracycline, approximately half of patients older than 60 years will achieve a CR. Unfortunately, even with postremission consolidation chemotherapy, the overall survival for this group is less than 10% after 4 years.[52,70,72]

Hematopoietic Growth Factors

Several large controlled trials that studied the use of GM-CSF or G-CSF mostly in older patients with AML demonstrated that the duration of neutropenia was only minimally decreased when growth factors were given after remission-induction chemotherapy.[72,73] Even though a more rapid recovery of neutrophils has been observed in some trials, the nadir has not been affected, and thus, the incidence of severe infection remains high. At the same time, stimulation of leukemia regrowth by myeloid growth factors appears to be uncommon in vivo. There may be greater benefit from using growth factors after consolidation chemotherapy, when patients are already in remission, than there is from using growth factors earlier, during remission induction.[74] As yet, growth factors have not had a marked impact on survival or remission duration for patients with AML.

Acute Lymphoblastic Leukemia

ALL accounts for approximately 20% of adult acute leukemias. In contrast, ALL is by far the most common malignant disease in childhood.

DIAGNOSIS

Clinical Features

The clinical presentation in adults is most often acute. Symptoms are usually present for only a few weeks before diagnosis. Malaise, lethargy, weight loss, fevers, and night sweats may be present but are typically not severe. Bone pain and arthralgias occur occasionally but much less frequently in adults than in children. Infection and hemorrhage are present in one third of patients at diagnosis but are most often not as severe as in AML. Lymphadenopathy, splenomegaly, and hepatomegaly are more common than in AML, affecting half of adults with ALL. Chest radiographs may reveal a thymic mass in 10% to 15% of adults. The majority of these patients have T cell ALL.

CNS involvement by leukemia occurs in 5% to 10% of adult cases but is uncommon at diagnosis. Cranial nerve palsies most often involve the sixth and seventh cranial nerves. Headache and papilledema may be present, resulting from meningeal in-

filtration and obstruction of the outflow of CSF, leading to increased intracranial pressure. Retinal hemorrhages may be the result of thrombocytopenia.

Varying degrees of neutropenia, anemia, and thrombocytopenia are detected on the peripheral blood examination. In one series of over 1,200 adult cases, the granulocyte count was below 1,500/μl in only one fifth of patients.[75] Mild to moderate reductions in hemoglobin level were typical, but in almost one third of patients, the hemoglobin level was below 8 g/dl. Thrombocytopenia was frequent, and in over one half of patients, the platelet count was below 50,000/μl. The total leukocyte count was diminished in about one third of patients and normal or moderately elevated in close to one half. Characteristic lymphoblasts can be identified in the peripheral blood in over 90% of cases. Marked leukocytosis (> 100,000/μl) was present at diagnosis in 16% of cases, but symptomatic leukostasis is uncommon in ALL, even at these levels.

Cytogenetic Abnormalities

It is now possible to characterize subsets of ALL by distinctive genetic features. These more homogeneous subgroups of ALL have shown important clinical differences in response to specific treatment regimens.[39,76] Subgroups include precursor B cell and Burkitt cell leukemia and precursor T cell ALL cases [*see Table 5*]. However, the precursor B cell group of cases can be subdivided according to cytogenetic and molecular features. Two important subgroups are associated with a more favorable outcome. Hyperdiploid ALL with less than 50 chromosomes accounts for 25% of ALL in childhood; these cases have an 80% to 90% cure rate. Similarly, in another 20% to 25% of childhood ALL cases, patients have the *TEL/AML1* fusion gene (also called *ETV6/CBFA2*), which results from the cryptic (12;21) translocation; these cases also have an 85% to 90% cure rate. Unfortunately, these genetic subtypes are rarely seen in adult series. Instead, the single largest subgroup of adult patients with ALL are those with the *BCR-ABL* fusion gene, which results from the (9;22) translocation. The resulting subtype of ALL, also known as Philadelphia chromosome–positive (Ph^+) ALL, makes up 25% to 30% of cases of adult ALL and may not be curable with conventional chemotherapy alone. In contrast, patients with a translocation involving chromosome band 14q11 or overexpression of the *HOX11* gene usually have T cell ALL and have a good prognosis with conventional multiagent regimens. Patients with Burkitt cell ALL usually have an 8;14 translocation (*MYC/IGH* fusion gene) and also have a good prognosis, but they require quite different chemotherapy. The other recurring chromosomal abnormalities and fusion genes [*see Table 3*] are less common but again appear to identify patients that may have very different prognoses.

It is important to note that the considerable differences in long-term outcome between these various cytogenetic subgroups are not so apparent when examining only the initial CR rate. That is, with current intensive induction programs, 80% of the patients with poor-risk cytogenetics nevertheless achieve a remission comparable to 90% of those with normal karyotypes or other abnormalities. The clinical importance of this fact is that these poor-risk patients respond sufficiently well to initial treatment to become candidates for an early allogeneic SCT.

TREATMENT

The aims of modern ALL treatment regimens are the rapid restoration of bone marrow function by use of multiple chemotherapy drugs at acceptable toxicities to prevent the emergence of resistant subclones; the use of adequate prophylactic treatment of sanctuary sites, such as the CNS; and postremission consolidation therapies to eliminate minimal (undetectable) residual disease. Postremission therapy has traditionally been categorized as intensification or consolidation treatment followed by prolonged maintenance.

Four or five drugs (e.g., vincristine, prednisone, daunorubicin, L-asparaginase, and cyclophosphamide) are typically used for remission induction, followed by similar agents plus antimetabolites for remission consolidation treatment.[36,76-79] The vast majority of adults (80% to 90%) do enter CR. Approximately 30% to 50% will be alive and free of disease 3 years later.

Important adverse prognostic factors in ALL have a major influence on complete remission rates and on remission duration and survival.[36,76,77] In multivariate analyses, patients presenting with leukocyte counts greater than 30,000/μl have had significantly shorter durations of remission than patients with lower leukocyte counts. However, extreme leukocytosis does not negatively affect outcome in patients with T cell ALL.[36] Older age (> 60 years) is another adverse characteristic. Karyotype at diagnosis is an independent predictor of outcome and the key to successful treatment planning.[39,77] Minor factors, or factors that have had some significance with certain treatment regimens, are the percentage of circulating blast cells; the degree of bone marrow involvement; the presence of hepatomegaly, splenomegaly, or lymphadenopathy; LDH levels; CNS involvement at presentation; and the time required to achieve complete remission (e.g., > 4 to 6 weeks).

Remission Consolidation Treatment

Remission consolidation treatment is designed to eradicate the rapidly proliferating neoplastic cells that are thought to be responsible for early relapses. In general, drugs given during this period are cell-cycle phase–specific antimetabolites. Unlike remission-induction therapy, whose importance is securely established, intensive consolidation therapy is not indisputably needed for achieving cure. The relative benefit of any particular consolidation therapy is likely to be inversely proportional to the intensity of the initial induction therapy and its efficacy in rapidly reducing the leukemia cell mass. Transplantation has not proved to be better than intensive chemotherapy for ALL in first CR, in general, but it clearly leads to cures in patients with chemotherapy-resistant subtypes of ALL.[80-82]

Maintenance Therapy

A prolonged period of treatment with low doses of chemotherapy drugs, called remission-maintenance or continuation therapy, is still standard in ALL. This approach stands in marked contrast to treatment of most other so-called curable cancers, such as Hodgkin disease, large cell lymphoma, or testicular cancer, in which cure follows the initial intensive cytoreductive therapy and low-dose maintenance chemotherapy provides no additional benefit. The necessity of prolonged maintenance therapy for adults with ALL may also be a function of the intensity and the success of initial chemotherapy. Traditionally, 1 to 3 years of treatment with 6-mercaptopurine and methotrexate, often with monthly pulses of vincristine and prednisone, have been given. As yet, the need for maintenance therapy has not been proved in adults, but it is likely to be important at least for some types of ALL.

CNS Prophylaxis

The CNS is an important site of involvement by ALL.[83] Although not commonly found at diagnosis, CNS involvement is common at the time of relapse. The meninges may harbor leukemia cells, and the blood-brain barrier may shelter them from systemic chemotherapy. Recurrence within the CNS usually coincides with systemic relapse. The likelihood of an isolated CNS relapse for adults with ALL appears to be about 5%. Preventive treatment of the CNS during postremission therapy, termed CNS prophylaxis, has become an integral part of virtually all current adult ALL treatment protocols. Although the true value of CNS prophylaxis in adults is controversial, studies have shown that adult patients who either refused or could not receive CNS prophylaxis had a higher rate of CNS relapse than patients receiving prophylaxis. CNS leukemia is more easily prevented than treated; once overt CNS leukemia has developed, there is a high likelihood of subsequent CNS relapse despite treatment.

CNS prophylaxis typically consists of cranial irradiation plus intrathecal methotrexate. Cytarabine and hydrocortisone are sometimes added to methotrexate for triple intrathecal therapy. In lieu of cranial irradiation, some investigators have substituted high-dose systemic chemotherapy with methotrexate or cytarabine because therapeutic levels of these drugs can be achieved in the CSF when the drugs are administered intravenously in high doses.[79] Overall, the superiority of any one prophylactic therapy has not been established.

BURKITT CELL ALL

The first of the high-risk subsets that warrants special attention is Burkitt cell ALL, also known as FAB L3 or mature B cell ALL. This subset makes up 3% to 5% of adult ALL cases. The ubiquitous biologic features are the presence of monoclonal surface immunoglobulin, the 8;14 translocation or one of its two variants—t(2;8) or t(8;22)—and the constitutive expression of the oncogene *MYC*. It is relatively easily recognized at diagnosis from the characteristic clinical findings of hepatosplenomegaly and lymphadenopathy. The LDH and uric acid levels are usually markedly elevated, and there is often leptomeningeal involvement. The lymphoblasts usually lack TdT reactivity. In the past, few if any of these patients survived after standard ALL treatment regimens. Now, however, short, intensive chemotherapy programs for B cell ALL yield a high CR rate and a survival plateau in the range of 50%.[84] These regimens, which may require as few as 16 to 18 weeks of treatment, use high doses of methotrexate, cytarabine, and cyclophosphamide or ifosfamide together with other ALL drugs.

PHILADELPHIA CHROMOSOME–POSITIVE ALL

Ph^+ ALL is identified by the t(9;22)(q34;q22) or the *BCR-ABL* fusion gene. It is currently the major challenge in curing ALL because it makes up 25% to 30% of all adult cases and perhaps one half of all B-lineage ALL.[39,85] Some progress has been made. Approximately 70% of patients achieve a CR, but the remission durations are markedly shorter (median, 7 months) for Ph^+ cases than for those without a Ph chromosome (remission of almost 3 years).[36,39,79,82,86] As yet, no chemotherapy regimen alone appears to have the potential to cure this group of patients. In contrast, allogeneic SCT cures about one third of patients with Ph^+ ALL.[80,82] The probability of relapse after transplantation is approximately 30% to 50%, further attesting to the therapy-resistant nature of this disease.

Table 8 Treatment Outcome for Adults with Acute Leukemia

Disease Subset	*Complete Remission (%)*	*Disease-Free Survival (%)*
AML, overall	60–70	20–40
Favorable karyotype	90	60–70
APL, t(15;17)	90	70–75
< 60 yr	70–80	40
≥ 60 yr	45–55	5–10
ALL, overall	80–90	30–40
T-ALL	90–95	60–65
Precursor B cell ALL	75–85	30–40
Ph^+ ALL	70–75	0–10
Burkitt cell ALL	75	70
≥ 60 yr	75–80	10–25

ALL—acute lymphoblastic leukemia AML—acute myeloid leukemia APL—acute promyelocytic leukemia Ph^+—Philadelphia chromosome–positive T-ALL—T cell acute lymphoblastic leukemia

Thus, at this time, the treatment for Ph^+ ALL should include an intensive remission-induction chemotherapy program, followed by allogeneic SCT in the first CR if a donor is available. Considerable interest exists in investigating new agents, especially the tyrosine kinase inhibitor imatinib mesylate, in this high-risk group of patients.[87]

ALL patients with a t(4;11)(q21;q23) are another cytogenetic subset that has had a poor outcome after conventional therapy and should undergo allogeneic transplantation, if possible. The involved gene on chromosome 11 was named *MLL*, for mixed-lineage leukemia.[15] The incidence is 3% to 6% in adult cytogenetic series.[39] The immunophenotype is progenitor B cell (CD19, CD22, and HLA-DR positive and CD10 negative).[88] In adults, these patients are often older women (more than half are older than 50 years) with high leukocyte counts.

Despite major advances in the treatment of adults with acute leukemia in the past decade, many patients continue to die of their disease or of complications of its treatment [*see Table 8*]. However, a number of novel experimental and clinical approaches hold promise for improving cure rates. Application of modern molecular technologies designed to detect minimal residual leukemia may aid clinicians in monitoring disease during and after chemotherapy.[89] It could, for example, lead to the early detection of patients likely to experience relapse, for whom further therapy may be necessary. Novel methods of circumventing multidrug resistance, exploiting immune mechanisms, or altering the control of malignant cell growth need to be investigated.

The author has received grants for clinical research or educational activities or has served as advisor or consultant during the past year for Novartis AG, Sanofi-Synthelabo Inc., and Wyeth.

XVII CHRONIC MYELOGENOUS LEUKEMIA AND OTHER MYELOPROLIFERATIVE DISORDERS

Stefan Faderl, m.d.
Hagop M. Kantarjian, m.d.

The myeloproliferative disorders (MPDs) represent clonal disorders of the pluripotential hematopoietic stem cell and include chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), myeloid metaplasia, and idiopathic myelofibrosis (IM). Patients with hybrid, or mixed, MPD may sometimes present with features of several of these entities (e.g., elevated hemoglobin and platelet counts), or features may shift from one to another.

Although each of these conditions represents a predominant expansion of one cell type (such as neutrophils in CML, erythrocytes in PV, and megakaryocytes in ET), cytogenetic studies have demonstrated that these cells are all clonally identifiable and are therefore derived from the same parental cell. Although myelofibrosis is recognized as a primary disorder, it frequently accompanies the other MPDs to various degrees. In all these circumstances, the bone marrow fibrosis is polyclonal, suggesting that this phenomenon is secondary to the activity of an abnormal stem cell clone, a theory supported by the fact that myelofibrosis can disappear if the abnormal stem cell clone is ablated. Clonal evolution follows at various frequencies, occurring in 5% to 90% of patients; it results in cell transformation and disease progression that frequently is manifested as acute leukemia–type clinical syndromes or so-called burnt-out fibrotic bone marrows.

Although the MPDs have similarities in the proliferation of cell lineages, peculiar molecular-pathogenetic differences distinguish the MPDs from one another in clinical presentation and clinical course, rate of transformation to acute leukemia, choice and response to therapy, and prognosis [*see Table 1*]. The molecular-cytogenetic pathophysiology has been extensively described in CML but is less well understood in other MPDs. Unraveling the molecular events involved in the initiation and transformation of CML has provided novel therapies that have changed the natural history of CML and made the disease a paradigm for our understanding of leukemogenesis and drug development.

Chronic Myelogenous Leukemia

EPIDEMIOLOGY

An estimated 4,300 patients are diagnosed with CML each year in the United States; CML accounts for 14% of all cases of leukemia in adults.[1] CML occurs at an incidence of 1 to 2 per 100,000 population; this incidence is remarkably constant worldwide.[1] Males are affected more often than females. The median age at presentation is 45 to 55 years. A third of the patients are older than 60 years. Age is important when considering therapeutic options such as stem cell transplantation (SCT), which is associated with a high procedure-related mortality; interferon alfa, which has more side effects in older patients than in younger patients; and, more recently, imatinib, which is active and well tolerated even in older patients. CML is uncommon in children and adolescents, accounting for less than 5% of the leukemias.[2]

PATHOPHYSIOLOGY AND CYTOGENETICS

CML is caused by the transforming capability of the protein products resulting from the Philadelphia translocation, t(9;22)(q34;q11), and cytogenetic-molecular changes acquired

Table 1 Distinguishing Characteristics of Myeloproliferative Disorders

Disorder	*Incidence*	*Age at Onset (years)*	*Cytogenetic Molecular Markers*	*Risk of Leukemic Transformation*	*Treatment Options*
CML	1–2 per 100,000 population	45–55	Philadelphia translocation (9;22)(q34;ql1) in up to 95% of patients	Invariable transformation to accelerated and blastic phases (85%–90%)	Stem cell transplantation, imatinib mesylate (single agent, high dose in combination with other agents [e.g., interferon alfa]), other targeted therapies (e.g., FTI, SRCI, decitabine, homoharringtonine), phlebotomy
PV	0.5–1.0 per 100,000 population	60	Cytogenetic abnormalities in up to 20% of patients at diagnosis (trisomy 8, trisomy 9, and deletion [20q$^-$] are most frequent)	10% at 15 years after diagnosis; up to 50% 20 yr after diagnosis	Phlebotomy, hydroxyurea, anagrelide, low-dose aspirin, interferon alfa
ET	Probably lower than in PV	40–50	< 5%; no consistent cytogenetic abnormalities	< 5%	Hydroxyurea, anagrelide, interferon alfa, low-dose aspirin
IM	Scarce epidemiologic data	60	No consistent cytogenetic abnormalities	5%–20%	Symptomatic therapy, hydroxyurea, interferon alfa, stem cell transplantation, thalidomide, antiangiogenesis agents

CML—chronic myelogenous leukemia ET—essential thrombocythemia FTI—farnesyl transferase inhibitors IM—idiopathic myelofibrosis PV—polycythemia vera SRCI—Src kinase inhibitors

during clonal evolution and progression of the disease. The history of the Philadelphia translocation dates back to 1960, when Nowell and Hungerford discovered an abnormal G-group chromosome in bone marrow cells of two patients with CML.[3] However, not until a decade later was it possible to prove through chromosome banding techniques that the previously identified abnormality was a shortened chromosome 22.[4] Rowley then demonstrated that the abnormality was a result of a translocation of segments between the long arms of chromosomes 9 and 22.[5] Further work in the 1980s unraveled much of the molecular details underlying the cytogenetic events.[6] The Philadelphia translocation was thus the first chromosomal abnormality to be associated with a malignant disease and has become the hallmark of CML.

That the Philadelphia translocation and its molecular sequelae represent more than just a diagnostic marker has been demonstrated by in vivo animal models.[7] Transfection of the *bcr-abl* gene into mice can generate a syndrome that closely resembles the clinical picture of human CML. Conversely, inhibition of the protein product of the *bcr-abl* gene appears to reverse the disease in humans.

Lack of concordance in monozygotic twins and the demonstration of the Philadelphia chromosome (Ph) in hematopoietic progenitor cells only suggest that CML is an acquired disorder. Predisposing factors, however, remain mostly unidentified. The incidence of CML is significantly higher for survivors of the atomic-bomb explosions in Hiroshima and Nagasaki. Effects of therapeutic doses of radiation on the development of CML are more disputed.[8] No association has been established with infectious, toxic, or environmental factors.

Up to 95% of patients with CML express Ph, which results from a reciprocal translocation between the long arms of chromosomes 9 and 22. This process involves exchanges of genetic material from a segment of the *abl* (abelson) gene on chromosome 9q34 with part of the *bcr* (breakpoint cluster region) gene on chromosome 22q11, creating a fusion *bcr-abl* gene on 22q11. The segments from the *abl* gene can be transposed into different regions on the *bcr* gene. According to the location of the breakpoint cluster region on *bcr,* messenger RNAs of various lengths are created that are then translated into fusion proteins of various sizes ($p190^{bcr\text{-}abl}$, $p210^{bcr\text{-}abl}$, and $p230^{bcr\text{-}abl}$). Most patients with CML express $p210^{bcr\text{-}abl}$. Expression of the smaller protein $p190^{bcr\text{-}abl}$ is more frequently found in children and adults with acute lymphoblastic leukemias, and $p190^{bcr\text{-}abl}$ may be associated with monocytosis in CML. Expression of the larger $p230^{bcr\text{-}abl}$ variant has been associated with chronic neutrophilic leukemia and with thrombocytosis.[9,10]

The Bcr-Abl proteins trigger molecular transformations through their increased tyrosine kinase activity and their interactions with other cellular proteins. The *abl* gene encodes a nonreceptor tyrosine kinase ($p145^{abl}$) that is involved in signal transduction and the regulation of cell growth; the activity of $p145^{abl}$ is rigorously controlled. By contrast, $p210^{bcr\text{-}abl}$ is a pleiotropic molecule that exhibits higher and uncontrolled kinase activity. Uncontrolled activation of the kinases initiates downstream signaling pathways that upregulate transcription of gene complexes mediating proliferation and transformation of CML hematopoietic progenitor cells. A central element of Bcr-Abl signaling is Ras. Activation of Ras is mediated through a series of adapter proteins that in turn connect $p210^{bcr\text{-}abl}$ to other kinases and messenger systems.[9,11] Other cytotoxic effects of $p210^{bcr\text{-}abl}$ include alterations in the cytoskeletal structure of CML stem cells and progenitor cells, as well as perturbations of adhesion molecule expression, suppression of programmed cell death (apoptosis), abrogation of growth factor dependence, and alteration of DNA repair mechanisms; these effects lead to subtle genetic errors that may result in clonal evolution and progression to the blast phase.[12] However, the multiple signaling pathways dysregulated by $p210^{bcr\text{-}abl}$ may be sufficient to explain the initial manifestations of the chronic phase of CML.

Table 2 Criteria for Defining Accelerated-Phase and Blast-Phase CML

Accelerated Phase	*Blast Phase**
Peripheral blood blasts 15%	≥ 30% blasts in blood and/or marrow
Peripheral blood blasts and promyelocytes ≥ 30% Peripheral blood basophils ≥ 20% Platelet count < 100×10^9/L unrelated to therapy Cytogenetic evolution	Extramedullary infiltrates of leukemic cells

*Lymphoid in one third of patients (TdT+, CD10+, CD19+, CD20+; frequent coexpression of myeloid markers), myeloblastic or undifferentiated in two thirds of patients.

DIAGNOSIS

CML is characterized by the expansion of myeloid progenitor cells at various stages of their maturation, their premature release into the circulation, and their tendency to home to extramedullary sites. In most patients, CML develops in two or three phases [*see Table 2*]. At diagnosis, more than 90% of patients are in the stable or chronic phase.

Clinical Presentation

Symptoms at presentation reflect the increase in mass and turnover of the leukemic cells. Patients may complain of lethargy and weakness, night sweats, and weight loss. Occasionally, increase in abdominal girth and abdominal discomfort are caused by an enlarged spleen. Less frequently, easy bruising and bleeding resulting from platelet dysfunction are recorded. In older series, 10% to 20% of patients displayed no symptoms, but in recent studies, as many as 50% of patients have shown no symptoms and have been diagnosed through routine blood tests, indicating a trend toward earlier diagnosis of CML. Presentations in accelerated or blastic phases are rare and occur in 5% to 10% of patients. Generalized lymphadenopathy and fever, which are rare in patients with chronic-phase CML, may indicate an accelerated disease course.[13] An enlarged spleen is the most common finding on physical examination and can be observed in up to 50% of patients. Hepatomegaly and lymphadenopathy are infrequent.

Laboratory Findings

Peripheral blood and bone marrow The typical laboratory manifestations in chronic-phase CML are myeloid hyperplasia in the marrow and thrombocytosis, neutrophilic leukocytosis, and basophilia in the peripheral blood. During the chronic phase, the peripheral blood is characterized by the presence of myeloid cells in all stages of their maturation, from normal neutrophils to circulating blasts that resemble the cells seen in a bone marrow aspirate smear. Peripheral blood leukocytosis of more than $100 \infty 10^9$/L is seen in 70% to 90% of patients. Dys-

plastic changes of neutrophils are not typical. An absolute monocytosis may occur. Anemia of varying degrees is frequent. The marrow is hypercellular with a myeloid-to-erythroid ratio of between 9:1 and 15:1. Myeloid cells usually show all stages of maturation, with a preponderance of immature precursors such as myelocytes and promyelocytes. The level of megakaryocytes is frequently increased, especially in accelerated phases; megakaryocyte proliferation may be marked. Marrow fibrosis may be focal in early disease stages; it progresses to a more diffuse pattern with disease evolution.

Cytogenetic analysis and molecular assays Examination of metaphase spreads from marrow samples is the definitive test for demonstration of the Philadelphia translocation. It may also reveal additional karyotypic abnormalities, which are frequently observed with disease progression (clonal evolution). Cytogenetic analysis is, however, tedious and time-consuming, and only a limited number of metaphases (< 20 to 25 per sample) are examined. In about 10% of patients with CML, no Philadelphia translocation can be identified by cytogenetic analysis. In up to one third of these patients, molecular studies will detect *bcr-abl* rearrangements that are otherwise missed by routine cytogenetics. The remaining patients test negative for Ph and for the *bcr-abl* gene and are referred to as having atypical CML, Ph-negative CML, or, in some cases, chronic myelomonocytic leukemia (CMML). The prognosis for these patients is significantly worse than the prognosis for patients who test positive for the *bcr-abl* gene.

Molecular techniques have become a mainstay in the diagnosis of CML and in the assessment of response to therapy. Polymerase chain reaction, Southern and Northern blot testing, and immunoprecipitation can determine the exact breakpoints of the fusion gene, detect *bcr-abl* transcripts at the RNA level, and demonstrate the $p210^{bcr\text{-}abl}$ protein by use of antibodies against parts of the Bcr-Abl protein. Patients who are receiving therapy are frequently followed by use of PCR and fluorescence in situ hybridization (FISH).[14] Both techniques provide a higher degree of sensitivity than can be achieved with routine cytogenetics. A practical approach to the monitoring of patients with CML during therapy involves a combination of laboratory assays [*see Table 3*].

Table 3 Use of Laboratory Assays in the Monitoring of Patients with CML on Imatinib

Time	*Assay*
Before therapy	Cytogenetics FISH (peripheral blood) Quantitative PCR (peripheral blood)
During therapy	Cytogenetics every 6 to 12 mo (when < 10% positive, confirm complete response with FISH) FISH every 2–3 mo
During complete cytogenetic response	Cytogenetics every 6–12 mo Quantitative PCR every 2–3 mo

FISH—fluorescence in situ hybridization PCR—polymerase chain reaction

Differential Diagnosis

CML can usually be diagnosed by careful examination of peripheral blood and bone marrow slides in conjunction with the presenting clinical picture. Either detection of the Philadelphia translocation on metaphase spreads or detection of the *bcr-abl* rearrangement by molecular assays is definitive for the diagnosis of CML. Uncertainty may arise in cases where either no cytogenetic-molecular studies are available or test results are negative [*see Table 4*].

Table 4 Differential Diagnosis of Philadelphia Chromosome and *bcr-abl*–Negative Chronic Myelogenous Leukemia

Condition	*Characteristics*
Leukemoid reaction	Total white blood cell count rarely $< 100 \times 10^9$/L Left shift on peripheral blood differential does not usually involve promyelocytes/myelocytes No basophilia Cytoplasmic inclusions (toxic granulation, Döhle bodies) Usually elevated leukocyte alkaline phosphatase Usually underlying etiology (infection, shock, hemolysis, chronic inflammation, other underlying malignancy)
Other myeloproliferative disorders (myelofibrosis, polycythemia vera, essential thrombocythemia)	Lesser degree of leukocytosis Larger spleen Leukoerythroblastic peripheral blood smear (teardrop cells) Established criteria for diagnosis
Atypical chronic myelogenous leukemia	Dysplastic changes in leukocytes of peripheral blood/bone marrow No basophilia
Chronic neutrophilic leukemia	Leukocytosis usually consisting of mature neutrophils Splenomegaly High leukocyte alkaline phosphatase test score
Chronic myelomonocytic leukemia (myeloproliferative)	Increase in absolute and relative monocyte counts Minimal dysplastic changes in leukocytes No basophilia Immature cells of neutrophil series present
Juvenile chronic myelogenous leukemia	Disease in children < 4 yr Hepatomegaly and splenomegaly common at presentation Markedly increased fetal hemoglobin levels

CLINICAL COURSE

At the time of diagnosis of CML, most patients are in the chronic phase. However, the natural history of CML leads invariably either to a blastic transformation directly (i.e., conversion to an acute leukemia–type disease) or, more frequently, to a blastic transformation with an intervening accelerated phase. Whereas the median time from diagnosis of the chronic phase to blastic transformation is about 36 to 40 months, blastic transformation may result in death within 3 to 6 months. Transformation is frequently heralded by refractoriness to treatment, leukocytosis with significant increases in blood and marrow blasts, increases or decreases in platelet counts unrelated to therapy, and clinical signs and symptoms such as unexplained fever, lymph-

Table 5 Drug Dosages and Side Effects in the Management of Patients with Chronic Myelogenous Leukemia

Drug	*Dosage*	*Side Effects*
Imatinib*	Chronic phase: 400 mg p.o. daily Advanced phases: 600 mg p.o. daily Avoid doses < 300 mg p.o. daily	Nausea and vomiting, bone and muscle aches, diarrhea, fatigue, fluid retention, rash
Busulfan	Administer 0.1 mg/kg daily until white blood cell (WBC) count decreases by 50%, then reduce dose by 50%; maintain WBC count between 20 and 50 × 10^9/L	Severe, prolonged myelosuppression (10%); idiosyncratic pulmonary fibrosis (busulfan lung); fibrosis of the endocardium; Addison disease–like syndrome
Hydroxyurea	40 mg/kg p.o. daily; maintain WBC count between 2 and 10 × 10^9/L	Nausea and vomiting, skin changes (scaling, atrophy, alopecia, ulcerations)
Interferon alfa	Administer 5 million units (MIU)/m^2 S.C. daily in cases of high WBC counts: cytoreduction with hydroxyurea (1 to 5 g/day) to decrease WBC count to 10 × 10^9/L; increase interferon dose gradually (3 MIU/day × 3 to 7 days, then 5 MIU/day × 3 to 7 days, then 5 MIU/m^2 or maximum tolerated dose)	*Early effects:* flulike symptoms, such as fever, chills, postnasal drip, anorexia *Late effects:* fatigue, depression, insomnia, weight loss, alopecia, reduced libido, impotence, autoimmune phenomena (hemolytic anemia and thrombocytopenia, Raynaud disease, collagen vascular disease, hypothyroidism), nephrotic syndrome, cardiac arrhythmias

*First-line therapy in chronic-phase CML (alone or in combination with other agents).

adenopathy, progressive splenomegaly, extramedullary disease, weight loss, and bone and joint pain. One third of the leukemias that follow blastic transformation are morphologically and immunophenotypically consistent with acute lymphoblastic leukemia (ALL) and respond to ALL therapy. Two thirds of the patients have an acute myeloblastic or undifferentiated leukemialike phenotype and may respond to anti–acute myeloid leukemia (AML)-type regimens. The possibility of development of myeloid or lymphoid blast crisis provides further evidence that an early stem cell clonal abnormality is the basis for this disease. Criteria for the definition of accelerated-phase and blastic-phase disease have been proposed [*see Table 2*].[15]

The progression of CML is also characterized by further abnormalities at the cytogenetic-molecular level. Ph predominates throughout the chronic phase, but additional cytogenetic abnormalities develop in up to 80% of patients as the disease progresses (clonal evolution). These findings may even precede the clinical and hematologic manifestations of the transformation. Commonly observed changes during clonal evolution of CML are trisomy 8, isochromosome i(17q), trisomy 19, and an additional Ph. Trisomy 8 and isochromosome i(17q) are common during myeloid transformation.[16] Molecular markers that undergo alterations during clonal evolution include *p53, Rb1, c-myc, $p16^{INK4a}$, ras,* and AML/EVI-1, a fusion protein resulting from translocation t(3;21)(q26;q22). Abnormalities of *p53* occur in 20% to 30% of patients and are mainly associated with myeloid transformation, whereas abnormalities of *Rb1* are mainly seen with lymphoid transformation.[17]

PROGNOSIS

The prognosis for patients with CML has changed significantly in the past 2 decades. Patients who are diagnosed with chronic-phase CML can expect a median survival of 5 to 7 years and up to 9 years if they have a good prognosis (i.e., age younger than 50 years; asymptomatic at diagnosis; no organomegaly; absence of marrow fibrosis, basophilia, anemia, and peripheral blood or bone marrow blastosis; short time to achieve hematologic remission on therapy; long remission duration; and good initial hematologic and cytogenetic response to interferon-alfa therapy). Five-year and 10-year survival rates are 60% to 70% and 30% to 40%, respectively.[15] Earlier diagnosis, better supportive care, and more effective anti-CML therapies such as allogeneic SCT, imatinib, and interferon alfa have contributed to this progress. Therapies targeting distinct molecular pathways of CML leukemogenesis, better understanding of risk stratification of patients, and risk-oriented therapies will further improve outcomes.

TREATMENT

The development of imatinib has revolutionized the therapeutic approach to patients with CML. In the few years since the first clinical trials, imatinib has been confirmed as an active agent in the treatment of both chronic and transformed phases of CML. Although the long-term impact of imatinib therapy on CML cure cannot yet be assessed, if the early clinical experience of high cytogenetic response rates, low rates of disease progression, and safe toxicity profile persists, imatinib will soon be established as the most effective therapy in CML. Currently, SCT remains the only cure for CML; however, the morbidity associated with this form of therapy has limited its use to certain patient groups. On the basis of current evidence, imatinib is supplanting interferon alfa as the treatment of choice for patients whose age and disease stage make them poor candidates for SCT [*see* Imatinib versus Stem Cell Transplantation, *below*]. Hydroxyurea and busulfan are the most commonly used agents in the treatment of CML; however, treatment with either drug is not curative and only rarely results in cytogenetic response. Thus, therapy with these agents must be considered palliative.

Conventional Agents and Adjuvant Therapy

Busulfan, an alkylating agent, was introduced as a treatment for CML in the 1950s and was the first chemotherapy agent found to be effective for this disease. Hydroxyurea, a cell cycle–specific inhibitor of DNA synthesis, has been available since the early 1970s. Busulfan and hydroxyurea can be given orally and are inexpensive [*see Table 5*]. Although both drugs can result in complete hematologic remission (CHR) (i.e., normalization of peripheral blood counts and disappearance of palpable splenomegaly and signs and symptoms of the disease) in up to 60% to 80% of patients with chronic-phase CML, cytogenetic remissions are rare. In other words, even though peripheral blood counts may return to normal, the identifiable cells in the blood

and bone marrow most often still contain Ph, suggesting that proliferation has been suppressed but the abnormal clone has not been eliminated. Therefore, both agents have little or no effect on the natural course of the disease, and patients will inevitably experience progression to the blastic phase and die of its complications.[15]

Hydroxyurea is very effective in initial cytoreduction as an adjunct to more definitive therapies (e.g., before allogeneic SCT). It is occasionally used in patients in whom interferon-based regimens, imatinib therapy, or allogeneic SCT has failed and who are not candidates for or who are between investigational therapies.

Splenectomy does not improve survival if it is performed during the chronic phase of CML.[18] It may benefit some patients who have persistent massive or symptomatic splenomegaly and refractory cytopenias. If performed before bone marrow transplantation, splenectomy reduces the time to marrow recovery but does not influence long-term prognosis.

Stem Cell Transplantation

In carefully selected patients, allogeneic SCT can cure a substantial percentage of patients who have suitable donors. Novel transplant modalities are being developed that use unrelated donors, donor lymphocytes, autologous stem cells that are subjected to various purging procedures, or peripheral blood as the stem cell source.[19] Peripheral blood stem cells appear to be as good as if not better than bone marrow stem cells and are being used more frequently in the treatment of hematologic cancers. A randomized, controlled trial indicated that peripheral stem cells restore blood counts faster than bone marrow stem cells without increasing the risk of graft versus host disease.[20]

Matched related allogeneic stem cell transplantation Allogeneic SCT results in long-term survival in 50% to 80% of patients with chronic-phase CML; disease-free survival rates are 30% to 70% for such patients. Applicability of allogeneic SCT is, however, limited by availability of matched siblings and age restrictions. Fewer than 30% of patients in Europe and North America receive stem cells from matched sibling donors. Outcome of allogeneic SCT is best in young patients who receive transplants early in chronic-phase CML, ideally within the first 2 years after the diagnosis of the disease. Studies from the Fred Hutchinson Cancer Center indicate favorable outcomes for patients 50 years of age and older, but results from most other transplant centers are worse.[21-23]

Relapses after transplantation occur in 10% to 70% of patients. The two most significant factors influencing transplant outcome are age and disease stage. The rate of relapse is lowest in younger patients and in those who receive transplants during the chronic phase; it is highest in patients who receive transplants during the blastic phase.[24,25] The prognosis of patients who have relapsed after allogeneic SCT is not necessarily dismal and depends mostly on the time interval between transplantation and relapse. Second transplants from HLA-identical sibling donors, infusion of donor lymphocytes to stimulate the so-called graft-versus-leukemia effect, and treatment with imatinib or interferon alfa have been associated with disease-free survival rates of 30% to 80%.[26] Donor lymphocyte infusions (DLIs) induce cytogenetic and complete hematologic response in 60% to 80% of patients, and those responses are durable. Responses are, however, far less frequent and short-lived in transformed CML phases.[26] Nevertheless, the impressive clinical responses to infusion of donor lymphocytes provide evidence of the role of the immune system in controlling the disease. Treatment with imatinib has resulted in a complete hematologic response rate of 74% and a cytogenetic response rate of 58% and may soon supplant DLI as the treatment of choice for patients who relapse after allogeneic SCT, especially in patients with graft versus host disease.[27] Combinations of DLI and imatinib are currently being explored.

Matched unrelated donor transplantation Matched unrelated donor transplants have high rates of treatment-related morbidity and mortality that can exceed 50%, depending on age and degree of matching. In carefully selected patients, 5-year survival rates may be as high as 70%, relapse rates less than 10%, rates of graft failure below 10%, and rates of severe acute graft versus host disease below 50%.[28] Until a high level of experience with matched unrelated donor transplantation has been achieved, the procedure should be offered preferentially to younger patients with chronic-phase CML who are resistant to imatinib and who have a fully matched donor available.[29]

Reduced-intensity transplantation Reduced-intensity transplantation (also called nonmyeloablative SCT or "mini" SCT) is designed to induce immunosuppression and allow engraftment of donor cells rather than to ablate the marrow. The rationale is twofold: (1) to induce an optimal graft-versus-leukemia effect by eliminating leukemic cells through the action of donor alloreactive immunocompetent cells and (2) to avoid standard high-dose myeloablative chemoradiotherapy, thereby reducing transplant-related morbidity and mortality and extending treatment options to older patients. Early results of reduced-intensity transplants show rapid engraftment, complete eradication of host hematopoietic cells, and minimal procedure-related toxicities.[30]

Imatinib Mesylate (Imatinib, STI571)

The Bcr-Abl proteins require phosphorylation for their increased tyrosine kinase activity, a process that can be blocked by small molecules such as imatinib. Imatinib has been shown to selectively inhibit both $p210^{bcr\text{-}abl}$ and $p190^{bcr\text{-}abl}$ disease, suggesting a role not only in CML but also in Ph-positive acute lymphoid leukemia.[31] In a phase I study of patients with blast-phase CML and patients with chronic-phase CML who were resistant to or intolerant of interferon alfa–based therapy, doses of imatinib were escalated from 25 mg to 1,000 mg daily. No dose-limiting toxicities were established, and significant clinical benefits were observed at daily oral doses of 300 mg or higher. Complete hematologic response rates occurred in 53 of 54 chronic-phase patients treated with imatinib at daily doses of 300 mg or higher; treatment responses were durable in most of these patients. Major cytogenetic responses occurred in 31% of the patients.[32] In patients with blast-phase CML, responses to imatinib therapy occurred in 55% of patients who experienced a myeloid blast crisis and 70% of patients who experienced a lymphoid blast crisis. These responses were, however, transient.[33]

Phase II studies confirmed high response rates with imatinib therapy in patients with chronic-phase CML. These studies demonstrated that imatinib was the most active single agent in accelerated-phase CML and that imatinib had single-agent biologic activity in blast-phase CML [*see Table 6*].[34-38] A multinational, randomized study compared imatinib (400 mg daily) with a regimen of interferon alfa (5 mIU/m^2 daily) and cytarabine (20 mg/m^2 daily for 10 days/mo) in patients with newly diagnosed, early chronic-phase CML.[39] A total of 1,106 patients were

enrolled and randomized equally to either treatment arm. Patients were allowed to cross over to the other treatment arm if they experienced disease progression or intolerance to therapy or if they failed to achieve a major cytogenetic response after 24 months of treatment. At a median follow-up of 19 months, imatinib proved superior to a regimen of interferon alfa and cytarabine as first-line therapy for patients with newly diagnosed chronic-phase CML in terms of major (87.1% versus 34.7%) and complete (76.2% versus 14.5%) cytogenetic responses, less likelihood of progression to advanced-stage CML (1.5% versus 7%), and increased tolerability of treatment (intolerance of 0.7% for imatinib versus 7% for interferon alfa and cytarabine).

Imatinib versus Stem Cell Transplantation

Stem cell transplantation can be curative, but treatment-related mortality and disabling morbidity may be substantial. Therapy with imatinib achieves high rates of major and complete cytogenetic responses in patients with chronic-phase CML. On the basis of experience with interferon alfa, the major cytogenetic response rate achieved with imatinib may be viewed as a surrogate end point for prolonged survival. If the results from the interferon alfa studies can be extrapolated, the median survival of patients with CML may exceed 10 years. However, more patients and longer follow-up are needed to fully appreciate the impact of imatinib on the prognosis of patients with CML. The decision regarding how best to treat a patient with CML remains, therefore, controversial, and treatment algorithms need to be continuously updated in the light of emerging data [*see Figure 1*].[40,41]

Novel Therapeutic Approaches in CML

Although rare, resistance to imatinib poses further challenges. Combination treatments with imatinib and interferon alfa–based therapy are currently in clinical trials. High-dose imatinib (up to 800 mg daily) is being evaluated in newly diagnosed patients with chronic-phase CML and has produced positive results that will require further confirmation.[42] Interferon attached to polyethylene glycol (PEG-interferon) increases the serum half-life of interferon alfa, can be given subcutaneously once a week, may be less toxic and more effective than regular interferon alfa therapy, and when combined with imatinib may prove an effective treatment for patients resistant to imatinib in single-agent regimens.[43] Other combinations of imatinib with homoharringtonine, decitabine, farnesyltransferase, and Src kinase inhibitors are being explored. Their value in the overall treatment algorithm of CML is as yet undefined.[44]

Polycythemia Vera

Polycythemia vera (PV) is a clonal disorder of hematopoietic stem cells. Unlike CML, however, no clear causative cytogenetic-molecular lesion has been identified. PV occurs with an incidence of about 1 to 2 per 100,000 population a year in Western Europe and the United States and may be more frequent than previously thought.[45,46] The median age at diagnosis is 65 years, and a slight male predominance exists. PV is extremely rare in patients younger than 30 years.[45,46]

PATHOPHYSIOLOGY

PV is characterized by an absolute increase in total red blood cell mass that may be accompanied by thrombocytosis or leukocytosis. The chromium-51 (^{51}Cr) dilution technique is simple and is well established for measurements of red blood cell mass. This expansion of red cell mass is caused by increased production by hypercellular bone marrow and is not dependent on serum levels of erythropoietin. Indeed, erythropoietin levels are typically low in PV. This distinguishes PV from the secondary polycythemia associated with certain tumors (e.g., renal cell carcinoma and hepatocellular carcinoma) and with pulmonary, cardiac, and renal disorders.[47] The pathogenesis of erythrocytosis in PV is under investigation. In vitro hypersensitivity to various cytokines caused by defects of cellular receptors or intracellular signal transduction pathways has been suggested.[48,49]

DIAGNOSIS

The clinical manifestations of PV are a consequence of the excessive proliferation of hematopoietic cell lines and are mainly characterized by microvascular and macrovascular thrombotic events. On physical examination, the most common findings in patients with PV include ruddy cyanosis, hepatosplenomegaly, conjunctival plethora, and hypertension. About 20% of patients present with thrombotic complications, and such complications will develop in 30% more patients during the course of the disease. Microvascular symptoms such as acroparesthesias, erythromelalgia, peripheral gangrene, and ischemic neurologic and visual disturbances are frequent. Particularly serious thrombotic events involve the cerebral, coronary, hepatic and inferior vena cava (Budd-Chiari syndrome), and mesenteric vessels.

The diagnosis of PV requires exclusion of secondary causes of increased red blood cell mass and blood volume. Independent determination of red cell mass and plasma volume by isotope dilution is mandatory. Identification of cytogenetic abnormalities such as trisomy of chromosomes 8 and 9 and deletions of the long arm of chromosome 20 (20q–) are firm evidence of the clonality of the process, but these findings can be demonstrated in only a minority of patients. The Polycythemia Vera Study Group (PVSG) has established diagnostic criteria that are continuously being modified [*see Table 7*].[47,50,51]

DIFFERENTIAL DIAGNOSIS

The diagnosis of PV can be masked by concurrent iron defi-

Table 6 Summary of Results of Treatment with Imatinib in Late Chronic-Phase, Accelerated-Phase, and Blast-Phase CML

Response to Imatinib (%)	*Late Chronic Phase (n = 454)*[33]	*Accelerated Phase (n = 181)*[34]	*Blast Phase (n = 229)*[35]
Hematologic response	430 (95)	125 (69)	66 (29)
Major cytogenetic response	272 (60)	43 (24)	36 (16)
Complete	188 (41)	30 (17)	15 (7)
Partial	84 (19)	13 (7)	21 (9)

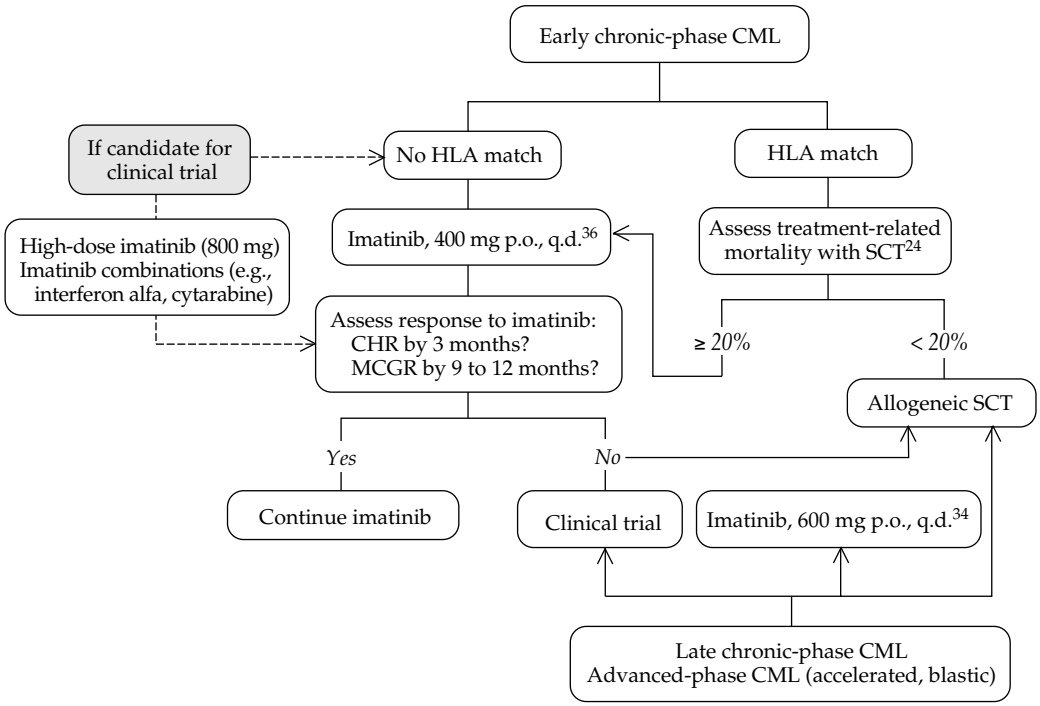

Figure 1 **For patients in early chronic-phase chronic myelogenous leukemia (CML), allogeneic stem cell transplantation and imatinib are possible first-line therapies. The treatment decision depends on several factors: (1) availability of a suitable donor; (2) the risk-benefit ratio of SCT versus imatinib; (3) the socioeconomic situation; and (4) patient preference. For patients who have a matched sibling donor and whose physical condition allows stem cell transplantation with an acceptable treatment-related morbidity and mortality (< 20%), allogeneic stem cell transplantation may still be the first choice. Although stem cell transplantation is still considered the only curative modality and concerns exist about delaying transplantation for other treatment modalities, numerous arguments favor a more conservative approach (i.e, chemotherapy using imatinib): (1) delaying transplantation for up to 24 months in chronic-phase CML does not inadvertently influence transplant outcome; (2) on the basis of experience with interferon alfa, complete and major cytogenetic response rates achieved with imatinib are valid surrogate markers for survival; (3) allogeneic transplantation is associated with mortality and considerable morbidity (e.g., cataracts, sterility, hip necrosis, second cancers, graft versus host disease); and (4) experience with imatinib has not shown any unusual or unexpected side effects, and resistance during the chronic phase is low. If a conservative approach to therapy is preferred, the patient may be considered for clinical trials utilizing high-dose imatinib (800 mg p.o. daily), combinations of imatinib with other agents (e.g., interferon alfa, PEG–interferon alfa, cytarabine), other targeted therapies (e.g., farnesyltransferase inhibitors), or other active agents (e.g., decitabine, histone deacetylase inhibitors, homoharringtonine). Patients in late chronic phase or accelerated phase should be offered investigational therapies (see above) or should undergo allogeneic transplantation. (CHR—complete hematologic remission; MCGR—major cytogenetic response; SCT—stem cell transplantation)**

ciency, resulting in a clinical picture resembling essential thrombocythemia. Unlike ET, venous and arterial thromboses occur with equal frequency in PV. The main risk factors for vascular complications include advanced age, a history of vascular events, and consistently high hematocrit values. Whereas thrombotic complications are the cause of death in 30% to 40% of patients, bleeding complications are far less frequent and are seen in about 5% to 10% of patients.[49,52]

CLINICAL COURSE

The natural history of PV in the absence of therapeutic intervention has been difficult to define. PV may transform into a myelofibrosis-type syndrome (spent phase, postpolycythemic myeloid metaplasia) or progress to a leukemic phase; however, it is difficult to exclude the impact of therapy (such as with radiophosphorus ^{31}P or alkylating agents) in all cases. The PVSG estimates that the incidence of leukemia among PV patients is 10% at 15 years after diagnosis and 50% at 20 years after diagnosis, regardless of the treatment utilized.[47] Untreated patients with persistently high hematocrit levels do poorly and may die

Table 7 Diagnostic Criteria for Polycythemia Vera*

Major Criteria	*Minor Criteria*
Increased red cell mass (in males, ≥ 36 ml/kg; in females, ≥ 32 ml/kg)	Platelet count > 400 × 10^9/L
Normal oxygen saturation, ≥ 92%	Leukocytosis > 12 × 10^9/L (no fever or infection)
Splenomegaly	Leukocyte alkaline phosphatase score > 100
	Serum B_{12} > 900 pg/ml
	Unbound B_{12} binding capacity > 2,200 pg/ml

*A diagnosis of polycythemia vera can be considered when all major criteria are present or in the presence of the first two major criteria and any two minor criteria.

from a thrombotic complication, which is the cause of death in 20% to 40% of patients.[53]

TREATMENT

Phlebotomy, low-dose aspirin, and possibly hydroxyurea represent the best approach to treatment. Low-dose aspirin (50 to 100 mg/day) is particularly effective in controlling the microvascular symptoms associated with thrombocytosis when used in combination with either phlebotomy or myelosuppressive treatments.

Reduction of the red cell mass to a safe level (i.e., reducing the hematocrit level to less than 45% in men and less than 42% in women) by phlebotomy should be a primary treatment goal.[49] Patients treated with phlebotomy alone have a low risk of leukemic transformation; in addition, patients who are maintained at a stable hematocrit level are at low risk for incurring thrombotic complications.[54] Hydroxyurea is efficient in improving thrombocytosis and erythrocytosis.[55] Because of uncertainty as to whether hydroxyurea is a potential cause of leukemic transformation, treatment with hydroxyurea should be restricted to situations where other remedies have failed. Anagrelide and interferon alfa are used in patients with persistent thrombocytosis and thrombosis.[56-58] Anecdotal evidence suggests that the tyrosine kinase inhibitor imatinib may be active against PV.[59]

Chlorambucil, an alkylating agent, and radiophosphorus ^{32}P are mainly of historical interest and should be considered obsolete as treatment of PV because of their association with the development of secondary leukemias and lymphomas.

Essential Thrombocythemia

ET, or thrombocytosis, is a clonal stem cell disorder mainly characterized by sustained proliferation of megakaryocytes, resulting in peripheral blood thrombocytosis.

EPIDEMIOLOGY

The incidence of ET is similar to that of PV. The median age at presentation is 40 to 50 years. Unlike in PV, up to 20% of patients with ET are younger than 40 years.[46]

PATHOPHYSIOLOGY

The elevated platelet count in ET is caused by increased production by megakaryocytes with normal platelet survival. Increased platelet production appears to depend on the effect of several cytokines. Lack of the growth-inhibiting effect of platelet factor 4 and transforming growth factor–β on megakaryocyte colony formation has been demonstrated. Unlike the diminished serum levels of erythropoietin in PV, thrombopoietin levels do not correlate with platelet count or megakaryocyte mass and can even be elevated in ET.[60] However, ET has been associated with dysregulation of the relationship of thrombopoietin to its receptor, c-Mpl.[61] The presence of a heterogenous pattern of c-Mpl expression in bone marrow megakaryocytes has recently been found to be a useful marker in the differential diagnosis of thrombocytosis.[62]

DIAGNOSIS

ET is diagnosed after secondary causes of elevated platelet counts (e.g., iron deficiency, malignancies, inflammatory conditions, or infections) have been excluded. In addition, criteria have been established by the PVSG: (1) although subject to question,[63] a platelet count greater than $600 \infty 10^9$/L on two occasions at least 1 month apart; (2) normal red cell mass; (3) the absence of significant fibrosis of the marrow; (4) the presence of splenomegaly; and (5) no Ph or *bcr-abl* gene rearrangements.

Two thirds of the patients present with thrombotic or hemorrhagic events. Major thrombotic complications occur in 20% to 30%. Thrombotic complications frequently manifest as deep vein thrombosis and pulmonary embolism. Thrombosis of hepatic veins leads to Budd-Chiari syndrome; thrombosis of renal veins can cause nephrotic syndrome. Erythromelalgia and digital ischemia constitute microvascular forms of arterial thrombosis in ET. Hemorrhagic events occur in up to 40% of patients, with the gastrointestinal tract, urinary tract, skin, eyes, or brain being possible bleeding sites.[64] Individual patients can suffer from both thrombotic and hemorrhagic episodes.[65]

ET is increasingly being diagnosed in asymptomatic patients as an incidental finding.

CLINICAL COURSE

Unlike PV, ET rarely progresses to leukemia, which develops in only 3% to 4% of patients.[66] The correlation between the degree of thrombocytosis and the risk of thrombosis is poor. Untreated asymptomatic patients and those who are at low risk for thrombohemorrhagic complications (no history of thrombohemorrhagic episodes, age younger than 60 years, and shorter duration of thrombocytosis) may have the same life expectancy as an age-matched and sex-matched control group without ET.[66]

TREATMENT

The indications for therapeutic intervention have to be considered carefully according to the risk of vascular complications. In general, treatment should be considered only in patients at high risk for thrombohemorrhagic events. Anagrelide, an oral imidazoquinazolin derivative, effectively reduces platelet counts at a dose of 2.5 mg/day. However, side effects (e.g., fluid retention, edema, cardiac arrhythmias, headache, dizziness, nausea, vomiting, bloating, diarrhea) are frequent and necessitate discontinuance of the drug in about 15% of patients.[67] Interferon alfa is also effective in reducing platelet counts, but its use is restricted, especially in elderly patients, by its toxicity profile.[68] The role of PEG–interferon alfa in ET has yet to be assessed.[69] Low-dose aspirin is indicated in patients with a high cardiovascular risk, previous thrombotic complications, and a history of digital or cerebrovascular ischemia.[70] Use of hydroxyurea reduces the risk of thrombosis[71] but should be used only in patients in whom anagrelide or interferon alfa have proved ineffective or cannot be tolerated.

Idiopathic Myelofibrosis

Idiopathic myelofibrosis (agnogenic myeloid metaplasia with myelofibrosis) is a clonal hematopoietic stem cell disorder predominantly affecting the megakaryocyte lineage in the bone marrow. It is characterized by splenomegaly, extramedullary hematopoiesis, and bone marrow fibrosis. The fibrosis is caused by deposition of abnormal collagen by polyclonal fibroblasts that in turn are stimulated by growth factors such as transforming growth factor–β secreted by adjacent megakaryocytes. In some cases, it may be difficult to recognize IM as a distinct entity because many different conditions can cause bone marrow fibrosis and each of the myeloproliferative disorders can terminate in a fibrotic phase.[72,73] Myeloid metaplasia often refers to the earlier phases of IM, when fibrosis is less prominent and

extramedullary hematopoiesis is evident (e.g., in the spleen or liver).

DIAGNOSIS

More than half of the patients with IM present with anemia and thrombocytosis. Most commonly, symptoms such as weakness, fatigue, or dyspnea on exertion are caused by anemia. Bleeding problems and nonspecific constitutional symptoms may accompany the clinical course. Splenomegaly and hepatomegaly occur in up to 70% of patients. Splenomegaly may be massive and reflects, at least partly, the amount of extramedullary hematopoiesis taking place in IM. Leukoerythroblastosis and the presence of teardrop cells in the peripheral blood are typical laboratory features. Bone marrow aspiration will frequently reveal a so-called dry tap, whereas biopsy demonstrates extensive fibrosis and sometimes osteosclerosis.[72]

TREATMENT

No definitive therapy exists for IM. Median survival of patients with IM is about 5 years, and the incidence of transformation to acute leukemia is estimated to be between 5% and 20%.[74] However, half of the patients studied had been exposed to alkylating agents or radiotherapy, which causes leukemic transformation that does not reflect the natural course of IM. These modalities are now rarely used. Treatment is usually reserved for patients who are symptomatic because of anemia or massive splenomegaly. Steroids, androgens, and erythropoietin have been used successfully in some cases for alleviation of anemia. Splenectomy may be indicated in patients with massive splenomegaly and may provide significant relief. However, it can cause substantial perioperative morbidity and mortality and is contraindicated in the presence of thrombocytosis. Also, a high risk of blast transformation has been reported in patients who have undergone splenectomy.[75] Hydroxyurea can improve leukocytosis and constitutional symptoms. Its effect on the natural course of the disease is, however, uncertain. Experience with interferon alfa is still limited.[72,73] Antiangiogenesis inhibitors such as thalidomide are under investigation. Intensive anti-AML–like regimens are investigational and are associated with high occurrences of morbidity and mortality. Allogeneic SCT has been attempted with various degrees of success and may reverse fibrosis.[76]

XVIII HEAD AND NECK CANCER

EVERETT E. VOKES, M.D., F.A.C.P.

Head and neck cancer occurs in the United States at an annual incidence of approximately 45,000 cases.[1] The vast majority of these tumors arise from the mucosa of the upper aerodigestive tract and are squamous cell carcinomas (SCCs) [*see* Squamous Cell Carcinoma of the Head and Neck, *below*]. Anatomically, head and neck cancers are heterogeneous—arising from the pharynx (including the nasopharynx, oropharynx, and hypopharynx), the oral cavity, the larynx, and the cervical esophagus [*see Figure 1*]. Salivary gland tumors and thyroid cancers differ from other head and neck tumors in their etiology, histology, and standard therapy [*see* Salivary Gland Tumors, *below*].

Overview of Head and Neck Cancer

ETIOLOGY AND RISK FACTORS

Tobacco and Alcohol Use

The primary risk factors for development of SCC of the head and neck are the use of tobacco and alcohol. Tobacco use has clearly been demonstrated to be an independent risk factor. The likelihood of a malignancy increases with the duration and extent of exposure. Cigarette smoking, in particular, is an important risk factor for laryngeal cancer. Cigar smoking has been associated primarily with cancers of the lip and oral cavity, presumably because cigar smoke is not typically inhaled. When inhaled, cigar smoke places the smoker at risk for other head and neck malignancies. There is also concern about the use of smokeless tobacco as a risk factor for malignancies of the oral cavity. After discontinuance of the use of tobacco, the risk of SCC of the head and neck diminishes gradually over time. Evidence, however, suggests that the risk does not decline to the level associated with persons who never smoked.[2]

Alcohol use is also associated with SCC of the head and neck. By itself, alcohol use is a smaller risk factor than tobacco use and is of particular importance for malignancies of the oral cavity, oral pharynx, and hypopharynx. However, the use of alcohol and tobacco in combination results in a multiplicative risk of SCC; in persons who are both heavy smokers and heavy drinkers, the risk of SCC may be 200 times that of persons who neither smoke nor drink.[3]

Viral Infection

Chronic viral infections may be associated with SCC of the head and neck. The strongest association between a virus and head and neck cancer is that of Epstein-Barr virus (EBV) and na-

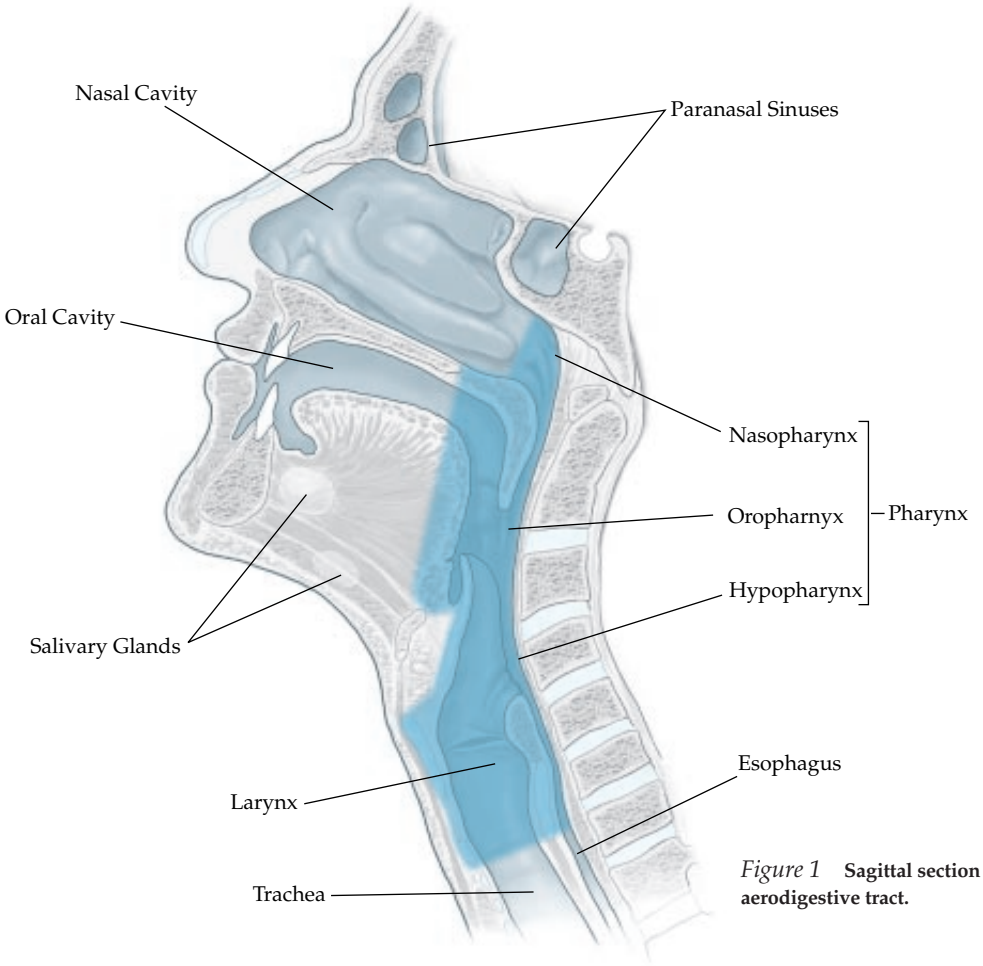

Figure 1 **Sagittal section of the upper aerodigestive tract.**

sopharyngeal carcinoma (NPC). Accumulating evidence suggests that EBV is a primary etiologic agent in the development of NPC.[4,5] In one series evaluating 11 patient samples of nasopharyngeal dysplasia or carcinoma in situ, EBV infection was detected in all cases.[4] Invasive NPC eventually developed in five of the 11 patients, strengthening the concept that EBV infection is an early event in the development of NPC.

Human papillomavirus (HPV), primarily type 16, has been detected in 8% to 36% of SCC cases of the head and neck. Infection with high-risk HPV subtypes (e.g., HPV-16) may contribute to SCC both by direct effects on proliferation and by increasing mutational frequency in the host cells. Studies have found high-risk HPV to be an independent risk factor for SCC. One study found a statistically significant synergistic effect between high-risk HPV and heavy alcohol consumption; an additive effect was found between high-risk HPV and tobacco use.[6]

Additional Risk Factors

Other risk factors that may play a role in the development of head and neck cancer include occupational exposures,[7-9] radiation,[10] dietary factors,[11] and genetic susceptibility [*see* Genetic Alterations, *below*]. In occupational exposure, the relative risk of head and neck cancer increases with increasing intensity and duration of exposure to a variety of occupational chemicals and chemical by-products.

GENETIC ALTERATIONS

Molecular characterization of head and neck cancer includes consistent chromosomal abnormalities, the activation of specific oncogenes, and deletion of tumor suppressor genes. The most frequent mutation is inactivation of the *p53* tumor suppressor gene. This abnormality is found in 50% to 70% of established tumors, but it can also be demonstrated in premalignant tissue and in normal-appearing mucosa in smokers.[12]

PATHOGENESIS

An important concept in understanding the pathogenesis of head and neck cancer is so-called field carcinogenesis, which recognizes that tobacco and alcohol are toxic not only to one specific site in the upper aerodigestive tract but to the entire exposed mucosa. Premalignant lesions such as leukoplakia or erythroplakia may develop wherever mucosa is exposed, and these lesions can progress to invasive carcinoma. Although a specific anatomic site may be characterized as malignant and another as normal or premalignant (e.g., dysplastic or hyperplastic), patients with head and neck cancer are at risk for second malignancies after treatment or may present at the time of diagnosis with multiple areas of abnormality.[13,14] Grossly normal epithelium adjacent to the lesion frequently contains dyplasia, carcinoma in situ, or invasive carcinoma, suggesting that the entire mucosal field has been damaged by a carcinogen. The morphologic equivalent of premalignant lesions are white or red patches that cannot be scraped off (leukoplakia or erythroplakia). Histopathologically, they are usually hyperplastic or dysplastic lesions. However, they may also represent carcinoma in situ or early-stage SCC. These premalignant lesions occur in high-risk patients and frequently have genetic alterations that can also be detected in fully developed head and neck cancers. They may progress to invasive cancer at an estimated rate of 3% to 5% a year.[15]

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is a distinct clinicopathologic entity. NPC occurs in two forms: (1) an endemic type, which is observed in Mediterranean countries, in Southeast Asia, and in the native population of Alaska, and (2) a sporadic type, which is observed in Europe and in the United States.[16] The endemic form is linked to EBV exposure. Histologically, NPC is frequently referred to as lymphoepithelioma because it is composed of lymphoid and epidermoid cells. The lymphoid cells, however, are not transformed malignant cells but normal T cells infiltrating the tumor area. In the United States, NPC has been diagnosed in younger patients as lymphoepithelioma. In adults, NPC most commonly occurs as SCC. Although integration of EBV into the cancer cell genome can be frequently documented, the SCC variant appears to be linked to smoking and alcohol use. Thus, the etiology for adult NPC in the United States is similar to that for other SCCs of the head and neck.

Squamous Cell Carcinoma of the Head and Neck

DIAGNOSIS

Clinical Features

Early disease The signs and symptoms of early-stage head and neck cancer are usually vague and differ with the specific site of the primary disease. Patients whose tumors arise from the mucosa of the oral cavity can present with nonhealing ulcers, ill-fitting dentures, nonspecific pain, and slurred speech. Patients with tumors in the oropharynx can present with vague symptoms of unilateral pain and otalgia. Patients with tumors of the larynx can present with hoarseness even at an early stage. Thus, nonresolving hoarseness is one of the potential early warning signs of cancer and should be pursued if it persists longer than 2 to 4 weeks.

Patients with nasopharyngeal cancer present with classic symptoms of otalgia (caused by blockage of the eustachian tube), otitis media, and nasal obstruction with or without nosebleeding. Patients in more advanced stages will present with lymphadenopathy of the neck, which is usually bulky and bilateral, and cranial neuropathies. Patients with tumors of the paranasal sinuses can present with vague symptoms of pain and pressure that will advance to cranial neuropathies, ocular symptoms, or both.

Advanced disease Advanced tumors of any sites involved in head and neck cancer can cause massive unilateral or bilateral lymphadenopathy. Slurred speech, bleeding, severe pain, otalgia, trismus, dysphagia, odynophagia, ocular symptoms, cranial neuropathies, stridor, and airway obstruction can all be observed in these patients.

Examination

The evaluation of a patient for possible head and neck cancer should be guided by a high index of suspicion, particularly if the patient has a known history of tobacco or alcohol use. A thorough inspection of the oral cavity and all visible mucosa should be part of any general examination. If leukoplakia, erythroplakia, or any masses are identified, they should be biopsied. As part of the history, the patient should be questioned about pain, ill-fitting dentures, bleeding, or hoarseness. A symptomatic patient should undergo further evaluation by an otolaryngologist, who uses a mirror or an endoscope to visualize the pharynx and nasopharynx, oral cavity, larynx, and esophagus. If lesions are identified, further evaluation proceeds with the patient under anesthesia, and biopsy samples are obtained from all suspicious

lesions. It is advisable to examine the esophagus and respiratory tract because of the high incidence of second primary tumors (panendoscopy) occurring in this region. CT or MRI scanning establishes the extent of locoregional involvement.

A somewhat common clinical situation is that of a patient presenting with lymphadenopathy of the head and neck area but with no detectable primary site on initial examination. Evaluation of such patients should proceed with a fine-needle aspiration of the neck node, which frequently yields a diagnosis of SCC. Further evaluation should include a panendoscopy with the patient under anesthesia to permit biopsy of sites where primary tumors frequently occur—namely, the tonsils (the biopsy entailing a tonsillectomy), the base of the tongue, the nasopharynx, and the piriform sinus. If evaluation reveals no primary site, the cancer is staged as TX, and further management is performed according to the exact nodal stage. The evaluative process then focuses on locating primary tumors outside of the head and neck region (e.g.., lung and gastrointestinal tract).

STAGING

Head and neck cancers are staged by the TNM staging classification.[17] In general, T1 to T3 describes an increasing size of the primary site, and T4 involves invasion of an additional structure, such as bone, cartilage, or the base of the tongue. Neck lymph node involvement is classified as N1, N2, or N3 on the basis of the number, location, and size of involved lymph nodes. Staging is consistent for all anatomic sites except nasopharyngeal cancer, where location of the node is taken into consideration**.**

Head and neck cancer can be categorized into three major groups: (1) early disease (stages I and II), which is characterized by small primary T1 or T2 lesions with no clinically detectable lymph node involvement; (2) locoregionally advanced disease (stages III and IV), which is characterized by large primary tumors that may or may not be resectable and possibly by significant clinical lymph node involvement, but without detectable distant metastases; and (3) recurrent or metastatic disease, which is characterized by local or regional tumor recurrence after surgery or radiation and by the identification of metastases distant from the primary site. The 2002 American Joint Committee on Cancer (AJCC) Cancer Staging Manual contains important changes in staging classifications—notably, it includes a uniform description of advanced tumors (T4 divided into stage T4a, or advanced resectable disease, and stage T4b, or advanced unresectable disease) and metastatic disease (stage T4c).[17] The newer classifications are intended to identify patients who are candidates for curative therapy.

Unlike many other malignancies, head and neck cancer is predominantly a local and regional disease. Even patients with clinically advanced stages are rarely found to have distant metastases at the time of initial diagnosis. Approximately 30% of patients present with early disease, 65% with locoregionally advanced disease, and 5% with distant metastases. However, autopsy studies have suggested that a much higher percentage of patients have distant metastases.[18] The most common organs to be involved with metastases are the lungs, bones, and liver.

Recurrent disease usually occurs within the head and neck region. Thus, most therapeutic interventions in head and neck cancer are aimed at eradication of locoregional disease.

TREATMENT

Early Disease

Early-stage head and neck cancer is treated with curative intent. Approximately 60% to 90% of patients can be expected to be cured.[19,20]

In general, patients undergo either surgery or radiation therapy, and patients who develop subsequent locoregional disease may be treated with the alternative therapeutic modality. The exact choice of primary modality depends on the location of the disease. For early-stage laryngeal or nasopharyngeal cancer, the use of radiotherapy is generally preferred. Radiotherapy will result in few side effects and allows for preservation of a functional voice. Surgery can be used for disease recurrence. On the other hand, a small lesion in the oral cavity might be easily excised with no loss of function, whereas radiotherapy to the oral cavity would require a 6-week course of treatment and carry long-term sequelae of xerostomia, loss of taste, and accelerated dental decay.

Patients cured of head and neck cancer (all stages) are known to be at high risk for second malignancies.[21] Thus, such patients remain at significant risk (estimated at about 3% to 5% a year) of a second smoking-related or alcohol-related malignancy in the upper aerodigestive tract. Finally, because most patients are elderly, with the median age of onset being 60 years, they are at risk for significant medical comorbidity and require supervision by an internist or medical oncologist.[22]

Locoregionally Advanced Disease

The therapeutic goal in locoregionally advanced head and neck cancer is to control and cure disease while preserving organs and normal function.

Historically, standard treatment for locoregionally advanced disease consisted of surgery followed by postoperative radiotherapy (or radiotherapy alone for unresectable disease, such as some advanced tongue tumors or nasopharyngeal tumors). By using this approach, cure rates were consistently less than 30% for stage IV patients.[23] In addition, the treatment of these tumors required extensive surgical procedures resulting in significant subsequent organ dysfunction. In particular, total laryngectomy and total or partial glossectomy resulted in significant alteration of function; in addition, the cosmetic and psychological sequelae resulting from these procedures or the frequently utilized radical neck dissection were of great significance. Thus, two treatment goals could readily be defined: increased cure rates and decreased treatment-related morbidity.

To improve treatment outcomes for locoregionally advanced head and neck cancer, chemotherapy has been added to the treatment regimen of surgery and radiation, most commonly in the form of induction chemotherapy.[24] Concomitant (concurrent) chemoradiotherapy is another widely used therapeutic approach that has been examined in numerous randomized trials. As studies have evolved over the past two decades, it has become evident that there are advantages to both induction chemotherapy and concomitant chemoradiotherapy.[25] This perception has led to the combination of the two approaches.

Induction chemotherapy The administration of two or three cycles of chemotherapy before surgery and radiotherapy, usually utilizing cisplatin and fluorouracil, has been shown to result in tumor shrinkage in as many as 90% of patients.[24] Nevertheless, randomized trials have demonstrated that overall survival rates are not increased through the use of induction chemotherapy, because local and regional control is not better than that achieved with surgery and radiation alone.[26] The addition of a taxane to induction regimens has resulted in increased 2-year

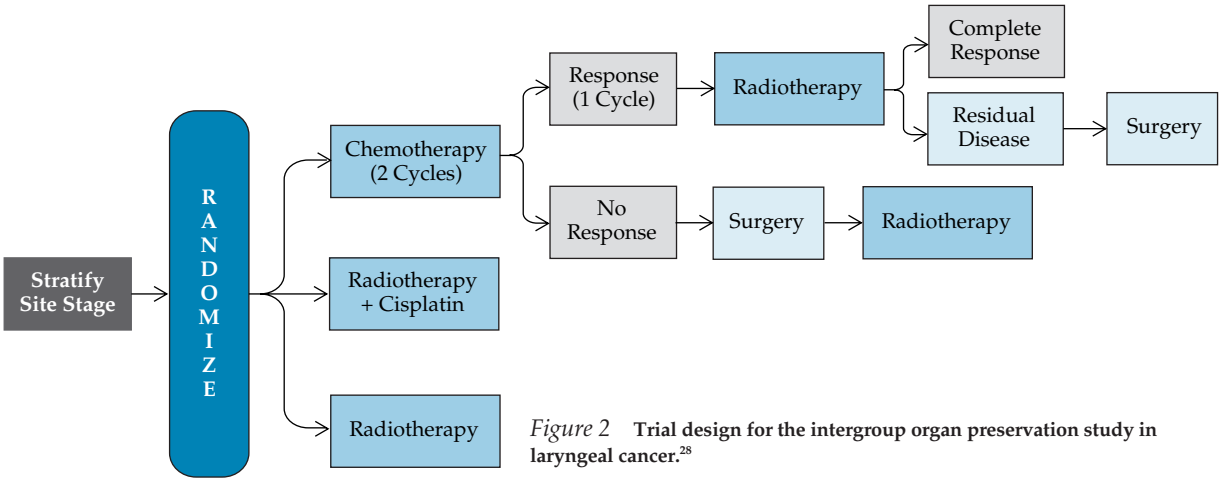

Figure 2 **Trial design for the intergroup organ preservation study in laryngeal cancer.[28]**

survival rates; however, a meta-analysis of six trials could not determine whether improved survival rates were the result of the pharmacologic effect of the taxane or that of uncontrolled prognostic factors across the various trials.[27]

Two findings of interest have been consistently reported. First, patients receiving induction chemotherapy have a lower incidence of disease progression outside of the head and neck area.[24] Thus, induction chemotherapy is able to successfully eradicate micrometastatic systemic disease. However, this result does not translate into increased survival rates, because local and regional failure is not influenced. Second, organ preservation of the larynx can be achieved. Randomized studies have specifically evaluated the use of induction chemotherapy with the goal of larynx preservation.[28-30] In these studies, patients received either surgery followed by radiotherapy or chemotherapy followed by radiotherapy; the latter patients underwent larynx resection only if they failed to respond to initial chemotherapy or had persistent or recurrent disease after completion of radiotherapy [*see Figure 2*]. Interestingly, induction chemotherapy did not increase survival rates but did allow for larynx preservation in approximately two thirds of surviving patients. In addition, patients with a preserved larynx reported less pain and better quality of life than patients who underwent surgery.[29] On the basis of these data, induction chemotherapy can be considered a standard treatment option for patients with locoregionally advanced laryngeal or hypopharyngeal cancer. Until recently, induction chemotherapy followed by radiation therapy was the standard of care for organ preservation[31]; however, the findings of a large randomized multicenter trial indicate that concomitant chemoradiotherapy is superior to induction chemotherapy for organ preservation.[32]

Concomitant chemoradiotherapy Concomitant (concurrent) chemoradiotherapy is an attractive concept for treatment of head and neck cancer. In such cases, chemotherapy is utilized primarily to sensitize tumor cells to radiotherapy and increase locoregional control. In addition, it is possible that chemotherapy can decrease systemic failure rates, although the doses and schedules of chemotherapy administered during radiotherapy may not be sufficient to achieve that goal.[24] Several randomized trials have been published in which patients received either radiotherapy alone or concomitant chemoradiotherapy (usually radiation plus cisplatin and fluorouracil). The patients treated with concomitant chemoradiotherapy had a statistically significant increase in disease-free survival and, in some studies, overall survival. These studies suggest that 3-year survival rates may be increased by as much as 20% (i.e., from 30% to 50%) through the use of concomitant chemoradiotherapy[33-37]; and they are also supported by large meta-analyses that evaluated approximately 15 trials investigating concomitant chemoradiotherapy during the 1970s and 1980s that typically involved administration of a single chemotherapeutic agent, such as bleomycin, methotrexate, mitomycin-C, or cisplatin. The meta-analysis of these older trials show a highly positive response rate, suggesting an 8% gain in absolute survival at 5 years.[38,39]

Randomized trials and a meta-analysis of three phase II trials also support concomitant chemoradiotherapy for advanced nasopharyngeal cancer.[36,40,41] On the basis of findings of the randomized trials and meta-analysis, concomitant chemoradiotherapy can be considered as a standard treatment option for the majority of patients with head and neck cancer. In addition, evidence indicates that concomitant chemoradiotherapy is viable as an organ-preserving strategy.[32] It is clear that patients achieving a complete response with concomitant chemoradiotherapy do not require surgery.[42] Therefore, this treatment modality may provide both an increased survival rate and an improved organ-preservation rate.

The findings of a 9-year multicenter study suggested that locoregional and distant recurrence rates may be dependent on treatment strategy. In that study, intensive induction chemotherapy followed by split-course chemoradiotherapy had a 13% distant failure rate, as compared with a 22% rate with chemoradiotherapy alone.[43] The study concluded that randomized clinical trials combining induction chemotherapy with concurrent chemoradiotherapy are warranted to determine whether this sequential approach is more effective in decreasing distant metastases and thus increasing overall survival rates.

Gene therapy Because head and neck cancer is a locoregional disease for most of its natural history, gene therapy has been applied to local tumor masses in an effort to reconstitute normal *p53* cellular status. Pilot data indicate that when a normal *p53* gene linked to an adenovirus is injected into locoregional tumors, tumor shrinkage can be observed, at least in some patients.[44]

Recurrent and Metastatic Disease

Patients with recurrent or metastatic disease are treated with palliative intent.[45] Curative surgery and radiotherapy are rarely

options. Thus, chemotherapy is considered standard for this group of patients. Overall response rates to current combination-chemotherapy regimens such as cisplatin and fluorouracil, cisplatin and paclitaxel, and cisplatin and docetaxel are approximately 30% to 40%.[46,47] In addition, quality of life is improved in patients receiving chemotherapy. However, the overall survival rate remains poor, with a median survival time of approximately 6 months and a 1-year survival rate of less than 30%.[48] Thus, the evaluation of new chemotherapeutic agents and other novel treatment approaches should have high priority.[49]

Salivary Gland Tumors

Salivary gland tumors arise either from one of the three major salivary glands or from the minor salivary glands lining the mucosa of the upper aerodigestive tract. Histologically, they represent very heterogeneous tumors, including mucoepidermoid cancers, pleomorphic adenoma, and adenoid cystic carcinomas, which are the more frequent specific tumor types. In a 35-year study of 2,807 patients with salivary gland tumors, 54% had benign tumors, the majority of which were pleomorphic adenomas.[50] The clinical manifestations of salivary gland tumors and diagnostic considerations are determined in part by the location of the tumor. Parotid tumors and submandibular gland tumors generally present as a solitary, asymptomatic mass. Minor salivary gland tumors arising in the oral cavity frequently present as a painless submucosal mass in the palate, lips, or buccal mucosa. Fine-needle aspiration biopsy can be used to distinguish nonneoplastic from malignant parotid masses. Its accuracy varies depending on the skill of the clinician; in experienced hands, accurate cytologic diagnosis approaches 100%.[51]

Treatment of salivary gland tumors is predominantly surgical, which leads to a proper definition of local and regional tumor stage. Surgery combined with radiotherapy, either adjuvant or postoperative, appears to increase survival.[52,53] For unresectable salivary gland tumors, neutron irradiation can be used instead of conventional radiotherapy. Chemotherapy is reserved for patients with recurrent or metastatic disease.

II DEPRESSION AND BIPOLAR DISORDER

Michael T. Compton, m.d., m.p.h.
Charles B. Nemeroff, m.d., ph.d.

Definition

Depression and bipolar disorder are two forms of psychiatric illness that lie at opposite ends of the spectrum of affect [*see Figure 1*]. Both are characterized by disturbances in feelings, thoughts, and behaviors and, consequently, by considerable impairment in functioning.

Mood disorders are divided on the basis of polarity. Unipolar depression is characterized by depressive episodes only, whereas bipolar disorder (formerly termed manic-depressive illness) is marked by hypomanic, manic, or mixed episodes, often in addition to depressive episodes. The most commonly utilized classifications rely on this division, including the two gold standards in the field, the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th edition of the *International Classification of Diseases and Related Health Problems* (ICD-10).

Mood disorders (also known as affective disorders) are syndromes consisting of signs and symptoms that are clearly abnormal for the individual experiencing them. Episodes tend to occur in periodic fashion, with varying degrees of residual symptoms between them. Mood disorders are distinguished from other major mental illnesses, such as schizophrenia, on the basis of the presence or absence of specific clusters of symptoms and the longitudinal course of the illness. Many patients with mood disorders fulfill the diagnostic criteria for other psychiatric disorders, such as anxiety disorders, substance-use disorders, and personality disorders.

Depressive Disorders

EPIDEMIOLOGY

The most commonly cited prevalence estimates for psychiatric disorders in the United States are derived from the 1980–1985 Epidemiologic Catchment Area (ECA) study and the 1990–1992 National Comorbidity Survey (NCS).[1,2] The ECA found the 1-year prevalence of major depression and dysthymia (mild, chronic depression) in adults to be 5.0% and 5.4%, respectively. NCS 1-year prevalence rates were 10.3% for major depressive episode and 2.5% for dysthymia. Of note, 1-year prevalence rates for major depressive episode and dysthymia were 12.9% and 3.0%, respectively, in females and 7.7% and 2.1% in males.[2] Subsyndromal symptomatic depression is defined as a depressive state characterized by two or more symptoms of depression of the same quality as that which occurs in major depression, excluding depressed mood or anhedonia.[3] The 1-year prevalence of subsyndromal symptomatic depression in the general population has been estimated to be 11.8%.[4] In a nationally representative sample of adolescents and young adults 15 to 24 years of age from the NCS, the 1-year prevalence of major depression was found to be 12.4%.[5] Of considerable concern was the observation that 21.9% of those adolescents and young adults with major depression reported a suicide attempt at some point in their lives. In children, the prevalence rates of major depression are approximately the same in girls and boys, whereas in adolescents, the female-to-male ratio is approximately 2:1,[6] which is consistent with the adult gender ratio. The NCS found that the lifetime prevalence rates for a major depressive episode were 12.7% and 21.3% for men and women, respectively; the lifetime prevalence rates for dysthymia were 4.8% in men and 8.0% in women.

Epidemiologic studies reveal that mood disorders are more prevalent in persons younger than 45 years; the average age of onset is between 20 and 40 years. The age of onset of unipolar depression has decreased dramatically over the past several decades. The incidence of depressive episodes, but not bipolar disorder, is about twice as high in women as in men—a sex difference that begins in early adolescence and persists into midlife. The prevalence of affective disorders does not vary significantly by race or ethnicity. Major depression appears to be more prevalent in urban residents; in single, divorced, or widowed people; in patients seen in primary care settings; in patients with comorbid medical illness; in unemployed people; in those with a history of traumatic early childhood experiences (e.g., loss of parents at an early age, sexual or physical abuse); and in those with perceived social stresses. Affective disorders in general are also more prevalent in persons with a family history of affective disorders, suicide, or alcoholism.

Depression is widespread in the elderly. Depression in late life is a serious public health concern; comorbidity of depression with other illnesses, both medical and psychiatric, is particularly problematic in older persons.[7] The prevalence of depressive symptoms in those 65 years of age and older has been estimated to be 16.9%.[8]

According to some estimates, depression ranks as the number one cause of disability worldwide, causing twice as much disability as the second leading cause, which is iron deficiency anemia. Disability from mood disorders often exceeds that from other chronic and debilitating diseases, such as hypertension, arthritis, and diabetes, causing more days in bed and higher numbers of missed days from work.

ETIOLOGY AND GENETICS

The strongest known risk factors for the development of depression are family history and previous episodes of depression. The risk of depressive disorders in first-degree relatives of patients with depression is two to three times that of the general population. If one parent has a mood disorder, a child's risk of a mood disorder is 10% to 25%; if both parents are affected, the risk roughly doubles. The importance of genetic factors in pathogenesis is also highlighted by the higher concordance rate of depression in monozygotic twins than in dizygotic twins. The likelihood that a person will develop a mood disorder is influenced by a number of factors, including gender (women are at greater risk than men), early parental loss, inadequate rearing by parents (e.g., neglect), a history of prepubertal traumatic events, certain personality characteristics, personal or family history of mood disorders, the extent of social support, and recent stressful life events.

Psychological models for the etiology of mood disorders, especially depressive disorders, have also been proposed. Some of these theories have focused on the influence of early life ex-

periences—a view supported by considerable recent neurobiologic research. Other schools of thought have advanced behavioral and cognitive factors as preeminent in the etiology of mood disorders.

Contemporary psychiatry views the etiology of depression as a multifactorial process with a definite biologic basis, though social and psychological influences are clearly important. The genetics of unipolar depression and many other psychiatric illnesses is an area of active research. Depression is undoubtedly a genetically complex disease and one that, like many medical disorders, results from an interaction between genetic susceptibility and environmental factors.[9] For example, current research suggests that the likelihood of developing depression in response to stressful life events is moderated by genotype at a functional polymorphism in the promoter region of the serotonin transporter gene.[10]

PATHOGENESIS

No single physiologic mechanism for mood disorders has been identified. Nonetheless, considerable evidence suggests the involvement of several neurotransmitter systems, especially the monoamines (noradrenergic, serotoninergic, and perhaps dopaminergic pathways), as well as abnormalities in the hypothalamic-pituitary-adrenal (HPA) and hypothalamic-pituitary-thyroid (HPT) axes. Noradrenergic systems are involved in mood, arousal, appetite, reward, and drives; serotoninergic systems are involved in mood, sleep, and impulsivity; and dopaminergic systems are important for pleasure and reward, as well as for psychomotor activity. These monoamine systems arise in cell groups in the brain stem and are widely dispersed throughout the forebrain. Chronic hyperactivity of the HPA axis is arguably the biologic finding that is most often reported in severe and psychotic depression, and it normalizes with clinical recovery. The pathogenesis of depression in relation to biogenic amines and the HPA axis is an area of intensive research.[11]

Biogenic Amine Hypotheses

It has been posited that mood disorders are caused by relative deficiencies in the availability of the catecholamine norepinephrine (NE) or the indoleamine serotonin (5-hydroxytryptamine [5-HT]) within the central nervous system, perhaps involving alterations in receptor function, signal transduction, or both.[12,13] Findings related to the adrenergic system include alterations in cerebrospinal fluid concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), which is the major metabolite of CNS NE, and alterations in NE availability. Several subtypes of adrenergic receptors have also been studied, and several alterations have been noted. These include an increase in the binding of alpha$_2$-adrenergic receptors in platelets; a blunting of the growth hormone response to clonidine (an alpha$_2$ receptor agonist); and an increase in the density of beta-adrenergic receptors in the brains of suicide victims post mortem. Furthermore, a multitude of studies have documented downregulation of beta-adrenergic receptors after long-term treatment with antidepressants—particularly monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs)—and after electroconvulsive therapy (ECT). During recent decades, close scrutiny of the serotoninergic system in the brain has revealed alterations in various measures of serotoninergic neural activity and integrity, as well as 5-HT receptor alterations, in patients with depression. The CSF concentration of the serotonin metabolite 5-hydoxyindoleacetic acid (5-HIAA) has repeatedly been reported to be decreased in depressed patients, especially those who are suicidal. Alterations in 5-HT transporters and receptors have also been studied; such alterations include an increase in the density of postsynaptic 5-HT$_2$ receptors and a decrease in the density of 5-HT transporter sites. The response to fenfluramine, an agent that releases 5-HT from the presynaptic terminal, is diminished in some patients with depression.

Neuroendocrine and Neuropeptide Hypotheses

Other hypotheses have focused on the multiple endocrine alterations reported to be present in patients with mood disorders, most prominently in the HPA[14] and HPT axes. Several of the hierarchical components of neuroendocrine axes may be involved in the pathophysiology of mood disorders. In the HPA axis, corticotropin-releasing factor (CRF) from the hypothalamus stimulates the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which in turn regulates the secretion of glucocorticoids from the adrenal cortex (cortisol being the most important hormone released from the adrenal gland). Corticosteroid receptor signaling is impaired in patients with major depression,[15] and studies document marked CRF neuronal hyperactivity in depressed patients.[16,17] Several measures of HPA-axis hyperactivity have been reported in depressed patients. These include (1) increased concentrations of CRF in CSF, (2) a blunted ACTH response to exogenous CRF administration, (3) decreased CRF receptor density in the frontal cortex of suicide victims, (4) pituitary and adrenal gland enlargement, (5) increased ACTH and cortisol production, and (6) nonsuppression of plasma cortisol levels after the administration of dexamethasone (the dexamethasone suppression test).

Hypothyroidism has long been known to be frequently associated with a markedly depressed mood. The HPT axis involves the secretion of thyrotropin-releasing hormone (TRH) by the hypothalamus, which stimulates the anterior pituitary gland to release thyroid-stimulating hormone (TSH). This in turn stimulates the secretion of thyroxine and triiodothyronine from the thyroid gland. A multitude of alterations in the activity of the HPT axis have been observed in patients with depression. Such abnormalities include increased TRH concentrations in CSF, blunted or exaggerated TSH response to TRH stimulation, decreased nocturnal plasma TSH concentrations, and the presence of antimicrosomal thyroid or antithyroglobulin antibodies. Mood disorders have also been reported to be associated with alterations in the activity of the growth hormone axis and the hypothalamic-pituitary-gonadal (HPG) axis. The burgeoning field of psychoneuroimmunology has provided evidence of abnormal immune function, including alterations in cytokine secretion, in depressed patients.

Neuroimaging and Sleep Studies

Brain imaging techniques, including both structural and functional magnetic resonance imaging and positron emission tomography, are being increasingly used to study CNS pathophysiology in patients with affective disorders.[18,19] These neuroimaging studies show clear abnormalities in the activity of several circuits in depressed patients, including decreased metabolism in the frontal cortex and increased metabolism in certain limbic areas.[20] Sleep abnormalities in depression include increased time to sleep (initial insomnia), earlier onset of rapid eye movement (REM) sleep (decreased REM latency),[21] reduced sleep stages 3 and 4, changes in phasic REM activity, disturbances in the continuity of sleep, and early morning awakenings.

Clinical Manifestations

A major depressive episode consists of at least a 2-week period during which five or more specific symptoms are experienced, representing a change from previous functioning. According to DSM-IV, at least one of these symptoms must be either depressed mood or loss of interest or pleasure (anhedonia). Other potential symptoms include significant change in appetite or body weight, insomnia or excessive sleeping, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or inappropriate guilt, poor concentration or indecisiveness, and thoughts of death or suicidal ideation. Patients with a major depressive episode often experience negative cognitive patterns, including helplessness, hopelessness, and preoccupation with inadequacy. Low self-esteem and overwhelming guilt or self-reproach are commonly present. When the episode is accompanied by psychotic features, the psychotic symptoms tend to be mood-congruent—for example, the patient may experience nihilistic delusions or auditory hallucinations of derogatory commentary. Distinguishing between psychotic depression and schizoaffective disorder is important, because the two entities confer different prognoses[22] and have different treatments.

Patients experiencing depressive episodes sometimes have features described as melancholic; these include early morning awakenings, loss of appetite, marked psychomotor changes, diurnal mood variation (i.e., the mood is worse in the morning than later in the day), and unremitting anhedonia. Melancholic depression may be more severe and more likely to include biologic abnormalities; it may be most appropriately treated with pharmacotherapy or ECT. The term atypical depression describes a syndrome of prominent mood reactivity, reversed neurovegetative symptoms (increased appetite and excessive sleep rather than the typical pattern of neurovegetative symptoms that includes decreased appetite and insomnia), considerable anxiety, reversed diurnal mood variation (i.e., symptoms are more severe in the evening), prominent fatigue, and extreme sensitivity to rejection.

Other subtypes of depression include those characterized by a seasonal pattern of recurrence and, in women, worsening of depression during the premenstrual phase. In as many as 10% of patients with depression, episodes recur in a seasonal pattern, and seasonal affective disorder is an increasingly recognized subtype of depression.[23,24] Premenstrual worsening of depression has been a phenomenon of increasing interest. Some women experience a severe syndrome of mood and physiologic symptoms during the luteal phase of the menstrual cycle that generally resolves shortly after the onset of menstruation. This clinical entity is known as premenstrual dysphoric disorder (PMDD).[25,26]

Unipolar depressive disorders, as defined by DSM-IV, include major depressive disorder (characterized by either a single episode or recurrent episodes) and dysthymic disorder (chronic depressive symptoms that do not meet the full criteria for a major depressive episode) [*see Figure 1*]. Dysthymic disorder is a mild form of depression that often has an early onset (i.e., in childhood, adolescence, or early adult life) and usually lasts for long periods (i.e., for at least 2 years in adults, according to DSM-IV). Dysthymic disorder is an undertreated condition,[27] despite the significant psychosocial impairment associated with the disorder. In patients with a personality disorder, the symptoms of dysthymic disorder can be difficult to disentangle from the chronic affective symptoms of the personality disorder. Major depressive disorder may arise in persons with dysthymic disorder (so-called double depression). Subsyndromal affective symptoms are also recognizable in some individuals. A thorough history and mental status examination are necessary in differentiating between clinically significant affective symptoms and normal fluctuations in mood.

Mental Status Examination

The general appearance and attitude of the patient should be noted. When depressive symptoms become severe, the patient may become quite socially withdrawn and may begin to neglect personal hygiene and grooming. The patient's attitude may reflect sadness, irritability, or restlessness. Notable behaviors may include diminished eye contact, stooped posture, hand-wringing (a sign of anxiety or agitation), and psychomotor retardation or agitation. An assessment of speech may reveal increased response latency and decreased rate and rhythm of speech. Patients may describe their mood using such terms as down, depressed, sad, blue, unhappy, empty, helpless, or hopeless. The affect (which can be thought of as an objective assessment of the patient's internal emotional state) is often sad, tearful, or anxious. Thought processes are often slower than normal. Thought content may be characterized by inappropriate guilt and self-reproach; thoughts of worthlessness, hopelessness, or helplessness; mood-congruent psychotic features (e.g., hallucinations or delusions); and suicidal thoughts or plans. Insight into the illness, as well as judgment in general, may range from impaired to good. Impaired insight may have important implications for compliance with treatment. A cognitive assessment may reveal subtle or obvious impairments in memory and concentration.

The initial manifestations of depression may include somatic complaints such as fatigue, gastrointestinal problems, pain, or sleep disturbances. A thorough medical and psychiatric review of systems, as well as a substance-use history, should be conducted to exclude other causes of the mental status examination findings or somatic complaints. A suicide risk assessment will help determine the severity of depression and the appropriate locus of care for the initiation of treatment.[28] Having patients complete a brief, self-administered screening tool may facilitate the diagnosis of depression. Such scales include the Beck Depression Inventory, the Carroll Rating Scale for Depression, and the Zung Depression Self-Report Rating Scale.

Assessment of suicide risk A vital aspect of the mental status examination is a thorough assessment of suicidality, which includes suicidal thoughts, plans, means, intent, and attempts. Practical interviewing strategies have been developed for efficiently eliciting suicidal ideation, such as the Chronological Assessment of Suicide Events approach.[29] Evaluation of current suicidality should include extent and details of planning, lethality of such plans, intent to act on them, availability of means, and preparatory plans, such as drafting a will or securing means.[30] Because a previous suicide attempt is an important predictor of future attempts, the clinician should thoroughly evaluate details of any past suicidality. Gathering collateral history from family and friends is an important aspect of a thorough assessment. Potential risk factors for suicide include family history of suicide, concomitant anxiety or panic attacks, hopelessness, low self-esteem, psychosis, aggressive or impulsive personality characteristics, comorbid substance abuse, comorbid medical conditions, inadequate treatment of depression, and poor social supports. It is very important for clinicians to document a competent suicide

risk assessment that guides subsequent clinical interventions. Specialty psychiatric care should be obtained for patients with depression complicated by suicidal ideation.

Laboratory Tests

At present, there are no validated routine laboratory tests to diagnose depression. The dexamethasone suppression test, a measure of HPA-axis activity, is not sufficiently sensitive or specific for diagnosis or for monitoring response.[31] Instead, diagnosis is made according to the descriptive clinical criteria set forth in DSM-IV.

Several laboratory tests should be ordered to help exclude other potential causes of depressive symptoms. Medical conditions that may be physiologically associated with depression include endocrinopathies (e.g., hypothyroidism, hyperthyroidism, parathyroid disorders, Cushing syndrome, or Addison disease), neurologic disorders (e.g., stroke, subcortical dementias, neurosyphilis, multiple sclerosis, Parkinson disease, neurosarcoidosis, CNS vasculitis, or HIV-associated CNS pathology), and other disorders (e.g., vitamin deficiencies, anemia, hypoglycemia or hyperglycemia, hypoxia, end-stage renal disease, lupus, or occult malignancies such as pancreatic cancer).

DIFFERENTIAL DIAGNOSIS

The initial presentation of a patient with clinically significant depression can include a broad range of symptoms, such as somatic complaints (e.g., fatigue, insomnia, anorexia, or various nonspecific somatic symptoms), emotional concerns (e.g., sadness, anxiety, or feelings of guilt), and other problems (e.g., difficulty at work, marital problems, irritability, or memory impairment). Before making a diagnosis of major depressive disorder or dysthymic disorder, the clinician should conduct a search for medical causes of the depressive disorder. Several medical conditions (see above) can mimic the symptoms of depression. Additionally, a variety of substances of abuse can be causally implicated in depression. These include alcohol, sedative-hypnotics, and cocaine. Iatrogenic causes of depression include antihypertensives that reduce central catecholamine neurotransmission (e.g., beta blockers, reserpine, methyldopa, guanethidine, and clonidine), corticosteroids, antineoplastic agents, interferon alfa, and, possibly, isotretinoin.[32,33] Whether the depression is substance induced or caused by a general medical condition, the underlying cause should be treated; if improvement in depressive symptoms fails to occur after approximately 4 to 6 weeks, the depression should be independently diagnosed and treated.[34]

After exclusion of medical causes or substance-induced depression, the clinician should consider primary psychiatric conditions associated with depressive symptoms. The distinction between unipolar depression (i.e., a major depressive episode with no history of hypomania or mania) and bipolar depression (i.e., a major depressive episode in a patient with a history of hypomania or mania) is of vital importance and significantly affects treatment decisions. In bipolar disorder, it is not uncommon for patients to experience several episodes of depression before their first manic episode; bipolar disorder should therefore always be a part of the differential diagnosis of depression. Any history of hypomanic or manic episodes should be reviewed. Patients with bipolar depression are more likely to experience a switch to hypomania or mania or an acceleration in mood cycling if they are treated with an antidepressant in the absence of concomitant treatment with a mood stabilizer.[35] In women, the incidence of depression is increased during times of hormonal change, including pregnancy and the postpartum period. In fact, postpartum depression occurs in about 13% of women after delivery.[36] Depression after miscarriage is a common but underrecognized condition.

Other psychiatric disorders must also be excluded. Primary anxiety disorders (e.g., generalized anxiety disorder, posttraumatic stress disorder, and social anxiety disorder) should be considered in the differential diagnosis of depression [*see 13:VIII Anxiety Disorders*]. In the elderly, depression with cognitive impairment that is reversed by antidepressant treatment may be an early predictor of the development of an irreversible dementia.[7] Patients with late-onset depression are more likely to have cognitive impairment and to have more deep white-matter lesions on imaging studies.[37] However, the so-called pseudodementia of depression is common and should not be mistaken for a primary dementia. The term double depression refers to a major depressive disorder superimposed on chronic dysthymia. Many patients with personality disorders can present with symptoms of depression, and an assessment of the longitudinal history of symptoms is vital in establishing the correct diagnosis. Many patients actually have two or more comorbid psychiatric disorders, such as major depression and generalized anxiety disorder.

MANAGEMENT

Depression is often undiagnosed or inadequately treated.[38] This is extraordinarily unfortunate because a number of effective treatments are available. Incorporating depression treatment programs into primary care settings improves mental health and social outcomes,[39] and the United States Preventive Services Task Force recommends screening adults for depression in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up. These recommendations are available on the Internet (http://www.ahrq.gov/clinic/uspstf/uspsdepr.htm).[40,41]

Pharmacologic Therapy

A broad array of antidepressants is available for the treatment of depression, allowing clinicians to select a regimen on the basis of potential side-effect profiles, subtype of depression, personal or family history of response to specific medications, and comorbid psychiatric or medical conditions.

Monoamine oxidase inhibitors MAOIs, one of the first classes of antidepressants developed, block the enzyme that metabolizes biogenic amines, increasing the availability of these neurotransmitters. In the United States, three MAOIs are currently available: phenelzine, isocarboxazid, and tranylcypromine. They are rarely used because their use is complicated by side effects (including hypotension), lethality in overdose, and lack of simplicity in dosing. Patients treated with MAOIs must follow a specific tyramine-free diet because of the potential for a pharmacodynamic interaction with tyramine that can result in a hypertensive crisis. Drugs that have been reported to interact with MAOIs include carbamazepine, cyclobenzaprine, dextromethorphan, fenfluramine, certain hypoglycemics, L-tryptophan, meperidine, selective serotonin reuptake inhibitors (SSRIs), stimulants, sympathomimetics, and TCAs. Nonetheless, the MAOIs appear to be more effective than other antidepressants in the treatment of atypical depression, though their use is usually limited to psychiatrists who have experience with these agents. MAOIs are also often effective in patients with depression that is refractory to treatment with other antidepressants.

Selective MAOIs (e.g., moclobemide), which are available outside of the United States, are easier to use because of the lack of dietary constraints and drug-drug interactions. A transdermal system for delivery of selegiline, an MAOI approved by the Food and Drug Administration for the treatment of Parkinson disease, may be effective in the treatment of depression.[42,43]

Tricyclic antidepressants TCAs act at several transporters and receptors, but their antidepressant effect is likely produced by the blocking of the reuptake of NE, 5-HT, or both at their presynaptic terminals, increasing the availability of these neurotransmitters. The TCAs can be subdivided into the tertiary amines, which are dual 5-HT/NE reuptake inhibitors (e.g., amitriptyline, imipramine, and clomipramine) and the secondary amines, which are primarily NE reuptake inhibitors (e.g., desipramine and nortriptyline).

The use of TCAs is limited by their unfavorable side-effect profile (largely resulting from their anticholinergic, antiadrenergic, and antihistaminic properties); these side effects include blurred vision, dry mouth, tachycardia, constipation, urinary retention, cognitive dysfunction, postural hypotension, dizziness, sedation, weight gain, and sexual dysfunction. TCAs also have a narrow therapeutic index and are lethal in overdose (resulting in part from an inhibition of sodium channels that causes a slowing of cardiac conduction and potentially fatal arrhythmias). Efficient use of TCAs is also limited by the need to slowly titrate the dose and the need for therapeutic drug monitoring to avoid toxicity. Although these medications are still occasionally used in refractory cases, their use should be limited to experienced practitioners and to patients who can be relied on to comply with the regular electrocardiographic and blood-drug-level monitoring that is required.

Selective serotonin reuptake inhibitors and newer antidepressants The first SSRI, fluoxetine, was introduced in the United States in 1988. There are currently six SSRIs approved by the FDA: fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram, and escitalopram. These agents all share the property of blocking the reuptake of 5-HT, but there is increasing evidence that they produce other effects as well.

The SSRIs are effective in treating depression and many primary anxiety disorders. They offer several important advantages over the older medications. They require minimal dose titration, and the starting dose is sometimes an effective and even optimal dose [*see Table 1*]. Perhaps most important, these medications are safe in overdose.[44] Generic formulations of fluoxetine, paroxetine, fluvoxamine, and citalopram are currently available.

The SSRIs have a relatively mild side-effect burden. The sexual side effects of these medications (i.e., delayed ejaculation, anorgasmia, and decreased libido) are being increasingly recognized and studied; sexual side effects are one of the leading causes of discontinuance or noncompliance.[45,46] Although the correlation between SSRI treatment and increased suicide risk remains controversial, the potential for increased risk has prompted the FDA to require that manufacturers of all antidepressants include in their labeling a boxed warning (http://www.fda.gov/cder/drug/antidepressants/default.htm).[47-49]

Other, newer agents are believed to act on serotoninergic and noradrenergic pathways in the brain by a variety of mechanisms, including dual 5-HT/NE reuptake blockade (venlafaxine), 5-HT_2 blockade (trazodone, nefazodone,[50] and mirtazapine[51]), and alpha$_2$ autoreceptor blockade (mirtazapine). Bupropion was originally thought to act as a dopamine and NE reuptake inhibitor, but its mechanism of action remains somewhat obscure.[52] In addition to having FDA approval for depression, bupropion is approved for smoking cessation,[53] and venlafaxine is approved for generalized anxiety disorder.[54] Venlafaxine may be particularly effective in refractory and severe depression.[55,56] The noradrenergic effects of venlafaxine emerge at higher dosages; at lower dose ranges, it is essentially an SSRI.[57] However, venlafaxine has been reported to be similar to TCAs with regard to potential overdose and in having proconvulsant and cardiac side effects.[58] Duloxetine is a 5-HT/NE reuptake inhibitor approved by the FDA for the treatment of depression and diabetic peripheral neuropathic pain.[59,60]

Table 1 Usual Starting Doses and Dose Ranges for First-Line Antidepressant Agents

Drug (Trade Name)	*Typical Daily Starting Dose*	*Typical Daily Dose Range*
Fluoxetine (Prozac)	20 mg	20–80 mg
Paroxetine (Paxil)	20 mg	20–60 mg
Paroxetine, continuous release (Paxil CR)	12.5–25 mg	50–75 mg
Sertraline (Zoloft)	50 mg	50–200 mg
Fluvoxamine (Luvox)	50 mg	100–300 mg
Citalopram (Celexa)	20 mg	20–60 mg
Escitalopram (Lexapro)	10 mg	10–20 mg
Venlafaxine, extended release (Effexor XR)	37.5 mg	75–225 mg
Bupropion, sustained release (Wellbutrin SR)	100 mg	100–200 mg b.i.d.
Nefazodone (Serzone)	100 mg	200–600 mg
Mirtazapine (Remeron)	15 mg	15–45 mg
Duloxetine (Cymbalta)	20–30 mg	40–60 mg

Clinicians using SSRIs and newer antidepressants should be familiar with their potential for pharmacokinetic drug-drug interactions resulting from the inhibition of various cytochrome P-450 microsomal hepatic enzymes.[61] Different SSRIs and some of the other, newer antidepressants inhibit different isoenzymes of the hepatic cytochrome P-450 system; this can lead to elevation in blood levels of other medications. Nefazodone inhibits cytochrome P-450 3A4 activity and therefore increases the levels of benzodiazepines and of protease inhibitors used in the treatment of HIV infection. Fluoxetine inhibits cytochrome P-450 2D6 activity and therefore increases plasma levels of propranolol and risperidone, as well as other 2D6 substrates.

Various symptoms have been associated with the abrupt discontinuance of certain SSRIs with short half-lives and of newer agents, particularly paroxetine and venlafaxine; such symptoms include dizziness, paresthesias, asthenia, myalgias, nausea, loose stools, visual disturbances, irritability, insomnia, mood worsening, electric-shock–like sensations in the upper extremities, and headache.[62,63] With all antidepressants, tapering before discontinuance is recommended, especially for agents with short half-lives.

Research targets Development of antidepressant drugs continues to be a high priority in psychiatry, as exemplified by the efforts to develop CRF_1 and neurokinin-1 (NK_1) receptor antagonists for the treatment of depression, as well as the use of glucocorticoid receptor antagonists for the treatment of psychotic depression. The future of the treatment of depression will probably include greater knowledge of features that predict treatment response, likely through genomics and functional brain imaging.

Medication selection The vast majority of patients with depression can be treated with SSRIs and other, newer antidepressants. The patient's medical history and personal or family history of response often help predict response and side effects. Like major depression, dysthymic disorder and PMDD are effectively treated with antidepressants.[64] PMDD is especially responsive to SSRIs; the SSRIs can be used intermittently in patients with PMDD, with administration of medication limited to the luteal phase (14 days premenstrually).[65-68] Research suggests that low-dose oral contraceptive pills containing drospirenone may alleviate some symptoms of PMDD in some patients, although placebo response rates are relatively high (as is true of most randomized studies of depressive symptoms).[69]

In patients who present with clinically significant anxiety as an integral component of their depressive illness, treatment often begins with an antidepressant and an anxiolytic (e.g., clonazepam or diazepam, which are long-acting benzodiazepines). Many of the newer antidepressants, including the SSRIs, are effective anxiolytics; but their anxiolytic effects, like their antidepressant effects, do not appear until several weeks after the initiation of treatment. For this reason, it is judicious in such cases to use a brief course of a benzodiazepine anxiolytic along with the antidepressant.

Depression with associated psychotic features must be treated with an antidepressant and an antipsychotic medication.[70] Atypical antipsychotic agents are currently the first-line choice; such drugs include risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole. Severe depression is most effectively treated with ECT.[71] Patients with bipolar depression should be treated with an optimal dose of a mood-stabilizing medication (e.g., lithium, valproate, carbamazepine, or an atypical antipsychotic agent) before starting therapy with an antidepressant.[72] Lamotrigine, an anticonvulsant, may be particularly effective in the treatment of bipolar depression.[73] An olanzapine-fluoxetine combination capsule (Symbyax) also has FDA approval for the treatment of bipolar depression.[74,75]

Herbal remedies and dietary supplements A number of agents have been reported to have an effect on depressive symptoms. Most herbal remedies and dietary supplements have not yet been adequately studied. Initial enthusiasm about the potential effectiveness of *Hypericum perforatum* (St. John's wort) was diminished by two double-blind, randomized multicenter trials that failed to support the efficacy of St. John's wort in major depression when compared with placebo[76] or with placebo and sertraline.[77] However, in the latter study, there was no statistical difference between sertraline and placebo in terms of main outcome measures, which is a reminder of the relatively high placebo response rate in randomized, controlled trials for depression.[78] Other herbal remedies that may hold promise for the treatment of depression, such as S-adenosyl-methionine (SAM-e) and kava, require further study before their use can be recommended.[79] Dietary supplements, including B vitamins and omega-3 fatty acids, also require additional study to substantiate reports.

Managing therapeutic response Treatment of depression is recommended for at least 4 to 6 weeks before a decision regarding efficacy can be made. Measurement of depression severity by an observer or through use of a self-report rating scale is essential for monitoring the patient's response to antidepressant therapy. Improvement may be variable, with some symptoms improving before others, and the patient may experience occasional days of increased symptoms during the course of recovery. Complete failure to respond (which may be defined as less than 25% decrease on an accepted symptom-rating scale in a patient who has received an adequate dosage for 4 weeks) may best be addressed by switching to an agent with a different mode of action or to a dual-action agent[80] (e.g., switching from an SSRI to venlafaxine, bupropion, nefazodone, mirtazapine, or duloxetine). Considerable data suggest that many patients who do not respond to one SSRI do respond to a different SSRI.

Patients who experience a partial response (i.e., a 25% to 50% decrease on rating scales after 4 to 6 weeks at an adequate dosage) may be treated with dose escalation. If full remission still does not ensue, an augmentation or combination strategy can be tried.[81] Reassessment of the diagnosis may reveal psychiatric comorbidity, the presence of depressive subtypes, or the contribution of a previously undiagnosed medical disorder or iatrogenic cause. Augmentation agents include thyroid hormone, lithium, psychostimulants (e.g., methylphenidate, dextroamphetamine, or modafinil), buspirone, atypical antipsychotics, and other antidepressants.

Nonresponse or partial response despite adequate antidepressant treatment occurs in a substantial portion of patients. The most common cause of initial treatment failure, however, is undertreatment, which can result from an insufficient duration of treatment, a subtherapeutic dosage of medication, or poor adherence to treatment.[82] Adherence should be encouraged and monitored. Factors that may affect a patient's adherence to the medication regimen include the complexity and side-effect burden of the antidepressant regimen; concurrent substance abuse; and poor or incomplete understanding of symptoms, illness, and treatment. Sexual side effects have been widely recognized as a major cause of poor compliance with SSRI regimens, particularly after improvement of depressed mood. Several of the newer antidepressants (including bupropion, nefazodone, and mirtazapine) may be much less likely to induce these troubling side effects.

Improvement of the illness should not be interpreted by the patient or the physician as an indicator that antidepressants are no longer necessary. The continuation phase of treatment consists of 16 to 20 weeks of continued treatment (using the same antidepressant that was used in the acute phase) after remission, with the goal of preventing the relapses that typically occur in untreated patients. Maintenance-phase treatment should be considered for the prevention of recurrence; the decision whether to prescribe maintenance treatment should be based on the patient's longitudinal history and the severity of illness. Maintaining antidepressants at the dosage used to treat the acute episode is an effective means of preventing recurrence,[83] the risk of which increases with each successive episode. The optimal duration of maintenance-phase treatment has not yet been determined.[28] Clinicians should base such decisions on the estimated level of the risk of recurrence. Patients who have experienced three or

more past episodes of severe major depression should probably be treated with an antidepressant indefinitely, in view of the high risk of further relapse.

Nonpharmacologic Somatic Therapy

ECT is a highly effective treatment for depression, although its use is limited by the following factors: the need for general anesthesia; the potential for short-term memory impairment; the relatively limited number of sites at which ECT is available (generally in high-population areas); and the social stigma attached to the procedure, which is related to its historical development. Thus, despite its effectiveness, ECT is often reserved for severe or refractory depression.

Patients with a recurrent seasonal pattern of depression may be effectively treated with daily exposure to bright artificial light.[84] Potential new somatic treatments are being studied, including rapid transcranial magnetic stimulation.[85] Vagus nerve stimulation, which uses a surgically implanted device, has FDA approval for the adjunctive long-term treatment of chronic or recurrent/refractory depression.[86] Stimulation-related side effects may include hoarseness, cough, neck pain, or shortness of breath.

Psychotherapy

Psychotherapy is often used in conjunction with medications for major depression or dysthymic disorder. Only two forms of psychotherapy have been shown in controlled trials to be effective in the treatment of depression: interpersonal psychotherapy (IPT) and cognitive-behavioral therapy (CBT).

IPT explores at least three interacting components: symptom formation, social and interpersonal experiences, and enduring personality patterns. IPT is a short-term structured therapy consisting of 12 to 16 sessions; the aims of therapy are to reduce the patient's depressive symptoms, to improve self-esteem, and to help the patient develop more effective strategies for dealing with social and interpersonal relations.

CBT is a highly structured, effective short-term psychotherapy that aims to correct negative thought patterns, specific dysfunctional schemas, and cognitive distortions. Basic components of CBT include didactic aspects, cognitive techniques, and behavioral techniques.

Some studies have concluded that CBT is as effective as pharmacotherapy. IPT has also repeatedly been demonstrated in controlled trials to be effective in the treatment of depression. Some studies have shown that a combination of an antidepressant and IPT or CBT is more effective than either treatment alone, both in relieving depression and in preventing relapse.[28,87-89]

Inpatient Treatment

Hospitalization is sometimes necessary for the treatment of depression. This strategy is indicated for patients with psychotic features or major comorbid medical conditions or for those who are exhibiting suicidality. Hospitalization is also indicated for patients who are unable to meet their basic needs because of functional impairment.

COMPLICATIONS

Mood disorders are present in 50% to 70% of all cases of suicide, and patients with recurrent, serious depression (i.e., depression requiring hospitalization) have an 8% to 15% suicide rate.[90] Depressive disorders are frequently associated with significant and pervasive impairments in social functioning, causing enormous personal, social, and economic burden.[91] Furthermore, depression is associated with high levels of health care system utilization and increased morbidity and mortality related to comorbid medical conditions. For example, depression is a major risk factor for the development of cardiovascular disease and for death after an index myocardial infarction.[92-94] The mortality 6 months after a myocardial infarction has been reported to be more than five times higher in depressed patients than in those without depression.[95]

PROGNOSIS

The chance of a recurrence of depression after one episode is about 50%; the chance increases to approximately 90% after three episodes. The frequency of recurrence increases as the number of past episodes increases. Recurrence is also more likely in patients in whom the onset of depression occurred at an early age.[96] Poor prognosis is predicted by chronicity and severity of symptoms. In patients who experience a first episode of a mood disorder in later life, a medical cause can often be diagnosed. Depression arising in later life is often followed by the development of dementia. Indeed, later-life depression is now considered by many to be a risk factor for the development of Alzheimer disease. Because of the often chronic nature of affective disorders, treatment beyond the acute phase is almost always necessary to prevent recurrent episodes or to decrease their intensity.

Bipolar Disorder

EPIDEMIOLOGY

The 1-year prevalence of any bipolar disorder in adults in the ECA study was 1.2%.[1] The NCS found the 1-year prevalence of a manic episode to be 1.3%.[2] Bipolar I disorder affects men and women equally.[97] Rates of bipolar disorder are consistent across diverse cultural and ethnic groups.[98] Onset usually occurs during adolescence or young adulthood. The NCS found the lifetime prevalence rate for a manic episode to be 1.6% and 1.7% for men and women, respectively.[2]

ETIOLOGY AND GENETICS

Affective disorders are considered complex genetic disorders, with multiple genes (genetic heterogeneity) likely accounting for at least 50% to 70% of the etiology. The genes that transmit the increased diathesis for affective disorders remain obscure. However, several groups have identified chromosome 18 as a site for several genes associated with bipolar disorder.[99,100] Twin, adoption, and family studies have established a clear genetic etiology for bipolar disorder. The most frequent mood disorder identified in family members of patients with bipolar disorder is major depression; this suggests some common genetic underpinnings between the two forms of affective disorder. The genetic nature of bipolar disorder is even stronger than that of unipolar depression, with a fivefold to 10-fold greater risk of illness in first-degree relatives than in the general population (in which the risk is approximately 1%).[101] The concordance rate for affective disorders in monozygotic twins is approximately 80% to 90%, many times that of dizygotic twins (approximately 15%), indicating a significant genetic factor.

PATHOGENESIS

The pathophysiology of bipolar disorder in general—and mania in particular—is far less understood than the pathophysiology of unipolar depression, in part because of the inherent diffi-

culty in studying acute mania. The available studies suggest that in patients with mania, abnormalities in the HPA axis and in neurotransmission are actually quite similar to those seen in patients with depression. This is particularly the case for patients who experience mixed episodes [*see* Diagnosis, Clinical Manifestations, *below*].

Sleep deprivation or antidepressants can induce a manic episode in persons with bipolar disorder but not in persons without bipolar disorder; these may be the first manic episodes in a case of hitherto undiagnosed bipolar disorder. Stressful life events, changes in sleep-wake cycles, and substance abuse may affect the course of illness and lengthen time to recovery.[102] Ongoing neuropsychological and neuroimaging research will surely advance the elucidation of this complex disorder.[103,104]

DIAGNOSIS

Clinical Manifestations

The diagnosis of bipolar disorder is made whenever an episode of mania occurs. A manic episode is a distinct period of abnormally elevated, expansive, or irritable mood lasting at least a week (or less if hospitalization is required). During this period, three or more specific symptoms (four or more if the mood is only irritable) must be present: inflated self-esteem or grandiosity; a decreased need for sleep; being more talkative than usual or feeling a need to keep talking; having flight of ideas or the subjective experience that one's thoughts are racing; distractibility; experiencing an increase in goal-directed activity or psychomotor agitation; and excessive involvement in pleasurable activities that have a high potential for painful consequences. Manic symptoms are often the opposite of those of depression (e.g., euphoric mood rather than depressed mood; psychomotor agitation rather than psychomotor retardation; a speeding of speech and thoughts rather than a slowing of thoughts and an increased response latency). Mood-congruent psychotic features occur in approximately 50% of manic episodes and often consist of grandiose delusions or auditory hallucinations. About a quarter of persons with mania develop hallucinations. Mania often confers special creativity and productivity; but these characteristics are usually curtailed as the episode escalates and manifestations (which may include psychotic symptoms) become severe and psychosocial impairment ensues.

A hypomanic episode, which is less severe than mania, is a distinct period of elevated, expansive, or irritable mood lasting at least 4 days, during which time three or more symptoms of a manic episode are experienced (four if the mood is only irritable). The symptoms represent an unequivocal change in functioning and are observable by others but are not severe enough to cause marked impairment or to necessitate hospitalization. No psychotic features are present. Thus, a hypomanic episode can be thought of as a mild manic episode. Research indicates that 5% to 15% of persons with hypomania will ultimately have a manic episode.

A mixed episode is a period of at least 1 week during which the patient meets the criteria for having a major depressive episode and a manic episode simultaneously. As with both major depressive episodes and manic episodes, a mixed episode is a mood disturbance sufficiently severe to cause marked impairment in functioning (such as necessitating hospitalization to prevent harm to self or others or having associated psychotic features). Patients in the mixed state are dysphoric but hyperactive, agitated, and unable to sleep.

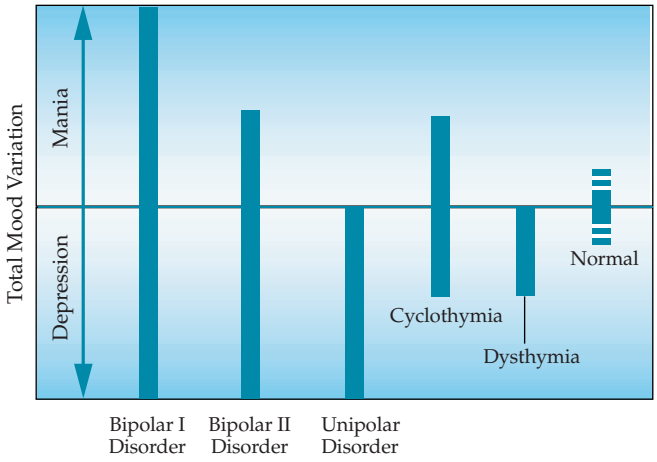

Figure 1 **The spectrum of mood disorders.**

For all four of the mood states described—mania, hypomania, depression, and mixed episode—DSM-IV specifies that the symptoms must not result from the direct physiologic effect of a substance (e.g., a drug of abuse or a medication) or a general medical condition.

Bipolar disorders include bipolar I disorder (involving the presence of one or more manic or mixed episodes, often alternating with major depressive episodes), bipolar II disorder (recurrent major depressive episodes with hypomanic episodes), and cyclothymic disorder [*see Figure 1*]. Cyclothymic disorder consists of at least 2 years of fluctuating mood disturbance involving numerous periods of hypomanic symptoms and numerous periods of depressive symptoms. Bipolar disorder is specified as rapid cycling if four or more episodes occur within a year.[105] Depressive episodes in persons with bipolar disorder are commonly marked by reversed neurovegetative symptoms and anergia (lack of energy)—so-called atypical depression. Although individual cases of unipolar mania have been reported, they are extraordinarily rare.

When psychotic symptoms are present during a manic episode, it is important to distinguish bipolar disorder from a primary psychotic disorder (e.g., schizophrenia) because the two disorders have different treatments. The diagnosis is based on the specific symptoms present and the course of the illness.

Mental Status Examination

The general appearance and attitude of the patient should be noted. During a manic episode, the patient may dress in an eccentric fashion, as exemplified by brightly colored clothing, excessive makeup, or multiple pieces of jewelry. Conversely, because of distractibility and hyperactivity, the patient's appearance may be disheveled or unkempt. The patient's attitude may reflect euphoria, excitement, intrusiveness, or irritability. Notable behaviors may include psychomotor agitation and an increase in goal-directed activity. An assessment of speech may reveal increased rate and rhythm of speech. Manic patients are commonly hyperverbal, and speech may be very rapid or even pressured. Patients may describe their mood as high or elated. The mood may be characterized as irritable in some cases. The affect is often elevated or euphoric. Thought processes may be faster than normal. Flight of ideas (described by the patient as racing thoughts) may be present, and thought disorganization

sometimes results in puns, clang associations, and loosening of associations. Thought content may be characterized by elevated self-worth, grandiosity, mood-congruent psychotic features (e.g., auditory hallucinations or delusions), and sometimes suicidal thoughts or plans. Insight into the illness—and judgment in general—may range from impaired to good but is often quite poor. As with depression, impaired insight may have important implications for compliance with treatment. A cognitive assessment may reveal subtle or obvious impairments in memory and frequent difficulties with concentration. Patients with bipolar disorder are at serious risk for suicide, both in the manic and in the depressive phases of their illness.

A thorough medical and psychiatric review of systems, as well as a substance-use history, should be conducted to exclude other causes of the mental status examination findings. A risk assessment, including assessment of the ability to adequately care for one's health and safety, excessive spending, and psychotic processes, will help determine the severity of the episode and the appropriate locus of care for the initiation of treatment. As in major depressive disorder, a thorough suicide risk assessment should be conducted [*see* Assessment of Suicide Risk, *above*].

Laboratory Tests

As is true for major depression, there are no diagnostic tests for bipolar disorder. The diagnosis is based on the presence of specific symptoms and the longitudinal course, as described in DSM-IV. During the evaluation for manic symptoms, a drug history and urine drug screen are important. Other commonly ordered tests include basic serum chemistries, thyroid function studies, and syphilis serology. Before lithium is started, baseline thyroid and kidney function studies are necessary. Blood counts and liver function are assessed before starting valproic acid–divalproex sodium or carbamazepine.

DIFFERENTIAL DIAGNOSIS

Bipolar disorder must be distinguished from other psychiatric conditions, including schizophrenia and schizoaffective disorder, personality disorders, and the abuse of certain drugs (e.g., alcohol, amphetamines, hallucinogens, and cocaine). Schizoaffective disorder is classified as a primary psychotic disorder in which a major depressive episode, a manic episode, or a mixed episode occurs and psychotic symptoms are present for at least 2 weeks in the absence of prominent mood symptoms. Certain personality disorders are characterized by chronic and pervasive rapidly fluctuating affective lability. However, many patients with cluster B personality disorders (e.g., borderline personality disorder) may also meet DSM-IV criteria for dysthymic disorder, bipolar II disorder, or cyclothymic disorder. Urine or blood toxicologic screens must be performed to differentiate primary mania from a substance-induced mood disorder with manic features. However, there is a very high rate of comorbidity between bipolar disorder and substance-use disorders, and a positive urine drug screen does not exclude the possibility of a primary bipolar disorder. In an elderly patient, the diagnosis of mania is sometimes made difficult by the overlapping of manic symptoms with other syndromes that are common in the elderly, including delirium, dementia, and medical illnesses[106] [*see CE:X Symptom Management in Palliative Medicine*].

MANAGEMENT

Immediate management of acute mania often requires hospitalization. Patients may be at risk for self-harm from erratic behavior, excessive spending, and delusional thought content. Patients with mania, a mixed episode, or bipolar depression must be evaluated thoroughly for evidence of suicidal intent.

Because bipolar disorder is a recurrent, often severely impairing psychiatric disorder, the search for effective pharmacologic treatments continues to be in the forefront of psychiatric research. The mainstays of treatment have been the traditional mood stabilizers: lithium, valproic acid–divalproex sodium, and carbamazepine [*see Table 2*]. However, the efficacy of newer agents, particularly lamotrigine and the atypical antipsychotic agents, has now been demonstrated. The precise mechanisms of action of all these mood-stabilizing medications are still unknown.

Lithium

Lithium was discovered to have antimanic properties in 1949. It is now considered the gold standard for treatment of bipolar disorder. Remarkably, the mechanism of action of lithium remains unknown, though some evidence suggests that it acts via signal transduction pathways such as the phosphatidylinositol second-messenger system. As with other mood stabilizers, full improvement with lithium may take several weeks. Lithium is most effective in classic bipolar disorder, which consists of discrete episodes of mania and depression, with symptom-free periods between episodes.[107] Continued medication use reduces the number and intensity of episodes of illness.

Renal and thyroid function should be assessed before initiating treatment with lithium, and an electrocardiogram should be obtained. Lithium is a natural element and is distributed with total body water. It is excreted unchanged into the urine. Diuretic therapy, sodium restriction, and sodium wasting increase reabsorption of lithium and thus increase serum levels. Patients taking lithium should therefore avoid nonsteroidal anti-inflammatory drugs and diuretics, and they should maintain uniform salt intake. Administering lithium with meals may minimize gastrointestinal side effects.

Table 2 Usual Starting Doses, Dose Ranges, and Therapeutic Blood Level Targets for Traditional Mood-Stabilizing Agents

Drug (Trade Name)	*Typical Daily Starting Dose*	*Typical Daily Dose Range*	*Therapeutic Blood Level*
Lithium (Lithobid, Escalith)	300 mg t.i.d. or 450 mg b.i.d.	900–1,800 mg	0.8–1.2 mEq/L
Valproic acid or divalproex sodium (Depakene, Depakote, Depakote ER)	250 mg b.i.d.	750–2,000 mg	100–125 mg/L
Carbamazepine (Tegretol, Equetro)	100–200 mg b.i.d.	400–600 mg	6–10 µg/ml

Serum levels of lithium must be monitored. The goal for the treatment of acute mania is a lithium level of 1.0 to 1.2 mEq/L [*see Table 2*]. Serum levels should be measured 10 to 12 hours after the last oral dose, and levels should be drawn 4 to 5 days after the latest change in dosage. Lithium levels should be monitored periodically, and renal function indicators (i.e., blood urea nitrogen and serum creatinine) and TSH should be measured every 6 months. Common side effects include cognitive slowing, nausea, diarrhea, polyuria, polydipsia, weight gain, tremor, and a metallic taste in the mouth. Lithium is usually administered as lithium carbonate ($LiCO_3$) three times daily, but controlled-release forms may be administered twice daily.

Anticonvulsant Medications

Several anticonvulsant medications are also effective as mood stabilizers, including valproic acid–divalproex sodium and carbamazepine. These agents may act by decreasing neuronal membrane excitability, perhaps by effects on γ-aminobutyric acid (GABA) systems. Valproic acid–divalproex sodium appears to be more effective for manias that are dysphoric or mixed and for rapid cycling.[108] Gastrointestinal side effects may be minimized by administering the medication with food. Carbamazepine may be associated with a number of pharmacokinetic drug-drug interactions because of its induction of microsomal P-450 enzymes. Carbamazepine also induces its own metabolism, so-called autoinduction, resulting in a decrease in plasma levels several weeks to months after initiation of treatment. An extended-release form of carbamazepine is approved by the FDA for acute manic and mixed episodes.

Several newer anticonvulsant medications have been studied as potential treatments of bipolar disorders.[109-111] Lamotrigine has been shown to be effective in the acute treatment of bipolar depression and as maintenance therapy for bipolar disorder, but it does not appear to possess acute antimanic properties.[112] The olanzapine-fluoxetine combination capsule has FDA approval for bipolar depression. Early evidence suggested that topiramate may be an effective mood stabilizer,[113] but three randomized, controlled clinical trials in acute mania failed to demonstrate any efficacy. Whether or not these agents or tiagabine,[114] another anticonvulsant, may be helpful as adjunctive treatments in bipolar disorder remains unclear.

Atypical Antipsychotics

The atypical antipsychotic agents are effective for the treatment of acute mania. Olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole have FDA indications for bipolar mania. The risks of weight gain and metabolic disturbances are increasingly being recognized with some of these agents, and therefore, clinical monitoring is necessary.[115,116]

Additional Therapeutic Strategies

Other strategies are frequently used in addition to mood stabilizers, specific anticonvulsants, and atypical antipsychotics, including psychotherapy, mood charting, bipolar support groups, optimizing sleep patterns, eliminating the use of substances of abuse, and the use of other medications to augment response. During episodes of depression in patients with bipolar disorder, antidepressants must be used cautiously because of their potential for inducing hypomania or mania or accelerating cycling. Limited research suggests that adjunctive omega-3 fatty acid supplements may enhance outcomes in patients with bipolar disorder.[117]

Contemporary treatment of bipolar disorder focuses almost exclusively on psychopharmacologic treatment; most often, combination and even triple-drug therapy are essential. Nonetheless, psychotherapy is useful as adjunctive treatment; it can help relieve social and interpersonal dysfunction secondary to the disorder, improve medication compliance, teach stress management, and provide psychoeducation. Although psychotherapy alone is not recommended for the treatment of bipolar disorder, evidence suggests that cognitive therapy in conjunction with mood-stabilizing medications may be beneficial in preventing relapses, alleviating symptoms, and promoting social functioning.[118]

The treatment of depression associated with bipolar disorder is somewhat distinct from that of unipolar depression. For mild cases of bipolar depression, a mood stabilizer, such as lithium, may be sufficient.[119] When an antidepressant is required, adequate mood stabilization is recommended before the initiation of treatment with an antidepressant.[72] Alternatively, lamotrigine or the olanzapine-fluoxetine combination may be utilized.

Psychotic symptoms during a manic episode should be treated with antipsychotic agents. The atypical antipsychotic agents are first-line treatment; these agents are also effective for the treatment of acute mania itself, aside from their effects on psychotic symptoms. The short-term use of a benzodiazepine may also be required for anxiety or agitation.

COMPLICATIONS

Suicide rates are high in patients with bipolar disorder. For example, completed suicide occurs in approximately 10% to 15% of those with bipolar I disorder.[102] The illness also causes substantial psychosocial impairment, involving multiple aspects of the patient's life, including interference with interpersonal relationships and occupational and financial difficulties.

PROGNOSIS

In many patients with bipolar disorder, early episodes occur years apart. Episodes tend to occur more frequently with the passage of time, with associated worsening of functioning.[107] Although some persons may experience only a single manic episode, most patients with bipolar disorder experience recurrent episodes. Between episodes, patients may be symptom free, although many patients have some residual symptoms. Women with bipolar disorder tend to have more episodes of depression, whereas men tend to have more episodes of mania. Rapid cycling in bipolar disorder may develop over time and tends to be associated with poorer outcome.

Michael T. Compton, M.D., M.P.H., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Charles B. Nemeroff, M.D., Ph.D., holds stock in Corcept Therapeutics, Inc., and Neurocrine Biosciences, Inc., and has received grants for clinical research from, served as consultant for, or been a member of the speakers' bureaus of the following companies and organizations: Abbott Laboratories; Acadia Pharmaceuticals, Inc.; the American Foundation for Suicide Prevention; AstraZeneca Pharmaceuticals LP; Bristol-Myers Squibb Co.; Corcept Therapeutics, Inc.; Cypress Bioscience, Inc.; Cyberonics, Inc.; Eli Lilly and Company; Forest Pharmaceuticals, Inc.; GlaxoSmithKline; Janssen Pharmaceutica Products, LP; Merck & Co., Inc.; the National Alliance for Research on Schizophrenia and Depression; the National Institute of Mental Health; Neurocrine Biosciences, Inc.; Novartis Pharmaceuticals Corp.; Organon International, Inc.; Otsuka America, Ltd.; Pfizer, Inc.; Sanofi-Aventis; SCIREX; Somerset Pharmaceuticals, Inc.; Stanley Foundation/NAMI Research Institute; and Wyeth.

The following medications have not received FDA approval for the treatment of depression: isocarboxazid, moclobemide, selegiline, clomipramine, fluvoxa-

mine, reboxetine, gepirone, thyroid hormone, lithium, methylphenidate, dextroamphetamine, modafinil, buspirone, olanzapine, risperidone, St. John's wort, S-adenosyl-methionine, kava, B vitamins, and omega-3 fatty acids.

III ALCOHOL ABUSE AND DEPENDENCY

PATRICK G. O'CONNOR, M.D., M.P.H.

Alcohol use is associated with a wide range of behavioral and medical disorders.[1] An estimated 4% to 40% of medical and surgical patients experience problems related to alcohol.[2] In the United States, more than 85,000 deaths a year are directly attributed to alcohol use.[3] The annual economic cost of alcohol use in the United States is estimated to be over $185 billion.[3] Thus, alcohol and its associated health problems have a major impact on the practices of generalists and other physicians.[4]

Patients with alcohol-related problems present several unique challenges for physicians.[5] As with other chronic diseases, alcohol-use disorders range from relatively asymptomatic to severe. To manage patients effectively, physicians should recognize all forms of alcohol-related problems, from the earliest to the most advanced stages. They should be able to manage patients along the entire spectrum of the disease process.[6]

Available from the National Institute on Alcohol Abuse and Alcoholism (NIAAA) are guidelines for physicians on the management of patients with alcohol-related problems; these guidelines are available on the Web, at http://www.niaaa.nih.gov.[7,8] The NIAAA guidelines address behavioral and social problems, as well as the medical manifestations of alcohol use. This chapter provides an overview of the major clinical features and recent developments in the identification and management of alcohol-related problems in clinical practice.

Definitions and Classification

When considering patients who may have alcohol-related problems, it is helpful to distinguish between three types of alcohol use: nonproblematic, moderate drinking; hazardous, or at-risk drinking, which places patients at risk for alcohol-related problems; and harmful drinking, which directly causes specific alcohol-related problems. Patients with more advanced alcohol-related problems may meet the criteria for alcohol dependence or abuse.[9] One study suggests that in patients seen in primary care settings, the prevalence of hazardous drinking ranges from 4% to 29% and that of harmful drinking, from 1% to 10%.[10] These definitions are based on epidemiologic studies that demonstrate an association between specific levels of alcohol consumption and increasing health problems and mortality.[11,12]

MODERATE DRINKING

The NIAAA has defined moderate drinking in terms of the average number of drinks consumed a day that places an adult at relatively low risk for alcohol-related health problems.[7] For men younger than 65 years, moderate drinking is defined as drinking an average of, at most, two drinks a day. For men older than 65 years and for all women, moderate drinking is defined as drinking less than two drinks a day. Although some evidence suggests that low levels of alcohol intake may be beneficial,[13,14] the degree to which moderate drinking may confer health benefits and may be associated with reduced mortality—specifically, reduction of cardiovascular mortality—is controversial. When it exists, this benefit likely occurs at low levels of alcohol consumption (i.e., less than one drink a day).[15]

AT-RISK DRINKING

At-risk drinking (which corresponds to the category of hazardous use in the schema developed by the World Health Organization [WHO][16]) occurs when those moderate drinking levels are exceeded or when the number of drinks consumed during a single occasion exceeds a specified amount (four drinks per occasion for men and three drinks per occasion for women).

HARMFUL DRINKING

Harmful drinking is defined as alcohol consumption that results in physical or psychological harm. This disorder is also recognized by the WHO and is defined by criteria of the International Classification of Diseases, 10th Revision (ICD-10), which include (1) clear evidence that alcohol is responsible for physical or psychological harm, (2) the nature of the harm is identifiable, (3) alcohol consumption has persisted for at least 1 month or has occurred repeatedly over the previous 12-month period, and (4) the individual does not meet the criteria for alcohol dependence. The ICD-10 criteria are found on the Web, at http://www.who.int/classifications/icd/en.

ALCOHOL ABUSE

Specific criteria for diagnosing alcohol abuse have been developed by the American Psychiatric Association (APA).[9] In the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV), alcohol abuse is defined as a maladaptive pattern of alcohol use leading to clinically significant impairment or distress, manifested in a 12-month period by one or more of the following problems[9]: (1) failure to fulfill role obligations at work, school, or home; (2) recurrent use of alcohol in hazardous situations; (3) legal problems related to alcohol; and (4) continued use despite alcohol-related social problems.

ALCOHOL DEPENDENCE

By APA criteria, alcohol dependence is manifested by a maladaptive pattern of use over a 12-month period that includes three or more of the following problems[9]: (1) physiologic tolerance, characterized either by an increase in the amount of alcohol consumed or by a decrease in the effects of the amount of alcohol customarily consumed; (2) symptoms of withdrawal; (3) use of greater amounts of alcohol over a longer period than intended; (4) a persistent desire or unsuccessful attempts to control use; (5) a great deal of time spent obtaining alcohol, using alcohol, or recovering from use; (6) a reduction in the level of important social, occupational, and recreational activities; and (7) continued use despite knowledge of physical or psychological problems.

ALCOHOLISM

The term alcoholism, which is perhaps the most widely used term to describe patients with alcohol problems, has lost much of its usefulness because of the imprecision in its definition and the stigma associated with the term. A panel of 23 experts convened by the National Council on Alcoholism and Drug Dependence and the American Society of Addiction Medicine defined alcoholism as a primary, chronic disease with genetic, psychosocial, and environmental factors that is often progressive and fatal and is characterized by impaired control over drinking, pre-

occupation with the drug alcohol, use of alcohol despite adverse consequences, and distortions in thinking, most notably denial.[17] However, precise terminology for specific alcohol problems is more clinically useful.

Epidemiology

In a nationwide survey, 62% of adults in the United States reported that they drink alcohol.[18] Alcohol-related problems are common in the general population; however, prevalence of these problems has varied with different studies. The Centers for Disease Control and Prevention's Behavioral Risk Factor Surveillance System reported that in 2003, 16.4% of adults were at risk for binge drinking (having five or more drinks on one occasion), and 5.7% were at risk for heavier drinking (having two or more drinks a day).[19]A nationwide survey based on face-to-face interviews reported that the 12-month prevalence rates of alcohol abuse and dependence, as defined by DSM-IV, in 2001 through 2002 were 4.65% and 3.81%, respectively.[20] Abuse and dependence were more common in males and in younger persons. Studies have demonstrated that alcohol-related problems are highly prevalent in primary care patients. For example, in two intervention studies, at-risk or problem drinking was identified in 41% of men and 28% of women from 47 general practices in the United Kingdom[21] and in one in six patients in 17 general practices in Wisconsin.[22] With regard to more severe alcohol-related problems, one study found that 20% of inpatients screened positive for alcoholism.[23] In various studies of outpatients, the lifetime prevalence of alcohol abuse and dependence ranged from 13% to 22%.[24-26]

Genetics

Evidence from family, twin, and adoption studies supports a strong genetic component for the risk of alcohol dependence.[27] In general, most studies of twins have demonstrated a higher concordance of alcohol dependence in monozygotic twins than in dizygotic twins. Adoption studies generally document that adopted children with a biologic parent who is alcoholic have a twofold to threefold greater risk of alcoholism than adopted children whose biologic parents are not alcoholic. Studies have shown that there are a variety of electroencephalographic differences and differences in behavioral and physiologic responses to test doses of alcohol between nonalcoholic adolescents and young adults with a family history of alcoholism and those without such a history. Overall, individuals with a family history of alcohol dependence have a twofold greater risk of this condition than those without such a family history.[28]

Several genetic factors may influence the risk of alcohol dependence. A lower inherent level of response to alcohol is genetically influenced and may predict the development of alcohol dependence.[27] The genes responsible for determining the level of response to alcohol have not been identified, although the γ-aminobutyric acid (GABA) receptor and serotonin transporter gene may be involved.[29] Other putative alcoholism-vulnerability genes include alcohol dehydrogenase–2 (*ADH2*), aldehyde dehydrogenase–2 (*ALDH2*), and D_2 dopamine receptor (*DRD2*).[27] Although genetic predisposition is clearly a major risk factor for alcohol-related problems, environmental influences may also impart risk. Such environmental influences include negative life events, occupational stress, expectancies about alcohol, personality factors (e.g., problem-prone behavior during adolescence), and interpersonal influences (e.g., the behaviors of family members or peers).[1,27,30]

Common Problems Associated with Alcohol Abuse

Familiarity with the wide variety of medical, behavioral, and psychiatric complications of heavy drinking or alcohol dependence facilitates detection and management of alcohol-related problems in patients.

MEDICAL PROBLEMS

The numerous medical complications associated with excessive alcohol consumption have been well documented.[1,2] Patients may present to physicians with acute and chronic clinical signs and symptoms that are the direct or indirect results of alcohol use. The most common medical effects of alcohol are seen in the central and peripheral nervous systems[31]; these effects are intoxication, withdrawal, seizures, delirium and dementia, stroke, and peripheral neuropathy. Similarly, alcohol has a wide variety of effects on the gastrointestinal system[32]; these effects include esophageal diseases (e.g., Mallory-Weiss tears and carcinoma), gastritis, and peptic ulcer disease.

Liver diseases, including acute alcoholic hepatitis and cirrhosis, are also highly prevalent.[33] Along with having the typical manifestations of liver disease, patients with alcoholic liver disease are at increased risk for toxicity from acetaminophen, even when used in therapeutic doses.[34] In addition, continued alcohol use may worsen the clinical outcomes in patients with hepatitis C.[35] Acute and chronic pancreatic disease is also a common manifestation of alcohol use.[36]

Finally, patients with alcohol-related problems may suffer a wide range of cardiovascular effects, such as hypertension, left ventricular hypertrophy and cardiomyopathy, arrhythmias, and sudden death.[37] Increased levels of alcohol consumption are associated with increased risks of both heart failure[38] and atrial fibrillation.[39] Cessation of alcohol use may result in improvement of some alcohol-related conditions. For example, alcohol users with dilated cardiomyopathy who stop using alcohol appear to have improved cardiac function over time.[40]

Along with causing major neurologic, digestive system, and cardiovascular effects, alcohol use is associated with a variety of other organ-based effects. Heavy drinking is associated with cancer of the upper digestive and respiratory tracts, the liver, and, in at least one study, the prostate, pleura, and cervix.[41] Data linking alcohol to cancers of other organs (e.g., pancreas, colon, and breast) have been less convincing.[42]

Alcohol use may present as bleeding from various sites because of dysfunction of hepatic synthesis or thrombocytopenia. Alcohol use has also been associated with metabolic and endocrine abnormalities, such as osteoporosis, menstrual dysfunction, male hypogonadism, and thyroid and adrenal dysfunction.[43,44] Gout is associated with alcoholism and may occur at serum urate levels lower than those seen in nonalcoholic patients.[45] Toxic effects of alcohol on the kidney are generally subclinical or secondary to other alcohol-related effects. Alcohol has been related to important dermatologic problems, such as psoriasis and the dermatologic findings associated with chronic liver diseases.[46] Finally, high levels of dental and periodontal disease have been documented in populations of alcoholic patients.[47]

PSYCHIATRIC PROBLEMS

Epidemiologic surveys have demonstrated high rates of psy-

chiatric illness in persons diagnosed with alcohol abuse or dependence, and comorbid psychiatric disease is associated with increased health care utilization in patients with alcohol-related problems.[48] Data from the Epidemiologic Catchment Area Study demonstrated that 45% of such persons had a lifetime psychiatric diagnosis.[49] The most common disorders were anxiety and affective and antisocial personality disorders.[49] The National Comorbidity Study found a high 12-month prevalence of anxiety disorders (36.9%) and affective disorders (29.2%) in alcohol-dependent patients.[50]

These data indicate that patients with alcohol problems require careful evaluation for comorbid psychiatric symptoms and problems. Treatment of comorbid psychiatric conditions such as depression is effective if the underlying alcohol-use disorder is treated concurrently.[51]

Similarly, patients with psychiatric disorders are at high risk for comorbid substance-use disorders.[52] A review of the medical literature revealed that the prevalence of current alcohol problems in patients with major depression is 16%, whereas that of the general population is 7%.[53] Studies have shown that the presence of an alcohol-use disorder in adolescence is predictive of both continued alcohol problems and psychiatric disease in adulthood.[54,55]

OTHER BEHAVIOR-RELATED PROBLEMS

Alcohol misuse can harm persons other than the user; it has been linked to increased rates of accidents and injuries, violence against others, and spousal abuse. Alcohol misuse is also linked to high-risk behaviors (e.g., drug and tobacco use and high-risk sexual activity) that carry increased risk of disease.

Accidents and Injuries

Alcohol use is the leading cause of accidents (most notably, automobile accidents), injuries, and trauma (e.g., drownings, head injuries, burns, and spinal cord injuries).[3,56] Alcohol use increases the risk of injury and is associated with more severe injury in trauma patients[57,58] Emergency departments are important intervention sites for patients with alcohol-related problems.[59] Intervention with these patients has been shown to reduce both alcohol consumption and subsequent use of emergency department services.[60] Despite these data, one study showed that emergency physicians did not refer any patients with an elevated blood alcohol level to alcohol treatment.[61] Another study, however, indicated that screening and brief interventions are becoming more routine in emergency departments. More widespread use of brief-intervention therapy would likely reduce recurrent alcohol-related injury.[62]

Violence and Abuse

Alcohol use is associated with injuries and trauma related to acts of violence; such acts include assault and homicide, as well as domestic violence toward children and spouses.[63,64] In one study of patients in urban trauma centers, victims of violence were more likely to use alcohol, to be male, and to possess a knife or a gun.[59] A history of childhood victimization has been identified as a predictor of the development of alcohol-related problems in women.[63] Thus, a patient's history as a victim of violence or psychological abuse should prompt a careful assessment of the patient's drinking behavior. The drinking behavior of the victim's partner should be assessed, as well. In one large study examining risk factors for injury in women related to domestic violence, alcohol abuse and drug abuse by the victims' partners were identified as the most important risk factors.[64]

Risk of HIV Infection

HIV seroprevalence may be higher in patients with more severe impairment from alcohol, and women may be at especially increased risk.[65] In two cross-sectional surveys, HIV seroprevalence in heterosexual, non–drug-injecting patients was 5%.[66] Heavy drinkers are more likely to engage in high-risk sexual behaviors, such as having many sexual partners and engaging in sex without condoms.[56,67] Counseling patients about the association between alcohol use and high-risk sexual behaviors may result in safer sexual practices. The use of alcohol by patients who have HIV infection may increase their risk of HIV-related problems, such as cognitive dysfunction.[68]

Tobacco and Other Drug Abuse

Alcohol-dependent persons are more likely to smoke tobacco than the general population. Alcohol acts as a cocarcinogen with tobacco, substantially increasing the risk of head, neck, and lung cancers.[42] Alcohol-dependent patients who stop drinking may be up to 60% more likely to quit smoking than those who continue to drink.[69] Treatment of tobacco abuse in patients with alcohol-related problems is critical to the improvement of long-term health outcomes in these patients.[70] Alcohol abuse and dependence are commonly seen in association with abuse of and dependence on prescription drugs[71] and illicit substances.[72] Careful screening is often required to identify a patient with coexisting alcohol and drug use, and treatment of such a patient must address both alcohol- and drug-related problems.

Screening and Diagnosis of Alcohol-Related Problems

Despite the prevalence of alcohol-related problems and their impact on health, most studies demonstrate that alcohol-related problems are not routinely detected in primary care settings.[73] Rates of failure to detect alcohol-related problems vary by setting and level of practitioner training. Alcohol abuse or dependence is most likely to be identified in patients experiencing severe medical complications, such as alcoholic hepatitis or cirrhosis,[23] and is less likely to be detected in women.[74] Earlier detection of medically hazardous levels of drinking before the onset of organ damage or of alcohol abuse or dependence may be critical in preventing late sequelae. Simple, brief interventions are effective in reducing heavy drinking in high-risk drinkers.[1,7,22] The most recent U.S. Preventive Health Task Force (USPHTF) recommendations concerning alcohol screening strongly endorse routine screening in primary care[75]; however, screening techniques are used inconsistently by primary care physicians.[73,76]

Easy-to-use techniques for screening patients for alcohol-use disorders are currently available. Although these techniques are used inconsistently by primary care physicians, screening for alcohol-related problems should be incorporated into the routine care of all patients[76] One such screening technique involves a four-step process for identifying and diagnosing alcohol-related problems [*see Table 1*].[3,5,7] Step 1 is to inquire about current and past alcohol use in all patients. Patients with alcohol-related problems may be somewhat sensitive about these and other questions about their drinking behavior. It is therefore critical that the patient be approached in a nonjudgmental manner. In addition, these questions may need to be asked on multiple occasions to obtain an accurate history of the patient's alcohol use. The questioner needs to be specific about current and past alco-

Table 1 Screening and Diagnosis of Alcohol Problems

General Questions to Be Asked of All Patients
Do you drink alcohol (ever or currently)?
Do you have a family history of alcoholism?

Questions Concerning Quantity and Frequency of Alcohol Use
What type(s) of alcohol (beer, wine, spirits) do you use?
How often do you drink?
How much do you usually drink on a typical drinking day?
Do you ever drink more (if so, how much) than your usual amount?

Screening Questionnaires
CAGE
- Have you ever felt you should ***c***ut down on your drinking?
- Have people ***a***nnoyed you by criticizing your drinking?
- Have you ever felt bad or ***g***uilty about your drinking?
- Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (***e***ye opener)?

Other Questionnaires
Alcohol Use Disorder Identification Test (AUDIT)
TWEAK (*T*olerance, *W*orry, *E*ye opener, *A*mnesia, *K*ut down)
Short Michigan Alcoholism Screening Test (S-MAST)
Rapid Alcohol Problems Screen 4 (RAPS4)

Specific Areas to Assess in Patients with Potential Alcohol Problems
Criteria for alcohol abuse and dependence [*see text*]
Evidence of medical and psychiatric problems
Evidence of behavioral and social problems
History of use of other substances
- Tobacco
- Mood-altering prescription drugs
- Illicit drugs (e.g., heroin, cocaine)

Previous treatment for alcohol or substance use

hol use. Because genetic predisposition and family environment are important risk factors for alcohol-related problems,[2] inquiries into family history should routinely include questions about relatives with alcohol-related problems.

Steps 2 through 4 apply to all patients who report a history of alcohol use. In step 2, a more detailed history regarding quantity and frequency of alcohol use is obtained. The type of alcohol consumed is critical. Some patients may consider beer a safer form of alcohol and may not report its use unless specifically asked. Questions can help establish the frequency of alcohol use (e.g., daily as opposed to less frequent use) and a baseline of the amount of alcohol usually consumed. It is also important to establish other patterns of alcohol consumption; for example, a patient may have only two drinks a day from Monday through Thursday but may consume 10 to 15 drinks on Friday and Saturday nights. Questions about the quantity and frequency of alcohol use may help distinguish moderate drinking from at-risk and problem drinking [*see Table 1*] and may help identify specific patterns of use, such as binge drinking.

In step 3, a standardized questionnaire is used to detect possible alcohol-related problems.[77] The most commonly studied screening instrument in primary care settings is the CAGE questionnaire [*see Table 1*]. This questionnaire screens for lifetime alcohol-related problems. It consists of four questions designed to identify ongoing alcohol use and withdrawal phenomena that demonstrate alcohol dependence. In scoring the CAGE questionnaire, each "yes" response counts as 1 point. A score of 2 or more is generally considered to be a positive result. The CAGE questionnaire is useful in identifying patients with alcohol-related problems who are seen in primary care settings; its sensitivity ranges from 43% to 95%, and its specificity ranges from 70% to 95%.[24,76,78] Supplementing the four questions of the CAGE questionnaire with additional questions about tolerance (e.g., "How many drinks can you hold?") and substituting a question about whether any of the patient's friends or family members have expressed worry or concern about the patient's alcohol use may improve the usefulness of the CAGE questionnaire.[79]

The CAGE questionnaire is a reliable screening instrument in a variety of health care settings; however, it may be less useful in specific patient groups. In one study of patients older than 60 years, the CAGE questionnaire performed poorly in identifying heavy drinkers or binge drinkers, among whom fewer than 50% had a positive CAGE score.[80] The CAGE questionnaire may also perform less well in women and persons of specific ethnic groups.[81] The sensitivity of the CAGE questionnaire and other screening instruments may vary by gender or ethnicity; thus, it may be necessary to use a combination of screening techniques to identify alcohol-related problems in some patients.

The Alcohol Use Disorder Identification Test (AUDIT) may provide additional useful information when patients are being screened for alcohol-related problems in primary health care settings.[10,77] AUDIT was developed by the WHO and was designed to identify hazardous and harmful drinking, as well as alcohol dependence. Among the 10 AUDIT questions are three quantity and frequency questions regarding current drinking behavior and seven questions regarding past drinking behavior. Each question is scored on a scale of 0 to 4; a total score of 8 or greater is considered to be a positive result. AUDIT has demonstrated a sensitivity of 92% to 96% and a specificity of 94% to 96%.[82] A three-question version of the AUDIT (AUDIT-C) has been demonstrated to be effective in men and women.[83] Other screening instruments (e.g., TWEAK [*t*olerance, *w*orried, *e*ye-openers, *a*mnesia, *k*/cut down], S-MAST [Short Michigan Alcoholism Screening Test], and RAPS4 [Rapid Alcohol Problems Screen]) are available for use in clinical practice [*see Table 1*]; however, evaluation of the effectiveness of each test in specific patient groups is ongoing.[84,85]

Step 4 involves asking further questions with regard to potential alcohol-related problems. Step 4 is applied to those patients who were identified in steps 1 through 3 as having potential alcohol-related problems. A diagnosis of alcohol abuse or dependence is made on the basis of the criteria described in DSM-IV.[9] The examination for evidence of specific alcohol-related medical and psychiatric problems should include a thorough history and physical examination. Although not useful as screening tests for alcohol-use disorders,[78] laboratory tests, such as liver enzyme assay, may be useful in identifying undiagnosed alcohol-related medical problems. Questioning patients about alcohol-related behavioral and social problems is also essential when evaluating patients suspected of having alcohol-related problems. In addition, knowledge of previous treatment of alcohol-related problems is essential when referring patients for treatment.

Treatment Approaches for Patients with Alcohol-Related Problems

Screening and diagnosis represents a basic initial step in the management of patients with alcohol-related problems. Factors such as patient denial may make the initiation of a treatment

Table 2 Management of Patients with Alcohol Problems

For all patients
- Screen for alcohol problems
- Educate about risky drinking and its consequences
- Perform a detailed alcohol history for all patients who may have problem drinking [*see Table 1*]

For at-risk drinkers
- Assess patients for alcohol-related medical, psychiatric, and behavioral problems
- Advise nondependent at-risk problem drinkers to decrease their alcohol consumption to an amount below at-risk levels (e.g., brief intervention therapy) [*see Table 4*]
- Advise those at-risk drinkers who cannot follow suggestions to decrease their alcohol use to recommended levels to abstain from alcohol
- Monitor and assess drinking behavior over time

For alcohol-dependent patients
- Advise alcohol-dependent drinkers to abstain from alcohol, and refer them to appropriate alcohol treatment services for detoxification (if needed) and prevention of relapse
- Identify and manage alcohol-related medical, psychiatric, and behavioral problems
- Monitor patients in recovery to promote abstinence and assess for relapse

plan very challenging. In addition, as with all chronic health problems and diseases, treatment is no guarantee of cure. Patients with more severe alcohol-related problems, such as alcohol dependence, may require treatment from alcohol treatment specialists, whereas those in the at-risk and problem-drinking categories may be managed in primary care settings. The primary care physician can play a critical role in the management of all patients with alcohol-related problems, regardless of the severity of those problems. For patients with more severe alcohol dependence, the primary care physician's role includes identifying patients with severe dependence, referring such patients to treatment specialists, evaluating those patients for medical complications, providing support for ongoing treatment, and monitoring for signs of relapse [*see Table 2*].

A six-stage model has been proposed for assessing patients' readiness for behavior change and treatment [*see Table 3*].[83] These stages represent a continuum, and patients may move from one stage to another. Physician assessment of readiness for behavior change may be helpful in tailoring the advice given to patients with alcohol-related problems.[82] Being in the precontemplation stage, in which a patient is unaware of the alcohol problem, is associated with poorer treatment outcomes.[86] The overall goal for physician counseling is to move patients from the precontemplation stage to the action stage so that maintenance can be achieved.[87]

MANAGEMENT OF AT-RISK AND PROBLEM DRINKERS WITH BRIEF INTERVENTION THERAPY

Brief intervention therapy typically involves providing patients with feedback about the problems associated with their drinking habits and advising them to reduce their alcohol consumption to levels considered medically safe (i.e., below the level of at-risk drinking). Brief interventions typically include counseling sessions lasting 5 to 20 minutes that are conducted on one or more occasions. The FRAMES acronym (*f*eedback, *r*esponsibility, *a*dvice, *m*enu, *e*mpathy, *s*elf-efficacy) summarizes a counseling strategy commonly used in brief interventions [*see Table 4*].[88] This counseling strategy, as well as others commonly employed in brief intervention therapy, are useful for primary care physicians, and their use in primary care settings has been advocated by government agencies and experts in the field.[7]

Three meta-analyses have examined the efficacy of brief (under 1 hour) intervention therapy.[89-91] One such study concerned over 40 controlled trials that enrolled over 6,000 patients; it concluded that brief intervention therapy is more effective than no counseling at all and is often as effective as more extensive treatment.[1,89] Another meta-analysis, of eight studies, demonstrated that patients who received brief intervention therapy were almost twice as likely to decrease their drinking as those who did not receive such therapy.[90] Finally, a third meta-analysis, which examined data from 12 controlled trials of adult primary care patients, indicated that patients who received brief intervention therapy experienced a decrease of 13% to 34% in drinks consumed per week.[91]

One study illustrates the process of brief intervention therapy.[22] In this study, a sample of 723 persons were recruited from 17 primary care practices in Wisconsin. The group receiving brief intervention therapy was given a health booklet on general health issues and also received structured counseling about their drinking behaviors during two visits with a physician [*see Table 4*]. After each visit to the physician, the patients received a telephone call from a nurse who reinforced the advice given by the physician. The control group received only the health booklet. Patients were followed for 1 year; the main outcomes used to evaluate the brief intervention therapy were measures of alcohol use (i.e., drinks per week and episodes of binge drinking), the

Table 3 Stages of Readiness to Change Addictive Behaviors and Stage-Specific Approaches

Stage	*Patient Features*	*Possible Approaches*
Precontemplation	Unaware of alcohol problems	Express concern about health problems and their link to alcohol use
Contemplation	Recognizes alcohol problems	Reinforce links between alcohol use and problems; promote behavior change
Determination	Decides to change behavior	Support decision; provide advice about short-term and long-term actions to change behavior
Action	Changes behavior	Monitor compliance with advice and outcomes
Maintenance	Continues new behavior	Continue follow-up of alcohol problems; support behavior change and treatment efforts; monitor for relapse
Relapse	Recurrence of alcohol problems	Support return to behavior change or reentry into or continuation of treatment; monitor for alcohol problems

Table 4 Components of a Brief Intervention

FRAMES Counseling Strategy for Brief Interventions

Feedback: review the problems experienced by the patient because of alcohol use

Responsibility: emphasize that changing patterns of alcohol use is the patient's choice and responsibility

Advice: advise the patient to cut down or abstain from alcohol

Menu: provide menu of options and strategies for changing behavior

Empathy: use a warm, empathic, understanding approach with the patient

Self-efficacy: encourage optimism about likelihood and benefits of changing behavior

Specific Brief Intervention Therapeutic Techniques and Visit Characteristics[21]

Interventions

- Workbook with feedback on health behavior
- Review of the prevalence of problem drinking and adverse effects of alcohol
- Worksheet on drinking cues
- Drinking agreement "prescription"
- Drinking diary

Visit characteristics

- Two 15-min visits with physician
- Phone call from nurse 2 wk after visit with physician

number of alcohol-related emergency department visits, and the number of days spent in the hospital. A 12-month follow-up evaluation showed that the mean number of drinks consumed per week decreased by more than 7.5 drinks in the group receiving brief intervention therapy, compared with a decrease of just over three drinks a week in the control group. The treatment group also had significantly fewer episodes of binge drinking over a 30-day period and experienced fewer episodes of excessive drinking. In addition, men in the treatment group had a significantly shorter length of hospitalization than men in the control group.[22] This study, along with many of the others reviewed in the three meta-analyses, demonstrates that relatively simple clinical interventions that take a minimum amount of time and are well within the skill level of most primary care physicians can effectively improve patients' drinking behaviors.

Important questions remain to be studied. The effectiveness of brief intervention therapy over time is unknown. In addition, the optimal number of brief interventions, the optimal length of time over which brief interventions should be made, and the optimal frequency of repeated brief interventions are uncertain. Other aspects of brief intervention therapy that have not yet been determined are the long-term benefits of such therapy and the effect that brief interventions have on progression to more severe alcohol-related problems.

SELF-HELP GROUPS

Alcoholics Anonymous (AA) and similar groups, such as Rational Recovery and Narcotics Anonymous, are based on a 12-step recovery model. In this model, 12 steps describe specific attitudes, beliefs, and actions that are regarded as critical to the recovery process. Meetings are held 7 days a week in multiple locations throughout the country and include both open meetings, which are open to everyone, and closed meetings, which are restricted to group members.

Physicians who are interested in encouraging their patients to attend AA meetings should obtain an AA meeting schedule from their local AA organization. In addition, it is often recommended that physicians attend at least one open meeting so that they can better counsel their patients on how AA works. AA chapters and other 12-step groups are widely available and are free of charge.

Attention has been paid to the question of the effectiveness of 12-step approaches. Studies have demonstrated that attendance at AA meetings correlates with positive drinking outcomes.[92,93] In addition to attendance, greater involvement in AA (e.g., whether the patient has a program sponsor and the degree to which the patient participates in meetings) appears to correlate with decreased alcohol consumption.[94] In one study, participants in an employee-assistance program were given compulsory treatment on an inpatient basis, were required to attend AA meetings, or could choose just one of these two options. Patients in all three groups showed improvement in alcohol consumption, and there were no significant differences in job-related outcome between the three groups.[95] A significant number of patients in AA were subsequently referred for inpatient treatment; those who received inpatient treatment had the best outcomes. Future research on AA that is methodologically rigorous and attends to important clinically oriented outcomes is needed.[92]

MANAGEMENT OF ALCOHOL ABUSE AND DEPENDENCE

In addition to providing office-based evaluation, management, and referral to self-help groups, primary care physicians will often need to provide more intensive services to patients who meet criteria for alcohol abuse and dependence. These services can include management of the alcohol withdrawal syndrome and referral to an alcohol treatment program.

Alcohol Withdrawal Syndrome

Signs and symptoms of alcohol withdrawal, which can occur in alcohol-dependent persons who stop drinking alcohol or who reduce their alcohol intake, include abnormalities in vital signs (e.g., tachycardia, hypertension, and fever), other symptoms of autonomic hyperactivity (e.g., tremor, diaphoresis, and insomnia), GI symptoms (e.g., nausea, vomiting, and diarrhea), and central nervous system effects (e.g., anxiety, agitation, hallucinations, seizures, and delirium). Withdrawal severity and response to treatment may be assessed using the revised Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar).[96] This instrument describes 10 clinical features of withdrawal that are rated by the clinician on the basis of observation of the patient. Although many patients presenting with mild withdrawal can be managed as outpatients, those with more severe withdrawal or with significant comorbid medical or psychiatric problems may require inpatient care.

When managing alcohol withdrawal, physicians should keep the following specific goals in mind.[97] Patients' symptoms should be monitored closely and treated in a manner that minimizes discomfort. Inadequate treatment of withdrawal symptoms may be a major stimulus to return to drinking. Patients should be monitored for major withdrawal complications such as seizures or delirium and treated accordingly. Clinical features such as elevated baseline blood pressure, medical comorbidities, and prior complicated withdrawal may indicate an increased risk of a severe withdrawal episode (e.g., delirium tremens).[98] Withdrawal treatments are designed to decrease the occurrence of these complications. Patients should be fully evaluated for other alcohol-related problems, and their general health status should be assessed. It is critical to immediately plan for post-

withdrawal treatment of alcohol-related problems to help patients maintain abstinence. All patients who are treated for alcohol withdrawal should be referred for ongoing treatment.

Pharmacologic therapies for alcohol withdrawal syndrome have been the focus of much research over the past 40 years. A variety of drugs, including the barbiturates, phenothiazines, carbamazepine, and alcohol itself, have been used. The benzodiazepines (e.g., chlordiazepoxide, diazepam, lorazepam, and oxazepam) are the safest and most effective medications for this purpose.[99] In addition to preventing or alleviating withdrawal symptoms, benzodiazepines may also decrease the incidence of seizures and possibly delirium tremens.[99,100] Control of agitation can be achieved using a parenteral, rapid-acting benzodiazepine that is cross-tolerant with alcohol.[100] Adequate doses should be used to maintain light somnolence for the duration of the delirium. A working group assembled by the American Society of Addiction Medicine reviewed the world literature on pharmacologic therapy for alcohol withdrawal syndrome to provide an evidence-based guideline for clinicians.[99] Their review of over 130 papers yielded 65 prospective, controlled trials, which examined over 40 drugs. This review provided strong evidence in favor of the benzodiazepines over placebo and all other drugs and suggested that the longer-acting benzodiazepines provide a smoother withdrawal and may be more effective in preventing seizures.[99] Generally, however, shorter-acting benzodiazepines are considered to be safer in the elderly and in patients with severe liver disease. Older benzodiazepines, such as chlordiazepoxide and diazepam, are the best studied and are also the least expensive.[99] Research has suggested that clonidine, beta blockers, and carbamazepine are effective in decreasing the severity of certain withdrawal symptoms but are not as effective as the benzodiazepines and presumably do not protect against seizures, as do benzodiazepines.[99] Thus, these alternative treatments are generally considered to be adjuvants to benzodiazepines. In addition, when benzodiazepines are used, a so-called symptom-triggered approach, in which benzodiazepines are administered in response to signs and symptoms assessed using careful monitoring, may have advantages over more traditional dosing practices.[101]

Alcohol Treatment Programs

Problem drinkers and drinkers who are at risk for alcohol-related problems who do not respond to brief intervention therapy, as well as patients who meet criteria for alcohol abuse and dependence, may require referral to specialists and formal alcohol treatment programs. Such referrals are particularly necessary for patients who are suffering significant medical, psychiatric, or social comorbidity that is related to their alcohol use or for patients who are alcohol dependent. The referral process can be more successful if physicians are familiar with the structure and types of treatment used in their local programs. It is important to communicate effectively with caregivers of alcohol treatment programs and to reinforce their treatment strategies when patients present for follow-up medical care.

Most patients can be treated safely and effectively in an outpatient treatment environment. Criteria have been developed by the American Society of Addiction Medicine[102] that are designed to aid in patient placement. Clinical variables that are important in determining level of service needed include the presence of medical or psychiatric comorbidity, the risk of withdrawal, the level of social support available, and previous treatment experience.

Psychotherapeutic Approaches to the Treatment of Alcohol Dependence

The psychotherapeutic approaches used in alcohol treatment programs may vary from one program to another. Common approaches may be in the form of individual or group therapy. Common objectives of alcohol treatment programs are to (1) motivate patients to change their behavior and lifestyles; (2) teach patients coping skills to avoid alcohol use; (3) encourage patients to develop activities that do not reinforce drinking and that reward abstinence; (4) help patients to improve interpersonal interactions; and (5) promote compliance with pharmacotherapy and medical care.[103] Treatment typically takes a long time and becomes less intensive as patients begin demonstrating achievement of prolonged abstinence. Along with individual and group therapy, other approaches, such as family therapy and network therapy, may have a role in the treatment of selected patients.[104]

Three commonly used psychotherapeutic approaches were evaluated in a randomized clinical trial, Project MATCH.[105] The three approaches studied were cognitive-behavioral coping-skills therapy, motivational-enhancement therapy, and 12-step facilitation. In each program, therapy was administered for 12 weeks. Two parallel but independent randomized clinical trials assessed these approaches in inpatients and outpatients. Both inpatients and outpatients experienced significant and sustained improvements in drinking outcomes, as measured 1 year after treatment. The groups did not differ in their degree of improvement. In the inpatient arm of the study, patients experienced a 70% increase in the percentage of days they were abstinent (from 20% to 90%); 35% remained completely abstinent. In the outpatient arm, patients experienced an 80% increase in the percentage of days they were abstinent; 19% maintained complete abstinence. Of note was the large percentage of both inpatients and outpatients (25% and 35%, respectively) who had a slip in abstinence but not a complete relapse (with relapse being defined as 3 consecutive days of heavy drinking).[105] For the majority of patients enrolled in this study, treatment resulted in significant improvement. In a follow-up evaluation of a subset of individuals enrolled in Project MATCH, their alcohol problems on enrollment in the program were found to be at least as severe as, if not more severe than, those of people who did not participate in the study, suggesting that the positive results of the therapeutic interventions evaluated in the original study could be achieved among larger populations of inpatients and outpatients.[106]

Pharmacologic Treatments to Prevent Relapse

Pharmacotherapy is a useful adjunct to psychotherapy in helping patients drink less alcohol [*see Table 5*].[107] Three medications have been studied extensively for this purpose: disulfiram, naltrexone, and acamprosate. Other medications, including topiramate, nalmefene, lithium, and serotoninergic agents, have also been or are being investigated.[107] Disulfiram was the first of these medications to become available. It works through the inhibition of the enzyme alcohol dehydrogenase. Patients who are receiving disulfiram and who subsequently drink alcohol are at risk for a severe adverse reaction, which includes flushing, nausea, vomiting, and diarrhea. Patients on disulfiram must avoid unintended alcohol consumption, which may occur through the consumption of alcohol-containing foods or medications. Disulfiram has demonstrated limited effectiveness in decreasing alcohol use.[107] It appears to be most effective in combination with behavioral therapies and in highly motivated patients.[107,108] Disulfi-

Table 5 Pharmacotherapeutic Agents

Drug	*Starting Dose*	*Maintenance Dose*	*Interval*	*Comments*
Disulfiram	500 mg	125–500 mg	Every morning for 1–2 wk	Requires careful patient education about disulfiram-alcohol interaction
Naltrexone	50 mg	50 mg	Once a day	Contraindicated in patients with severe liver disease; side effects generally infrequent, mild, and self-limited (e.g., nausea)
Acamprosate	1.3–2.0 g	—	Every day in three divided doses	Not approved by the FDA; side effects generally infrequent, mild, and self-limited (e.g., diarrhea)

ram has also been shown to be helpful in the management of patients who use cocaine and alcohol together.[109]

Naltrexone is an opioid antagonist that was originally developed for the treatment of opioid dependence. Subsequently, naltrexone was shown to decrease the pleasurable effects and craving associated with alcohol use.[110] A meta-analysis of 27 studies indicated that short-term treatment with naltrexone decreases the chance of alcohol relapse for 35% of alcohol-dependent patients and lowers the risk of treatment withdrawal for 28%.[111] Larger randomized, controlled trials are needed to determine how long alcohol-dependent patients should continue naltrexone treatment.

Although most of the naltrexone studies have focused on patients enrolled in formal alcohol treatment programs, one small study found that naltrexone can be effectively administered in primary care settings.[112] In this study, 29 alcohol-dependent persons received naltrexone at a dosage of 50 mg a day for 10 weeks. The majority of patients (72%) completed treatment; 35% relapsed to heavy drinking. When compared with baseline values, all drinking behaviors improved significantly in these individuals, including the percentage of days in which the patients were abstinent, which increased from 36.6% to 88.8%, and the mean number of drinks consumed per occasion, which decreased from 9.5 drinks to 2.5 drinks. Managing both side effects and patients' expectations about the effectiveness of naltrexone seems to be an important factor in determining compliance with medication.[113] Research has demonstrated that naltrexone treatment by primary care providers may be as effective as naltrexone provided in alcohol treatment programs and that extended treatment (6 months or more) with naltrexone may be especially effective in primary care.[114]

Acamprosate, which was approved by the Food and Drug Administration for the treatment of alcohol dependence in 2004,[115] has been studied extensively in Europe and more recently in the United States. In an analysis of 11 randomized, placebo-controlled trials involving a total of 3,338 patients with alcohol dependence, patients who received acamprosate demonstrated superior abstinence rates and duration of abstinence during a 6- to 12-month posttreatment follow-up period.[116] In clinical trials of acamprosate, dosages have ranged from 1.3 to 2.0 g/day in divided doses, and side effects (most commonly diarrhea) have been minimal. Research suggests that the use of acamprosate may be associated with economic as well as clinical benefits.[117]

Concomitant administration of disulfiram has improved the effectiveness of acamprosate without adverse interactions between the drugs.[118] Research is also under way to evaluate the effectiveness of acamprosate in combination with naltrexone.[107] Early research has suggested that this combination results in enhanced treatment outcomes[119]; however, more data are needed to understand the potential benefits of combination therapy. Further study is needed to establish the relative efficacies of these three drugs.

Additional Information

Additional information on the treatment of alcohol problems may be obtained from the National Institute on Alcohol Abuse and Alcoholism (http://www.niaaa.nih.gov), the National Clearinghouse for Alcohol and Drug Information (http://www.health.org), and Alcoholics Anonymous (http://www.alcoholics-anonymous.org).

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII SCHIZOPHRENIA

William T. Carpenter, Jr., m.d.
Gunvant K. Thaker, m.d.

As recently as the mid-20th century, schizophrenia was one of the most devastating psychiatric illnesses. No effective treatment was available, and most patients suffered lifelong debilitating symptoms and required institutionalization. Research during the latter part of the 20th century better defined the syndrome, provided clues to the causes, clarified the pathophysiology, provided evidence for effective treatments and against potentially harmful ones, and permitted the transfer of many schizophrenic patients from inpatient institutions to less restrictive outpatient facilities. However, challenges remain: specific causes and causal pathways are unknown, pathophysiology is ill defined, treatments are effective only for the psychotic aspect of the syndrome, and homelessness has replaced institutionalization.

Definition

Schizophrenia is a clinical syndrome probably comprising several as-yet undefined disease entities. There is substantial heterogeneity between cases, which presumably reflects multiple overlapping etiologic factors, including contributions from several genes. The presence of schizophrenia is indicated by chronic psychotic symptoms, especially hallucinations and delusions. Disorganization of thought and behavior are common and distinguish schizophrenia from the many other causes of reality-distortion symptoms (e.g., psychotomimetic drugs). Diminished emotional experience and expression, low drive, and reduced speech are observed in a subgroup of patients. Most patients have subtle impairments in cognition. Cognitive impairments and the emotional and social aspects of the disease often appear early in life; the psychotic symptoms typically begin in late adolescence or early adulthood in men and a little later in women.

Subclassification

At the end of the 19th century, Emil Kraeplin conceptualized dementia praecox as comprising seemingly discrete diseases known as hebephrenia, catatonia, and paranoia. Eugen Bleuler suggested renaming dementia praecox as *schizophrenia*, a term he coined to capture the split within thought and between thought and emotion. Bleuler also added simple schizophrenia as a fourth subtype of the disease.

Throughout most of the 20th century, the clinical presentation of schizophrenia was often described in terms of specific subtypes. These subtypes included hebephrenic, paranoid, catatonic, and simple schizophrenia. Hebephrenic schizophrenia (now termed disorganized schizophrenia) is characterized by shallow and incongruent affect and disorganized thought and behavior. Paranoid schizophrenia is characterized by predominance in males; a later age of onset; intact cognition and affect; and hallucinations and delusions, often persecutory and bizarre. Catatonic schizophrenia is characterized by extreme psychomotor manifestations, including stupor, prolonged posturing, or excitement; it must be differentiated from periodic catatonia, which is a separate syndrome unrelated to schizophrenia. For unknown reasons, catatonic schizophrenia is now rarely seen in developed countries. Simple schizophrenia denotes a milder psychosis (i.e., fewer hallucinations and delusions and less disorganization), with cases typically featuring a schizoid lifestyle of reduced emotional experience and expression and reduced social drive and engagement. A later term, schizoaffective schizophrenia, described the combination of mood disturbances—mania or depression—with schizophrenic psychotic manifestations. Other subtypes were suggested but did not gain wide acceptance.

In general, however, schizophrenia has been approached as a diagnostic class rather than in terms of these subtypes. The traditional subtypes appear not to differ substantially in etiology, pathophysiology, or treatment response. Moreover, a patient's subtype may change over time: a patient who presents with paranoid schizophrenia may later be seen to have disorganized schizophrenia; a patient who presents with schizoaffective psychosis may eventually be seen to have a disorganized or undifferentiated subtype.

Another approach to subclassification categorizes cases on the basis of three distinct domains of psychopathology: reality distortion (i.e., hallucinations and delusions), disorganization of thought and behavior, and negative symptoms such as reduced drive and affect. Kraeplin described two "maladies"—dissociation and avolition—as the central features of dementia praecox, but in the late 20th century, psychiatrists placed diagnostic emphasis on reality distortion and disorganization of thought. It turns out that many patients do not manifest negative symptoms, whereas others have chronic reduction in drive, reduced expression of emotion, and poverty of speech. We have divided schizophrenia into two subgroups: deficit schizophrenia, in which schizophrenia causes negative symptoms and psychosis; and nondeficit schizophrenia, in which negative symptoms are absent. Clinical features, family history, neuroanatomy, treatment response, course of illness, and postmortem pathology suggest that deficit schizophrenia is a separate disease entity within the schizophrenia syndrome. Deficit schizophrenia constitutes about 15% to 20% of all schizophrenia cases and appears to occur predominantly in males.[1]

Epidemiology

The annual incidence of schizophrenia approximates one in 10,000 adults younger than 60 years, with a lifetime risk of 0.8. The onset of psychosis (i.e., reality distortion or disorganization of thought) usually occurs at about 17 to 27 years of age in males and at 20 to 37 years in females. Population-based estimates suggest that the lifetime incidence of the disease is roughly equal in males and females; in clinical populations, however, males often constitute the majority of patients. Females have often been reported to have a more favorable course of illness. One explanation is that males are more likely to have deficit schizophrenia, which tends to have a chronic course with poor functional oucome.[2]

Race does not appear to influence the distribution of schizophrenia. Some United States studies have suggested a racial bias in diagnostic practice, with the term schizophrenia being used more in African-American patients and the term affective psychosis used more in white Americans.[3]

Geographically, schizophrenia appears to be evenly distributed throughout the world.[4] A country's stage of economic development, degree of urbanization, or climate seem to have little influence on schizophrenia prevalence. However, the course of the illness has been more favorable in developing countries than in developed countries. This may reflect the tendency for developing countries to have sociocentric cultures and for developed countries to have egocentric cultures. Sociocentric cultures may be more supportive of marginal function than egocentric cultures, in which demands for autonomous function may be particularly challenging for persons with schizophrenia. The difference may also reflect the inclusion of cases with a better prognosis in the syndrome definition; patients with acute onset of bizarre psychosis tend to have a more favorable course of illness.

Decreases in rates of schizophrenia were reported in the second half of the 20th century.[5] However, these decreases have not been substantiated and may simply reflect increasingly stringent criteria for the diagnosis.

Schizophrenia is the fourth leading cause of disability in adults worldwide. In the United States, about 80% of persons with schizophrenia are unemployed, and many of the remainder are underemployed. Perhaps a third of homeless persons have schizophrenia.[6]

More than half of schizophrenic patients abuse substances, especially alcohol.[7] Over 80% of schizophrenics smoke cigarettes, and nicotine intake in schizophrenics who smoke is well above that of nonschizophrenic smokers.[8] Smoking represents a substantial financial burden to this generally impoverished population and combines with other lifestyle risk factors (e.g., inadequate diet and exercise) to place schizophrenic patients at increased risk for diabetes, cardiovascular disease, and cancer.

Etiology and Genetics

Considerable data suggest that schizophrenia is a heritable illness. The risk of the disease rises with the closeness of kinship to a schizophrenic proband. Compared with the risk in the general population, the risk is fivefold higher in second-degree relatives of schizophrenia patients, 10-fold to 15-fold higher in first-degree family members and dizygotic twins, and 40-fold to 50-fold higher in monozygotic twins or in persons whose parents both have schizophrenia.[9] There is also higher risk in adopted biologic relatives of schizophrenia probands than in their adoptive families.

Other data strongly suggest that environmental factors, either on their own or interacting with genetic factors, play a critical role in causing or modifying the clinical presentation of the illness.[10] Most of the environmental factors associated with schizophrenia are active early in development, particularly during the intrauterine period. These include maternal malnutrition; infections during critical periods of fetal development; fetal hypoxia; and other birth and obstetric complications. Further supporting an environmental role is the finding that overall, patients with schizophrenia were more likely to have been born during the winter, whereas the subgroup of patients with deficit schizophrenia were more likely to have been born during the summer.[11] How season of birth affects risk is unclear. Environmental insults that occur later in life, such as use of psychoactive drugs, also play a role.

The initial search for genes that might cause schizophrenia produced disappointing results. The first significant linkage of a broadly defined schizophrenia phenotype to a specific locus, chromosome 5q11-q13, stirred excitement, but subsequent studies failed to replicate this finding.[12] Ensuing linkage studies identified several chromosomal loci, some of which were likely false positive findings, given that replications were not forthcoming. Significant linkage findings that were subsequently replicated by other studies implicated regions on chromosomes 1, 5, 6, 8, 13, 15, and 22.[13,14] Most of these findings were not robust, however; in addition, some studies failed to identify linkages at the same locus, and many replicating studies only suggested linkage (i.e., log odds ratio scores ranged from 2 to 3). Further investigation of these loci has identified several candidate genes: *RGS4,* the dysbindin gene (*DTNBP1*), neuregulin 1, the alpha-7 nicotinic receptor gene, *COMT, G72,* and *GAD 65/67*.[15-21] Further work is needed to identify other candidate genes using other genetic approaches (see below) and to confirm the role of candidate genes in the etiology, pathophysiology, and treatment of schizophrenia.

The search for genes in schizophrenia has proved particularly challenging because of the complex and multifactorial nature of the disorder. It appears that many genes may cause vulnerability to schizophrenia, each with a modest effect, and that these genes probably interact with one another and with environmental factors. Thus, the clinical phenotype of schizophrenia may well be the common expression of a variety of genotypes; this may explain failures to replicate identified disease loci.

Arguing that schizophrenia encompasses multiple phenotypes of different genetic vulnerability profiles, several investigators have focused on a search for the genes underlying specific deficits seen in schizophrenia. Freedman and colleagues, using an electrophysiologic measure of sensory gating, demonstrated that a deficit in sensory gating in familes with schizophrenia is a result of an autosomal dominant effect of a single gene, the alpha-7 nicotinic receptor gene, on chromosome 15q14.[22] Other phenotypes that are associated with schizophrenia and that have been used in the search for schizophrenia-related genes are smooth-pursuit eye movement deficit; cognitive impairments in dimensions of attention, language, and memory; deficits in levels of the neuronal marker *N*-acetyl-aspartate in the hippocampal region; and abnormal membrane phospholipid metabolism in the prefrontal cortex, as measured by phosphorus-31 magnetic resonance spectroscopy.[23,24] Preliminary findings have suggested linkage of the smooth-pursuit phenotype to a locus on chromosome 6p and an association of prefrontal executive functional deficit with the *val* allele of the *COMT* gene.[25,26]

Pathophysiology

The pathophysiology of schizophrenia is not well understood. That schizophrenia results from an excess of dopamine has been the dominant hypothesis for decades, with several modifications and expansion of the hypothesis made during the 1990s.[27-29] Brain imaging studies have shown evidence of increased synaptic dopamine release in response to amphetamine administration in the striatum of schizophrenic patients.[30-32] Excess dopamine may explain the positive symptoms but not the negative symptoms or other aspects of the disease. The pathophysiologic mechanisms are presumably complex—even a deficiency of dopamine is a viable explanation for negative symptoms. The clinical observations that long-term phencyclidine (PCP) use produces a broader cluster of schizophrenia-like symptoms than seen with use of dopamine agonists has led to

speculation that a lack of glutamine may be involved. In contrast to the predominantly paranoid symptoms associated with long-term use of dopamine agonists, long-term PCP use produces negative symptoms and cognitive impairment in addition to reality distortion.[28] These schizophrenia-like symptoms from PCP are hypothetically initiated by blockade of the ion channel in the *N*-methyl-D-aspartate (NMDA) receptor complex, resulting in diminished glutamatergic neurotransmission. Both dopaminergic and glutamatergic terminals converge on the spines of pyramidal neurons in cortex. This suggests a shared mechanism by which glutamate and dopamine play a role in schizophrenia.[28,29] Although the two neurotransmitter systems share complex presynaptic and postsynaptic interactions,[33,34] modulation of glutamate release by D_1 dopamine receptors may mediate some of the effects of dopamine on psychosis.

Postmortem findings in schizophrenia have not been consistent. Furthermore, interpretation of postmortem findings is difficult because of the confounding effects of long-term drug treatment received by most patients. Massive cell loss or gliosis is generally not found, thus ruling out degenerative changes in the brain. Earlier postmortem histopathologic examination of the brains of patients with schizophrenia showed slight reductions in neocortical gray matter volume, decreased neuronal size, and neuronal disarray in several corticolimbic structures.[35-37] Subsequent investigations have focused on changes of neuronal connectivity or microcircuitry within the cortical layers and have noted an increase in cell packing density without a change in the number of neurons. These findings suggest a decrease in neuropil and a reduction in dendritic spine density on pyramidal neurons in the prefrontal cortex.[38,39] Using complementary DNA microarrays, Mirnics and colleagues noted a decrease in the expression of several genes involved in glutamate and γ-aminobutyric acid (GABA) transmission and in the regulation of presynaptic function and signal termination in the prefrontal cortex of patients with schizophrenia.[40] Together, these findings indicate a decrease in cortical or thalamic excitatory synaptic inputs to the pyramidal neurons.

In addition to drug probe and postmortem studies exploring the pathophysiology of schizophrenia, in vivo structural imaging studies of the brain show cortical volume reductions of one or more of the constituent structures of the medial temporal lobe (comprising the hippocampus, the amygdala, and the parahippocampal gyrus). Some studies note smaller prefrontal cortical volume, but this finding is not consistent across studies and may be limited to a subgroup of schizophrenic patients.[41] Reductions in thalamic volume, particularly of the thalamic nuclei forming part of the temporal-thalamic and prefrontal-thalamic circuitry, are also noted.[42] Functional imaging studies of neuronal circuitry during performance of cognitive tasks have found reduced neuronal activation in several cortical regions of schizophrenic patients compared with normal control subjects. However, interpretation of these data is somewhat confounded by the fact that schizophrenic patients perform poorly in such tasks. Several studies have examined brain activation during the performance of tasks that schizophrenic patients performed as well as the control subjects. These studies show that to perform equally well on a working memory task, schizophrenic patients show increased activation of the prefrontal cortical network. On other tasks, patients activated different cortical networks than were activated by healthy control subjects, suggesting that the patients used a different strategy or required compensatory mechanisms [*see Figure 1*].[43]

Clinical Course

Persons with schizophrenia often come to medical attention because of a public manifestation of bizarre behavior, disorganized thought, and reality-distortion symptoms. However, the history taken at first presentation often reveals a prolonged period of more subtle manifestations of the psychotic state, averaging perhaps 2 years; cognitive impairments and negative symptoms may have been present for years, if not throughout life. Although the course of schizophrenia varies considerably between individuals, a brief case description will illustrate several characteristic features of the disease.

A young man had a declining academic performance during the last 2 years of high school. He seemed to lose friends and motivation and gradually became a loner with strange ideas. He relinquished plans to attend college, and after high-school graduation he took a job. Soon after he began working, he acted in a bizarre and hostile manner in a confrontation; recurrence of this behavior caused dismissal from the job. He spent the next year working odd jobs, living at home, and displaying a growing indifference to his life goals. His parents suspected substance abuse and were concerned that he was not interested in having a girlfriend. On his 20th birthday, he was found sitting nude in the backyard; he claimed that he was receiving messages through solar radiation. He was taken to the emergency department.

As this case illustrates, the opportunity for intervention often occurs before the conspicuous onset of illness. Although the development of overt psychotic symptoms defines the onset of the illness, subtle impairments occur early in some patients and persist through the peaks and troughs of the psychotic symptoms. Some schizophrenic patients appear to be born with subtle motor and emotional impairments. Early in childhood and adolescence, many persons who later develop schizophrenia manifest a range of cognitive impairments on psychological tests of attention, memory, and executive function and on physiologic tests of information processing.

There is a variable course of illness after the initial psychotic break. Later in life, some patients even show clinical improvement in psychotic symptoms. In contrast, a smaller subgroup may show rapid cognitive decline. The manifestation of psychosis only modestly defines long-term morbidity, which instead is best understood in terms of functional capabilities, social and occupational roles, and quality of life. Cognitive impairments and negative symptoms are more robust determinants of these outcomes.

Diagnosis

CLINICAL MANIFESTATIONS

Diagnosis of schizophrenia is based on clinical manifestations and the clinical course. Internationally accepted criteria have been published in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders—Text Revision* [*see Table 1*] and in the 10th edition of the *International Classification of Diseases and Related Health Problems*.

The diagnosis of schizophrenia should be considered in a patient who presents with hallucinations and delusions. The presence of disorganized thought and behavior increases the likelihood of schizophrenia. In the absence of other known causes of such symptoms (e.g., substance abuse, temporal lobe epilepsy), the principal diagnostic task is to discriminate between severe

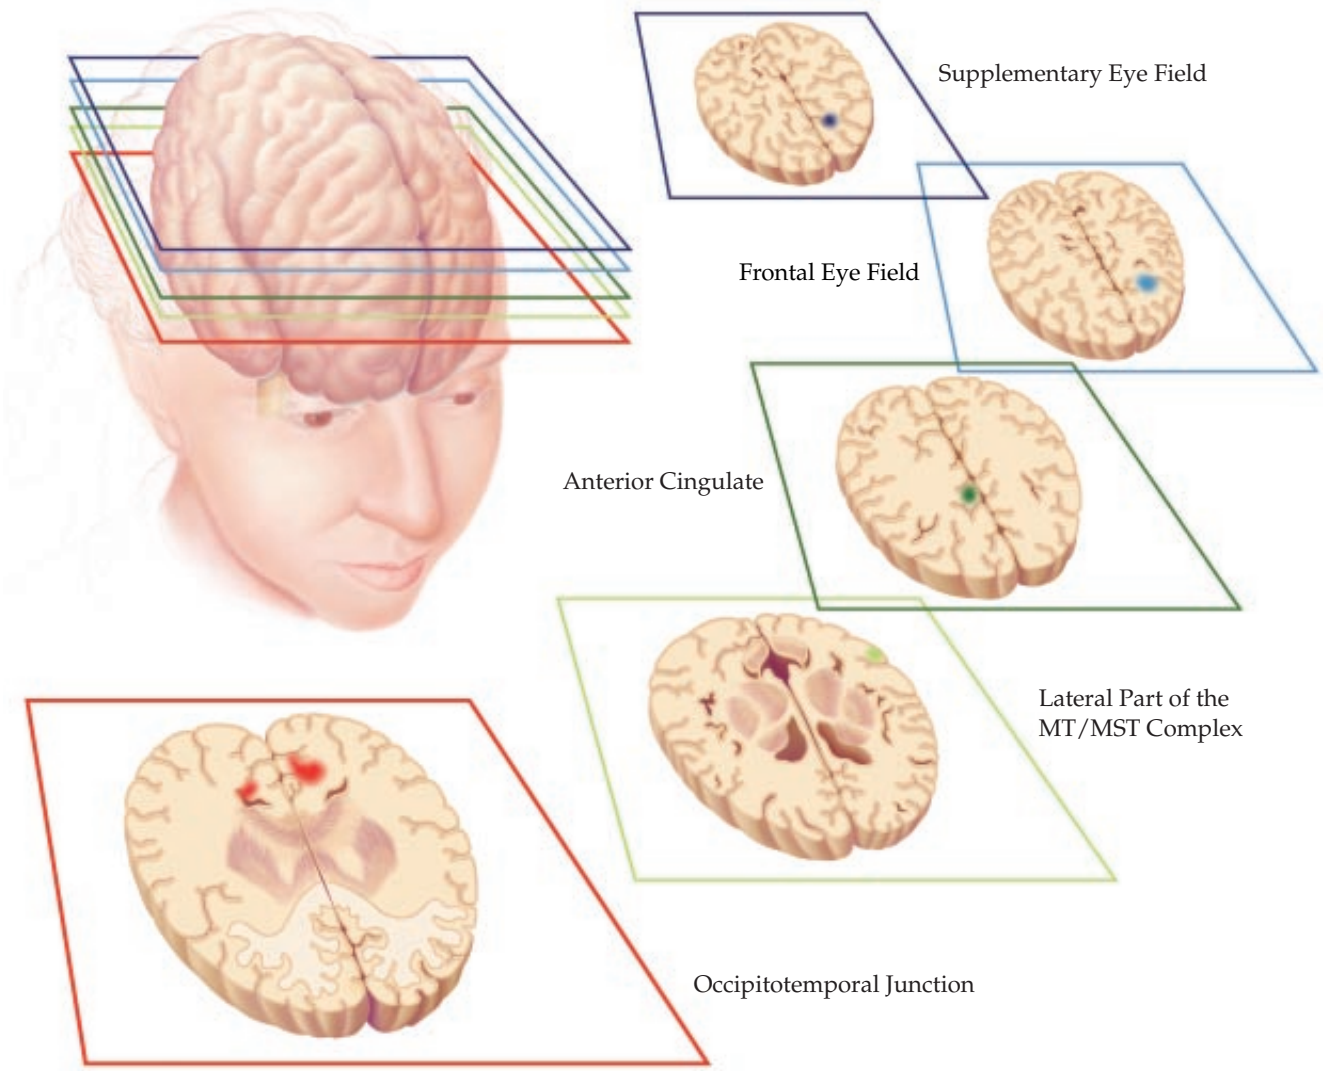

Figure 1 **In a functional magnetic resonance imaging (fMRI) study, schizophrenic patients and healthy comparison subjects were matched on the basis of how well they were able to keep their eyes on a moving target (so-called smooth-pursuit eye movement). Earlier data suggested that persons at risk for schizophrenia use a strategy different from that of healthy control subjects to maintain normal smooth pursuit. Whereas healthy persons depend more on the internal representation of target velocity (so-called extraretinal motion signals) and less on the immediate visual feedback from the retina (retinal motion signals), persons at risk for schizophrenia (i.e., relatives of schizophrenic patients) depended more on the retinal signals.[53] In schizophrenic patients who were able to maintain smooth pursuit, as well as in healthy control subjects, the fMRI analyses showed increased activation in some regions and decreased activation in others. A comparison of related brain activation in control subjects and relatives of schizophrenic patients showed that the latter had reduced activities in left frontal eye field, left supplementary eye field, anterior cingulate, and left medial superior temporal lobe; many of these areas have previously been identified as sites of extraretinal motion processing in nonhuman primates. In addition, relatives of schizophrenic patients showed increased activation in the occipitotemporal junction, an area at the medial part of the middle temporal (MT) lobe/medial superior temporal (MST) lobe that is commonly associated with retinal motion information processing.**

mental illnesses. If the patient does not have a mood disorder and the psychotic symptoms are accompanied by restricted affect, low drive, and speech disturbance [*see Table 2*], the probability of schizophrenia is high. The diagnosis can be made with greatest confidence, however, on the basis of the longitudinal pattern of the disorder, which includes the occurrence of prodromal symptoms before the initial episode, residual symptoms between psychotic episodes, and psychotic episodes that cannot be attributed to mood disturbance (e.g., manic or depressive psychosis) or other known causes of psychotic behavior [*see* Differential Diagnosis, *below*].

PHYSICAL EXAMINATION

Physical examination is unlikely to provide evidence for the diagnosis of schizophrenia but may help rule out rare cases of psychosis caused by physical ailments. Evidence of self-mutilation can alert the physician to potential risks and affect the choice of inpatient or outpatient treatment.

Although physical findings are not very informative for diagnosis, they are critical in guiding selection of drugs for treatment. About 12% to 15% of schizophrenic patients manifest motor abnormalities before antipsychotic drug treatment is initiated. The finding of involuntary movements during physical

examination should direct the clinician to select a drug with a low potential for causing extrapyramidal symptoms or tardive dyskinesia. The presence of obesity dictates avoidance of drugs that increase weight.

LABORATORY TESTS

Toxicology screens are important in the workup of schizophrenia. Positive results may provide an alternative explanation for psychosis or may confirm comorbid substance abuse. Lipid profiles may identify patients at risk for hyperlipidemia associated with the use of some antipsychotic drugs, and a metabolic profile may identify patients at risk for diabetes. An electrocardiogram is relevant as a baseline measure for patients who are subsequently prescribed antipsychotic medications that can prolong the QT interval. Electroencephalography may be used to exclude the diagnosis of temporal lobe epilepsy. Rarely, unusual presentations (e.g., the emergence of symptoms of schizophrenia after head trauma) may require magnetic resonance imaging of the brain to rule out other causes of psychosis.

There are a number of physiologic and neuroimaging findings that are helpful in distinguishing groups of schizophrenic patients from groups of healthy control subjects. However, these findings may not be unique to patients with schizophrenia, and their accuracy is inadequate for diagnostic purposes. Such findings include impairment of sensory gating as measured by evoked-potential response of P50 and by oculomotor physiologic dysfunction and prefrontal cortical dysfunction as assessed by brain imaging studies. Differences found on testing groups of schizophrenic patients have not led to the development of tests with adequate sensitivity and specificity and positive or negative predictive power for diagnosis in individual cases.

Table 1 Diagnostic Criteria for Schizophrenia[54]

All six criteria must be met for a patient to fit the diagnosis of schizophrenia.

1. *Presence of psychosis for a significant length of time*
   Any two or more of the following symptoms must be present for a significant duration during a 1-month period (less if treated):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech
   4. Negative symptoms (e.g., lack of emotion and social drive and engagement)
   5. Grossly disorganized behavior
2. *Deterioration in social/occupational functioning*
   Functioning in at least one of the following areas is markedly below the level achieved before the illness:
   1. Work
   2. Interpersonal relationships
   3. Self-care
3. *Continuous signs of the disturbance for 6 months*
   The 6 months must include at least 1 month of positive symptoms. However, during prodromal or residual periods, the disturbance may be manifested by negative symptoms only.
4. *Exclusion of schizoaffective and mood disorders*
   No major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; if such episodes have occurred, their total duration has been much briefer than the periods of active and residual psychosis.
5. *Exclusion of substance-induced or medical disorders*
   The disturbance is not the result of direct physiologic effects of a substance or caused by a medical condition.
6. *Relationship to pervasive developmental disorders*
   If the patient has a history of autistic disorder or another pervasive developmental disorder, a diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least 1 month.

Table 2 Cognitive Disturbances Seen in Schizophrenic Speech

Abstract Thought Impairment
For example, when asked to interpret a proverb, the patient may provide a concrete description

Blocking
A halt in the flow of speech; the person is unable to continue the train of thought even with cueing

Clang Associations
Speech connections based on similarities in the sounds of words rather than on their meanings

Delayed Response
Long latency before responding to questions; at the extreme, the patient may be mute

Poverty of Content
The speech conveys little information even when it is more or less coherent

Tangentiality
Response to questions such that the answers become progressively less related to the original question

Loosening of Associations
Speech consisting of ideas that have no discernible connection to one another

Word Salad
Incoherent speech from extreme loosening of associations

Genetic Testing

Rapidly advancing knowledge concerning genotypic vulnerability to schizophrenia may lead to better susceptibility testing. However, it appears unlikely that genotypes unique to schizophrenia will be defined. At present, genetic information mainly suggests that a number of genes that individually make minor contributions to vulnerability may combine in persons with schizophrenia and may interact with certain environmental etiologic factors. It is also suggested that genes conferring vulnerability to schizophrenia may overlap with those that predispose to depression and bipolar disorder. If these suggestions prove true, specific genetics-based diagnoses of schizophrenia are unlikely to be forthcoming in the near future. However, genetic testing may eventually help guide therapy in individual patients by indicating their likelihood of response and risk of side effects with specific drugs.

Differential Diagnosis

Because schizophrenia is defined as a psychotic illness with functional impairments, distinguishing schizophrenia from normalcy is usually not difficult. However, because the clinician depends on information provided by patients regarding their inner experiences, recognition of mild psychosis is difficult in patients who are guarded and who are not forthcoming with information.

Schizotypal personality disorder shares some of the clinical characteristics of schizophrenia, such as social and physical an-

hedonia, suspiciousness, magical thinking, blunting of affect and emotional experience, and poor functioning. However, schizotypal patients do not experience overt and persistent psychotic symptoms, although rare and brief psychotic symptoms may occur.

In a patient with persistent psychosis, the differential diagnosis consists mainly of affective disorders with psychosis, substance abuse, and delusional disorders. Psychosis that coincides with depression is typically associated with such affective features as delusions of poverty or accusatory voices. Similarly, delusions of grandeur are common during manic episodes. Psychotic symptoms in affective disorders typically follow the emergence of depression or mania and fade once the affective symptoms recede. Depressive symptoms often occur in schizophrenia, particularly in the first episode. Alternatively, excitement and hyperactivity in patients with schizophrenia may mimic manic symptoms. Differential diagnosis depends on the timing of psychosis in relation to the occurrence of affective symptoms and the content of delusions and hallucinations. Psychotic symptoms can be caused by many medical conditions [*see Table 3*], as well as by alcohol, illicit drugs, and over-the-counter and prescription medications [*see Table 4*]. The history and toxicology screen can rule out psychosis caused by drug abuse, such as use of PCP or the long-term abuse of steroids. Delusional disorder is diagnosed on the basis of persistent and circumscribed delusions (more realistic and less bizarre than those associated with schizophrenia) in the absence of disorganization and negative psychopathology.

Occasionally, neurologic conditions such as brain tumor or temporal lobe epilepsy may be misdiagnosed as schizophrenia. When such conditions are suspected, MRI and EEG can help with the diagnosis.

Table 3 Drugs and Medications Commonly Associated with Psychotic Symptoms

Abused Drugs
- Alcohol (withdrawal and alcoholic hallucinosis)
- Amphetamines
- Cocaine (especially free-base or crack)
- Marijuana (panic reaction)
- Phencyclidine (PCP) and hallucinogens (acute intoxication and flashbacks)
- Sedative-hypnotics (withdrawal)

Analgesics
- Meperidine (toxic metabolite)
- Nonsteroidal anti-inflammatory drugs
- Pentazocine and other opiate mixed agonist-antagonists

Antibiotics
- Antituberculous drugs (e.g., cycloserine, isoniazid, rifampin)
- Many others

Anticholinergics
- Anticholinergic antiparkinsonians
- Antihistamines (e.g., diphenhydramine)
- Atropine and derivatives
- Cyclic antidepressants
- Low-potency antipsychotic drugs (e.g., thioridazine, clozapine)
- Meclizine
- Scopolamine

Cardiovascular Drugs
- Antiarrhythmics (e.g., amiodarone, digitalis, procainamide)
- Captopril

Dopamine Agonists
- Amantadine
- D_2 dopamine receptor agonists (e.g., bromocriptine, pergolide)
- Levodopa

Endocrine Drugs
- Estrogens, testosterone
- Glucocorticoids and adrenocorticotropic hormone (ACTH)
- Thyroid hormone (overdose)

H_2 Receptor Antagonists
- Cimetidine, ranitidine

Stimulants and Sympathomimetics
- Dextroamphetamine
- Methylphenidate
- Over-the-counter decongestants (e.g., pseudoephedrine), diet pills, and pep pills

Table 4 Medical Conditions Associated with Psychotic Symptoms

Cancer and Hematologic Malignancies
- CNS neoplasm
- Hyperviscosity syndromes (resulting from hematologic malignancy)
- Paraneoplastic syndromes (e.g., limbic encephalitis)

Cardiovascular
- Anoxia and postanoxic encephalopathy
- Hypertensive encephalopathy

Infections and Sequelae
- AIDS encephalopathy
- Encephalitis, meningitis, brain abscess
- Lyme disease
- Neurosyphilis

Metabolic and Endocrine Disorders
- Acute intermittent porphyria
- Addison disease
- Cushing disease
- Hepatic encephalopathy
- Hypocalcemia and hypercalcemia
- Hypoglycemia
- Hypothyroidism and hyperthyroidism

Neurologic Disorders
- Alzheimer disease
- Complex partial seizures
- Huntington chorea (Huntington disease)
- Multiple sclerosis
- Stroke
- Wilson disease

Nutritional Deficiencies
- Folic acid deficiency
- Pellagra (niacin deficiency)
- Vitamin B_{12} deficiency

Rheumatologic Disorders
- Lupus cerebritis

Management

Patients with schizophrenia require acute treatment for psychotic exacerbations; long-term treatment, involving mainte-

nance and prophylactic strategies to sustain symptom improvement and prevent recurrence of psychosis; and support for living. Unfortunately, the avolitional (negative) symptoms and impairments in cognition, which account for poor functional outcomes, show little response to current treatments. The future may offer treatment for these nonpsychotic aspects of the illness, as well as preventive measures for persons at high risk for schizophrenia.

ACUTE TREATMENT

The first-line therapeutic approach for an acute exacerbation of schizophrenia—whether it is the first episode or a relapse—involves antipsychotic medication (see below). To determine whether the patient requires hospitalization, the physician must evaluate patient safety and cooperation. This evaluation is clinically based and often includes discussion with family members or other informants. The patient's ability to care for himself or herself, the setting most likely to ensure adherence to therapy, and the risk of suicidal or aggressive behavior are at the forefront of this evaluation.

MAINTENANCE THERAPY

Most patients show at least a partial therapeutic response to the initiation of antipsychotic medication. Longer-term care involves maintenance therapy to minimize the expression of psychosis and prevent or delay psychotic exacerbation. Some patients will have a full remission of psychotic symptoms, but even in such cases, the continuous administration of antipsychotic drugs will delay recurrence of a psychotic exacerbation. Psychosocial treatments and pharmacologic treatments have proved effective in reducing exacerbation rates over the long term. The clinical relationship involved in these treatments also provides for ongoing evaluation of life needs, suicide risk, medication adherence, and success in coping with the many practical problems facing individuals with a chronic debilitating disease. Many patients need assistance in obtaining shelter, in developing an occupational niche or receiving vocational rehabilitation, and in participating in substance abuse programs.

Involvement of the people in the patient's life is critically important. Family members and significant others need to be educated about the disease, its treatment, and the approach to changes in clinical status.

If the patient recovers from psychosis, remains free of psychotic symptoms, and is stable for several years, the gradual discontinuance of medication may be warranted, provided that close clinical observation can be ensured. However, most patients will experience subsequent exacerbations. Early detection and intervention may be effective. Because a few patients have only a single episode of psychosis and may not require continuous antipsychotic treatment and because the risk of medication side effects is substantial, a medication-free trial is justified in selected cases.

Pharmacologic and psychosocial management need to be integrated. The two approaches appear to be synergistic in their effects, and each is crucial to the effectiveness of the other. Early detection of exacerbation is most likely when continuous clinical observation is provided in the context of psychosocial treatment; successful participation in skills training, vocational rehabilitation, living arrangements, and substance abuse treatment is most likely to be successful in the context of continuous antipsychotic drug treatment. For patients who have an established pattern of exacerbations and remission, continuous antipsychotic drug treatment is recommended for relapse prevention.

Table 5 Antipsychotic Drugs Used in the Treatment of Schizophrenia

Antipsychotic Category	*Drug (Trade Name)*
First-generation (neuroleptic)	Chlorpromazine Fluphenazine Haloperidol (Haldol) Loxapine (Loxitane) Mesoridazine (Serentil) Molindone (Moban) Perphenazine (Trilafon) Pimozide (Orap) Thioridazine Thiothixene (Navane) Aripiprazole (Abilify)
Second-generation (atypical)	Clozapine (Clozaril) Olanzapine (Zyprexa) Quetiapine (Seroquel) Risperidone (Risperdal) Ziprasidone (Geodon)

PHARMACOLOGIC TREATMENT

Antipsychotic Drugs

The antipsychotic drugs used to treat schizophrenia have a wide variety of pharmacologic properties, but all are antagonists acting at the postsynaptic D_2 dopamine receptors in the brain. Conventional, or first-generation, antipsychotic agents are often referred to as neuroleptics because of their neurologic side effects. Second-generation antipsychotic drugs also act at the dopamine receptors but are less likely to exhibit neuroleptic effects; these agents have been termed atypical antipsychotics [*see Table 5*].

Antipsychotic drug therapy is usually initiated at low doses (e.g., 1 to 5 mg of haloperidol, 5 mg of olanzapine, or 2 mg of risperidone administered once or twice a day) and titrated upward. Although the onset of therapeutic effect occurs promptly, symptom reduction is gradual, occurring over many weeks. Optimal dosing parameters have not been established for most of these drugs; an increase in dosage often results in an increase in adverse effects without a commensurate increase in therapeutic response. Blood levels have not proved effective in guiding dosing decisions; clinical response is the best guide for titrating the dose of an antipsychotic agent. The clinical effect of antipsychotics is to diminish positive psychotic symptom expression and reduce relapse rates. Although sedation may be a side effect and diminished anxiety may be a clinical effect, the primary value of these drugs is their remedial effect on positive psychotic symptoms, not their sedating or tranquilizing properties. The antipsychotic efficacy of these drugs extends beyond schizophrenia to include reducing positive psychotic symptoms associated with mental illnesses other than schizophrenia. In contrast to their effect on positive psychotic symptoms, first-generation antipsychotic agents have not been shown to be effective for either primary, enduring negative (deficit) symptoms or the cognitive impairments observed in schizophrenia.

The first atypical antipsychotic was clozapine. During the 1970s, clozapine was shown to be effective in some cases in which conventional antipsychotics did not work. However, cessation of white blood cell production occurs in approximately

1% of patients receiving clozapine; after a series of deaths from agranulocytosis in Finland during the mid-1970s, the use of clozapine declined in Europe and the drug was not marketed in the United States. Interest in clozapine was rekindled by the results of a large-scale multicenter study that yielded convincing evidence of the superior efficacy of clozapine for ameliorating positive psychotic symptoms in treatment-resistant patients with schizophrenia.[44] Consistent with the worldwide experience in the late 1970s and early 1980s, the study also showed that clozapine can be used with relative safety, provided that patients are carefully monitored for agranulocytosis. Clozapine has many pharmacologic actions and weaker affinity for the D_2 dopamine receptor; however, the basis for its superior antipsychotic action in treatment-resistant cases is not known.

The success of clozapine spawned considerable interest in the development of other antipsychotics for the treatment of schizophrenia. In the 1990s, five new antipsychotics were introduced in the United States: risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole [*see Table 5*]. It was hoped that these new drugs would have the efficacy of clozapine but without the risk of agranulocytosis and the other side effects that have limited clozapine's use. However, these new medications appear to be no more effective than the conventional antipsychotics for reducing positive psychotic symptoms. This is not surprising, given that both first- and second-generation antipsychotic drugs act as dopamine antagonists (although aripiprazole, as a partial agonist, has a different pharmacologic mechanism). These new drugs' main advantage over the conventional antipsychotics is their substantially lower incidence of extrapyramidal motor side effects. This decrease in side-effect burden may account for their apparent greater effectiveness, and it appears to have reduced the incidence of persistent dystonia and tardive dyskinesia in patients with chronic schizophrenia. Several of the second-generation antipsychotic drugs have shown greater benefit than the conventional antipsychotic agents for the treatment of depressive symptoms and the prevention of relapse and rehospitalization. These considerations have led to the second-generation antipsychotics' replacing conventional antipsychotics as first-line pharmacologic treatment for first-episode and chronic schizophrenia; this shift is controversial, however, in part because the new drugs are substantially more expensive than conventional antipsychotics. A recent study from the Department of Veterans Affairs has rekindled this debate: Rosenheck and colleagues found little difference in clinical response between patients given one of the newer drugs and those given moderate doses of haloperidol; moreover, the cost advantage of all aspects of care favored the first-generation drug.[45]

The second-generation antipsychotics are not without their limitations. Several of these agents have been associated with the development of clinically significant metabolic disturbances, including weight gain, hyperlipidemia, and new-onset type 2 diabetes mellitus. These side effects are of particular concern because patients with schizophrenia are already at increased risk for cardiovascular disease as a result of their lifestyle. Long-term studies will eventually clarify whether the decreased risk of extrapyramidal side effects, including tardive dyskinesia, warrants the increased risk of these metabolic side effects.

Do second-generation antipsychotic agents reduce the negative symptoms and cognitive impairment of schizophrenia? A number of studies have indicated that second-generation antipsychotic drugs are more effective than the first-generation drugs for negative symptoms, but the differences are usually related to concurrent changes in extrapyramidal or depressive symptoms, or excessive dosages of the first-generation drug used for comparison. In studies that have controlled for these potential sources of artifact, the apparent superior efficacy of the new-generation antipsychotics disappears. A similar story is emerging for the comparative efficacy of second-generation and conventional antipsychotics with regard to cognitive impairments. First-generation antipsychotic agents produce little improvement in cognitive function, even when they significantly relieve positive psychotic symptoms; moreover, at higher doses, they may impair cognitive function. Second-generation agents improve performance on neuropsychological measures of cognitive function, but the effect is relatively modest, and patients continue to exhibit considerable cognitive impairments compared with normal control subjects. The difference in cognitive effect between first- and second-generation antipsychotic agents is less pronounced when second-generation drugs are compared with conventional antipsychotics given at lower doses.[46]

Other Agents

The limited efficacy of conventional and atypical antipsychotic drugs against the negative symptoms and cognitive impairment of schizophrenia has led researchers to investigate drugs in other categories. Glutamatergic agents that bind to the glycine site of the NMDA glutamatergic receptor have shown potential utility for the treatment of primary, enduring negative (deficit) symptoms. Preliminary controlled clinical trials of glycine, D-cycloserine, and D-serine have produced encouraging results. In part because of the genetic linkage findings implicating the alpha-7 nicotinic receptor gene in the physiologic deficits of schizophrenia, several trials have examined the acute effects of nicotine on cognitive deficits in schizophrenia. These studies have demonstrated significant but transient reversal of impairments in sensory gating, attention, and aspects of eye tracking.[47,48] These results suggest that heavy smoking in schizophrenia may partly be self-medication on the part of the patients and have encouraged the search for nicotinic agonist drugs that have long-term efficacy. The delineation of the physiology of normal cognition has also led researchers to consider treating cognitive impairment in schizophrenia by augmenting antipsychotic therapy with drugs from other classes. Dopaminergic, adrenergic, and other pharmacologic agents are currently under study.

Augmentation strategies have also been used to treat positive psychotic symptoms that fail to respond to antipsychotic agents. However, lithium, antiepileptic drugs, antidepressants, and antianxiety agents have not been shown to substantially reduce these symptoms. It is theoretically possible that some small patient subgroups may respond to a class of drugs other than antipsychotics, but there is no way to identify such patients in advance, so it is difficult to prove or disprove this proposition. On the other hand, drugs from other classes may be effective for specific symptom targets. For example, antianxiety drugs reduce anxiety in schizophrenic patients, and drugs used for depression and mania in affective disorders are sometimes useful for these symptoms in schizophrenia.

Aggression is a special problem in schizophrenia. When aggression is the result of psychosis, antipsychotic drugs are the best treatment. Aggression may also be caused by akathisia, an intense inner restlessness and tension caused by some antipsychotic drugs; this is treated with a change in drug or the addition of another drug to counteract this side effect. Otherwise,

hostility with the threat of violence is a difficult clinical issue that is only partly addressed with concomitant administration of beta blockers such as propranolol. New-generation antipsychotic drugs appear advantageous for this aspect of the illness. Close supervision, restraints, and the use of a safe room continue to be necessary in the care of a minority of patients.

It is now common practice to add a second or third antipsychotic drug to the regimen in patients with persistent positive psychotic symptoms. There is little theoretical basis for this practice, and there is no research evidence to support this empirical strategy. The probable effects are an increase in side effects and poorer patient adherence to therapeutic recommendations.

ELECTROCONVULSIVE THERAPY

Before the introduction of antipsychotic drugs, electroconvulsive therapy (ECT) was frequently used in the treatment of patients with schizophrenia. ECT is particularly effective for catatonic stupor, excitement, and acute psychotic conditions. Results are similar to those obtained with antipsychotics—that is, positive symptoms are reduced, but long-term functional impairments are not reversed.[49] Although ECT is safe and painless, it has several limitations: it is not widely available, litigation and societal attitudes restrict its use, and any therapeutic advantage gained in an initial series of treatments is not easily maintained. Also, there is no compelling evidence that electroconvulsive treatments are effective in patients who are resistant to antipsychotic drugs. For these reasons, drug treatment is generally preferred.

PSYCHOSOCIAL INTERVENTIONS

The debate over whether schizophrenic patients should be treated with pharmacologic or psychosocial treatments has given way to the search for how these treatments should be optimally integrated. Controlled clinical trials have conclusively demonstrated that intensive psychotherapy is less effective than pharmacologic treatment; that it is not superior to cheaper, less ambitious psychosocial forms of psychotherapy; and that it should not be considered as an alternative to the use of antipsychotic drugs. On the other hand, studies have repeatedly demonstrated that supportive forms of psychosocial treatment are entirely compatible with drug treatment and can increase the effectiveness of overall treatment, reduce the amount of medication needed, enhance patient participation in the full range of treatment, and optimize social and occupational functioning. Especially impressive are studies documenting the considerable additional benefit achieved in reducing relapse and hospitalization rates when family therapy and education programs are added to maintenance pharmacologic treatment. These studies make it clear that psychosocial and rehabilitative interventions have become essential components of the comprehensive treatment of patients with schizophrenia.[50-52]

Psychosocial and rehabilitation interventions include cognitive-behavioral therapy for treatment-resistant positive psychotic symptoms; supportive, problem-solving, educationally oriented psychotherapy; family therapy and education programs aimed at helping patients and their families understand the patient's illness, reduce stress, and enhance coping capabilities; social and living skills training; supported employment programs; and the provision of supervised residential living arrangements. The development and increased utilization of psychosocial services has been complemented by the evolution of services designed to decrease the utilization of inpatient hospital services and maintain the patient in the community. Assertive community treatment teams provide intensive outreach services to patients who are unable to be maintained in the community with traditional outpatient clinical treatment. Crisis management services, including 24-hour crisis beds and partial hospitalization programs, represent alternatives to hospitalization during periods of symptom exacerbation.

The development of these services reflects the ongoing shift in the treatment of schizophrenic patients from a hospital-based to a community-based system of care. When optimal treatment with these services is provided, the rewards of therapeutic accomplishment, reduction in morbidity, and cost benefits are profound and rival therapeutic accomplishments found anywhere in medicine. The demonstrated benefits of these services challenge the field to establish an adequate community-based treatment approach that is prepared to meet the challenge and demands of broad-based integrated treatment. Society has failed to meet the challenge of providing evidence-based treatment to most persons who suffer from schizophrenia.

FUTURE TREATMENT

Intervention in the prepsychotic and early psychotic phases of schizophrenia is an unmet challenge in schizophrenia care. Early identification and treatment would clearly be preferable, but the earliest indicators of schizophrenia are usually not the psychotic features. Psychosocial treatment for nonpsychotic manifestations needs to be developed, just as pharmacologic treatments for cognitive impairments and negative psychopathology are required to address these features in patients at high risk for psychosis. It is hoped that gene discovery will lead to the development of new drugs targeting each domain of psychopathology.

The advancing knowledge of human gene and protein sequences is altering the course of schizophrenia research. These technologies promise to help delineate the molecular pathophysiology of the disease and define novel molecular targets that will provide a basis for drug development. Clinical and postmortem studies are presenting more compelling definitions of disease entities and phenotypes within the schizophrenia syndrome, which should permit the effective application of advances in genomics and proteomics.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII SCHIZOPHRENIA

William T. Carpenter, Jr., m.d.
Gunvant K. Thaker, m.d.

As recently as the mid-20th century, schizophrenia was one of the most devastating psychiatric illnesses. No effective treatment was available, and most patients suffered lifelong debilitating symptoms and required institutionalization. Research during the latter part of the 20th century better defined the syndrome, provided clues to the causes, clarified the pathophysiology, provided evidence for effective treatments and against potentially harmful ones, and permitted the transfer of many schizophrenic patients from inpatient institutions to less restrictive outpatient facilities. However, challenges remain: specific causes and causal pathways are unknown, pathophysiology is ill defined, treatments are effective only for the psychotic aspect of the syndrome, and homelessness has replaced institutionalization.

Definition

Schizophrenia is a clinical syndrome probably comprising several as-yet undefined disease entities. There is substantial heterogeneity between cases, which presumably reflects multiple overlapping etiologic factors, including contributions from several genes. The presence of schizophrenia is indicated by chronic psychotic symptoms, especially hallucinations and delusions. Disorganization of thought and behavior are common and distinguish schizophrenia from the many other causes of reality-distortion symptoms (e.g., psychotomimetic drugs). Diminished emotional experience and expression, low drive, and reduced speech are observed in a subgroup of patients. Most patients have subtle impairments in cognition. Cognitive impairments and the emotional and social aspects of the disease often appear early in life; the psychotic symptoms typically begin in late adolescence or early adulthood in men and a little later in women.

Subclassification

At the end of the 19th century, Emil Kraeplin conceptualized dementia praecox as comprising seemingly discrete diseases known as hebephrenia, catatonia, and paranoia. Eugen Bleuler suggested renaming dementia praecox as *schizophrenia*, a term he coined to capture the split within thought and between thought and emotion. Bleuler also added simple schizophrenia as a fourth subtype of the disease.

Throughout most of the 20th century, the clinical presentation of schizophrenia was often described in terms of specific subtypes. These subtypes included hebephrenic, paranoid, catatonic, and simple schizophrenia. Hebephrenic schizophrenia (now termed disorganized schizophrenia) is characterized by shallow and incongruent affect and disorganized thought and behavior. Paranoid schizophrenia is characterized by predominance in males; a later age of onset; intact cognition and affect; and hallucinations and delusions, often persecutory and bizarre. Catatonic schizophrenia is characterized by extreme psychomotor manifestations, including stupor, prolonged posturing, or excitement; it must be differentiated from periodic catatonia, which is a separate syndrome unrelated to schizophrenia. For unknown reasons, catatonic schizophrenia is now rarely seen in developed countries. Simple schizophrenia denotes a milder psychosis (i.e., fewer hallucinations and delusions and less disorganization), with cases typically featuring a schizoid lifestyle of reduced emotional experience and expression and reduced social drive and engagement. A later term, schizoaffective schizophrenia, described the combination of mood disturbances—mania or depression—with schizophrenic psychotic manifestations. Other subtypes were suggested but did not gain wide acceptance.

In general, however, schizophrenia has been approached as a diagnostic class rather than in terms of these subtypes. The traditional subtypes appear not to differ substantially in etiology, pathophysiology, or treatment response. Moreover, a patient's subtype may change over time: a patient who presents with paranoid schizophrenia may later be seen to have disorganized schizophrenia; a patient who presents with schizoaffective psychosis may eventually be seen to have a disorganized or undifferentiated subtype.

Another approach to subclassification categorizes cases on the basis of three distinct domains of psychopathology: reality distortion (i.e., hallucinations and delusions), disorganization of thought and behavior, and negative symptoms such as reduced drive and affect. Kraeplin described two "maladies"—dissociation and avolition—as the central features of dementia praecox, but in the late 20th century, psychiatrists placed diagnostic emphasis on reality distortion and disorganization of thought. It turns out that many patients do not manifest negative symptoms, whereas others have chronic reduction in drive, reduced expression of emotion, and poverty of speech. We have divided schizophrenia into two subgroups: deficit schizophrenia, in which schizophrenia causes negative symptoms and psychosis; and nondeficit schizophrenia, in which negative symptoms are absent. Clinical features, family history, neuroanatomy, treatment response, course of illness, and postmortem pathology suggest that deficit schizophrenia is a separate disease entity within the schizophrenia syndrome. Deficit schizophrenia constitutes about 15% to 20% of all schizophrenia cases and appears to occur predominantly in males.[1]

Epidemiology

The annual incidence of schizophrenia approximates one in 10,000 adults younger than 60 years, with a lifetime risk of 0.8. The onset of psychosis (i.e., reality distortion or disorganization of thought) usually occurs at about 17 to 27 years of age in males and at 20 to 37 years in females. Population-based estimates suggest that the lifetime incidence of the disease is roughly equal in males and females; in clinical populations, however, males often constitute the majority of patients. Females have often been reported to have a more favorable course of illness. One explanation is that males are more likely to have deficit schizophrenia, which tends to have a chronic course with poor functional oucome.[2]

Race does not appear to influence the distribution of schizophrenia. Some United States studies have suggested a racial bias in diagnostic practice, with the term schizophrenia being used more in African-American patients and the term affective psychosis used more in white Americans.[3]

Geographically, schizophrenia appears to be evenly distributed throughout the world.[4] A country's stage of economic development, degree of urbanization, or climate seem to have little influence on schizophrenia prevalence. However, the course of the illness has been more favorable in developing countries than in developed countries. This may reflect the tendency for developing countries to have sociocentric cultures and for developed countries to have egocentric cultures. Sociocentric cultures may be more supportive of marginal function than egocentric cultures, in which demands for autonomous function may be particularly challenging for persons with schizophrenia. The difference may also reflect the inclusion of cases with a better prognosis in the syndrome definition; patients with acute onset of bizarre psychosis tend to have a more favorable course of illness.

Decreases in rates of schizophrenia were reported in the second half of the 20th century.[5] However, these decreases have not been substantiated and may simply reflect increasingly stringent criteria for the diagnosis.

Schizophrenia is the fourth leading cause of disability in adults worldwide. In the United States, about 80% of persons with schizophrenia are unemployed, and many of the remainder are underemployed. Perhaps a third of homeless persons have schizophrenia.[6]

More than half of schizophrenic patients abuse substances, especially alcohol.[7] Over 80% of schizophrenics smoke cigarettes, and nicotine intake in schizophrenics who smoke is well above that of nonschizophrenic smokers.[8] Smoking represents a substantial financial burden to this generally impoverished population and combines with other lifestyle risk factors (e.g., inadequate diet and exercise) to place schizophrenic patients at increased risk for diabetes, cardiovascular disease, and cancer.

Etiology and Genetics

Considerable data suggest that schizophrenia is a heritable illness. The risk of the disease rises with the closeness of kinship to a schizophrenic proband. Compared with the risk in the general population, the risk is fivefold higher in second-degree relatives of schizophrenia patients, 10-fold to 15-fold higher in first-degree family members and dizygotic twins, and 40-fold to 50-fold higher in monozygotic twins or in persons whose parents both have schizophrenia.[9] There is also higher risk in adopted biologic relatives of schizophrenia probands than in their adoptive families.

Other data strongly suggest that environmental factors, either on their own or interacting with genetic factors, play a critical role in causing or modifying the clinical presentation of the illness.[10] Most of the environmental factors associated with schizophrenia are active early in development, particularly during the intrauterine period. These include maternal malnutrition; infections during critical periods of fetal development; fetal hypoxia; and other birth and obstetric complications. Further supporting an environmental role is the finding that overall, patients with schizophrenia were more likely to have been born during the winter, whereas the subgroup of patients with deficit schizophrenia were more likely to have been born during the summer.[11] How season of birth affects risk is unclear. Environmental insults that occur later in life, such as use of psychoactive drugs, also play a role.

The initial search for genes that might cause schizophrenia produced disappointing results. The first significant linkage of a broadly defined schizophrenia phenotype to a specific locus, chromosome 5q11-q13, stirred excitement, but subsequent studies failed to replicate this finding.[12] Ensuing linkage studies identified several chromosomal loci, some of which were likely false positive findings, given that replications were not forthcoming. Significant linkage findings that were subsequently replicated by other studies implicated regions on chromosomes 1, 5, 6, 8, 13, 15, and 22.[13,14] Most of these findings were not robust, however; in addition, some studies failed to identify linkages at the same locus, and many replicating studies only suggested linkage (i.e., log odds ratio scores ranged from 2 to 3). Further investigation of these loci has identified several candidate genes: *RGS4,* the dysbindin gene (*DTNBP1*), neuregulin 1, the alpha-7 nicotinic receptor gene, *COMT, G72,* and *GAD 65/67*.[15-21] Further work is needed to identify other candidate genes using other genetic approaches (see below) and to confirm the role of candidate genes in the etiology, pathophysiology, and treatment of schizophrenia.

The search for genes in schizophrenia has proved particularly challenging because of the complex and multifactorial nature of the disorder. It appears that many genes may cause vulnerability to schizophrenia, each with a modest effect, and that these genes probably interact with one another and with environmental factors. Thus, the clinical phenotype of schizophrenia may well be the common expression of a variety of genotypes; this may explain failures to replicate identified disease loci.

Arguing that schizophrenia encompasses multiple phenotypes of different genetic vulnerability profiles, several investigators have focused on a search for the genes underlying specific deficits seen in schizophrenia. Freedman and colleagues, using an electrophysiologic measure of sensory gating, demonstrated that a deficit in sensory gating in familes with schizophrenia is a result of an autosomal dominant effect of a single gene, the alpha-7 nicotinic receptor gene, on chromosome 15q14.[22] Other phenotypes that are associated with schizophrenia and that have been used in the search for schizophrenia-related genes are smooth-pursuit eye movement deficit; cognitive impairments in dimensions of attention, language, and memory; deficits in levels of the neuronal marker *N*-acetyl-aspartate in the hippocampal region; and abnormal membrane phospholipid metabolism in the prefrontal cortex, as measured by phosphorus-31 magnetic resonance spectroscopy.[23,24] Preliminary findings have suggested linkage of the smooth-pursuit phenotype to a locus on chromosome 6p and an association of prefrontal executive functional deficit with the *val* allele of the *COMT* gene.[25,26]

Pathophysiology

The pathophysiology of schizophrenia is not well understood. That schizophrenia results from an excess of dopamine has been the dominant hypothesis for decades, with several modifications and expansion of the hypothesis made during the 1990s.[27-29] Brain imaging studies have shown evidence of increased synaptic dopamine release in response to amphetamine administration in the striatum of schizophrenic patients.[30-32] Excess dopamine may explain the positive symptoms but not the negative symptoms or other aspects of the disease. The pathophysiologic mechanisms are presumably complex—even a deficiency of dopamine is a viable explanation for negative symptoms. The clinical observations that long-term phencyclidine (PCP) use produces a broader cluster of schizophrenia-like symptoms than seen with use of dopamine agonists has led to

speculation that a lack of glutamine may be involved. In contrast to the predominantly paranoid symptoms associated with long-term use of dopamine agonists, long-term PCP use produces negative symptoms and cognitive impairment in addition to reality distortion.[28] These schizophrenia-like symptoms from PCP are hypothetically initiated by blockade of the ion channel in the *N*-methyl-D-aspartate (NMDA) receptor complex, resulting in diminished glutamatergic neurotransmission. Both dopaminergic and glutamatergic terminals converge on the spines of pyramidal neurons in cortex. This suggests a shared mechanism by which glutamate and dopamine play a role in schizophrenia.[28,29] Although the two neurotransmitter systems share complex presynaptic and postsynaptic interactions,[33,34] modulation of glutamate release by D_1 dopamine receptors may mediate some of the effects of dopamine on psychosis.

Postmortem findings in schizophrenia have not been consistent. Furthermore, interpretation of postmortem findings is difficult because of the confounding effects of long-term drug treatment received by most patients. Massive cell loss or gliosis is generally not found, thus ruling out degenerative changes in the brain. Earlier postmortem histopathologic examination of the brains of patients with schizophrenia showed slight reductions in neocortical gray matter volume, decreased neuronal size, and neuronal disarray in several corticolimbic structures.[35-37] Subsequent investigations have focused on changes of neuronal connectivity or microcircuitry within the cortical layers and have noted an increase in cell packing density without a change in the number of neurons. These findings suggest a decrease in neuropil and a reduction in dendritic spine density on pyramidal neurons in the prefrontal cortex.[38,39] Using complementary DNA microarrays, Mirnics and colleagues noted a decrease in the expression of several genes involved in glutamate and γ-aminobutyric acid (GABA) transmission and in the regulation of presynaptic function and signal termination in the prefrontal cortex of patients with schizophrenia.[40] Together, these findings indicate a decrease in cortical or thalamic excitatory synaptic inputs to the pyramidal neurons.

In addition to drug probe and postmortem studies exploring the pathophysiology of schizophrenia, in vivo structural imaging studies of the brain show cortical volume reductions of one or more of the constituent structures of the medial temporal lobe (comprising the hippocampus, the amygdala, and the parahippocampal gyrus). Some studies note smaller prefrontal cortical volume, but this finding is not consistent across studies and may be limited to a subgroup of schizophrenic patients.[41] Reductions in thalamic volume, particularly of the thalamic nuclei forming part of the temporal-thalamic and prefrontal-thalamic circuitry, are also noted.[42] Functional imaging studies of neuronal circuitry during performance of cognitive tasks have found reduced neuronal activation in several cortical regions of schizophrenic patients compared with normal control subjects. However, interpretation of these data is somewhat confounded by the fact that schizophrenic patients perform poorly in such tasks. Several studies have examined brain activation during the performance of tasks that schizophrenic patients performed as well as the control subjects. These studies show that to perform equally well on a working memory task, schizophrenic patients show increased activation of the prefrontal cortical network. On other tasks, patients activated different cortical networks than were activated by healthy control subjects, suggesting that the patients used a different strategy or required compensatory mechanisms [*see Figure 1*].[43]

Clinical Course

Persons with schizophrenia often come to medical attention because of a public manifestation of bizarre behavior, disorganized thought, and reality-distortion symptoms. However, the history taken at first presentation often reveals a prolonged period of more subtle manifestations of the psychotic state, averaging perhaps 2 years; cognitive impairments and negative symptoms may have been present for years, if not throughout life. Although the course of schizophrenia varies considerably between individuals, a brief case description will illustrate several characteristic features of the disease.

A young man had a declining academic performance during the last 2 years of high school. He seemed to lose friends and motivation and gradually became a loner with strange ideas. He relinquished plans to attend college, and after high-school graduation he took a job. Soon after he began working, he acted in a bizarre and hostile manner in a confrontation; recurrence of this behavior caused dismissal from the job. He spent the next year working odd jobs, living at home, and displaying a growing indifference to his life goals. His parents suspected substance abuse and were concerned that he was not interested in having a girlfriend. On his 20th birthday, he was found sitting nude in the backyard; he claimed that he was receiving messages through solar radiation. He was taken to the emergency department.

As this case illustrates, the opportunity for intervention often occurs before the conspicuous onset of illness. Although the development of overt psychotic symptoms defines the onset of the illness, subtle impairments occur early in some patients and persist through the peaks and troughs of the psychotic symptoms. Some schizophrenic patients appear to be born with subtle motor and emotional impairments. Early in childhood and adolescence, many persons who later develop schizophrenia manifest a range of cognitive impairments on psychological tests of attention, memory, and executive function and on physiologic tests of information processing.

There is a variable course of illness after the initial psychotic break. Later in life, some patients even show clinical improvement in psychotic symptoms. In contrast, a smaller subgroup may show rapid cognitive decline. The manifestation of psychosis only modestly defines long-term morbidity, which instead is best understood in terms of functional capabilities, social and occupational roles, and quality of life. Cognitive impairments and negative symptoms are more robust determinants of these outcomes.

Diagnosis

CLINICAL MANIFESTATIONS

Diagnosis of schizophrenia is based on clinical manifestations and the clinical course. Internationally accepted criteria have been published in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders—Text Revision* [*see Table 1*] and in the 10th edition of the *International Classification of Diseases and Related Health Problems*.

The diagnosis of schizophrenia should be considered in a patient who presents with hallucinations and delusions. The presence of disorganized thought and behavior increases the likelihood of schizophrenia. In the absence of other known causes of such symptoms (e.g., substance abuse, temporal lobe epilepsy), the principal diagnostic task is to discriminate between severe

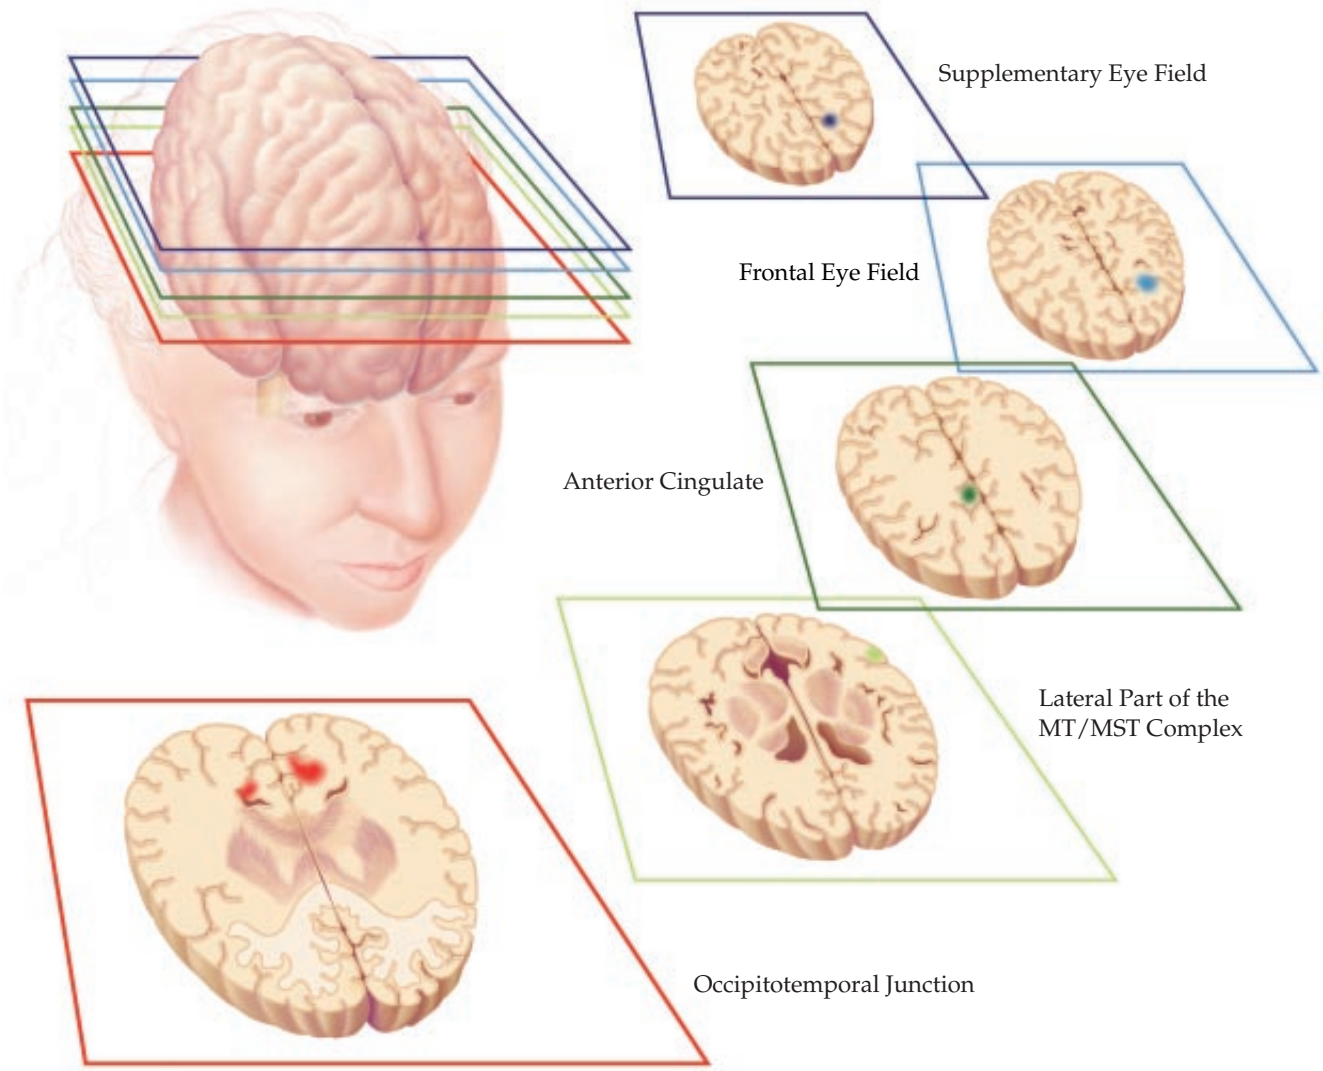

Figure 1 **In a functional magnetic resonance imaging (fMRI) study, schizophrenic patients and healthy comparison subjects were matched on the basis of how well they were able to keep their eyes on a moving target (so-called smooth-pursuit eye movement). Earlier data suggested that persons at risk for schizophrenia use a strategy different from that of healthy control subjects to maintain normal smooth pursuit. Whereas healthy persons depend more on the internal representation of target velocity (so-called extraretinal motion signals) and less on the immediate visual feedback from the retina (retinal motion signals), persons at risk for schizophrenia (i.e., relatives of schizophrenic patients) depended more on the retinal signals.[53] In schizophrenic patients who were able to maintain smooth pursuit, as well as in healthy control subjects, the fMRI analyses showed increased activation in some regions and decreased activation in others. A comparison of related brain activation in control subjects and relatives of schizophrenic patients showed that the latter had reduced activities in left frontal eye field, left supplementary eye field, anterior cingulate, and left medial superior temporal lobe; many of these areas have previously been identified as sites of extraretinal motion processing in nonhuman primates. In addition, relatives of schizophrenic patients showed increased activation in the occipitotemporal junction, an area at the medial part of the middle temporal (MT) lobe/medial superior temporal (MST) lobe that is commonly associated with retinal motion information processing.**

mental illnesses. If the patient does not have a mood disorder and the psychotic symptoms are accompanied by restricted affect, low drive, and speech disturbance [*see Table 2*], the probability of schizophrenia is high. The diagnosis can be made with greatest confidence, however, on the basis of the longitudinal pattern of the disorder, which includes the occurrence of prodromal symptoms before the initial episode, residual symptoms between psychotic episodes, and psychotic episodes that cannot be attributed to mood disturbance (e.g., manic or depressive psychosis) or other known causes of psychotic behavior [*see* Differential Diagnosis, *below*].

PHYSICAL EXAMINATION

Physical examination is unlikely to provide evidence for the diagnosis of schizophrenia but may help rule out rare cases of psychosis caused by physical ailments. Evidence of self-mutilation can alert the physician to potential risks and affect the choice of inpatient or outpatient treatment.

Although physical findings are not very informative for diagnosis, they are critical in guiding selection of drugs for treatment. About 12% to 15% of schizophrenic patients manifest motor abnormalities before antipsychotic drug treatment is initiated. The finding of involuntary movements during physical

examination should direct the clinician to select a drug with a low potential for causing extrapyramidal symptoms or tardive dyskinesia. The presence of obesity dictates avoidance of drugs that increase weight.

LABORATORY TESTS

Toxicology screens are important in the workup of schizophrenia. Positive results may provide an alternative explanation for psychosis or may confirm comorbid substance abuse. Lipid profiles may identify patients at risk for hyperlipidemia associated with the use of some antipsychotic drugs, and a metabolic profile may identify patients at risk for diabetes. An electrocardiogram is relevant as a baseline measure for patients who are subsequently prescribed antipsychotic medications that can prolong the QT interval. Electroencephalography may be used to exclude the diagnosis of temporal lobe epilepsy. Rarely, unusual presentations (e.g., the emergence of symptoms of schizophrenia after head trauma) may require magnetic resonance imaging of the brain to rule out other causes of psychosis.

There are a number of physiologic and neuroimaging findings that are helpful in distinguishing groups of schizophrenic patients from groups of healthy control subjects. However, these findings may not be unique to patients with schizophrenia, and their accuracy is inadequate for diagnostic purposes. Such findings include impairment of sensory gating as measured by evoked-potential response of P50 and by oculomotor physiologic dysfunction and prefrontal cortical dysfunction as assessed by brain imaging studies. Differences found on testing groups of schizophrenic patients have not led to the development of tests with adequate sensitivity and specificity and positive or negative predictive power for diagnosis in individual cases.

Table 1 Diagnostic Criteria for Schizophrenia[54]

All six criteria must be met for a patient to fit the diagnosis of schizophrenia.

1. *Presence of psychosis for a significant length of time*
   Any two or more of the following symptoms must be present for a significant duration during a 1-month period (less if treated):
   1. Delusions
   2. Hallucinations
   3. Disorganized speech
   4. Negative symptoms (e.g., lack of emotion and social drive and engagement)
   5. Grossly disorganized behavior
2. *Deterioration in social/occupational functioning*
   Functioning in at least one of the following areas is markedly below the level achieved before the illness:
   1. Work
   2. Interpersonal relationships
   3. Self-care
3. *Continuous signs of the disturbance for 6 months*
   The 6 months must include at least 1 month of positive symptoms. However, during prodromal or residual periods, the disturbance may be manifested by negative symptoms only.
4. *Exclusion of schizoaffective and mood disorders*
   No major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; if such episodes have occurred, their total duration has been much briefer than the periods of active and residual psychosis.
5. *Exclusion of substance-induced or medical disorders*
   The disturbance is not the result of direct physiologic effects of a substance or caused by a medical condition.
6. *Relationship to pervasive developmental disorders*
   If the patient has a history of autistic disorder or another pervasive developmental disorder, a diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least 1 month.

Table 2 Cognitive Disturbances Seen in Schizophrenic Speech

Abstract Thought Impairment
For example, when asked to interpret a proverb, the patient may provide a concrete description

Blocking
A halt in the flow of speech; the person is unable to continue the train of thought even with cueing

Clang Associations
Speech connections based on similarities in the sounds of words rather than on their meanings

Delayed Response
Long latency before responding to questions; at the extreme, the patient may be mute

Poverty of Content
The speech conveys little information even when it is more or less coherent

Tangentiality
Response to questions such that the answers become progressively less related to the original question

Loosening of Associations
Speech consisting of ideas that have no discernible connection to one another

Word Salad
Incoherent speech from extreme loosening of associations

Genetic Testing

Rapidly advancing knowledge concerning genotypic vulnerability to schizophrenia may lead to better susceptibility testing. However, it appears unlikely that genotypes unique to schizophrenia will be defined. At present, genetic information mainly suggests that a number of genes that individually make minor contributions to vulnerability may combine in persons with schizophrenia and may interact with certain environmental etiologic factors. It is also suggested that genes conferring vulnerability to schizophrenia may overlap with those that predispose to depression and bipolar disorder. If these suggestions prove true, specific genetics-based diagnoses of schizophrenia are unlikely to be forthcoming in the near future. However, genetic testing may eventually help guide therapy in individual patients by indicating their likelihood of response and risk of side effects with specific drugs.

Differential Diagnosis

Because schizophrenia is defined as a psychotic illness with functional impairments, distinguishing schizophrenia from normalcy is usually not difficult. However, because the clinician depends on information provided by patients regarding their inner experiences, recognition of mild psychosis is difficult in patients who are guarded and who are not forthcoming with information.

Schizotypal personality disorder shares some of the clinical characteristics of schizophrenia, such as social and physical an-

hedonia, suspiciousness, magical thinking, blunting of affect and emotional experience, and poor functioning. However, schizotypal patients do not experience overt and persistent psychotic symptoms, although rare and brief psychotic symptoms may occur.

In a patient with persistent psychosis, the differential diagnosis consists mainly of affective disorders with psychosis, substance abuse, and delusional disorders. Psychosis that coincides with depression is typically associated with such affective features as delusions of poverty or accusatory voices. Similarly, delusions of grandeur are common during manic episodes. Psychotic symptoms in affective disorders typically follow the emergence of depression or mania and fade once the affective symptoms recede. Depressive symptoms often occur in schizophrenia, particularly in the first episode. Alternatively, excitement and hyperactivity in patients with schizophrenia may mimic manic symptoms. Differential diagnosis depends on the timing of psychosis in relation to the occurrence of affective symptoms and the content of delusions and hallucinations. Psychotic symptoms can be caused by many medical conditions [*see Table 3*], as well as by alcohol, illicit drugs, and over-the-counter and prescription medications [*see Table 4*]. The history and toxicology screen can rule out psychosis caused by drug abuse, such as use of PCP or the long-term abuse of steroids. Delusional disorder is diagnosed on the basis of persistent and circumscribed delusions (more realistic and less bizarre than those associated with schizophrenia) in the absence of disorganization and negative psychopathology.

Occasionally, neurologic conditions such as brain tumor or temporal lobe epilepsy may be misdiagnosed as schizophrenia. When such conditions are suspected, MRI and EEG can help with the diagnosis.

Table 3 Drugs and Medications Commonly Associated with Psychotic Symptoms

Abused Drugs
- Alcohol (withdrawal and alcoholic hallucinosis)
- Amphetamines
- Cocaine (especially free-base or crack)
- Marijuana (panic reaction)
- Phencyclidine (PCP) and hallucinogens (acute intoxication and flashbacks)
- Sedative-hypnotics (withdrawal)

Analgesics
- Meperidine (toxic metabolite)
- Nonsteroidal anti-inflammatory drugs
- Pentazocine and other opiate mixed agonist-antagonists

Antibiotics
- Antituberculous drugs (e.g., cycloserine, isoniazid, rifampin)
- Many others

Anticholinergics
- Anticholinergic antiparkinsonians
- Antihistamines (e.g., diphenhydramine)
- Atropine and derivatives
- Cyclic antidepressants
- Low-potency antipsychotic drugs (e.g., thioridazine, clozapine)
- Meclizine
- Scopolamine

Cardiovascular Drugs
- Antiarrhythmics (e.g., amiodarone, digitalis, procainamide)
- Captopril

Dopamine Agonists
- Amantadine
- D_2 dopamine receptor agonists (e.g., bromocriptine, pergolide)
- Levodopa

Endocrine Drugs
- Estrogens, testosterone
- Glucocorticoids and adrenocorticotropic hormone (ACTH)
- Thyroid hormone (overdose)

H_2 Receptor Antagonists
- Cimetidine, ranitidine

Stimulants and Sympathomimetics
- Dextroamphetamine
- Methylphenidate
- Over-the-counter decongestants (e.g., pseudoephedrine), diet pills, and pep pills

Table 4 Medical Conditions Associated with Psychotic Symptoms

Cancer and Hematologic Malignancies
- CNS neoplasm
- Hyperviscosity syndromes (resulting from hematologic malignancy)
- Paraneoplastic syndromes (e.g., limbic encephalitis)

Cardiovascular
- Anoxia and postanoxic encephalopathy
- Hypertensive encephalopathy

Infections and Sequelae
- AIDS encephalopathy
- Encephalitis, meningitis, brain abscess
- Lyme disease
- Neurosyphilis

Metabolic and Endocrine Disorders
- Acute intermittent porphyria
- Addison disease
- Cushing disease
- Hepatic encephalopathy
- Hypocalcemia and hypercalcemia
- Hypoglycemia
- Hypothyroidism and hyperthyroidism

Neurologic Disorders
- Alzheimer disease
- Complex partial seizures
- Huntington chorea (Huntington disease)
- Multiple sclerosis
- Stroke
- Wilson disease

Nutritional Deficiencies
- Folic acid deficiency
- Pellagra (niacin deficiency)
- Vitamin B_{12} deficiency

Rheumatologic Disorders
- Lupus cerebritis

Management

Patients with schizophrenia require acute treatment for psychotic exacerbations; long-term treatment, involving mainte-

nance and prophylactic strategies to sustain symptom improvement and prevent recurrence of psychosis; and support for living. Unfortunately, the avolitional (negative) symptoms and impairments in cognition, which account for poor functional outcomes, show little response to current treatments. The future may offer treatment for these nonpsychotic aspects of the illness, as well as preventive measures for persons at high risk for schizophrenia.

ACUTE TREATMENT

The first-line therapeutic approach for an acute exacerbation of schizophrenia—whether it is the first episode or a relapse—involves antipsychotic medication (see below). To determine whether the patient requires hospitalization, the physician must evaluate patient safety and cooperation. This evaluation is clinically based and often includes discussion with family members or other informants. The patient's ability to care for himself or herself, the setting most likely to ensure adherence to therapy, and the risk of suicidal or aggressive behavior are at the forefront of this evaluation.

MAINTENANCE THERAPY

Most patients show at least a partial therapeutic response to the initiation of antipsychotic medication. Longer-term care involves maintenance therapy to minimize the expression of psychosis and prevent or delay psychotic exacerbation. Some patients will have a full remission of psychotic symptoms, but even in such cases, the continuous administration of antipsychotic drugs will delay recurrence of a psychotic exacerbation. Psychosocial treatments and pharmacologic treatments have proved effective in reducing exacerbation rates over the long term. The clinical relationship involved in these treatments also provides for ongoing evaluation of life needs, suicide risk, medication adherence, and success in coping with the many practical problems facing individuals with a chronic debilitating disease. Many patients need assistance in obtaining shelter, in developing an occupational niche or receiving vocational rehabilitation, and in participating in substance abuse programs.

Involvement of the people in the patient's life is critically important. Family members and significant others need to be educated about the disease, its treatment, and the approach to changes in clinical status.

If the patient recovers from psychosis, remains free of psychotic symptoms, and is stable for several years, the gradual discontinuance of medication may be warranted, provided that close clinical observation can be ensured. However, most patients will experience subsequent exacerbations. Early detection and intervention may be effective. Because a few patients have only a single episode of psychosis and may not require continuous antipsychotic treatment and because the risk of medication side effects is substantial, a medication-free trial is justified in selected cases.

Pharmacologic and psychosocial management need to be integrated. The two approaches appear to be synergistic in their effects, and each is crucial to the effectiveness of the other. Early detection of exacerbation is most likely when continuous clinical observation is provided in the context of psychosocial treatment; successful participation in skills training, vocational rehabilitation, living arrangements, and substance abuse treatment is most likely to be successful in the context of continuous antipsychotic drug treatment. For patients who have an established pattern of exacerbations and remission, continuous antipsychotic drug treatment is recommended for relapse prevention.

Table 5 Antipsychotic Drugs Used in the Treatment of Schizophrenia

Antipsychotic Category	*Drug (Trade Name)*
First-generation (neuroleptic)	Chlorpromazine Fluphenazine Haloperidol (Haldol) Loxapine (Loxitane) Mesoridazine (Serentil) Molindone (Moban) Perphenazine (Trilafon) Pimozide (Orap) Thioridazine Thiothixene (Navane) Aripiprazole (Abilify)
Second-generation (atypical)	Clozapine (Clozaril) Olanzapine (Zyprexa) Quetiapine (Seroquel) Risperidone (Risperdal) Ziprasidone (Geodon)

PHARMACOLOGIC TREATMENT

Antipsychotic Drugs

The antipsychotic drugs used to treat schizophrenia have a wide variety of pharmacologic properties, but all are antagonists acting at the postsynaptic D_2 dopamine receptors in the brain. Conventional, or first-generation, antipsychotic agents are often referred to as neuroleptics because of their neurologic side effects. Second-generation antipsychotic drugs also act at the dopamine receptors but are less likely to exhibit neuroleptic effects; these agents have been termed atypical antipsychotics [*see Table 5*].

Antipsychotic drug therapy is usually initiated at low doses (e.g., 1 to 5 mg of haloperidol, 5 mg of olanzapine, or 2 mg of risperidone administered once or twice a day) and titrated upward. Although the onset of therapeutic effect occurs promptly, symptom reduction is gradual, occurring over many weeks. Optimal dosing parameters have not been established for most of these drugs; an increase in dosage often results in an increase in adverse effects without a commensurate increase in therapeutic response. Blood levels have not proved effective in guiding dosing decisions; clinical response is the best guide for titrating the dose of an antipsychotic agent. The clinical effect of antipsychotics is to diminish positive psychotic symptom expression and reduce relapse rates. Although sedation may be a side effect and diminished anxiety may be a clinical effect, the primary value of these drugs is their remedial effect on positive psychotic symptoms, not their sedating or tranquilizing properties. The antipsychotic efficacy of these drugs extends beyond schizophrenia to include reducing positive psychotic symptoms associated with mental illnesses other than schizophrenia. In contrast to their effect on positive psychotic symptoms, first-generation antipsychotic agents have not been shown to be effective for either primary, enduring negative (deficit) symptoms or the cognitive impairments observed in schizophrenia.

The first atypical antipsychotic was clozapine. During the 1970s, clozapine was shown to be effective in some cases in which conventional antipsychotics did not work. However, cessation of white blood cell production occurs in approximately

1% of patients receiving clozapine; after a series of deaths from agranulocytosis in Finland during the mid-1970s, the use of clozapine declined in Europe and the drug was not marketed in the United States. Interest in clozapine was rekindled by the results of a large-scale multicenter study that yielded convincing evidence of the superior efficacy of clozapine for ameliorating positive psychotic symptoms in treatment-resistant patients with schizophrenia.[44] Consistent with the worldwide experience in the late 1970s and early 1980s, the study also showed that clozapine can be used with relative safety, provided that patients are carefully monitored for agranulocytosis. Clozapine has many pharmacologic actions and weaker affinity for the D_2 dopamine receptor; however, the basis for its superior antipsychotic action in treatment-resistant cases is not known.

The success of clozapine spawned considerable interest in the development of other antipsychotics for the treatment of schizophrenia. In the 1990s, five new antipsychotics were introduced in the United States: risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole [*see Table 5*]. It was hoped that these new drugs would have the efficacy of clozapine but without the risk of agranulocytosis and the other side effects that have limited clozapine's use. However, these new medications appear to be no more effective than the conventional antipsychotics for reducing positive psychotic symptoms. This is not surprising, given that both first- and second-generation antipsychotic drugs act as dopamine antagonists (although aripiprazole, as a partial agonist, has a different pharmacologic mechanism). These new drugs' main advantage over the conventional antipsychotics is their substantially lower incidence of extrapyramidal motor side effects. This decrease in side-effect burden may account for their apparent greater effectiveness, and it appears to have reduced the incidence of persistent dystonia and tardive dyskinesia in patients with chronic schizophrenia. Several of the second-generation antipsychotic drugs have shown greater benefit than the conventional antipsychotic agents for the treatment of depressive symptoms and the prevention of relapse and rehospitalization. These considerations have led to the second-generation antipsychotics' replacing conventional antipsychotics as first-line pharmacologic treatment for first-episode and chronic schizophrenia; this shift is controversial, however, in part because the new drugs are substantially more expensive than conventional antipsychotics. A recent study from the Department of Veterans Affairs has rekindled this debate: Rosenheck and colleagues found little difference in clinical response between patients given one of the newer drugs and those given moderate doses of haloperidol; moreover, the cost advantage of all aspects of care favored the first-generation drug.[45]

The second-generation antipsychotics are not without their limitations. Several of these agents have been associated with the development of clinically significant metabolic disturbances, including weight gain, hyperlipidemia, and new-onset type 2 diabetes mellitus. These side effects are of particular concern because patients with schizophrenia are already at increased risk for cardiovascular disease as a result of their lifestyle. Long-term studies will eventually clarify whether the decreased risk of extrapyramidal side effects, including tardive dyskinesia, warrants the increased risk of these metabolic side effects.

Do second-generation antipsychotic agents reduce the negative symptoms and cognitive impairment of schizophrenia? A number of studies have indicated that second-generation antipsychotic drugs are more effective than the first-generation drugs for negative symptoms, but the differences are usually related to concurrent changes in extrapyramidal or depressive symptoms, or excessive dosages of the first-generation drug used for comparison. In studies that have controlled for these potential sources of artifact, the apparent superior efficacy of the new-generation antipsychotics disappears. A similar story is emerging for the comparative efficacy of second-generation and conventional antipsychotics with regard to cognitive impairments. First-generation antipsychotic agents produce little improvement in cognitive function, even when they significantly relieve positive psychotic symptoms; moreover, at higher doses, they may impair cognitive function. Second-generation agents improve performance on neuropsychological measures of cognitive function, but the effect is relatively modest, and patients continue to exhibit considerable cognitive impairments compared with normal control subjects. The difference in cognitive effect between first- and second-generation antipsychotic agents is less pronounced when second-generation drugs are compared with conventional antipsychotics given at lower doses.[46]

Other Agents

The limited efficacy of conventional and atypical antipsychotic drugs against the negative symptoms and cognitive impairment of schizophrenia has led researchers to investigate drugs in other categories. Glutamatergic agents that bind to the glycine site of the NMDA glutamatergic receptor have shown potential utility for the treatment of primary, enduring negative (deficit) symptoms. Preliminary controlled clinical trials of glycine, D-cycloserine, and D-serine have produced encouraging results. In part because of the genetic linkage findings implicating the alpha-7 nicotinic receptor gene in the physiologic deficits of schizophrenia, several trials have examined the acute effects of nicotine on cognitive deficits in schizophrenia. These studies have demonstrated significant but transient reversal of impairments in sensory gating, attention, and aspects of eye tracking.[47,48] These results suggest that heavy smoking in schizophrenia may partly be self-medication on the part of the patients and have encouraged the search for nicotinic agonist drugs that have long-term efficacy. The delineation of the physiology of normal cognition has also led researchers to consider treating cognitive impairment in schizophrenia by augmenting antipsychotic therapy with drugs from other classes. Dopaminergic, adrenergic, and other pharmacologic agents are currently under study.

Augmentation strategies have also been used to treat positive psychotic symptoms that fail to respond to antipsychotic agents. However, lithium, antiepileptic drugs, antidepressants, and antianxiety agents have not been shown to substantially reduce these symptoms. It is theoretically possible that some small patient subgroups may respond to a class of drugs other than antipsychotics, but there is no way to identify such patients in advance, so it is difficult to prove or disprove this proposition. On the other hand, drugs from other classes may be effective for specific symptom targets. For example, antianxiety drugs reduce anxiety in schizophrenic patients, and drugs used for depression and mania in affective disorders are sometimes useful for these symptoms in schizophrenia.

Aggression is a special problem in schizophrenia. When aggression is the result of psychosis, antipsychotic drugs are the best treatment. Aggression may also be caused by akathisia, an intense inner restlessness and tension caused by some antipsychotic drugs; this is treated with a change in drug or the addition of another drug to counteract this side effect. Otherwise,

hostility with the threat of violence is a difficult clinical issue that is only partly addressed with concomitant administration of beta blockers such as propranolol. New-generation antipsychotic drugs appear advantageous for this aspect of the illness. Close supervision, restraints, and the use of a safe room continue to be necessary in the care of a minority of patients.

It is now common practice to add a second or third antipsychotic drug to the regimen in patients with persistent positive psychotic symptoms. There is little theoretical basis for this practice, and there is no research evidence to support this empirical strategy. The probable effects are an increase in side effects and poorer patient adherence to therapeutic recommendations.

ELECTROCONVULSIVE THERAPY

Before the introduction of antipsychotic drugs, electroconvulsive therapy (ECT) was frequently used in the treatment of patients with schizophrenia. ECT is particularly effective for catatonic stupor, excitement, and acute psychotic conditions. Results are similar to those obtained with antipsychotics—that is, positive symptoms are reduced, but long-term functional impairments are not reversed.[49] Although ECT is safe and painless, it has several limitations: it is not widely available, litigation and societal attitudes restrict its use, and any therapeutic advantage gained in an initial series of treatments is not easily maintained. Also, there is no compelling evidence that electroconvulsive treatments are effective in patients who are resistant to antipsychotic drugs. For these reasons, drug treatment is generally preferred.

PSYCHOSOCIAL INTERVENTIONS

The debate over whether schizophrenic patients should be treated with pharmacologic or psychosocial treatments has given way to the search for how these treatments should be optimally integrated. Controlled clinical trials have conclusively demonstrated that intensive psychotherapy is less effective than pharmacologic treatment; that it is not superior to cheaper, less ambitious psychosocial forms of psychotherapy; and that it should not be considered as an alternative to the use of antipsychotic drugs. On the other hand, studies have repeatedly demonstrated that supportive forms of psychosocial treatment are entirely compatible with drug treatment and can increase the effectiveness of overall treatment, reduce the amount of medication needed, enhance patient participation in the full range of treatment, and optimize social and occupational functioning. Especially impressive are studies documenting the considerable additional benefit achieved in reducing relapse and hospitalization rates when family therapy and education programs are added to maintenance pharmacologic treatment. These studies make it clear that psychosocial and rehabilitative interventions have become essential components of the comprehensive treatment of patients with schizophrenia.[50-52]

Psychosocial and rehabilitation interventions include cognitive-behavioral therapy for treatment-resistant positive psychotic symptoms; supportive, problem-solving, educationally oriented psychotherapy; family therapy and education programs aimed at helping patients and their families understand the patient's illness, reduce stress, and enhance coping capabilities; social and living skills training; supported employment programs; and the provision of supervised residential living arrangements. The development and increased utilization of psychosocial services has been complemented by the evolution of services designed to decrease the utilization of inpatient hospital services and maintain the patient in the community. Assertive community treatment teams provide intensive outreach services to patients who are unable to be maintained in the community with traditional outpatient clinical treatment. Crisis management services, including 24-hour crisis beds and partial hospitalization programs, represent alternatives to hospitalization during periods of symptom exacerbation.

The development of these services reflects the ongoing shift in the treatment of schizophrenic patients from a hospital-based to a community-based system of care. When optimal treatment with these services is provided, the rewards of therapeutic accomplishment, reduction in morbidity, and cost benefits are profound and rival therapeutic accomplishments found anywhere in medicine. The demonstrated benefits of these services challenge the field to establish an adequate community-based treatment approach that is prepared to meet the challenge and demands of broad-based integrated treatment. Society has failed to meet the challenge of providing evidence-based treatment to most persons who suffer from schizophrenia.

FUTURE TREATMENT

Intervention in the prepsychotic and early psychotic phases of schizophrenia is an unmet challenge in schizophrenia care. Early identification and treatment would clearly be preferable, but the earliest indicators of schizophrenia are usually not the psychotic features. Psychosocial treatment for nonpsychotic manifestations needs to be developed, just as pharmacologic treatments for cognitive impairments and negative psychopathology are required to address these features in patients at high risk for psychosis. It is hoped that gene discovery will lead to the development of new drugs targeting each domain of psychopathology.

The advancing knowledge of human gene and protein sequences is altering the course of schizophrenia research. These technologies promise to help delineate the molecular pathophysiology of the disease and define novel molecular targets that will provide a basis for drug development. Clinical and postmortem studies are presenting more compelling definitions of disease entities and phenotypes within the schizophrenia syndrome, which should permit the effective application of advances in genomics and proteomics.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VIII ANXIETY DISORDERS

M. Katherine Shear, m.d.

Anxiety disorders are the most common mental disorders in the community. Anxiety disorders include panic disorder, agoraphobia, specific phobia, social phobia, generalized anxiety disorder, obsessive-compulsive disorder, and acute and posttraumatic stress disorder. Shared features of these disorders are prominent somatic symptoms, panic attacks, anticipatory worry or fear, and avoidance or compulsive rituals. Persistent nagging health concerns are common and frequently cause patients with these disorders to seek medical treatment, where their anxiety disorders may go unrecognized. In addition to producing serious impairment in functioning, anxiety disorders can worsen the course of medical illnesses. Moreover, untreated anxiety symptoms lead to ineffective utilization of health care resources. Anxiety disorders frequently occur together with depression, a condition known to presage poorer medical outcomes. In addition to their similarities, the anxiety disorders have distinct clinical and neurobiologic features and typical presentations [*see Table 1*].

Approach to Management

Anxiety disorders are best managed through a systematic approach to diagnosis, treatment, and, when necessary, referral. To facilitate accurate detection of anxiety symptoms, physicians should be vigilant for the behavioral, physiologic, and cognitive features of anxiety and know the key criteria for different disorders. Anxiety disorders should be included in the differential diagnosis in many cases of apparently medical illness.

When taking the history in a patient who may have an anxiety disorder, direct and sensitive questioning is required. Phobic responses can be cognitive as well as behavioral, leading patients to neglect to mention anxiety. Fear of stigma may also lead to patient reticence.

Therapy for patients with anxiety can be initiated by the primary care physician or, in some cases, by a consulting physician. It is a truism in medicine that the first step in treatment is accurate diagnosis. Thus, upon recognition of anxiety disorder symptoms, the physician should identify the condition and provide the patient with information about its treatment and course. Such information is readily available on the Internet [*see Sidebar* Internet Resources for Anxiety Disorders]. In addition, information on panic disorders can be obtained from the Institutes of Mental Health by calling 1-800-64-PANIC.

Treatment by physicians usually entails the use of medication. Although drug treatment is certainly an appropriate intervention, the majority of patients with anxiety disorder prefer nonpharmacologic treatment. Highly effective cognitive-behavioral treatments are available. It is best if physicians discuss treatment preferences with their patients and are prepared to provide appropriate referrals if the patient so wishes.

When medications are used, effective management techniques include monitoring patients' responses to treatment by using one or more target symptoms. General rules for pharmacologic treatment of anxiety include the following: (1) serotonin-active medications are effective for every disorder except specific phobias, (2) patients with panic disorder are highly sensitive to medication, so drugs should be started at a very low dose and gradually increased to a therapeutic level, (3) barring adverse effects, a medication trial should be continued for 4 weeks before one declares the agent ineffective and changes medications, and (4) failure to respond to an initial trial of a selective serotonin reuptake inhibitor (SSRI) does not mean that another agent of this class will not work.

Referral to a mental health specialist is indicated for the following reasons: (1) uncertainty about the diagnosis, (2) presence of multiple concomitant psychiatric conditions, (3) acute suicidal ideation or a past history of serious suicide attempt or other serious behavioral disturbances, and (4) failure to respond to two trials of normally effective medications. Referral information is available at many Web sites devoted to anxiety disorders [*see Sidebar* Internet Resources for Anxiety Disorders].

Panic Disorder with or without Agoraphobia

The pathognomonic feature of panic disorder is unexpected panic attacks, which are characterized by sudden onset and rapid escalation of somatic symptoms referable to the autonomic nervous system (e.g., chest pain, shortness of breath, heart palpitations, and dizziness) along with fear or apprehension [*see Tables 1 and 2*]. Panic attacks typically last 10 to 20 minutes, but they can be shorter. Persons with panic disorder have recurrent panic attacks; between attacks, they are beset by fear of

Table 1 Key Symptoms of Anxiety Disorders

Disorder	*Symptoms*
Panic disorder	Recurrent unexpected panic attacks; fear of panic or its consequences
Agoraphobia	Fear and avoidance of places where it may be difficult to get help or easily leave (e.g., bridges, tunnels, restaurants, supermarkets, public transportation)
Posttraumatic stress disorder	Exposure to a life-threatening or physically threatening event, followed by (1) disturbing images, flashbacks, nightmares; (2) avoidance of trauma reminders; (3) hyperarousal (e.g., easy startle, irritability, difficulty concentrating, insomnia)
Generalized anxiety disorder	Excessive uncontrollable worries about everyday things; fatigue, muscle tension, insomnia; restlessness, irritability, difficulty concentrating
Social phobia	Fear and avoidance of specific social situations (e.g., fear of urinating in public bathrooms, fear of eating in restaurants, fear of public speaking) or social situations in general
Obsessive-compulsive disorder	Repeated intrusive thoughts, impulses, or images, recognized as irrational; compulsive ritualistic behaviors such as cleaning or checking
Specific phobias	Fear and avoidance of a specific place, activity, or situation (e.g., fear of blood or needles, fear of dental procedures, fear of childbirth)

the attacks and their consequences or implications. For example, the patient may believe that the panic attacks reflect underlying heart disease or schizophrenia.

Agoraphobia is a fear of situations in which the person would feel trapped or alone should a panic episode occur. Such situations typically include travel far away from home, on public transportation, or via bridges or tunnels; crowded places such as supermarkets, restaurants, theaters, churches, or shopping malls; standing in line; and being alone. Agoraphobia is characterized by avoidance of these situations. In its most severe form, sufferers can be housebound.

EPIDEMIOLOGY

The lifetime prevalence rates of panic disorder are about 3.5%.[1] Up to 10% of the population experience sporadic panic attacks. Panic disorder is more common in women and has an average-age-group onset of early adulthood. Persons with panic disorder are at risk for developing major depression, with over half meeting lifetime criteria for major depression.

Lifetime prevalence rates for agoraphobia are estimated at 6.7%, with a mean age of onset of 29 years.[2] Agoraphobia can occur when the panic attacks include frightening physical symptoms, such as those suggesting a medical disorder.

PATHOPHYSIOLOGY

In laboratory studies, paniclike symptoms have been provoked with pharmacologic agents such as carbon dioxide, sodium lactate, and cholecystokinin (CCK). Several neurotransmitter systems have been implicated in these symptoms, including serotonin (5-HT), norepinephrine, and γ-aminobutyric acid (GABA), along with the neuromodulatory CCK system. Theories involving 5-HT in panic disorder focus on opposing actions in the dorsal raphe nucleus (DRN) and the median raphe nucleus (MRN).[3] The MRN modulates fear and anticipatory anxiety, along with autonomic symptoms of panic, whereas the DRN modulates the behavioral aspects of panic, such as the fight-or-flight response. Both systems are involved in a feedback loop that also includes the locus coeruleus and lateral hypothalamus.[4]

Yohimbine, an α_2-adrenergic antagonist, can trigger anxiety or panic in susceptible patients,[5] which suggests that norepinephrine also has a role in panic disorder. The locus coeruleus has projections to brain structures thought to play a role in anxiety, including the amygdala, the bed nucleus of the stria terminalis (BNST), the periaqueductal gray area (PAG), the paraventricular nucleus of the hypothalamus, the lateral hypothalamus, and the nucleus of the tractus solitarius (NTS). Norepinephrine projections from the locus coeruleus also interact with corticotropin-releasing factor (CRF), which may play a role in anxious responses to stress.[6]

GABA has been implicated in the pathophysiology of panic disorder, perhaps as a nonspecific mechanism related to anxiety. Persons with panic disorder demonstrate decreased GABA ligand binding in the right orbitofrontal cortex and right insula.[7] Decreased platelet benzodiazepine receptor binding has also been observed in patients with panic disorders and other anxiety disorders. On magnetic resonance spectroscopy, patients with panic disorder have been shown to have decreased GABA function and lower levels of GABA in the occipital cortex.[8] GABA interacts with CCK in the amygdala, cortex, and hippocampus, and this interaction has been postulated to play a role in mediating anxious states.

Other models focus on the ethologic roots of panic disorder.

Table 2 Conditions Commonly Confused with Anxiety Disorders

Disorder	*Conditions*
Panic disorder	Heart palpitations, mitral valve prolapse, cardiac arrhythmias, hyperthyroidism, irritable bowel syndrome, migraine
Posttraumatic stress disorder	Insomnia, substance use disorders, unexplained fears of medical procedures, or unexplained worsening of course of medical illness
Generalized anxiety disorder	Insomnia, migraine or tension headaches, hypertension, peptic ulcer disease, irritable bowel syndrome
Social phobia	Unexplained urinary retention, academic or occupational underachievement, mood disorders, substance use disorders
Obsessive-compulsive disorder	Tourette syndrome, other tic disorders, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), excoriative dermatitis, unexplained fears of illness

In his false-suffocation alarm theory, Klein hypothesized a brain stem abnormality causing dysregulation and heightened sensitivity to carbon dioxide. Respiratory abnormalities have been consistently documented in patients with panic disorder[9]; these patients exhibit unstable respiratory patterns and high respiratory variability even when not experiencing panic.[10] The respiratory stimulant doxapram induces panic in many patients with panic disorder, as well as in some control subjects; a simple cognitive intervention can reduce the panic response to doxapram. Decreased heart rate variability related to decreased vagal tone has been documented in panic disorder.[11] Decreased vagal tone may play a role in the migraine and irritable bowel syndrome associated with some cases of panic disorder.[12]

DIAGNOSIS

Clinical Features

Panic attack is diagnosed when at least four of 13 symptomatic criteria occur unexpectedly and peak within 10 minutes [*see Table 3*]. The diagnosis of panic disorder requires recurrent panic attacks accompanied by significant worry or concern about panic, its consequences or implications, or a change in usual behavior.[13] Agoraphobia is diagnosed when the patient fears and avoids situations in which escape would be difficult or help would be unavailable if a panic attack were to occur.

Fear and hyperawareness of bodily sensations are hallmarks of panic disorder.[14] These patients misinterpret benign bodily sensations (e.g., dizziness, palpitation) as indications of serious medical illness.

Presentation in Medical Settings

Persons with panic disorder are more likely to present for medical treatment than for mental health treatment. The majority of cases of panic disorder seen in primary care practices and emergency departments go unrecognized.[15,16]

Panic disorder has four common clinical presentations in general medicine: (1) physical symptoms (e.g., heart palpitations, chest pain, shortness of breath, gastrointestinal complaints, headache, dizziness), (2) anxiety and tension, (3) hypochondriacal concerns, and (4) certain diagnosed medical conditions, such as migraine, asthma, chronic obstructive pulmonary disease (COPD), and labile hypertension.[17]

Panic disorder is often seen in patients referred for cardiologic complaints, especially atypical chest pain or chest pain despite angiographically normal coronary arteries. Patients with microvascular angina may have panic disorder. Because of prominent cardiovascular symptoms during panic attacks, this disorder should be considered in patients with intractable cardiac symptoms. Several studies have shown that men with phobic anxiety are at higher risk of cardiovascular mortality from fatal myocardial infarction and sudden cardiac death.[18] Idiopathic clinical and subclinical cardiomyopathies have been associated with panic disorder,[19] possibly related to increased adrenergic activity. Panic attacks are associated with transient increased blood pressure,[20] so this diagnosis should be considered in patients with labile hypertension. Panic disorder has been found in about 16% of patients with implantable cardioverter defibrillators.[21]

There is an association of respiratory illness with panic disorder. Patients with asthma have a higher incidence of panic disorder, and the presence of panic disorder predicts a poorer clinical course in asthma. A history of childhood respiratory illness is more common in patients with panic disorder than in those with other psychiatric disorders.[22] In adults, COPD is associated with panic disorder.

Panic disorder is frequently associated with other mood and anxiety disorders. Prognosis is poorer in such cases.

TREATMENT

Pharmacotherapy

Drug therapy can be markedly effective for patients with panic disorder [*see Table 4*]. However, the fear of bodily sensations in these patients may lead to difficulty taking medications, medication refusal, or poor adherence to prescribed medicine. Many patients with panic disorder believe they are allergic to medication. Physicians should convey understanding of this medication sensitivity. Whenever possible, medication for any purpose should be started at a very low dosage and then

Table 3 Diagnostic Criteria for Panic Attack*

Palpitations, pounding heart, or accelerated heart rate
Sweating
Trembling or shaking
Sensations of shortness of breath or smothering
Feeling of choking
Chest pain or discomfort
Nausea or abdominal distress
Feeling dizzy, unsteady, light-headed, or faint
Derealization (feelings of unreality) or depersonalization (being detached from oneself)
Fear of losing control or going crazy
Fear of dying
Paresthesias
Chills or hot flushes

*Four or more of these symptoms must develop abruptly and peak within 10 min.

Table 4 FDA-Approved Drugs for Anxiety Disorders

Disorder	*Drugs*	*Daily Dosages*	
		Starting	*Target*
Panic disorder	Imipramine	10–25 mg	150–200 mg
	Paroxetine	10 mg	10–60 mg
	Sertraline	25–50 mg	50–200 mg
	Alprazolam	0.25–0.50 mg b.i.d or t.i.d.	0.5–2.0 mg b.i.d. or t.i.d.
Posttraumatic stress disorder	Sertraline	50 mg	50–200 mg
	Paroxetine	10 mg	10–60 mg
Generalized anxiety disorder	Venlafaxine	75 mg in two or three divided doses	150–300 mg in two or three divided doses
Social anxiety disorder (social phobia)	Paroxetine	10–20 mg	10–60 mg
	Sertraline	50 mg	50–200 mg
Obsessive-compulsive disorder	Clomipramine	25–50 mg	150–300 mg
	Fluoxetine	5–10 mg	20–80 mg
	Fluvoxamine	50 mg h.s.	100–300 mg in two divided doses
	Paroxetine	10–20 mg	40–60 mg

gradually increased. This is especially important when using medication to treat the panic disorder itself. If the initial dose is too high, the patient may not tolerate the medication and a potentially effective treatment will be rendered useless. There is a psychological intervention of proven efficacy for fear of bodily sensations, so referral should be considered for patients in whom this fear complicates drug therapy.

Imipramine A tricyclic antidepressant with serotoninergic activity, imipramine was the first medication used for panic disorder. This drug has well-documented efficacy in controlling panic disorder and can prevent relapse with continued use.[23] The efficacy and tolerability of imipramine are similar to those of SSRIs, so patients who are responding well to imipramine need not necessarily be switched to an SSRI. However, most experts now start drug therapy for panic disorder with an SSRI.

Selective serotonin reuptake inhibitors SSRIs are the first-line pharmacotherapy for panic disorder. Every medication in this class has been proved effective. The Food and Drug Administration has approved paroxetine and sertraline for use in panic disorder, but citalopram, fluoxetine, and fluvoxamine also have well-documented beneficial effects[24] that are often lasting, even after discontinuance of the medication. However, several studies with different SSRIs show that continuing the medication for up to 80 weeks lowers relapse rates. There is a tendency for side effects to decrease over time.[25] Different SSRIs have different chemical structures and somewhat different side-effect profiles, so patients who do not respond to one agent or who fail to tolerate it may do well on a different drug in this class. Standard practice dictates trying several SSRIs before moving to another class of medication.

Other antidepressants Antidepressants with mixed neurotransmitter effects, such as venlafaxine or mirtazapine, can be used to treat panic disorder. It is less clear whether selective noradrenergically active medications are effective for panic disorder. Studies of nortriptyline suggest it may be therapeutic. Studies of bupropion have showed mixed results. Reboxetine has demonstrated efficacy in the treatment of panic disorder.

Benzodiazepines Although benzodiazepines are not first-line agents for the treatment of panic disorder, they provide relief for some patients who do not respond to other medications. Alprazolam is approved by the FDA for the treatment of panic disorder; clonazepam and lorazepam also have proven efficacy. When used, benzodiazepines should be prescribed on a daily basis rather than on an as-needed basis.

Many physicians are wary of prescribing benzodiazepines because these agents are potentially addictive. Certainly, benzodiazepines should be avoided if possible in patients with a personal or family history of alcohol or substance-abuse disorders. Patients without such a history are unlikely to abuse benzodiazepines, however.

Discontinuance of a benzodiazepine should be accomplished by very slow tapering. In patients who have difficulty being weaned from the drug, cognitive-behavioral therapy can be used to promote discontinuance.[26]

Psychological Treatment

Targeted cognitive-behavioral psychotherapy is as effective as medication in treating panic disorder.[27] Gains are maintained at 1-year follow-up, and a naturalistic follow-up study found that in some cases, the effects endured for as long as 14 years after treatment. A brief psychological intervention in the emergency department can reduce future visits by panic disorder patients.[28] Simple instructions advising patients not to avoid situations in which they experienced panic or feared the onset of panic, along with educational support about panic disorder, is helpful in an emergency setting.

When to Refer

Most cases of panic disorder, with or without agoraphobia, respond readily to drug therapy or targeted cognitive-behavioral treatment. Referral to a psychiatrist is indicated for patients whose panic disorder is relatively treatment resistant, those with comorbid depression (especially bipolar illness) or other psychological disorders, and those who are suicidal.

COMPLICATIONS

In part because clinicians fail to recognize the condition, per-

sons with panic disorder are heavy utilizers of health care services and have significant disability, with high rates of unemployment and substance abuse.[29] Panic disorder is associated with suicide risk, even in the absence of concomitant depression.

Acute and Posttraumatic Stress Disorders

Acute and posttraumatic stress disorders (ASD and PTSD) are conditions that follow exposure to violence. ASD is diagnosed up to 4 weeks after a traumatic episode. PTSD is a highly debilitating condition that is not apparent until at least 1 month after trauma exposure.

EPIDEMIOLOGY

Lifetime exposure to violence is common in the general population. In a recent large United States survey, 51% of women and 61% of men reported having a traumatic experience at some time in their lives.[30] Lifetime prevalence rates for PTSD are estimated at 7.8%, with women twice as likely to have the disorder as men (10.4% versus 5.0%). Approximately 9% to 25% of persons who experience a trauma eventually develop posttraumatic stress symptoms. Nearly 80% of those with ASD subsequently develop PTSD, compared with only 4.3% of persons who experience a trauma but do not qualify for an ASD diagnosis.

PATHOPHYSIOLOGY

Acute stress stimulates the hypothalamic-pituitary-adrenal (HPA) axis, leading to secretion of CRF and adrenocorticotropic hormone (ACTH). Increased levels of CRF have been found in the cerebrospinal fluid of patients with PTSD, as compared with CSF levels in control subjects.[31] Chronic stress has been shown to suppress development of granule neurons in the dentate gyrus of the hippocampus,[32] and patients with chronic PTSD have lower hippocampal volumes than control subjects[33]; this may result in reduced hippocampal inhibition of CRF. Increased CRF secretion then leads to greater CRF interaction with noradrenergic projections from the locus coeruleus, producing further increases in both CRF and norepinephine. Locus coeruleus activity increases with chronic uncontrollable stress. Patients with PTSD have higher urinary norepinephrine and epinephrine levels than nonanxious control subjects, and urinary catecholamine levels correlate with intrusive recollection of trauma in combat veterans.[34] Catecholamines are responsible for alertness and vigilance, and sympathetic arousal enhances memory encoding.

Alterations in benzodiazepine receptors may contribute to PTSD. Reduction in peripheral benzodiazepine receptor density has been documented in combat veterans with PTSD, and a single-photon emission computed tomography (SPECT) study showed reduced affinity for benzodiazepine receptor binding in the prefrontal cortex. On functional MRI studies, PTSD patients have an exaggerated amygdala response to threatening stimuli.[35]

DIAGNOSIS

Clinical Features

Diagnostic criteria for PTSD include exposure to an event that posed a risk of death or serious physical injury, along with subsequent symptoms that cluster in three areas: (1) reexperiencing the event (e.g., recurrent thoughts, images, dreams, illusions, and flashback episodes), (2) avoidance of trauma reminders, and (3) arousal (e.g., restlessness, insomnia, hypervigilance, difficulty concentrating, and irritability). Dissociative symptoms (e.g., numbing or detachment, reduced awareness of surroundings, depersonalization, derealization, and dissociative amnesia) may also be present, especially in the early period after a trauma. These reactions are predictive of PTSD, as is increased heart rate during the acute-trauma phase.

Presentation in Medical Settings

Evidence suggests that a patient with PTSD is more likely to present for treatment in a primary care setting than in a mental health setting. However, primary care physicians recognize anxious symptoms in these patients only about 50% of the time and often fail to make the diagnosis.[36]

Patients who present to a trauma or emergency service are at risk for PTSD, as are combat veterans and victims of rape or domestic violence. Frightening or painful medical illness or procedures also can trigger PTSD. Assisted ventilation for acute respiratory distress syndrome, cardiac defibrillation, cardiac and lung transplantation,[37] cancer diagnosis or treatment,[38] stillbirth,[39] and patient awareness during surgical procedures because of inadequate anesthesia[40] have all reportedly triggered PTSD. It is likely that any life-threatening medical event (e.g., cardiac arrest, diabetic coma, myocardial infarction, pulmonary embolism, or massive organ failure) could trigger these symptoms, especially in patients with a history of anxiety or depressive illness.

Physicians and other medical staff in the emergency department should provide patients with support and information about PTSD in the early aftermath of trauma; such measures can help with quick recognition of the disorder if it should develop. Early recognition may prevent the development of full-blown PTSD and its negative consequences for illness course.

TREATMENT

Acute Stress Disorder

No pharmacologic treatment has proved effective in acute stress disorder, although beta blockers are currently under investigation. Studies of cognitive-behavioral therapy in patients with acute stress disorder suggest that it might prevent PTSD in patients who have experienced trauma and seem to be struggling with their reaction to the event.[41]

Posttraumatic Stress Disorder

Pharmacotherapy SSRIs are effective in the treatment of PTSD. Sertraline and paroxetine have FDA approval for this indication: studies of sertraline show about a 50% reduction in symptoms in each symptom cluster, and response rates with paroxetine range from 54% to 62%. As with other anxiety disorders, however, every SSRI tested has been found to work. At least one study showed nefazodone to be helpful.

Psychological treatment An intensive form of cognitive-behavioral therapy that requires patients to imagine themselves being exposed to the traumatic event is highly effective for rape-related PTSD.[41] This technique produces significant reduction in all symptom clusters of the disorder in most patients. The limitations of the treatment are that it requires a skilled therapist and courage on the part of the patient. However, if a qualified therapist is available and the patient is willing to participate, cognitive-behavioral therapy is the treatment of choice.

COMPLICATIONS

Traumatic stress reactions are associated with debilitating psychosocial and physical impairment,[42] including increased length of hospital stay for medical conditions, independent of severity of medical illness or medical comorbidity. PTSD also contributes to prolongation of recovery from medical illness. PTSD is associated with nonadherence to medication regimens after myocardial infarction[43] and independently predicts mortality in heart transplant patients. PTSD frequently coexists with substance-abuse disorder or mood disorder.

Generalized Anxiety Disorder

The defining characteristic of generalized anxiety disorder (GAD) is persistent, excessive, and uncontrollable worry about everyday life situations. GAD can be highly debilitating and may predispose to the development of other mood or anxiety disorders.[44]

EPIDEMIOLOGY

Lifetime prevalence rates of GAD range from 4% to 7%, with nearly a 10% prevalence in women older than 40 years.[45] Onset is sometimes early in life but is also common in middle to late adulthood, with a large increase in incidence at 35 to 45 years of age. Once established, GAD often becomes a chronic condition lasting 20 years or longer. GAD is the most common anxiety disorder in the elderly.

PATHOPHYSIOLOGY

Patients with GAD exhibit reductions in heart rate variability. Heart rate variability—as measured by beat-to-beat changes in the R-R interval on ECG—is considered a measure of autonomic nervous system function, reflecting the net effect of sympathetic versus parasympathetic (vagal) stimulation. In studies of heart rate variability during experimentally induced periods of worry and periods of calmness, normal control subjects had lower heart rate variability during periods of worry than during periods of calmness, whereas patients with GAD showed little change in variability between the two states. Although worrying is potentially adaptive if it is specific and limited to problem solving, chronic emotional restraint and inhibition could lead to a reduced range in physiologic response in persons with GAD.[46]

Muscle tension is a criterion symptom for GAD. Electromyographic activity correlates with right hemispheric brain activity in patients with GAD, suggesting that right hemisphere activity may control muscle tension symptoms in this population.[47] The muscle tension in GAD patients does not reflect autonomic arousal, however; rather, GAD is characterized by decreased autonomic arousal and activity.[46] GAD patients react to stressors with less autonomic flexibility than nonanxious control patients do and have inaccurate perceptions of physiologic changes.

SPECT and MRI studies show decreased benzodiazepine receptor binding in the left temporal pole in patients with GAD.[48] Vagally mediated heart rate variability is positively correlated with blood flow to the medial prefrontal cortex during emotional processing tasks.[49]

DIAGNOSIS

Clinical Features

Worry is the key pathognomonic feature of GAD. Other diagnostic features include restlessness, fatigue, irritability, difficulties with concentration, muscle tension, and insomnia. The diagnosis of GAD is made when patients report at least 6 months of persistent worry accompanied by at least three of these associated clinical features.

Presentation in Medical Settings

GAD is the most common anxiety disorder seen in primary care settings,[50] often presenting as sleep disturbance or somatic symptoms such as muscle aches and tension headaches.[51] GAD is associated with chronic medical conditions, poor general health, frequent hospital admissions, and high health care costs and utilization.[52] Like other anxiety disorders, GAD often goes undiagnosed and untreated, especially when accompanied by physical illness. GAD patients are as likely to seek treatment from a cardiologist as are patients with panic disorder.[53]

TREATMENT

Pharmacotherapy

The FDA has approved venlafaxine for use in GAD, and most experts consider this agent to be the first-line treatment. Venlafaxine also relieves anxious and depressive symptoms in GAD patients with comorbid major depressive disorder. SSRIs have also been found to be effective in GAD.[54]

Benzodiazepines have been used to treat GAD, and at least one study suggests that their use does not lead to tolerance.[55] However, these drugs are generally not used as first-line treatment. Many patients with GAD also have depression, which benzodiazepines do not relieve.

Psychological Treatment

Cognitive-behavioral therapy for GAD has been less well studied than that for other anxiety disorders.[56] However, this approach appears promising. An intervention that targets worry has shown good results that were maintained at 6-month and 12-month follow-up. Because of the chronic nature of GAD, the efficacy of combining psychodynamic therapy with cognitive-behavioral techniques has been suggested, and a preliminary evaluation of psychodynamic treatment of GAD found positive results. A randomized trial of integrated interpersonal and cognitive-behavioral therapy, which is currently under way, suggests improved efficacy over either therapy alone.

Social Anxiety Disorder (Social Phobia)

Social phobia, or social anxiety disorder, is characterized by fear or avoidance of negative evaluation by others. Patients with this condition expect embarrassment or humiliation in a wide range of social encounters. Social phobia may occur in a specific form, with fear of one situation (most often, public speaking), or in a generalized form that is debilitating and chronic.

EPIDEMIOLOGY

In large, community-based studies, the lifetime prevalence of social phobia ranges from 7.2% to 9.5%.[57] The disorder is more common in women, normally begins in adolescence or early adulthood, and is characterized by a chronic course. One study suggests that only 30% of patients experience remission.[58]

PATHOPHYSIOLOGY

A recent review posits some interesting possibilities for amygdala involvement in social behavior and social anxiety,

suggesting that study of social primates, such as the macaque, may be informative for human anxiety.[59] Hypothetically, the amygdala may act as a behavioral brake mechanism, functioning to support adaptive evaluation of a novel situation. Social or other anxiety disorders may be associated with enhanced braking and, consequently, too little exposure and learning. A recent study of functional MRI in patients with social phobia has extended this idea by showing that these patients are hypersensitive to human facial displays of emotion, particularly anger, threat, or fear, and exhibit exaggerated amygdala responses to such facial expressions.[60] Patients with generalized social phobia have also been found to have low density of platelet peripheral benzodiazepine receptors, as occurs in other anxiety disorders.

DIAGNOSIS

Clinical Features

Persons with social phobia have persistent fear or avoidance of situations in which they expect to be scrutinized by others or to do something that is humiliating or embarrassing. Common examples are public speaking, eating in restaurants, writing in public (e.g., signing checks or sales slips), urinating in public bathrooms, talking with people in authority, or conversing in other situations of scrutiny, such as parties or social gatherings. Generalized social phobia can be very debilitating, because the person has persistent fear of almost any social situation, including speaking to a supervisor or teacher or even a physician, going to parties, or asking for assistance.

Persons with social phobia have a tendency toward negative interpretation of social events, self-focused attention, and negative-outcome–based cognitive processes (e.g., rumination and anticipatory anxiety). They have a memory bias for negative emotions in others' faces and expressions.[61] Normal individuals tend to blame negative social interactions on others while taking credit for positive experiences. Persons with social phobia often reverse this so-called self-serving bias, blaming themselves for negative experiences and crediting others when interactions are positive.[62]

Presentation in Medical Settings

A person with social phobia who fears urinating in a public bathroom can present with urinary retention. I have treated such a patient, who was serving in the military and thus had minimal privacy, and whose urinary retention was so severe that it resulted in hospitalization. Although there are few specific presentations of social phobia in medical settings, physicians should be alert to this condition. As is the case with other anxiety disorders, persons with social phobia frequent primary care settings[63] and are often not diagnosed.[64] A recent study found that only 2% of persons with social phobia who present to primary care clinicians are diagnosed and that fewer are effectively treated.[65]

TREATMENT

Pharmacotherapy

SSRIs are first-line pharmacotherapy for social phobia. Paroxetine and sertraline have FDA approval, but other SSRIs are also effective. Paroxetine response rates range from 55% to 70%. Fluvoxamine and sertraline response rates are similar.

High-potency benzodiazepines, especially clonazepam, are effective in the treatment of social phobia. Although benzodiazepines are not first-line treatment for social phobia, they can be a highly useful tool in the treatment of this disorder. Monoamine oxidase inhibitors are effective but are rarely used because of the risk of hypertensive crisis and the availability of other, less toxic choices.

Psychological Treatment

Cognitive-behavioral treatments are effective in social phobia,[66] although the disorder presents some special challenges for this approach. Several successful strategies have been developed and tested.[67] As with all the anxiety disorders, delivery of this treatment requires special training and expertise.

COMPLICATIONS

Social phobia is one of the most disabling anxiety disorders, because it can affect virtually every area of potential achievement. Patients with social phobia tend to have less education, lower occupational functioning, and lower health-related quality of life; and they utilize health care resources significantly more than nonanxious persons.[68] Comorbid mood disorders, other anxiety disorders, and substance-abuse disorders are common. Patients with social phobia are as likely to commit or attempt suicide as patients with major depressive disorder.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by repeated intrusive thoughts, ideas, or images (obsessions) and by repeated ritualistic behaviors (compulsions). Afflicted persons recognize the irrationality of their thoughts but are powerless to control them. Similarly, compulsive rituals are seen as senseless but frequently take many hours a day to perform. Obsessions have stereotyped content involving fear of contamination or aggression, persistent doubting, increased religiosity, or the need for symmetry. Associated compulsions often entail cleaning, checking, touching, or counting or other mental activities.

EPIDEMIOLOGY

OCD is relatively rare in comparison with other anxiety disorders, but it can be one of the most debilitating of psychiatric disorders. The estimated lifetime prevalence is approximately 1% to 3%, with monthly prevalence ranging from 0.6% to 3.3%. Mean age of onset is 24 years. The disorder is often chronic, lasting up to 40 years.[69]

PATHOPHYSIOLOGY

There is converging evidence for abnormal activity in the orbitofrontal basal-ganglia thalamocortical circuit in patients with OCD.[70] Positron emission tomography (PET) in these patients has shown that improvement after treatment with an SSRI is associated with decreased metabolism in the right caudate and putamen, the bilateral orbitofrontal cortex and thalamus, and parts of the prefrontal cortex. Functional MRI scans show increased metabolism in frontal subcortical regions after clinical improvement.

A possible autoimmune etiology of OCD has recently been suggested. The antibody D8/17, which is found in rheumatic fever and Sydenham chorea, is elevated in patients with OCD and Tourette syndrome; this elevation predicts larger basal ganglia volume. In childhood, OCD sometimes occurs as a poststreptococcal syndrome known as PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections).[71]

DIAGNOSIS

Clinical Features

OCD is diagnosed when obsessions, compulsions, or both are present for at least 1 hour a day or present at a level that interferes with functioning. Chronicity is the rule, although symptoms may change in focus over time.

Presentation in Medical Settings

A patient with OCD may present to any of several types of specialists, depending on the form the disorder takes. Approximately half of OCD patients partake in washing compulsions[72] in response to obsessive fears relating to germs and contamination. Repetitive hand washing is associated with increased risk for nonspecific dermatitis, which can result in these patients seeking dermatologic treatment.[73] OCD patients may also be seen by dermatologists for excoriation, or excessive picking and scratching of the skin. Those patients with contamination obsessions may present for treatment at an infectious disease practice as a result of their irrational fears.[73] OCD patients may be seen by rheumatologists for physical symptoms resulting from somatization. Many of those with contamination fears are hypochondriacal, fearing a wide range of illnesses. The result is increased utilization of health care resources and time spent with physicians. Primary care physicians may encounter patients with OCD. However, many patients with OCD feel considerable shame about their disorder and may be reluctant to reveal its existence. Like other psychiatric conditions, OCD is clinically recognized by primary care physicians in only 10% to 30% of cases.

TREATMENT

Pharmacotherapy

Serotonin-active antidepressants are the clear first-line pharmacotherapy for OCD. Clomipramine, a serotonin-active tricyclic antidepressant, was the first drug to receive FDA approval for treatment of OCD. Nearly 60% of patients improve substantially with clomipramine, compared with only 3% of those persons who receive placebo. Fluoxetine, sertraline, fluvoxamine, paroxetine, and citalopram have demonstrated comparable degrees of efficacy and tolerability in the treatment of OCD.[74]

Psychological Treatment

Cognitive-behavioral therapy focusing on exposure and response prevention is highly effective for OCD,[75] with over 85% of participants demonstrating clinical improvement in the hands of experts. Adding clomipramine therapy to cognitive-behavioral therapy does not result in improved outcome, whereas the addition of cognitive-behavioral therapy to pharmacotherapy does improve outcome. However, OCD patients with significant comorbid depression might benefit from SSRI treatment before beginning cognitive-behavioral therapy.

COMPLICATIONS

OCD is associated with significant social and occupational impairment, unemployment, and burden to family members.[76]

Specific Phobia in Medical Settings

Specific phobias are irrational fears, usually accompanied by avoidance of the feared stimulus. Physicians should be especially aware of phobias regarding blood and injections. Patients with such phobias may have syncopal episodes on exposure to blood or even to hypodermic needles. Because of their phobias, these patients may avoid obtaining needed tests or even seeking proper medical care; this can result in serious illnesses going undiagnosed and untreated.

Patients with blood-injury phobia may experience significant emotional distress if the medical staff is dismissive or unsympathetic about this problem. Blood-injury phobia differs from other anxiety and phobic reactions in that heart rate slows, rather than accelerates, on exposure to the phobic stimulus. These patients often have a family history of this condition, and it is considered to be a neurobiologic illness rather than a deficit in self-control. Studies document that short-term treatment for blood-injury phobia can be accomplished by trained therapists. Patients who receive effective treatment experience tremendous relief.

Other medically relevant phobias include dental phobia and phobia of childbirth (also called tokophobia). Persons with dental phobia experience extreme apprehension and may avoid dental treatment completely. Psychological intervention in the form of one-session exposure and stress management can be effective. Fear of childbirth can also be a clinically significant condition. At times, it may be so intense that a woman terminates a pregnancy, despite a desire to have children. Even in its milder form, this condition causes considerable emotional distress during pregnancy, and it is desirable to reduce such distress for the benefit of both mother and fetus. Again, referral to a trained therapist is indicated in such cases. No pharmacotherapy has proved effective, but cognitive-behavioral treatments are simple and beneficial.

The author has received grants for clinical research from Pfizer, Inc., and Forest Pharmaceuticals, Inc., and has served as a consultant for and member of the speakers' bureaus of Pfizer, Inc., and GlaxoSmithKline.

IX THE EATING DISORDERS

W. Stewart Agras, m.d.

The eating disorders—anorexia nervosa, bulimia nervosa, and binge eating—tend to be chronic conditions and are accompanied by an increased risk of psychiatric illness. In addition, serious medical problems are associated with anorexia nervosa because of chronic starvation and with binge-eating disorder because of obesity. Eating disorders may also be associated with marked life impairment, faulty interpersonal interactions, and social withdrawal.

Overview of the Eating Disorders

EPIDEMIOLOGY

In women, the lifetime prevalence of eating disorders meeting full diagnostic criteria is about 4%. About 10% of cases of eating disorders occur in males.[1] Bulimia nervosa and binge-eating disorder, either of which can occur as a full or partial syndrome, are the most commonly encountered eating disorders in clinical practice. Anorexia nervosa is seen less frequently. Evidence suggests that these disorders, particularly anorexia nervosa, may be increasing in prevalence.[2] If subclinical cases are included, the overall prevalence of eating disorders in the female population is probably between 6% and 8%. In adolescents, the prevalence of subclinical eating disorders may be substantially higher.[3]

Treatment for the eating disorders is expensive. A study using data from a large insurance database[2] found that the average annual treatment costs per patient were $6,045 for anorexia nervosa, $2,962 for bulimia nervosa, and $3,207 for an eating disorder not otherwise specified (EDNOS).[4] It is likely that most cases of EDNOS were in patients with binge-eating disorder. Furthermore, the expense of treating chronic eating disorders increases as the frequency of hospitalization increases—thus the need for early diagnosis and treatment.

MANAGEMENT

Outpatient Management

Most patients with an eating disorder are treated as outpatients [*see Figure 1*]. Treatment involves both the primary care physician and a mental health professional. In difficult cases, such as a patient with anorexia nervosa or a diabetic adolescent with bulimia nervosa, a close working relationship must be established between the treatment professionals. It is important to select a mental health professional with experience and expertise in the treatment of eating disorders. When the diagnosis of an eating disorder is made, the primary care physician should provide the patient with accurate information concerning the nature, complications, and treatment of the disorder; it may also be appropriate to give this information to the patient's family members. In the adolescent, early recognition and management of anorexia nervosa is particularly important because prompt treatment may prevent the disorder from becoming chronic. The primary care physician may offer a self-help manual, an antidepressant, or both for some patients with bulimia nervosa and binge-eating disorder. Should such treatment fail, the patient should be referred to a mental health professional for treatment.

Inpatient Management

The principal criterion for hospitalization of a patient with an eating disorder is weight less than 75% of ideal body weight; other criteria include dehydration, vascular instability, hypothermia, and, in the anorectic who purges and the patient with bulimia nervosa, depletion of potassium and other electrolytes. Thus, the medical treatment of anorexia nervosa includes rehydration and correction of electrolyte disturbances. The patient should be examined frequently, and the levels of electrolytes (sodium, potassium, chloride, bicarbonate, phosphorus, and magnesium) should be monitored frequently. It is important to warn the patient that temporary edema may occur because of rehydration and electrolyte correction; this information helps allay the patient's concerns about weight and shape. Congestive heart failure occasionally occurs early in the refeeding period; hence, careful evaluation of cardiovascular status during the early stages of refeeding is necessary.[5] Hypophosphatemia may also develop at this time, when reserves are depleted.[6] Inpatient care is best provided in specialized units and should be administered by professionals who have had considerable experience in the treatment of anorexia nervosa. After gaining some weight, the patient may best be treated in a partial hospitalization program aimed at restoration of weight to at least 90% of ideal body weight. Controlled studies indicate that outpatient psychotherapy may be as effective as inpatient treatment for anorectic patients,[7] which suggests that outpatient therapy for anorexia nervosa may be underutilized. Thus, for patients who weigh more than 75% of their ideal body weight and who do not have significant medical complications, outpatient treatment should be attempted before hospitalization.

Pregnancy in Patients with an Eating Disorder

Patients with anorexia and bulimia nervosa who become pregnant during the course of their illness should receive more intensive prenatal care because of increased risk of low-birthweight infants and other perinatal complications.[8] Women who have eating disorders may have difficulty feeding their children because of concerns about their children's weight and shape,[9,10] and inadequate feeding may result in lagging growth and development. Careful monitoring of the nutritional status and development of such children is necessary.

The National Institute for Health and Clinical Excellence (NICE) provides an excellent guide to the management of the eating disorders.[11]

Anorexia Nervosa

Anorexia nervosa is characterized by a reduction in ideal body weight of at least 15%, accompanied in females by amenorrhea. It is also characterized by an intense fear of gaining weight, a preoccupation with food, obsessions and rituals concerning food, a distorted body image (the patient feels fat despite evidence to the contrary), and excessive exercise. Marked and unexplained weight loss in an adolescent female should alert the physician to the possibility of anorexia nervosa.

Long-term follow-up studies have revealed that anorexia nervosa runs a protracted course; it has a mortality of 5% to 15%, depending on the length of follow-up.[12] About half the

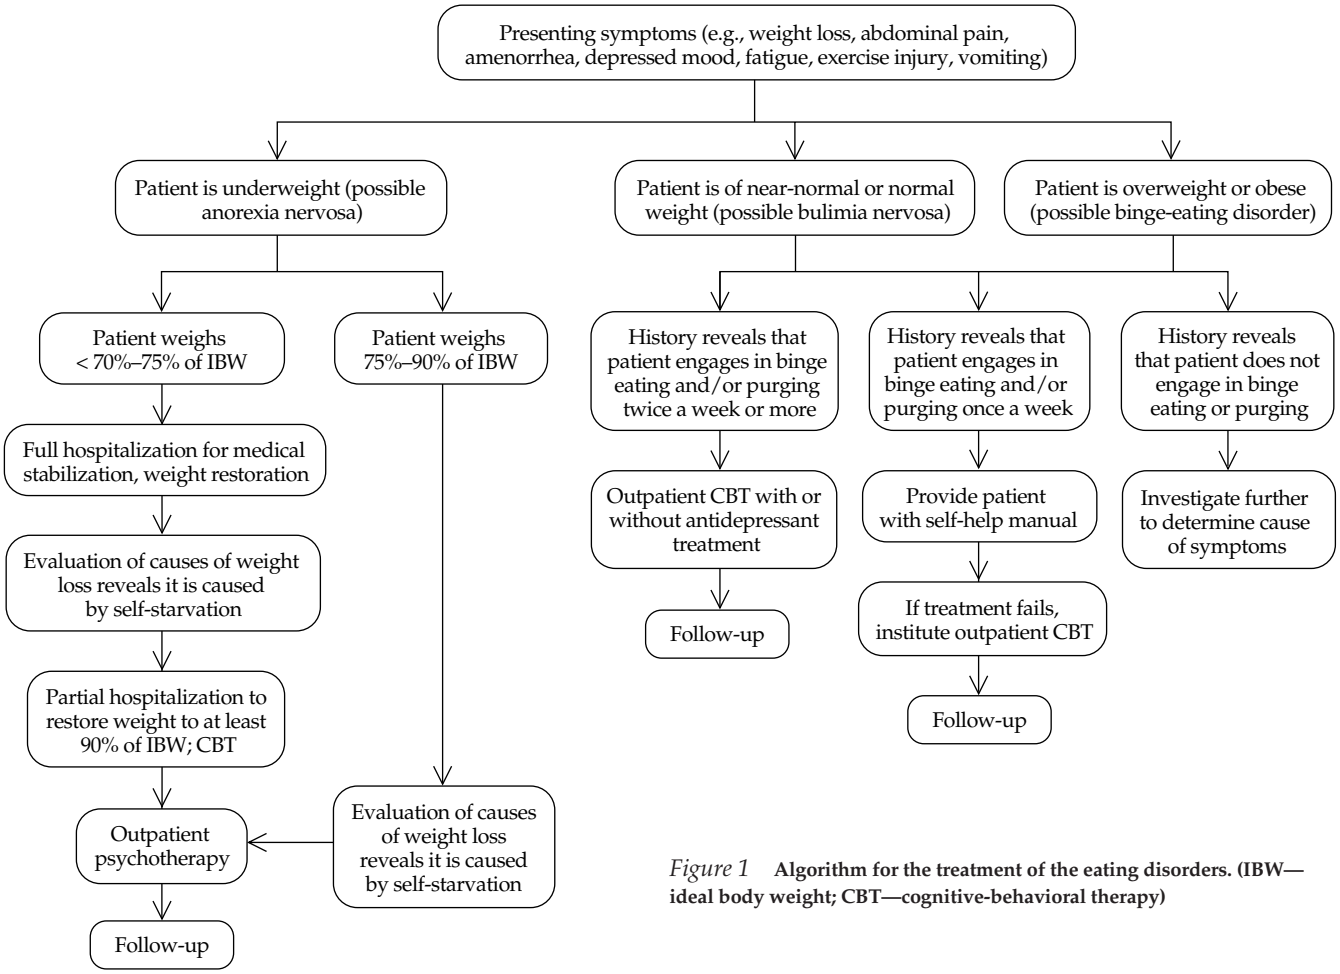

Figure 1 **Algorithm for the treatment of the eating disorders. (IBW—ideal body weight; CBT—cognitive-behavioral therapy)**

deaths are suicides associated with major depression; the other deaths result from medical complications associated with malnutrition. Both mental and physical status should be monitored throughout the course of the illness. Between 40% and 50% of anorectics recover within 10 years; the others continue to have an eating disorder, which is most frequently low-weight clinical or subclinical bulimia nervosa.[13]

EPIDEMIOLOGY

Anorexia nervosa is a relatively rare disorder, with an incidence of five to 10 cases per 100,000 population and a lifetime prevalence of 0.25% to 0.50% in the female population.[5] The disorder may begin in childhood but most frequently emerges in adolescence, with fewer cases beginning in adulthood.

ETIOLOGY/GENETICS

Family studies of anorexia nervosa have revealed that the disorder occurs more frequently in relatives of affected persons than in relatives of persons who do not have an eating disorder.[14] This finding suggests that genetic transmission, familial influences, or both play a role in etiology. The case for genetic transmission is strengthened by twin studies, which have shown that an eating disorder is more likely to develop in an identical twin than in a nonidentical twin of a person with anorexia nervosa.[15] Moreover, these studies suggest that heredity accounts for as much as 50% of the causal factors of anorexia nervosa. Family influences also undoubtedly play a part in the etiology of anorexia nervosa, although few adequate risk-factor studies exist for anorexia nervosa. Risk factors for the development of anorexia nervosa include picky eating in childhood and perfectionism. There also appears to be an overlap between obsessive-compulsive disorder and anorexia nervosa.

PATHOGENESIS

Disturbances of serotonin (5-hydroxytryptamine [5-HT]) pathways probably play a role in the pathogenesis of anorexia nervosa.[16] Serotonin pathways contribute to the modulation of a number of behaviors commonly associated with this disorder, such as behavioral inhibition, obsessionality, anxiety and fear, depression, and appetite regulation. Many studies show disturbances of 5-HT activity in persons who currently have or who have recovered from anorexia nervosa. In addition, cerebrospinal fluid concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of 5-HT that tends to inhibit eating, have been shown to be elevated in anorectics in long-term recovery. Accumulating evidence indicates that serotonin abnormalities affect the development of anorexia nervosa; however, appetite regulation is extremely complex, and it is unlikely that only the serotoninergic system would be implicated.

Genetic findings, although preliminary, also confirm abnormalities in serotonin functioning in patients with anorexia nervosa. The strongest genetic finding to date involves a functional polymorphism in the promoter region of the human 5-HT transporter (*5-HTT*) gene.[17] Several lines of evidence suggest

that the genotype that has two copies of the long allele has greater 5-HT reuptake than the genotypes that have either one or two copies of the short allele.[18] Because *5-HTT* regulates 5-HT concentrations by recycling released 5-HT, persons with the short allele are likely to have higher extracellular 5-HT concentrations. A meta-analysis suggested that the short allele appeared to increase the risk for anorexia nervosa.[19]

DIAGNOSIS

Clinical Manifestations

The primary symptoms of anorexia nervosa are severe dietary restriction and marked weight loss, which often occur after a period of mild weight gain. Sometimes, dietary restriction is triggered by negative comments concerning the weight gain. In other cases, the disorder emerges following a stressful life event. Amenorrhea is often seen soon after the onset of the disorder. Distortion of body-image perception is another signal feature: the patient is emaciated but believes that certain parts of the body (e.g., the stomach, thighs, and upper arms) are fat. Excessive exercise is also common. The patient often develops obsessive thinking regarding food and may have many irrational food rules (e.g., eat only green foods or always leave food on the plate). The patient may also perform rituals during food consumption (e.g., chewing food a certain number of times). All patients restrict their food intake; however, half of the patients also binge and purge, although the binges may be quite small. Depressive symptoms are common. A relatively high percentage of patients have an associated anxiety disorder, often a social phobia, or obsessive-compulsive disorder.

Physical Examination

Physical examination of a patient with anorexia nervosa reveals marked emaciation; dry skin that may be covered with fine body hair (lanugo); and cold, cyanotic extremities sometimes accompanied by peripheral edema, bradycardia, and hypotension. Pubic and axillary hair tend to be preserved. Bone density is reduced as a result of the poor nutrition and low estrogen levels that accompany the disorder. Over half of all patients with anorexia nervosa suffer from osteoporosis, and the risk of fractures is increased.[20] Gastric emptying is often slowed, leading to complaints of gastric distress after eating.[21] The starvation may impair cognitive function, leading to poor concentration, memory, and judgment. Cognitive impairment may not be evident on examination but may be demonstrated on psychological testing.

Laboratory Tests

Usually, few abnormalities are noted in electrolyte, enzyme, or protein levels, although potassium levels may be low in anorectics who are also bulimic, and hepatic function may occasionally be impaired. Both anemia and leukopenia are commonly present,[22] and cholesterol and β-carotene levels may be elevated. Levels of various hormones are abnormal, suggesting hypothalamic dysfunction. Plasma gonadotropin levels are significantly decreased, and the 24-hour luteinizing hormone pattern resembles that found in prepubertal girls. Follicle-stimulating hormone and estrogen levels are also low, and growth hormone levels are elevated. Total serum thyroxine and triiodothyronine levels are usually low, but the free thyroxine level is usually normal. Resting plasma cortisol levels are in the high-normal or elevated ranges, and the diurnal secretion pattern is diminished. These hormonal abnormalities are caused by starvation and are also found in other syndromes characterized by malnutrition and significant weight loss.[23]

DIFFERENTIAL DIAGNOSIS

The diagnosis of anorexia nervosa is usually straightforward because the presentation, history, and physical findings are typical of the condition. Other causes of marked weight loss in adolescence include malignancy, malabsorption syndromes, diabetes mellitus, and hyperthyroidism. The differential diagnosis in cases in which weight loss has not yet reached the diagnostic criterion (15% less than ideal body weight) may pose a problem, because amenorrhea may occur early in the disorder. In such cases, hypopituitarism may have to be ruled out, although a careful elicitation of the history usually reveals the patient's dietary restriction, preoccupation with weight and shape, and perhaps binge eating and purging. Occasionally, a patient with schizophrenia has delusions that center on food consumption (e.g., the delusion of being poisoned) and may lose considerable weight. However, the absence of weight and shape concerns and the presence of delusions usually make the diagnosis evident. Major depression accompanied by marked weight loss may also mimic anorexia nervosa, but the other features of anorexia nervosa are not present.

MANAGEMENT

A major problem in treating anorectic patients is their denial of the severity of their condition and refusal to cooperate with the treatment regimen. Because uncooperative patients will gain little from treatment, it is worth spending considerable time with patients and their families to at least partly overcome this resistance before referral for specialty care. In general, the earlier treatment begins after onset of the disorder, the more likely it is that the patient will benefit. This fact underlines the importance of early recognition and treatment of the syndrome during childhood and adolescence. Once the disorder enters the chronic phase, treatment is less likely to succeed, and rehabilitation and quality-of-life improvement become treatment goals.

Family Therapy

Small, controlled trials suggest that family therapy specifically aimed at the eating disorder should be the treatment of choice for the adolescent anorexic.[24] About two thirds of patients respond well to this form of outpatient therapy; thus, the costs associated with hospitalization are reduced. Therapy essentially consists of helping the parents take back control of feeding from the anorectic patient and initiate a program of refeeding. In later sessions, more general family problems relating to the anorectic patient are addressed.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy for anorexia nervosa, usually targeted at adult patients, has emerged as a treatment strategy. This psychotherapeutic approach focuses on giving nutritional advice, monitoring the effects of that advice, and counseling patients to overcome cognitive distortions and avoidant patterns present in their interpersonal relationships. No adequately controlled trials address the efficacy of this approach. Treatment of adults, who usually are in the chronic phase of anorexia nervosa, is difficult and may require long-term psychotherapy and rehabilitation. Such patients should be followed medically at regular intervals.

Pharmacologic Therapy

Pharmacologic therapy may be considered as adjunctive to family therapy or cognitive-behavorial therapy in patients with chronic anorexia nervosa; it should not be the sole treatment offered to the patient. The main use of pharmacologic agents in chronic anorexia nervosa is to treat associated psychopathologies, such as panic disorder, social phobia, and obsessive-compulsive disorder.

Various psychopharmacologic approaches to treatment of anorectic patients have been evaluated in controlled trials and have included the use of tricyclic antidepressants, fluoxetine, lithium, and antipsychotic compounds. There are various rationales for the use of these compounds—for instance, the observation that patients who take antipsychotic agents such as chlorpromazine tend to gain weight and the finding that anorectics often suffer from depressive symptoms. The results of these trials have been disappointing: no evidence of clinically useful effectiveness for any of these medications in the acute phase of treatment has been established.[25] Moreover, patients with anorexia nervosa are often reluctant to take medication, particularly if the medication might lead to weight gain. Symptoms such as depression often disappear as weight is gained.

Because obsessive-compulsive disorder is associated with anorexia nervosa and because the genetic findings implicate serotonin metabolism, interest has focused on the use of the selective serotonin reuptake inhibitors (SSRIs) that are effective in patients with obsessive-compulsive disorder. Small controlled and uncontrolled trials suggest that fluoxetine may be useful in helping patients maintain their weight gain.[26] Open-label trials also suggest that the newer antipsychotics, such as olanzepine, may be effective in reducing depression, anxiety, and core eating-disorder symptoms (e.g., food obsessions and distorted body image) and in enhancing weight gain.[27]

Hospitalization

The principal aim of hospitalization of the patient with anorexia nervosa is to enhance weight gain and attain physiologic stability. The refeeding syndrome is of particular concern in the early phase of hospitalization in severely malnourished patients. This syndrome involves major shifts in fluid and electrolyte levels, particularly phosphorus and potassium. The syndrome can be prevented by slow refeeding and daily monitoring of serum phosphorus and potassium levels for 7 to 10 days after admission to hospital. Studies conducted in hospital settings have shown that when caloric intake and promotion of weight gain are accompanied by some form of reinforcement, weight gain accelerates. Reinforcement strategies may be as simple as allowing the patient to leave the hospital room, to watch television, and later to leave the hospital for short periods. Such privileges are contingent on small and continued weight gains. When the patient's condition has stabilized, either partial hospitalization (i.e., day hospitalization) or outpatient treatment can begin. However, the chance of relapse is increased if the patient is discharged with a body mass index of less than 19.

Medical Complications

Cardiovascular complications Among the more serious medical complications seen in patients with anorexia nervosa are those that affect the cardiovascular system.[23] Electrocardiography typically shows a low-voltage pattern and bradycardia. However, arrhythmias, including ventricular arrhythmias, may be caused by both starvation and hypokalemia and are implicated in the sudden deaths that occasionally occur in low-weight anorectics. Cardiomyopathy secondary to starvation and to the abuse of ipecac (used to induce vomiting) may also be seen.

Renal complications Long-term dehydration accompanied by hypokalemia may cause renal complications, including irreversible damage to renal tubules. Renal calculi have also been reported to occur as a consequence of dehydration.

Osteopenia and osteoporosis Osteopenia and osteoporosis are seen in most cases of anorexia nervosa. One cross-sectional community-based study of women with anorexia nervosa found that 51.7% had osteopenia and 34.6% had osteoporosis.[22] The treatment of this important problem is uncertain. The best evidence to date suggests that adequate nutrition and weight gain, together with calcium intake of 1,500 mg/day, and vitamin D intake of 400 IU/day will result in increased bone density, but full recovery is uncommon. Hormone replacement therapy (estrogen/progestin combination) has not been shown to be helpful in patients with anorexia nervosa in a number of controlled clinical trials.[20]

PROGNOSIS

Anorexia nervosa has one of the highest mortality rates of any psychiatric disorder. In long-term follow-up studies, fewer than 50% of patients with anorexia nervosa have been shown to have recovered, and in patients who have recovered, social and work functioning are often poor. Recovered patients often suffer from anxiety and depression. The shorter the duration of the illness and the higher the weight at which the patient is initially treated, the better the prognosis.

Bulimia Nervosa

Bulimia nervosa is characterized by binge eating followed by compensatory purging. Binge eating consists of a sense of loss of control over eating and usually the consumption of large amounts of food that is typically high in simple carbohydrates and fat. Purging usually consists of self-induced vomiting and abuse of laxatives; less commonly, purging involves the use of diuretics or enemas or the practice of chewing food and spitting it out. Occasionally, patients with bulimia nervosa engage in episodes of fasting that last for several days. Bulimics also frequently engage in excessive exercise to compensate for binge eating. Concerns about weight and shape frequently dominate the thinking of these patients.

EPIDEMIOLOGY

Bulimia nervosa has a lifetime prevalence of 1.0% to 1.5% in females. The disorder rarely affects males.[1]

Cultural pressure for thinness, engendered by media, peer, or parental pressure, has increased in the United States over the past 25 years. Research has shown that concerns about weight and physique cross gender and racial and ethnic boundaries. The results of a comprehensive self-report health survey completed by 17,571 adolescent girls suggest that no relation exists between socioeconomic status and eating disorders.[28]

ETIOLOGY/GENETICS

Prospective studies have delineated several risk factors for the development of bulimic symptoms. Studies of adolescent girls have found that weight concerns and thin-body preoccupation,

together with social pressure to achieve a thinner body, strongly predict the onset of bulimic symptoms.[29] In addition, higher body weight gives rise to body dissatisfaction and to dieting. Negative affect (depression and anxiety) is also a risk factor for the development of bulimic symptoms. Physicians should be alert for the presence of such behaviors, particularly in female adolescents and preadolescents, and should monitor such patients for the development of binge eating and purging.

Family studies reveal that the relatives of probands with pure forms of anorexia nervosa or bulimia nervosa have an equal chance of having either disorder, suggesting that there may be a common genetic predisposition to both anorexia nervosa and bulimia nervosa.[24] Evidence demonstrates a partial overlap in the genetic predisposition to eating disorders and major depression, suggesting that a common genetic factor may increase the risk of both illnesses.[11] Family influences also appear to be important.

DIAGNOSIS

Clinical Manifestations

On presentation, patients with bulimia nervosa frequently complain of fatigue, decreased energy, abdominal pain, amenorrhea, recurrent vomiting (without revealing that it is self-induced), and depression; less frequently, they are found to spit up blood from a small esophageal tear. Patients may also have joint pain or other trauma after excessive exercise. The diagnosis of bulimia nervosa should also be considered when routine laboratory tests reveal an unexpectedly low serum potassium level, when there is unexplained enlargement of the parotid or submaxillary salivary glands, or when the patient has tooth decay and periodontal disease, which can result from bingeing on sweets and from the presence of acid in the mouth after purging.

Patients who meet the minimal clinical criteria for the diagnosis of bulimia nervosa (purging type) engage in binge eating and purging on an average of two or more times a week for 3 months. Alternatively, patients may not purge (nonpurging type) but may engage in compensatory behaviors such as fasting or excessive exercise.

Patients who do not meet the clinical criteria for a diagnosis of a full-fledged eating disorder or who have an atypical presentation are classified as having an EDNOS. However, evidence suggests that partial eating disorders and full-fledged eating disorders cause similar levels of disability and have similar related psychopathologies; therefore, partial cases should also be considered for referral for treatment.

Once the diagnosis of bulimia nervosa has been made, it is important to review the patient's history and current mental status for the presence of comorbid psychopathology. Over half of all patients with bulimia nervosa have a history of major depression, and about 20% have major depression at the time of diagnosis. Anxiety disorders are also fairly common. About one third of patients also have a history of alcohol or drug dependency or abuse, and a fairly high percentage are alcohol or drug dependent at the time of diagnosis.

Patient History

Bulimia nervosa usually begins in adolescence. Like patients with anorexia nervosa, patients with bulimia nervosa typically have a history of dieting after a modest weight gain; however, in bulimics, the weight loss associated with dieting is relatively small, and dieting is followed by binge eating and purging or other compensatory behaviors. The size of binges varies from small (no more than 100 kcal) to very large (several thousand kilocalories); the key feature of a binge is the sense of loss of control over eating, not the amount of food consumed. The average binge consists of about 1,500 kcal (i.e., about the size of two meals).

Binges may be precipitated by dietary restriction; however, the most commonly reported trigger is a negative emotion arising from interpersonal problems. During the binge, negative emotions may decline; as the binge progresses, however, guilt feelings increase. Although the weight of the typical bulimic is close to normal, some patients with the disorder are nearly anorectic; others are overweight and even obese. Many bulimics engage in excessive exercise and exhibit concerns about weight and shape. However, these concerns are not as extreme as the distortions of body image perceived by the anorectic.

Physical Examination

Making the diagnosis of bulimia nervosa can be difficult because patients tend to hide their symptoms from their families, friends, and physicians. Such hiding of symptoms results from the shame that these patients feel. It is essential for the clinician to establish a good relationship with the patient who is suspected of having an eating disorder and to take a detailed history using gentle, open-ended questions. Patients with eating disorders have been found to visit their family practitioner more frequently than other patients during the years before the eating disorders are diagnosed. It is important to remember that not all eating disorders are found in thin, young women. Approximately 15% of bulimics are overweight, and many are middle aged. Simple questions such as "Do you think you have an eating problem?" or "Do you worry excessively about your weight?" may be useful for general screening.[11] Although it may be difficult to obtain, a detailed history of food intake is helpful in making the diagnosis. This history can be obtained by determining the patient's food intake during the past 24 hours and then ascertaining how typical such intake is for the patient, noting differences between weekdays and weekends. The bulimic patient tends to restrict food intake early in the day but gradually loses control of eating, which leads to binge eating later in the day and in the evening.

The only findings on physical examination that suggest the presence of bulimia nervosa are dry skin, evidence of dehydration, and fluctuant hypertrophy of the salivary glands, which is seen fairly frequently. Resting bradycardia may also be present.

Laboratory Tests

The most common laboratory finding is an elevated serum amylase level that is usually of parotid origin. Metabolic alkalosis secondary to purging is also frequently found, with raised serum bicarbonate levels, hypochloremia, and, occasionally, hypokalemia, although this last disorder occurs in only 5% of patients with bulimia nervosa.

DIFFERENTIAL DIAGNOSIS

There are few conditions with symptoms similar to those of bulimia nervosa, although patients with spontaneous vomiting do need to be distinguished from those with self-induced vomiting.

MANAGEMENT

Psychotherapy

It is generally agreed that the most effective treatment for bulimia nervosa is an outpatient trial of cognitive-behavioral

therapy. A large number of controlled trials have demonstrated that such therapy is more effective than no treatment, other forms of psychotherapy, antidepressant medication, and placebo.[30,31] The usual course of treatment is 20 sessions over 6 months. Approximately 50% of patients who complete treatment with cognitive-behavioral therapy recover, and an additional 20% to 30% show significant improvement. A 5-year follow-up study of patients treated with cognitive-behavioral therapy found that the gains made during therapy are well maintained.[32]

Cognitive-behavioral therapy Cognitive-behavioral therapy is aimed at reversing the dietary restriction underlying the binge eating and purging. In the first phase of therapy, the patient monitors dietary intake, binge eating, and purging, and the therapist helps the patient move toward a pattern of eating three meals and two snacks daily, gradually increasing the amount and variety of foods that were previously avoided. In the second phase, attention shifts to overcoming the patient's distorted thinking about weight, shape, and food rules. Finally, attention is directed toward relapse prevention. These principles have recently been incorporated into self-help manuals.[33] Such manuals, combined with brief cognitive-behavioral therapy, have been helpful for about 25% of patients in several controlled trials.[31] It is unclear, however, whether brief cognitive-behavioral therapy, with or without pharmacologic therapy, is useful in nonspecialty settings. One controlled trial found very high rates of patient dropout and concluded that brief cognitive-behavioral therapy was ineffective.[34] A British study suggested that brief cognitive-behavioral therapy was as effective as specialist care; however, in that study, the number of visits to both the family practitioner and the psychiatrist or psychologist (4.9 and 4.8, respectively) were inadequate, and the improvement in bulimic symptoms was small.[35]

Interpersonal psychotherapy Interpersonal psychotherapy appears to be useful in the treatment of bulimia nervosa, although the beneficial effects of interpersonal psychotherapy are slower to manifest than those of cognitive-behavioral therapy. One large clinical trial found that cognitive-behavioral therapy was more effective than interpersonal therapy at the end of 20 weeks of treatment[36]; however, no differences between treatments were found at the 1-year follow-up. Interpersonal psychotherapy focuses directly on current interpersonal problems and may be effective because negative affect associated with faulty interpersonal interactions are reduced.[8]

Pharmacologic Therapy

Both the tricyclic antidepressants (e.g., desipramine, 150 to 300 mg/day) and the SSRIs (e.g., fluoxetine, 60 mg/day) have been shown to be effective in the treatment of bulimia nervosa.[37] However, only 20% to 30% of patients who complete a trial of medication stop binge eating and purging. A controlled trial used a sequence of two medications (i.e., desipramine followed by fluoxetine).[38] When desipramine did not work, it was discontinued and fluoxetine begun. This sequential use of medication was as effective as cognitive-behavioral therapy. Another controlled study found that fluoxetine was more effective than placebo in the treatment of patients who failed to respond to cognitive-behavioral therapy or who experienced relapses.[39] The anticonvulsant topiramate in doses up to 400 mg also appeared to be effective in reducing binge eating and purging.[40]

Treatment with antidepressants appears to be the most cost-effective approach (i.e., cost per recovered patient).[41] It may be appropriate to begin treatment with antidepressant medication, supplemented by the use of a self-help manual, and reserve cognitive-behavioral therapy for those patients who fail to improve. Medication should probably be continued for at least 6 months; it is important to taper medication gradually and monitor for symptom recurrence. If symptoms recur, medication should be restarted.

Medical treatment also includes potassium supplementation for patients with low serum potassium levels and the correction of laxative abuse. Potassium supplementation is important because as with the patient with anorexia nervosa, the low-weight bulimic patient with low potassium levels is at risk for the development of fatal arrhythmias. The best way to treat patients who abuse laxatives is to persuade the patient to abruptly stop using the laxatives or to replace stimulant laxatives with bulk laxatives; however, education and support must be provided to the patient with regard to the pain and discomfort that inevitably will occur as the gut readjusts to normal function.

Medical Complications

Dental complications Dental complications frequently occur and include erosion of enamel, which sometimes causes fillings to protrude, and periodontal disease; thus, patients should be advised not to brush their teeth after purging, to use a nonacidic mouthwash, and to seek regular dental care.[42] There are few effects on other major organ systems. Rarely seen complications are esophageal tears caused by purging and a ruptured stomach and acute dilatation of the stomach, both of which occur after very large binges. Abuse of stimulant laxatives may lead to chronic physiologic dependence on them. About one quarter of bulimics have had an episode of anorexia nervosa. In such patients, osteopenia or osteoporosis may be present and may require treatment.

Diabetes mellitus Subclinical eating disorders or bulimia nervosa may occur in a substantial number of adolescents with type 1 diabetes mellitus.[43] Adolescents with diabetes often lose weight before their diabetes is diagnosed. When treatment begins, they often gain weight rapidly. This weight gain may heighten concerns about weight and shape in adolescent females, leading to dieting and then to binge eating and purging. Unfortunately, modern intensive management of diabetes with restriction of carbohydrates, consistent eating habits, and careful titration of insulin may, because of the restrictions involved, pose a risk of an eating disorder. Adolescent diabetics often discover that they can decrease caloric intake by omitting insulin doses, despite awareness about the importance of compliance with the medical regimen. The presence of bulimia nervosa or a subclinical variant should be suspected in female adolescent diabetics who have poorly controlled diabetes. In one study, 29% of adolescent diabetics had highly or moderately disturbed eating patterns.[44] Hemoglobin A_{1c} levels were significantly higher in patients with disturbed eating behavior than in patients with normal eating patterns. At follow-up 4 years later, patients with disturbed eating patterns at baseline were more likely to demonstrate retinopathy. To prevent such early complications of diabetes, it is important to obtain a thorough history of dieting and eating habits from all adolescent female patients who are diabetic.

PROGNOSIS

The prognosis for patients with bulimia nervosa is more favorable than that for patients with anorexia nervosa; in long-term follow-up studies of patients with bulimia nervosa, approximately 70% have been shown to have recovered. After recovery, however, many patients have residual psychopathology, such as anxiety and depression. Unexpected deaths may occur in patients with bulimia nervosa, usually in the low-weight bulimic who has low blood potassium levels and cardiac arrhythmia.

Binge-Eating Disorder

Binge-eating disorder is characterized by episodes of binge eating without compensatory behaviors, such as purging, and it is often accompanied by overweight or obesity.

EPIDEMIOLOGY

Epidemiologic studies of binge-eating disorder suggest a lifetime prevalence of 2% for females,[45] and some studies suggest that the ratio of females to males with binge-eating disorder is 3 to 2, making it the only eating disorder with a substantial proportion of males. The prevalence of binge-eating disorder in the obese population is between 25% and 33%. The majority of patients with binge-eating disorder are overweight or obese; however, in adolescents and young adults, weight may be within normal limits.

ETIOLOGY

Little is known about the etiology of binge-eating disorder, although the similarity to bulimia nervosa would suggest that it shares many of the same risk factors.

DIAGNOSIS

Clinical Manifestations

Patients who meet the minimal clinical criteria for the diagnosis of binge-eating disorder engage in binge eating at least 2 days a week for 6 months. Whereas in bulimia nervosa binge eating is measured by the number of episodes, in binge-eating disorder it is measured by the number of days in which binge eating occurs, because the absence of purging in patients with binge-eating disorder makes it more difficult to delineate episodes accurately. Although patients with binge-eating disorder are often overweight, they exhibit greater dissatisfaction with their weight and shape than do overweight persons who do not binge.

Patient History

The diagnosis of binge-eating disorder should be considered for all overweight patients, particularly those with continued sizable weight gain or marked weight cycling. Binge-eating disorder usually begins in late adolescence. As with bulimic patients, patients who have binge-eating disorder have a history of weight gain followed by dieting and the onset of binge eating. Many patients report having attempted purging early in the course of the disorder but found such behavior repulsive or were unable to perform it easily or regularly. The disorder appears to be chronic and is usually accompanied by an inexorable weight gain. Patients do not usually seek treatment for binge-eating disorder; they are often diagnosed later in life when they enter a weight-loss program.

Binge-eating disorder is characterized by periods of dietary restriction that alternate with binges. The periods of dietary restriction are less striking than those of bulimic patients, and the binges are less clearly defined; one binge often merges into another. Although binges vary considerably in size, they are smaller than those seen in patients with bulimia nervosa, (1,000 kcal for binge eating, versus 1,500 kcal for bulimia nervosa). Like anorexia nervosa and bulimia nervosa, binge-eating disorder is often accompanied by major depression, anxiety disorders, and personality disorders. Because these conditions are more commonly found in patients with binge-eating disorder than in weight-matched obese persons without binge-eating disorder,[46] it appears that the psychopathology is related to the eating disorder, not to excess weight or obesity.

DIFFERENTIAL DIAGNOSIS

Apart from rare cases of brain injury associated with binge eating, there are few conditions with similar presentations.

MANAGEMENT

Psychotherapy

As with bulimia nervosa, controlled studies of binge-eating disorders suggest that cognitive-behavioral therapy is an effective approach.[46] However, cognitive-behavioral therapy has little effect on weight; therefore, concurrent treatment of overweight or obesity should be considered. The use of a self-help manual covering cognitive-behavioral principles, with brief therapist supervision, is also effective in reducing binge eating.[31] Controlled studies have also found that interpersonal psychotherapy is as effective as cognitive-behavioral therapy, both at the end of treatment and at follow-up, in the treatment of binge-eating disorder.

Because weight-loss treatment entails dietary restriction, some researchers have questioned whether such treatment leads to increased binge eating. Studies have provided little evidence to support this hypothesis. Indeed, studies have shown that weight-loss treatment reduces the rate of binge eating.[47] This reduction may occur because the chaotic eating habits exhibited by patients with binge-eating disorder are replaced by more regular eating habits once they enter weight-control programs.

Pharmacologic Therapy

As with bulimia nervosa, antidepressant medication (e.g., fluoxetine, 60 mg/day) is useful in the treatment of binge eating.[48] Although there is no evidence demonstrating that antidepressants add to the effectiveness of cognitive-behavioral therapy in alleviating the eating disorder, it has been shown that antidepressants with cognitive-behavioral therapy may lead to superior weight losses. Therefore, combining psychological and psychopharmacologic treatments should be considered. Topiramate (up to 600 mg/day) has been shown to reduce binge eating and is also associated with substantial weight loss. In one longer-term, controlled trial, participants on topiramate averaged a weight loss of 15 kg.[49] Sibutramine may also be helpful in reducing both binge eating and weight.[50]

As with weight-loss treatment in obese patients, the primary care physician can play an important role in the treatment of patients with binge-eating disorder by following up at regular intervals, monitoring both binge eating and weight

fluctuations, and reinstating appropriate treatment when necessary.

Medical Complications

The principal complication of binge-eating disorder is weight gain, which may be accompanied by the health problems that are usually caused by being overweight. Thus, for patients suspected of having binge-eating disorder, the physician should concentrate on detecting and treating problems such as hypertension, type 2 diabetes mellitus, hypercholesterolemia, and joint disorders. In addition, because of the high rates of comorbid psychopathology, a careful history should be taken for conditions such as depression, anxiety, and alcohol dependence or abuse.

PROGNOSIS

Long-term follow-up studies suggest that although most individuals recover from binge-eating disorder, about one third continue to have a subthreshold eating disorder. Binge-eating disorder appears to be more cyclical than the other eating disorders—that is, episodes of binge eating may alternate with subthreshold status or remission.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

The drugs topiramate and sibutramine have not been approved by the Food and Drug Administration for uses described in this chapter.

I LUNG FUNCTION ASSESSMENT AND THORACIC DIAGNOSTIC TECHNIQUES

ROLAND H. INGRAM, JR., M.D.

Although the history and physical examination are essential to the diagnostic process, pulmonary signs and symptoms often lack sufficient specificity to allow a definitive conclusion. Further information is often required, such as that acquired from assessments of physiologic function, imaging studies, and sampling procedures. Singly and in combination, these studies are important components of the clinical approach to respiratory disorders.

Assessment of Gas Exchange

The ultimate function of the lungs is to replenish the supply of oxygen in the blood and to eliminate the carbon dioxide produced by metabolic activity. Measurement of the partial pressure of oxygen and of carbon dioxide in arterial blood is central to the assessment of respiratory function. Arterial blood gases are obtained from a peripheral artery in a heparinized syringe. Care should be taken to avoid or expel air bubbles, and samples should be delivered to the laboratory on ice and should be processed promptly before cellular metabolism leads to an artifactual decrease in arterial oxygen tension (P_aO_2) and pH and an increase in arterial carbon dioxide tension (P_aCO_2).

OXYGEN

Abnormalities in oxygen exchange are commonly described in relation to the alveolar PO_2 (P_AO_2) or inspired oxygen concentration. Using the alveolar gas equation and assuming a normal resting respiratory exchange ratio (R) of 0.8 and that P_aCO_2 equals P_ACO_2, P_AO_2 can be estimated as follows:

$$P_AO_2 = P_IO_2 - (P_aCO_2 \times 1.2)$$

where P_IO_2 represents the inspired oxygen tension at body temperature, saturated with water.

The measured value of P_aO_2 is subtracted from the calculated value of P_AO_2 to give the alveolar-arterial difference in oxygen (A-aDO_2). Normal values for A-aDO_2 increase linearly with age because of a fall in P_aO_2 with essentially unchanged P_AO_2. Average values for A-aDO_2 range from approximately 9 mm Hg at 20 years of age to 15 mm Hg at 70 years of age. The A-aDO_2 is a commonly employed measure of the efficiency of oxygen exchange. However, even in the absence of changes in pulmonary gas exchanging function, it will change as a function of inspired oxygen fraction (F_IO_2), and it varies directly with cardiac output. The arterial-alveolar oxygen ratio, P_aO_2/P_AO_2, is somewhat more stable over varying inspired oxygen concentrations. The arterial-inspired oxygen ratio, P_aO_2/F_IO_2, is now widely used to quantitate abnormalities of oxygenation in critical care unit patients. A P_aO_2/F_IO_2 ratio of less than 250 indicates the presence of mild acute lung injury, and a P_aO_2/F_IO_2 ratio of less than 100 indicates a severe disorder.

Abnormalities of oxygen exchange [*see Table 1*] are most commonly caused by mismatching of pulmonary ventilation ($\dot{V}$) and perfusion ($\dot{Q}$) or by shunting. Impaired diffusion across the alveolar-capillary membrane generally does not cause abnormalities in oxygenation at rest but can cause abnormalities during exercise and at high altitudes. Abnormalities caused by diffusion impairment and $\dot{V}/\dot{Q}$ mismatching can be corrected by increasing the F_IO_2 and can be completely abolished by 100% inspired oxygen. Hypoxemia caused by shunts, which may be pulmonary or intracardiac, is not corrected by the administration of 100% inspired oxygen. By contrast, other causes of hypoxemia, such as hypoventilation and low inspired O_2 concentration, do not cause an increase in A-aDO_2.

Systemic Oxygen Transport

The total amount of O_2 delivered to the systemic circulation is the product of the cardiac output and the O_2 content per unit of arterial blood (C_aO_2). The C_aO_2 is determined by the concentration and characteristics of hemoglobin and the arterial oxygen saturation (S_aO_2), as indicated by the following equation:

$$C_aO_2 = \text{Hgb (g/dl)} \times S_aO_2\ (\%) \times 1.39\ \text{ml } O_2/\text{g Hgb}$$

The last term in the equation reflects the amount of oxygen that is normally bound to fully saturated hemoglobin, the so-called carrying capacity of normal hemoglobin. The arterial O_2 saturation refers to the percentage of the total O_2 binding sites on hemoglobin that is actually occupied by O_2. The S_aO_2 is in turn determined by the P_aO_2 and the physicochemical properties of hemoglobin, as reflected by the oxygen-hemoglobin dissociation curve [*see Figure 1*]. In the presence of acidemia, fever, elevated concentrations of 2,3-diphosphoglycerate, and certain abnormal hemoglobin types (e.g., hemoglobin Kansas), the oxy-

Table 1 Categorization of Hypoxemia

Cause	*Example*	*P_aO_2*	*P_aCO_2*	*A-aDO_2*	*Response to ↑ F_IO_2*
Low inspired oxygen tension	Mountaineering	↓	Normal or ↓	Normal	Good
Hypoventilation	Drug overdose	↓	↑	Normal	Good
Diffusion impairment	Pulmonary fibrosis plus exercise	↓	Normal or ↓	↑	Good
Ventilation-perfusion imbalance	Chronic obstructive pulmonary disease; pneumonia	↓	Normal, ↓, or ↑	↑	Good
Right-to-left shunt	Pulmonary edema	↓	Normal or ↓	↑	Poor or none

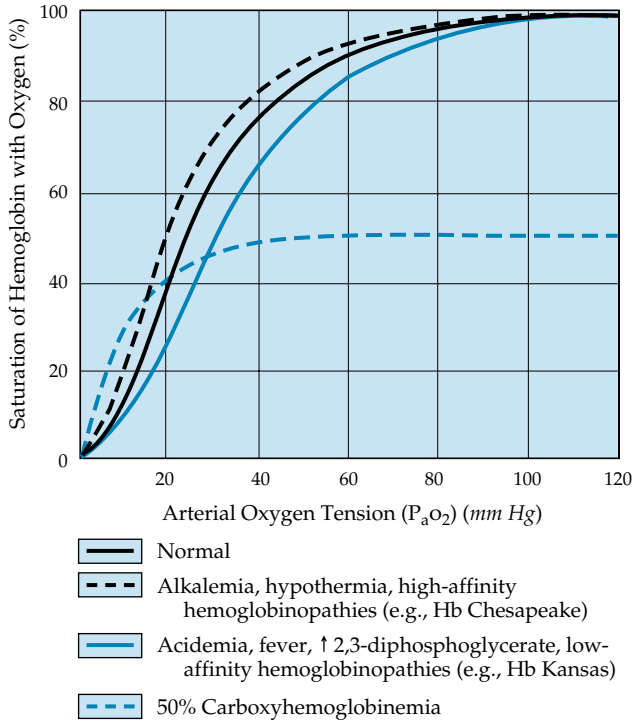

Figure 1 **The relation between arterial oxygen tension (P_aO_2) and the percentage of oxygen binding sites on hemoglobin that are saturated by oxygen is shown by the oxygen-hemoglobin dissociation curve. The sigmoidal shape of the normal curve reflects the cooperative binding of oxygen by hemoglobin. An alteration in pH or body temperature, a change in the concentration of 2,3-diphosphoglycerate, or the presence of certain abnormal hemoglobin types shifts the curve to the left or right, so that at any given P_aO_2, the hemoglobin saturation will be correspondingly increased or decreased. Carboxyhemoglobinemia, in which the oxygen binding sites of hemoglobin are occupied by carbon monoxide, results in both a deformation of the shape of the dissociation curve and a reduction in the maximum number of binding sites that are available to oxygen.**

gen-hemoglobin dissociation curve shifts to the right, which gives a decreased affinity of hemoglobin for oxygen and increased availability of oxygen to tissues. Alkalemia, hypothermia, and other abnormal hemoglobin types (e.g., hemoglobin Chesapeake) have the opposite effect and shift the position of the curve to the left, reflecting an increased affinity of hemoglobin for oxygen and reduced availability of oxygen to tissues.

Anemia does not alter P_aO_2 or S_aO_2. Anemia does, however, reduce the value for C_aO_2 and will decrease O_2 delivery to the tissues if there is not a commensurate increase in cardiac output. A fixed change in P_aO_2 causes a considerably larger change in S_aO_2 over the steep portion of the oxygen-hemoglobin dissociation curve than it does over flatter portions of the curve. For instance, with a fall in P_aO_2 from 100 mm Hg to 90 mm Hg, S_aO_2 decreases from 97.4% to 96.8%, assuming that hemoglobin type is normal and physiologic conditions are standard—pH of 7.40 and body temperature of 37° C (98.6° F). In contrast, a 10 mm Hg decrement in P_aO_2 from 55 mm Hg to 45 mm Hg causes the S_aO_2 to decrease from 88.2% to 80.5%.

A profound reduction in arterial O_2 content may be observed without a significant change in P_aO_2 if O_2 binding to hemoglobin is acutely altered, as occurs in carbon monoxide intoxication. Because of the strong affinity of carbon monoxide for hemoglobin, an arterial carbon monoxide tension (P_aCO) of less than 1 mm Hg is sufficient to cause a 50% saturation of hemoglobin with CO. Under these conditions, P_aO_2 may be 100 mm Hg, but severe tissue hypoxia may be present because S_aO_2 and C_aO_2 values have been reduced by half.[1]

Oximetry

Oxygenation can be monitored noninvasively by pulse oximetry. A pulse oximeter, placed on either a finger or an earlobe, measures the absorption of red (660 nM) and near infrared (940 nM) light through these tissue beds to estimate the ratio:

$$O_2\,Hb/O_2\,Hb + \text{reduced Hb}$$

By assuming the pulsatile portion of the signal represents arterial blood and by comparing the ratio of the pulsatile portion to the nonpulsatile component to a calibration curve of known mixtures of oxyhemoglobin and reduced hemoglobin, the pulse oximeter is capable of estimating S_aO_2. Oximetric estimates are accurate to within ± 1% to 2% for true saturations above 90%. Accuracy deteriorates at saturations below 80%, with errors of ± 5% to 8%. Pulse oximetry is commonly used in emergency and critical care settings, for in-hospital patient transportation, and for assessing oxygenation during sleep. Medicare guidelines allow the use of resting pulse oximetry for determination of qualification for long-term oxygen therapy, but arterial blood gas measurements are still necessary for exercise evaluations for adjudication of disability under Social Security Administration regulations. Accuracy of pulse oximetry is reduced by carboxyhemoglobin, methemoglobin, anemia, motion, bright ambient light, poor perfusion, nail polish, and darkly pigmented skin.[2]

CARBON DIOXIDE

Physiologic mechanisms normally act to maintain the P_ACO_2 level within a narrow range (35 to 45 mm Hg) despite large changes in metabolic CO_2 production. Elevated P_ACO_2 levels (> 45 mm Hg) are termed hypoventilation, and low P_ACO_2 values (< 35 mm Hg) are termed hyperventilation. Corresponding alterations in P_aCO_2 are termed hypercapnia and hypocapnia, respectively. The P_aCO_2 level is directly proportional to the ratio of carbon dioxide production to alveolar ventilation:

$$P_aCO_2 = K(\dot{V}CO_2/\dot{V}_A)$$

where $\dot{V}CO_2$ equals $\dot{V}_E \times F_ECO_2$ and represents the amount of CO_2 (in ml/min) produced by the body's metabolism; and K is a constant (equal to 0.863) that reflects the fact that gas exchange occurs at normal body temperature under conditions of full saturation with water, assuming P_ACO_2 is equal to P_aCO_2. Thus, for any given level of $\dot{V}CO_2$, the alveolar (and arterial) PCO_2 is determined by the level of alveolar ventilation. Hypercapnia is categorized according to causes [*see Table 2*].

VENTILATION

Alveolar ventilation ($\dot{V}_A$) is that portion of the minute ventilation ($\dot{V}_E$) that comes into equilibrium with alveolar gas and represents the difference between $\dot{V}_E$ and dead space ventilation ($\dot{V}_D$). A decrease in $\dot{V}_A$ results from either a reduction in $\dot{V}_E$ or an increase in $\dot{V}_D$.

Minute ventilation is the volume of gas that moves in and out of the lung. The minute ventilation can be calculated by multiplying the respiratory frequency (f) and the tidal volume (V_T), which is the volume of air expired with each breath. Typical resting values in the adult are as follows: respiratory frequency,

Table 2 Categorization of Hypercapnia

Cause	*Example*	P_aCO_2	$\dot{V}_E$	V_D/V_T	*A-a*DO_2
Defective central control of breathing	Drug overdose	↑	↓	Normal	Normal
Neuromuscular disease	Amyotrophic lateral sclerosis	↑	↓	Normal or ↑	Normal or ↑
Chest wall disease	Kyphoscoliosis	↑	↓	Normal or ↑	Normal or ↑
Primary lung disease	Chronic obstructive pulmonary disease	↑	Normal or ↑	↑	↑

14 breaths/min; tidal volume, 400 ml/breath; and minute ventilation, 5.6 L/min. However, there is considerable variability in these values among normal persons and in the same person throughout the day.

Dead space consists of two types: anatomic and functional (also called physiologic). Anatomic dead space is the portion of inspired tidal volume that does not communicate with perfused alveoli and therefore does not participate in gas exchange. Anatomic dead space consists of the tracheobronchial tree from the oropharynx and nasopharynx down through the nonalveolated terminal bronchioles. The volume of the anatomic dead space in milliliters is roughly equal to a person's lean body weight in pounds. Functional dead space ventilation is the sum of the excess ventilation relative to perfusion for all lung units where the ratio of ventilation to perfusion ($\dot{V}/\dot{Q}$) is significantly greater than 1.

A fixed volume of gas from each breath is required to fill the anatomic dead space. For any $\dot{V}_E$, fast and shallow breathing wastes a greater percentage of the minute ventilation because the anatomic dead space is proportionately greater as tidal volume decreases. Conversely, the alveolar ventilation at any $\dot{V}_E$ is greatest when breathing is slow and deep [*see Figure 2*]. Additionally, dead space ventilation can be caused by inequalities in the distribution of alveolar ventilation and perfusion. Certain lung regions have greater ventilation than perfusion. The excess of regional ventilation to blood flow can be thought of as wasted, although in most disease states, the mismatch is caused by regional deficits in perfusion rather than excessive ventilation.

Dead space can be assessed by measuring the fractional concentration of CO_2 in exhaled gas (F_ECO_2) and by estimating the fractional concentration of CO_2 in alveolar gas (F_ACO_2). The F_ACO_2 is estimated by assuming ideal alveolar air conditions, in which P_aCO_2 values are equal to P_ACO_2 values. V_D/V_T, the so-called dead space fraction, is calculated as follows:

$$\frac{(F_ACO_2 - F_ECO_2)}{F_ACO_2}$$

The normal value for V_D/V_T is less than 0.4. The increased work demands imposed by a high V_D/V_T contribute significantly to dyspnea and often to respiratory failure in clinical lung disease.

Pulmonary Function Tests

Pulmonary function testing is used to categorize the nature and severity of pathophysiologic disturbances, to follow the progression of known cardiopulmonary disorders, and to measure the response to therapy. Pulmonary function is often used as the basis for the definition of disability for insurance purposes. Lung resection is the only indication for preoperative pulmonary function testing for which a consensus currently exists. Otherwise, such testing offers little additional benefit over clinical parameters in assessing the risk for postoperative pulmonary complications, and prohibitive thresholds cannot be reliably established. A review reported that abnormal pulmonary function predicted a significantly increased relative risk for postoperative pulmonary complications in only four of 11 studies.[3]

The most commonly used pulmonary function tests are based on the forced vital capacity maneuver, measurements of lung volumes, and pulmonary diffusion capacity. Recording of the forced vital capacity maneuver produces a record of volume versus time, flow versus volume, or both during a forced exhalation from total lung capacity (TLC) to residual volume (RV). Forced vital capacity (FVC) is measured with a spirometer and is the most basic and useful lung function test. The test is simple and highly reproducible. However, valid values require maximal efforts by the patient, and these efforts may be compromised by pain or debilitation. The forced vital capacity maneuver shows whether obstruction is present and, if present, quantitates the severity. If there is no obstruction, a reduced vital capacity indicates restriction. In the absence of obstruction, the severity of restriction is defined by comparing vital capacity with the value predicted according to the patient's height, sex, age, and race.

LUNG VOLUMES

The balance between the physical properties of the lung and chest wall and the action of inspiratory and expiratory muscles determines lung volume. TLC is determined by the action of inspiratory muscles, chiefly the diaphragm, against the elastic recoil of the lung and of the chest wall. RV is determined by expiratory muscles opposing the outward recoil of the lung and chest wall at low lung volumes (in older persons, RV may be increased by airway closure). At the end of each tidal breath (expiration), the respiratory muscles are quiet and the lungs are expanded approximately one third of the way from RV. Functional residual capacity (FRC) is the mechanical resting position of the respiratory system and is determined by the balance of elastic recoil of the lung, which reduces respiratory system volume, and elastic recoil of the chest wall, which increases respiratory system volume. In obstructive lung diseases, FRC may be elevated above the lung–chest wall elastic balance volume if inspiration is initiated before that volume is reached. This is so-called dynamic hyperinflation (or air trapping). The vital capacity (VC) is the largest breath a person can take. The tidal volume at rest is the volume of air that is inspired and expired during normal quiet breathing. A person who has just exhaled a tidal breath (to reach FRC) can either inhale to the top of his or her lung volume (the TLC) or exhale further to the bottom of his or her lung volume (the RV). The inspiratory capacity (IC) is the volume from FRC up to TLC, and the expiratory reserve volume (ERV) is the volume from FRC down to RV. The inspirato-

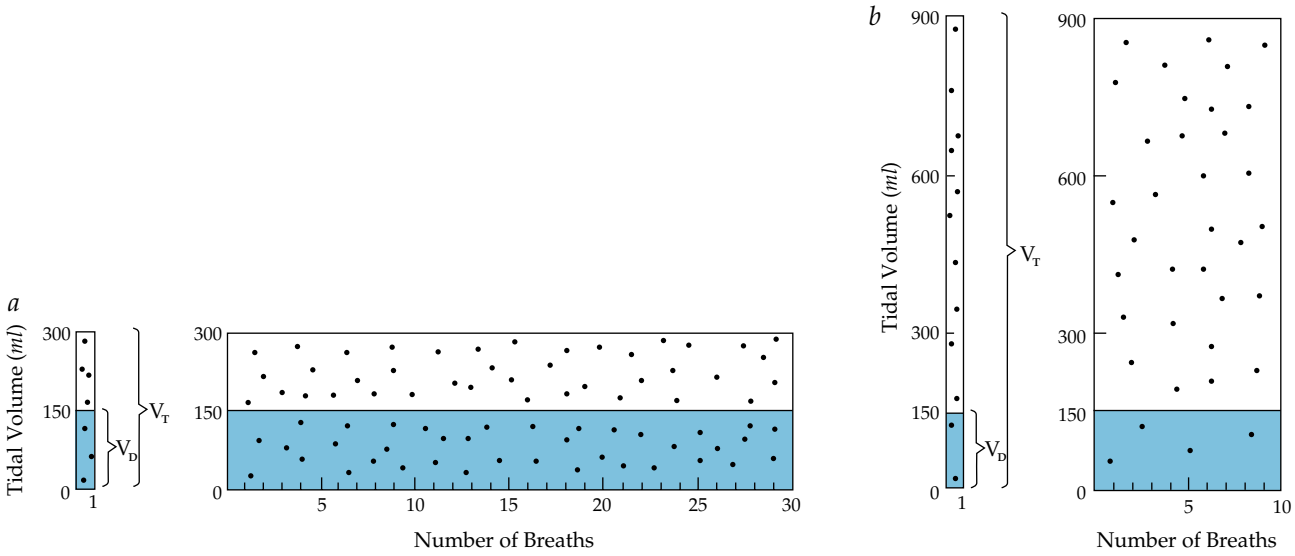

Figure 2 **The effect of varying the respiratory frequency (f) and the tidal volume (V_T) on the alveolar ventilation ($\dot{V}_A$) and the dead space ventilation ($\dot{V}_D$) is shown. Two different breathing patterns (*a* and *b*) in a normal person weighing 150 lb are shown; both patterns achieve a minute ventilation ($\dot{V}_E$) of 9 L/min. For each breath, the dead space volume (V_D) remains constant; its value in milliliters is estimated to be equal to the lean body weight in pounds, or 150 ml. In frame *a*, the person breathes rapidly and shallowly at a frequency of 30 breaths/min and a V_T of 300 ml. With each breath, 150 ml of the inspired air goes to filling the dead space; the remaining 150 ml equilibrates with the gas exchange areas of the lung. Thus, $\dot{V}_D$ equals 150 ml/breath × 30 breaths/min, or 4.5 L/min; and $\dot{V}_A$ equals 150 ml/breath × 30 breaths/min, or 4.5 L/min. The ratio of dead space volume to tidal volume, V_D/V_T, which represents the portion of the total ventilation that is not involved in gas exchange, is 0.50. In contrast, in frame *b*, breathing is slower and deeper, with a V_T of 900 ml and a frequency of 10 breaths/min. $\dot{V}_D$ remains constant at 150 ml; however, because 900 ml of air is now being taken in with each breath, the remaining 750 ml of air is available for gas exchange. Therefore, $\dot{V}_D$ equals 150 ml/breath × 10 breaths/min, or 1.5 L/min; and $\dot{V}_A$ equals 750 ml/breath × 10 breaths/min, or 7.5 L/min. The value of V_D/V_T in this example is 0.17.**

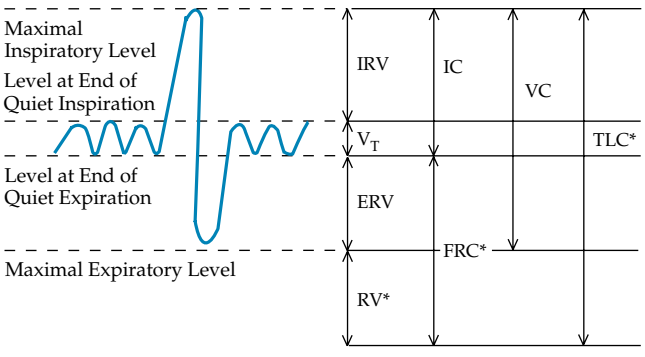
ry reserve volume (IRV) is the volume from the end of an inspired breath up to TLC.[4]

Most of these lung volumes are measured with a spirometer. In the forced expiratory maneuver, the patient breathes quietly until the tidal volume is stable, inhales to TLC, and then performs a maximal expiration followed immediately by a full inspiration to TLC. The lung volumes and capacities are determined from a mechanical or electronic record of the volume changes [*see Figure 3*]. The RV cannot be measured by spirometry. Instead, the FRC is measured indirectly by one of several methods. Once the FRC is known, the ERV is subtracted from the FRC to give the RV.



*Not determined by spirometry.

TLC= Total Lung Capacity
FRC= Functional Residual Capacity
RV= Residual Volume
VC= Vital Capacity
V_T = Tidal Volume
IC= Inspiratory Capacity
ERV= Expiratory Reserve Volume
IRV= Inspiratory Reserve Volume

Figure 3 **Most lung volumes and capacities can be measured by spirometry. Inspired and expired volumes during normal quiet breathing are shown here.**

Methods for measuring FRC include plethysmography (the so-called body box) and gas dilution techniques, such as helium equilibration and nitrogen washout.

Plethysmography

In the body plethysmograph, the patient breathes quietly at normal tidal volumes. At the end of a tidal breath (at FRC), a shutter occludes the airway. The individual pants against the occluded airway and, in so doing, expands the volume of gas in the chest with each inspiratory effort and compresses the volume of gas with each expiratory effort. The initial volume (FRC) can be calculated by the use of Boyle's law ($V_1P_1 = V_2P_2$).[5]

Gas Dilution

There are two gas dilution methods for measuring FRC: the open-circuit nitrogen washout technique and the helium dilution method.

With the open-circuit nitrogen washout technique, the patient breathes quietly at normal tidal volumes. At the end of a tidal breath, the inhaled gas is changed from air to 100% O_2. The amount of nitrogen in each subsequent exhalation decreases as O_2 replaces the resident air in the lung until the exhaled gas contains only O_2 and CO_2. The nitrogen in each breath is measured, and the nitrogen measurements of all the exhalations are then summed to give the total volume of nitrogen exhaled after the switch to pure O_2. The initial volume of gas required to provide

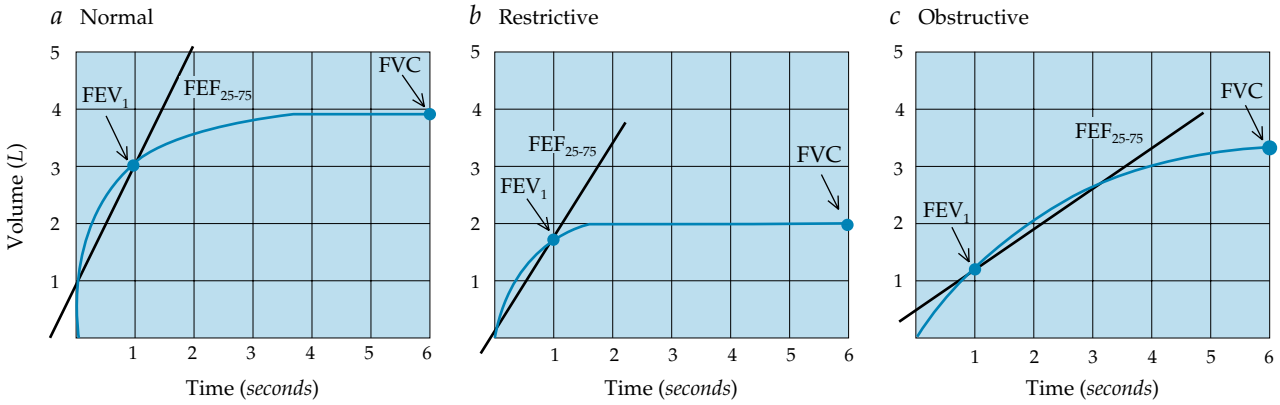


Figure 4 **The volume exhaled is plotted on the ordinate against time on the abscissa. Spirometry illustrates distinctive patterns for normal breathing (*a*), obstructive diseases (*b*), and restrictive diseases (*c*). FEV_1 is forced expiratory volume in 1 second, FVC is forced vital capacity, and FEF_{25-75} is forced expiratory flow between 25% and 75% of vital capacity.**

this much nitrogen (the FRC) can then be calculated, with the knowledge that 79% of room air is composed of nitrogen.

The helium dilution method uses a closed circuit. The patient breathes quietly at normal tidal volumes. At the end of a breath, the air is changed to a mixture that contains 10% helium. The person breathes until the helium concentration reaches a new steady state at a lower level. CO_2 is absorbed by soda lime, and O_2 is added to the system to replace that consumed. The initial and final concentrations of helium are used to determine the FRC by calculating how much helium-free gas had to be added to the volume of the closed system to cause the observed drop in helium concentration.[6]

FORCED EXPIRATORY VITAL CAPACITY (SPIROMETRY AND FLOW-VOLUME LOOPS)

The FVC maneuver is useful in assessing the dynamic mechanical properties of the lung.[7] From TLC to RV, given sufficient effort, flow rates are determined by the mechanical properties of the lung. The most likely mechanism for expiratory flow limitation is described by the wave-speed theory. During a forced exhalation, alveolar pressure exceeds pleural pressure by an amount equal to the elastic recoil pressure of the lung. As flow occurs, there is a decrease in pressure along the length of the airways because of frictional (resistive) losses, so that at some point or points in the airways, pleural (outside) pressure equals airway pressure. In points downstream (mouthward) from that point, there is compression of airways (negative transmural pressures). Flow becomes limited (i.e., a choke point forms) when and where gas velocity within the airway equals the speed of wave propagation in the airway wall (i.e., wave speed). Wave speed is directly proportional to airway area and stiffness. Larger, stiffer airways have higher wave speed and therefore allow higher maximal flow. Smaller, floppier airways have a lower wave speed and therefore allow lower maximal flows. All airway segments have a wave speed at all transmural pressures; choke points occur only when and where local intraluminal gas velocity equals the local wave speed.[8] Data from the FVC maneuver are displayed either as volume-time plots (spirometry) or flow-volume loops: they contain the same information, but the information is depicted in different formats.

Spirometric Patterns

Obstructive and restrictive disorders produce distinctive patterns on spirometry [*see Figure 4*]. A normal spirogram rises rapidly, with 95% of the vital capacity exhaled within the first 3 seconds. In obstruction, the rise is slower, and a considerable portion of the vital capacity is exhaled after 3 seconds; the spirogram fails to reach a plateau. Obstruction is identified also by an absolute reduction in the forced expiratory volume in 1 second (FEV_1) as well as the ratio with the forced vital capacity (FEV_1/FVC). A low FVC with a high FEV_1/FVC is typical of restrictive processes, such as pulmonary fibrosis, neuromuscular diseases, and chest wall deformities (e.g., kyphoscoliosis).

Flow-Volume Loop Patterns

Obstructive lung diseases reduce maximum expiratory airflow by decreasing elastic recoil pressure (e.g., emphysema), narrowing peripheral airways (e.g., chronic bronchitis and asthma), or both. Flow is reduced when airway obstruction is caused by parenchymal lung disease. As the lung empties during forced exhalation, flow rates decrease and become progressively lower than normal as volume decreases. Consequently, the curve acquires a scooped-out appearance [*see Figure 5*]. Flow rates become extremely low at the end of the FVC maneuver. In restrictive diseases, the peak flow is somewhat decreased. The total exhaled volume is small, and the flow-volume curve is horizontally compressed [*see Figure 5*]. Flow from the top of the vital capacity to the bottom decreases in a linear manner, as it does in normal lungs, and does not have the scooped-out appearance seen in airway obstruction caused by parenchymal lung disease. Variable intrathoracic airway obstruction, such as that caused by tracheomalacia, limits expiratory flow, so that the expiratory limb of the flow-volume loop is flat. During inspiration, the posterior membranous portion of the trachea billows outward in response to negative intrathoracic pressure, permitting greater flow. During expiration, pleural pressure is greater than the pressure in the intrathoracic airway, which causes a narrowing of the airway at the site of the obstruction.

The term variable indicates that the relation of intraluminal pressure to surrounding pressures [*see Figure 5*] determines flow. Variable extrathoracic airway obstruction is most common at the larynx and occurs as a result of vocal cord paralysis or tracheomalacia of the extrathoracic trachea. It causes inspiratory limitation. Because of the Bernoulli effect from laryngeal narrowing, the pressure in the extrathoracic upper airway during inspiration is less than the surrounding tissue pressure. As a

result, the airway tends to collapse, which aggravates any structural narrowing.[9]

Maximal inspiratory flow rates less than 2 L/sec suggest severe upper airway obstruction. A fixed airway obstruction such as stenosis of either the intrathoracic or the extrathoracic trachea causes equal and symmetrical flattening of the limbs of the curve that represent severe flow during inspiration and expiration [*see Figure 5*]. Lesions in either intrathoracic or extrathoracic locations may produce a fixed obstructive pattern.

DIFFUSING CAPACITY

The pulmonary diffusing capacity is physiologically determined by the surface area and thickness of the alveolar capillary membrane, by the volume of blood circulating in the alveolar capillary bed, and by the reaction rate of the test gas with hemoglobin. In actuality, the pulmonary diffusing capacity reflects the overall efficiency of gas transfer at each step from the mouth to pulmonary capillary hemoglobin. Because the process involves much more than just diffusion, the term transfer factor is more appropriate, but the term diffusing capacity remains in common use in North America.

The transfer factor of any gas is calculated by dividing the volume of gas taken up by the difference between the alveolar concentration and the mixed capillary concentration ($P_{C}O_2$). Carbon monoxide is usually used for measuring the transfer factor. The affinity of CO for hemoglobin is so high that the hemoglobin takes up almost all the CO entering the blood. The partial pressure in plasma remains so low that the value for mixed capillary PCO can be omitted from the calculation. Thus, the diffusing capacity for CO is expressed as the volume of CO taken up per minute per mm Hg of P_ACO and can be calculated by using the following equation:

$$D_{L_{CO}} = V_{CO} / P_A CO$$

Diffusing capacity is most commonly measured by the single-breath technique. The patient takes a vital capacity breath of a gas mixture containing 0.3% CO and 10% helium. After a 10-second breath hold, the patient exhales. The first portion of exhaled gas, which is contaminated with dead space ventilation, is discarded. The next liter is collected and analyzed. The helium is needed to calculate the amount of dilution of the inspired sample so that the initial alveolar CO can be calculated

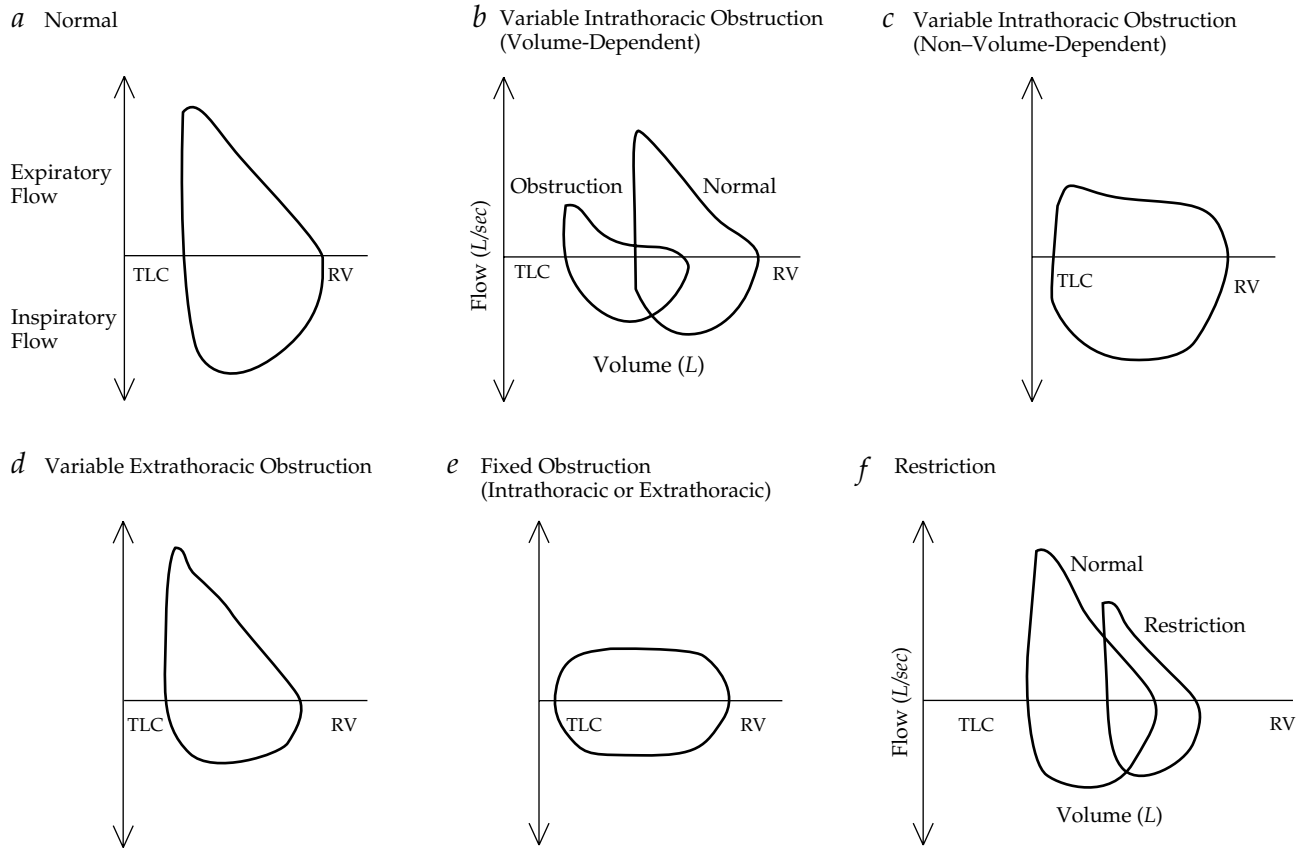

Figure 5 **Flow is depicted on the ordinate with expiration above and inspiration below the intercept. Volume is shown on the abscissa going left to right from TLC to RV. (*a*) A normal expiratory flow-volume curve is shown. (*b*) In variable intrathoracic obstruction, the expiratory flow-volume curve shows a scooped-out appearance as a result of progressive decreases in flow as lung volume becomes smaller. Obstruction is volume dependent. Flow rates at any given lung volume (isovolumic flow) are reduced. Because of air trapping, the entire curve may be shifted to a higher lung volume (leftward). This pattern is typical of chronic obstructive pulmonary disease or asthma. (*c*) The expiratory flow-volume curve shows a decreased flow that is the same at all lung volumes. Obstruction, which is not dependent on lung volume, is caused by upper airway obstruction, not by disease of the lung parenchyma. (*d*) Disproportionate reduction of inspiratory airflow is indicative of variable extrathoracic upper airway obstruction. (*e*) Fixed airway obstruction, the site of which is undetermined, shows volume-independent reduction of flow in both inspiration and expiration. (*f*) An expiratory flow-volume curve in a patient with a restrictive disorder is shown. Isovolumic flow rates are increased, whereas the volume axis is compressed and shifted toward lower volume (rightward).**

and is also used to calculate alveolar volume (VA). The slope of the natural logarithm of initial-final alveolar CO concentration versus time is the volume-normalized diffusing capacity ($D_{L_{CO}}$/VA). Multiplication by lung volume yields $D_{L_{CO}}$, the reported value. Other ways of measuring $D_{L_{CO}}$ include the steady state and rebreathing methods. Rapidly responding CO analyzers and computer technology have made it possible to measure diffusing capacity throughout a single exhalation, allowing the study of the effects of nonhomogeneities in ventilation and perfusion on diffusion, the so-called intrabreath method.

Interpretation of Pulmonary Function Tests

The results of pulmonary function tests are interpreted in comparison with predicted normal values that have been defined for various populations. Pulmonary function studies should be performed with carefully calibrated equipment that meets uniform standards, with the use of approved techniques in patients who are well coached to ensure a maximal effort and reproducible results. Interpretive errors can be minimized by adhering to the standards published by the American Thoracic Society (ATS) in 1994.[7] Newer standards are now being prepared jointly by the ATS and European Respiratory Society (http://www.thoracic.org). Results that are within the 95% confidence limits for the reference population are considered to be normal.

Pulmonary function tests seldom confirm a specific diagnosis. Rather, they show certain patterns, each of which may be consistent with a number of different diseases. Once a specific diagnosis has been made by combining the pulmonary function results with other clinical information, the quantitative results help in assessing the severity of the physiologic impairment caused by the disease. Vital capacity, FEV_1, and FEV_1/FVC are the basic spirometric parameters used for pulmonary function interpretation to make an assessment of normality or to define patterns of abnormality. TLC and $D_{L_{CO}}$ provide important additional information and may provide independent evidence of a pattern of physiologic abnormality.

OBSTRUCTION

An obstructive defect is defined as reduction in maximal expiratory flows and FEV_1/FVC. Although the earliest evidence of obstruction can be found in a reduction in the instantaneous flow after 75% of a vital capacity has been exhaled (FEF_{75}) or in average midflow rates ($FEF_{25–75}$), these are nonspecific findings of uncertain clinical significance.

When the presence of obstruction has been determined, its severity is best assessed with the FEV_1 as a percentage of the predicted value. Although there is some variability in interpretative schemes, an FEV_1 less than 50% of predicted is generally considered to be severe, a value between 50% and 70% of predicted is moderate impairment, and higher values of FEV_1 with a reduced FEV_1/FVC are considered to be mild disturbance. Obstruction with normal lung volumes and $D_{L_{co}}$ suggests airway disease with preservation of pulmonary parenchyma. These findings are consistent with mild asthma or chronic bronchitis.

Hyperinflation is defined by an elevated TLC, and air trapping is defined by an increased RV/TLC ratio. Obstruction with hyperinflation and air trapping is characteristic of more severe airway disease. Vital capacity may be reduced; the concave shape of the expiratory flow-volume curve and the flattened spirogram may provide indirect evidence of air trapping as the cause of the reduction of vital capacity, but lung volume measurements are often necessary to confirm the impression. Hyperinflation in the presence of a normal diffusing capacity for carbon monoxide indicates preservation of the alveolar capillary bed and may be suggestive of chronic obstructive bronchitis or chronic severe asthma. A low $D_{L_{CO}}$ in a patient with obstruction and hyperinflation suggests that emphysema is the cause of the obstruction. In this disorder, the obstruction occurs as a result of the loss of lung parenchyma, which ordinarily attaches to the outside of the small airways and, by radial traction, helps maintain the airway diameter during expiration. Loss of this supporting tissue allows the airways to collapse during expiration. Loss of elastic recoil also reduces expiratory flow. As the lung parenchyma is destroyed, the capillary bed is also lost, causing a low diffusing capacity for carbon monoxide.

RESTRICTION

A restrictive pattern is defined by a reduced TLC, although presence of a restrictive pattern may be inferred by a reduced VC in the presence of a normal or elevated FEV_1/FVC. A restrictive defect may be caused by parenchymal lung disease, by chest wall disorders, or by neuromuscular disorders. Patients whose vital capacity and residual volume are reduced by about the same amount have symmetrical reduction in lung volumes. These patients often have fibrotic diseases that shrink the lungs, such as pulmonary fibrosis and sarcoidosis. Destruction of the lung parenchyma results in reduced volume of the capillary bed and a lower $D_{L_{CO}}$. Patients with neuromuscular diseases often show a pattern in which the vital capacity is reduced but the residual volume is normal or even slightly increased. Weak inspiratory muscles limit the size of a maximal breath. Weak expiratory muscles, especially a weak rectus abdominis muscle, prevent complete emptying. Muscle weakness does not affect the lung parenchyma, and the $D_{L_{CO}}$ is normal when corrected for the lung volume. Patients with chest wall abnormalities caused by kyphosis and scoliosis have a similar pattern.

ISOLATED LOW DIFFUSION

If the patient is not anemic or does not have an elevated carboxyhemoglobin level, isolated low diffusion suggests loss of the pulmonary capillary bed, either because of pulmonary vascular disease (e.g., pulmonary emboli or pulmonary hypertension) or because of an early interstitial lung disorder that has not yet reduced the lung volumes or of early emphysema that has not yet produced airflow obstruction.

MUSCLE FUNCTION

Assessment of respiratory function is frequently performed in the intensive care unit (ICU), often to help determine reasons for prolonged ventilator dependence. The diaphragm is the chief inspiratory muscle. Abnormalities in diaphragmatic function generally manifest as exertional dyspnea accompanying reductions in VC and TLC with a preserved $D_{L_{CO}}$. Patients with weakness or paralysis of one or both hemidiaphragms typically experience more dyspnea when they are supine than when they are seated or in an upright position (orthopnea). On physical examination, the abdominal wall may retract with inspiration (abdominal paradox), which indicates that the diaphragm is neither performing active inspiratory work nor providing a pressure barrier between the abdominal and pleural compartments.

In any severe obstructive or restrictive ventilatory disorder, the muscles of breathing carry a heavy workload in providing

ventilation, even at rest. High respiratory muscle loads elicit reflex responses that manifest as a rapid, shallow breathing pattern. High inspiratory workloads may also cause the appearance of abdominal paradox. These two findings, once thought to reflect respiratory muscle fatigue, are nonspecific indicators of respiratory muscle load and may be seen before diaphragmatic fatigue is actually present. Continuous loads can lead to the development of inspiratory muscle fatigue, defined as the loss of contractile strength despite maximal stimulation. Diaphragmatic function can be assessed in the laboratory by several techniques. In patients with significant diaphragmatic weakness or paralysis, vital capacity may decline by 20% or more in the supine position compared with the upright position. Muscle strength can be assessed by having the patient perform maximal inspiratory and expiratory efforts against a closed system and measuring the static pressures that are generated.[10]

A young, healthy adult can generate negative pressures in excess of –100 cm H_2O on inspiration and positive pressures in excess of +120 cm H_2O on maximal expiratory effort. In certain clinical settings, serial measurements of muscle strength may be of particular value. Examples include progressive neuromuscular disorders, such as Guillain-Barré syndrome, in which it is important to identify respiratory muscle weakness or paralysis early in its course (before the development of overt respiratory failure) and disorders that are characterized by fluctuating periods of muscle weakness, such as myasthenia gravis.

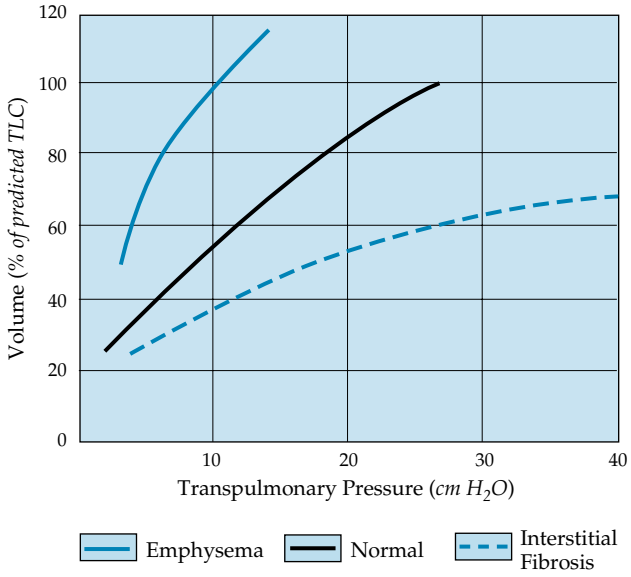

Figure 6 **Compliance is defined as the change in lung volume per change in unit pressure. The changes in pulmonary compliance that occur with various respiratory conditions are reflected in differences in the shape and position of the pressure-volume curve of the lung. Pressure-volume curves are obtained by measuring transpulmonary pressure at various lung volumes during a stepwise exhalation (or during in vitro deflation of the lung). The compliance of the lungs is abnormally high in emphysema and abnormally low in diffuse interstitial fibrosis.**

Nonroutine Pulmonary Function Tests

LUNG ELASTICITY

The elastic properties of the lung can be assessed by measuring the static transpulmonary pressure as a function of lung volume. Transpulmonary pressure is defined as the pleural pressure minus the oral pressure, and static denotes that the measurements are made at a time when no airflow is occurring. When the mouth is open, oral pressure is equal to atmospheric pressure, and pleural pressure can be approximated from intraesophageal pressure. Measurements of intraesophageal pressure require that the patient swallow a balloon-tipped catheter; thus, it is not a routine procedure in most clinical pulmonary function laboratories.

The static transpulmonary pressure, measured at various volume intervals during deflation of the lung, can be plotted against the percentage of the predicted total lung capacity [*see Figure 6*]. The change in lung volume divided by the change in pressure, measured over the volume interval extending from 500 ml above FRC to FRC, is known as the static compliance. Normal values for the static compliance range from 0.1 to 0.4 L/cm H_2O. Pressure-volume curves can also be plotted for obstructive and restrictive disorders and can be modeled mathematically for further analysis.[11] The static compliance is abnormally high in emphysema and abnormally low in interstitial fibrosis.

BRONCHIAL PROVOCATION

One of the defining characteristics of asthma is an increase in the responsiveness of the airways to a number of stimuli. If lung function is normal but the history suggests the presence of asthma, the demonstration of bronchial hyperresponsiveness to one of several constrictor challenges can be useful in establishing a diagnosis.[12]

Methacholine, carbacholine, and histamine aerosol challenges are common means of bronchial provocation. Because droplet size and the amount of drug delivered vary among aerosol-generating devices and because great care must be taken to monitor responses to avoid provoking severe obstructive episodes, such aerosol challenges should be performed only in laboratories with extensive experience in utilizing these techniques. In addition to the issue of safety, such laboratories have a large database on the distribution of airway responsiveness in a broad population, which allows a more reasonable assessment of the response measured.

An alternative constrictor challenge is 4 or 5 minutes of either exercise or voluntary hyperventilation with cold, dry air. Such approaches appear to be as valuable as drug challenges, and they avoid the problems of variations in aerosol delivery and the dangers of inadvertent overdose with a potent constrictor agent. Results of bronchoprovocation challenges are normally expressed as the provocative dose (PD) of a stimulus that produces a defined level of response in a pulmonary function parameter, most often the FEV_1 (e.g., $PD_{20}FEV_1$ is the dose that produces a 20% decrease in FEV_1) [*see Figure 7*]. The lower the PD_{20}, the greater the degree of responsiveness.

EXERCISE TESTING

Measurements of cardiovascular and respiratory performance at several levels of exercise are useful for the objective evaluation of patients for disability. Cardiopulmonary exercise tests can also be used to evaluate patients with unexplained dyspnea. The tests quantify the severity of the abnormality and may give clues to the etiology of the dyspnea.

Another use of exercise testing is to document the occurrence and severity of hypoxemia during exertion. Assessment of oxy-

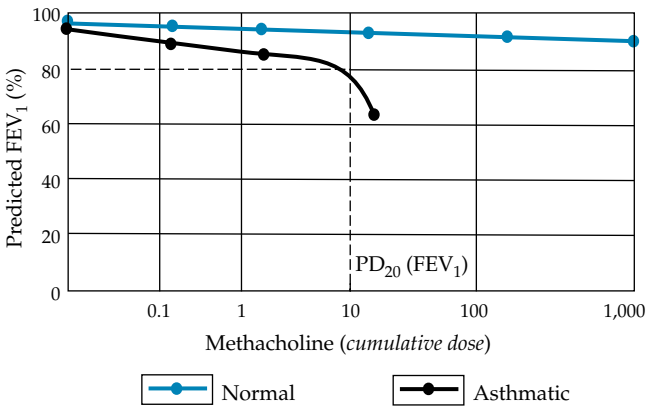

Figure 7 **Bronchoconstrictor challenge results are plotted as change in FEV_1 against cumulative dose of methacholine. Significant reaction is defined as a 20% drop in FEV_1. The dose at which this occurs is termed the PD_{20}. The lower the PD_{20}, the more reactive the airways.**

genation during exercise is particularly useful in two clinical situations. First, patients with restrictive defects caused by diffuse interstitial lung disease who have normal or near-normal $A\text{-}aDO_2$ values at rest often develop hypoxemia and widened $A\text{-}aDO_2$ values during exercise. This response has been attributed to a diffusion barrier between blood and alveolar gas that becomes apparent only during exercise, when contact time in the pulmonary capillaries is diminished by an increase in cardiac output. Second, patients with chronic airway obstruction who have only moderate hypoxemia at rest may experience more severe hypoxemia during exercise. This worsening of hypoxemia in the obstructive syndromes has been attributed to increasing ventilation-perfusion imbalance during the hyperpnea that accompanies exercise.

Hypoxemia can be documented by measuring arterial blood gases before and during exercise or by continuously monitoring capillary hemoglobin saturation by pulse oximetry. In both the restrictive and the obstructive syndromes, development or worsening of hypoxemia during exercise can explain, at least in part, why symptoms become more severe on exertion. This finding indicates the need for oxygen therapy during exercise, an intervention that may significantly improve exercise tolerance.

Oximeter readings during exercise may be falsely low because of vasoconstriction of arterial beds in nonexercising areas, such as the fingers and toes, ears, and skin. Low oxygen saturation recorded by oximetry during exercise should be confirmed by direct arterial blood measurements, especially if the oximetry readings are inconsistent with the clinical situation or if a prescription for portable oxygen during exercise is being considered. A formal exercise testing protocol is performed at graded levels of work output on a treadmill or cycle ergometer. Minute ventilation and tidal volume, heart rate, blood pressure, exhaled O_2 and CO_2 concentrations, and oxygen saturation are continuously monitored and correlated with the patient's perceived level of dyspnea on a visual analogue scale. Maximum oxygen uptake ($\dot{V}O_{2max}$) is reached when there is no further increase in $\dot{V}O_2$ with increasing work output. Anaerobic metabolism, reflecting a disproportionate increase in CO_2 output and ventilation with increasing $\dot{V}O_2$, occurs as a result of buffering the increase in lactic acid and signals the onset of anaerobic glycolysis; it is termed the anaerobic threshold. Common patterns of findings of exercise testing have been correlated with heart disease, obstructive and restrictive pulmonary diseases, pulmonary vasculopathies, and deconditioning.[13]

For severely disabled patients who are candidates for lung transplantation or lung volume reduction surgery, exercise capacity can be determined with the 6-minute-walk distance, a very simple test that requires only oximetry, a timepiece, and a measured distance. The 6-minute-walk distance test has been standardized and shown to be repeatable.[14]

POLYSOMNOGRAPHY

The term polysomnography is used to describe a collection of measurements made during sleep to assess sleep-associated respiratory and neurologic disturbances. These are discussed in detail elsewhere [*see 14:VI Ventilatory Control during Wakefulness and Sleep and 11:XIII Disorders of Sleep*].

Imaging Studies

STANDARD CHEST RADIOGRAPH

In patients with a pulmonary disorder, the relative lack of specificity of respiratory tract symptoms and the relatively poor reliability of the pulmonary physical examination make radiologic imaging techniques essential to the diagnostic process [*see Table 3*]. For this reason, the chest roentgenogram (posteroanterior and lateral) is the single most commonly utilized radiologic technique, accounting for some 40% of all radiologic procedures.

Standard radiographic imaging techniques depend on large differences in the densities of the various body components to discern structure and detect abnormalities. Four distinct densities—gas, water (solid tissues), fat, and metal (bones)—can be identified. Radiographic imaging brings the thoracic cage and the mediastinal structures into sharp contrast with the adjacent gas-containing lung, and any lesion within the lung is made apparent by this same contrast in densities. Several technically sophisticated diagnostic imaging techniques are also employed in the assessment of diseases of the thorax. These techniques include perfusion scans, ventilation scans, pulmonary angiography, computed tomography, magnetic resonance imaging, and ultrasonography.

RADIONUCLIDE SCANS

Ventilation Scans

Ventilation scans are used either to assess the distribution of pulmonary ventilation or to improve the diagnostic reliability of radionuclide perfusion scans performed for the diagnosis of pulmonary embolic disease. Ventilation scans can be performed with radioactive gases (usually xenon) or with a fine aerosol of particles labeled with technetium-99m (^{99m}Tc). When a gas is used, images are made after a wash-in phase (at equilibrium) and during a timed wash-out phase. Regions of lung that are poorly ventilated retain radioactivity. If a radioactive aerosol is used, multiple views can be obtained for comparison with the perfusion scan.

Perfusion Scans

Perfusion scanning is employed to assess the distribution of blood flow to the lung, either as a diagnostic tool for the evaluation of pulmonary embolic disease [*see 1:XVIII Venous Thromboembolism*] or to quantitate regional pulmonary blood flow for the assessment of physiologic operability for surgical pul-

Table 3 Summary of Imaging Techniques

Technique	*Indications*	*Contraindications*	*Comments*
Posteroanterior and lateral roentgenogram*	Wide variety of pulmonary disorders	—	Technique dependent; specificity and sensitivity are observer dependent and vary with disease process and clinical setting
Contrast angiography* Digital subtraction angiography*	Pulmonary thromboembolic disease	Contrast sensitivity, renal insufficiency, left bundle branch block	Gold standard for diagnosis of pulmonary embolism; used for evaluation of pulmonary vasculature; indicated when other studies are inconclusive and when treatment is invasive, hazardous, or contraindicated
Radionuclide scanning* Ventilation Perfusion	Pulmonary thromboembolic disease	Reports of complications, anecdotal only	Used to assess distribution of pulmonary ventilation and blood flow and in assessment of physiologic suitability for pulmonary resection
Computed tomography*	Emphysema, pulmonary nodules, infectious processes, parenchymal pulmonary disorders	Obesity (> 300 lb), inability to hold breath, contrast sensitivity	CT reconstructions provide sagittal sections of 10 mm thickness; increased sensitivity compared with plain film but with 100× radiation exposure, especially suited for evaluation of mediastinal anatomy and the pleura and for staging malignancies
Spiral CT*	Pulmonary thromboembolism		Spiral CT shortens breath-hold time; can be used for three-dimensional reconstructions of airway anatomy and lung masses
High-resolution CT*	Parenchymal pulmonary disorders, bronchiectasis		1–2 mm slices allow resolution of secondary pulmonary lobules by high-resolution CT
Magnetic resonance imaging MR angiography	Disorders of the chest wall, mediastinum, and soft tissues Pulmonary thromboembolic disorders	Presence of any ferrometallic objects, claustrophobia	No radiation exposure; provides coronal as well as sagittal reconstructions; resolves soft tissue anatomy
Positron emission tomography*	Moderate to large focal pulmonary lesions	—	Accuracy uncertain for lesions smaller than 1 cm
Ultrasonography	Pleural effusions	—	May help localize subpleural pulmonary nodules

*Radiation exposure requires caution for women of childbearing age.

monary resection. Isotopes that emit gamma rays, most often ^{99m}Tc, are attached to macroaggregated human albumin or to albumin microspheres having particle diameters of 10 to 50 μm. The radiolabeled particles are then injected into a peripheral vein and subsequently lodge in pulmonary capillaries. The distribution of the resulting emboli is proportional to the regional blood flow. Scanning is capable of resolving 3% of lung volume, with higher reliability for the left than for the right lung.

Because any pathophysiologic process that impedes circulation in that region may cause the abnormalities, a defect seen on perfusion scan is never in and of itself diagnostic of a specific disease or pathophysiologic process. The scan must be interpreted in the context of integrated information derived from clinical evaluation and a concurrent chest radiograph. Further, identification and assessment of the abnormalities are highly subjective. Only extreme scan results, such as totally normal perfusion or the absence of perfusion to a segment or lobe, are relatively free from observer variability.

Ventilation scans are almost always performed in conjunction with perfusion scans and are most useful in assessing the probability of pulmonary emboli. If a region with no perfusion ventilates well (ventilation-perfusion mismatch), there is an increased likelihood of pulmonary embolic disease. However, if ventilation and perfusion to a given region are both diminished (ventilation-perfusion matched defect), embolic disease is less likely. Perfusion scanning alone in combination with clinical history has been shown to have a positive predictive value of 0.99 and a negative predictive value of 0.97, suggesting that accurate diagnosis of pulmonary embolism is possible without benefit of a ventilation scan.[15] The degree of scintigraphic obstruction correlates well with pulmonary hemodynamics in acute pulmonary embolism, but less so in chronic pulmonary hypertension because of the presence of vascular remodeling.

According to the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study (which used pulmonary angiography as the standard), two or more large segmental mismatches, two or more moderate segmental mismatches and one large defect, or at least four moderate mismatches define a high probability scan that indicates an 80% or greater likelihood of pulmonary embolism. A nonsegmental perfusion defect, a perfusion defect much smaller than corresponding opacity on an accompanying chest roentgenogram, or three or fewer small matched defects in the presence of a normal chest film define a low-probability scan. A single moderate-sized mismatch or a moderate and a large defect, more than three matched defects in a lung zone or four in a whole lung, or a pattern that is neither high nor low probability defines an indeterminate scan. The positive predictive value of the ventilation-perfusion scan increases as the number and volume of mismatched defects increases. Two segmental mismatches carry an 80% positive predictive value for embolism.[16] As opposed to a completely normal study, 11% (8/75) of patients with a nearly normal ventilation-perfusion scan were subsequently found to have positive angiograms for pulmonary embolism. The PIOPED II study, which is currently under way, is assessing helical (spiral) CT in relation to pulmonary angiography, ventilation-perfusion scans, digital subtraction angiography, and lower extremity venous compression ultrasonography and contrast venography. PIOPED II is likely to generate new sensitivity and specificity data for these techniques. This study will be completed in 2004.[17]

Unfortunately, in more than 60% of cases, results of ventilation-perfusion scanning can neither confirm nor exclude pulmonary embolism. In a patient with normal D-dimer levels, an equivocal scan can reliably exclude pulmonary embolism.[18] In patients with an equivocal scan and elevated D-dimer levels, further clinical evidence is required [*see 1:XVIII Venous Thromboembolism*]. Positive noninvasive leg vein studies (plethysmography or venous Doppler ultrasonography) carry the same therapeutic implications as a definitive diagnosis of pulmonary embolism.

Pulmonary Angiography

Pulmonary angiography is currently the gold standard for the diagnosis of pulmonary thromboembolism [*see 1:XVIII Venous Thromboembolism*]. There are four indications for the use of pulmonary angiography in patients who may have pulmonary thromboembolic disease: (1) to confirm the diagnosis when anticoagulation carries significant risks to the patient or when a younger patient may face prolonged anticoagulation; (2) when aggressive therapy such as thrombolysis, vena caval interruption, or surgical clot extraction is contemplated; (3) to provide a definitive diagnosis when the clinical suspicion of thromboemboli is high, but less invasive studies are inconclusive; and (4) in the evaluation of pulmonary hypertension. If leg vein studies are negative and the clinical probability of pulmonary embolism is great, a pulmonary angiogram should be done because it is currently the only way to positively exclude pulmonary embolism. Pulmonary angiography as currently practiced is safe. Mortality is less than 1%. Major complications, such as hypotension, myocardial infarction, and renal failure, occur in 1.5%, and minor complications, particularly contrast nephrotoxicity, occur in 4.8%.[19] Most cases of renal failure occur in critically ill patients. Other risks include allergy to contrast media (0.1%), transient right bundle branch block, and nonsustained ventricular tachyarrhythmias. Pulmonary arterial pressure rises by an average of 4 mm Hg, linearly dependent on the size of the injectate. The rise in pulmonary arterial pressure is independent of the presence of pulmonary embolism. Most angiographic defects in pulmonary embolism are found in segmental or larger vessels. Reproducibility of interpretation is reduced in the 17% of patients with defects in subsegmental vessels.[20] When angiography is unavailable, excessively risky, or contraindicated, alternative imaging techniques may be considered.

Digital Subtraction Angiography

In digital subtraction angiography (DSA), images are taken before and after the injection of intravenous contrast medium, and a computer then subtracts the plain image from the contrast image. This enhances the resolution of the contrast image. DSA has been shown to be sufficiently sensitive to confidently exclude pulmonary embolism. Twelve-month follow-up of 54 patients with negative DSA examinations showed no indications of a missed diagnosis of pulmonary embolism, whether in the form of subsequent clinical events, positive angiograms, or positive scans.[21] The PIOPED II study (see above) will provide data on the utility of DSA in relation to other techniques.

COMPUTED TOMOGRAPHY

CT scanning utilizes standard radiographic signals that are processed by computer to provide detailed cross-sectional images of desired contrast. Although CT scanning offers significantly better visualization of anatomic structures than does standard radiography, a thoracic CT examination involves a radiation exposure equivalent to 100 standard chest radiographs. Risks and benefits must always be taken into consideration when ordering CT examinations.

CT scanning distinguishes gradations of density ranging from air (–1,000 Hounsfield units [HU]) to bone (+1,000 HU). Normal tissue has the density of water, 0 HU. Intravenous contrast media in modest doses allow CT scanning to be used to assess the intrapulmonary-versus-extrapulmonary location of a pulmonary lesion, the vascularity of lesions, and tracheobronchial pathology; to diagnose bronchiectasis; and to identify major vascular structures in regions of abnormality. The technique is employed to locate and characterize mediastinal masses and lymph nodes, intrapulmonary lesions, and pleural processes. CT scanning is now considered integral to the staging of most cases of lung cancer and to the evaluation of most mediastinal masses. CT scanning before bronchoscopy for suspected lung cancer increases the bronchoscopic yield from 71% to 90%.[22]

High-Resolution Computed Tomography

In high-resolution CT (HRCT), the thickness of the tomographic section is reduced from about 1 cm to 1 to 3 mm. Modified software improves resolution and shows fine morphologic detail. The technique is most useful for evaluating diffuse lung disease, and usually, only three to six scans are performed. Resolution of structures down to 200 μm can be achieved, so that secondary pulmonary lobules and even thickened intralobar septa can be visualized.

HRCT is a good screening test for interstitial lung disease, especially in patients with dyspnea whose chest roentgenogram is normal and whose lung volumes and diffusing capacity are in the low normal range or are mildly reduced. Negative results on HRCT are evidence against significant interstitial lung disease, although open lung biopsy specimens may still show evidence of abnormality in some cases. HRCT may be useful in assessing drug-induced lung damage; air-space abnormalities can be seen even when the chest roentgenogram is normal.

Certain patterns have been recognized and closely correlated with specific pathologic processes[23] [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]:

1. A ground-glass pattern correlates with active alveolitis. A higher proportion of ground-glass density in relation to septal thickening or honeycombing patterns suggests a more favorable prognosis in usual interstitial pneumonia.
2. Active tuberculosis is characterized on HRCT by ground-glass densities and centrilobular and poorly marginated nodules, whereas nontuberculous *Mycobacterium* infections frequently present as bronchiectasis associated with parenchymal nodules.
3. Idiopathic pulmonary fibrosis is characterized by crescentic subpleural reticular densities that are most dense in the posterior basal segments of the lower lobes. Scans taken with the patient in the prone position can ensure that such densities are not a result of increased perfusion of dependent zones. In advanced disease, reticular interstitial densities, regions of fibrosis, and cystic spaces are found throughout the lung. These changes are not specific to idiopathic pulmonary fibrosis but are seen in end-stage fibrotic lung disease from any cause.
4. Lymphangitic cancer has a rather characteristic appearance, with thickening of bronchovascular bundles and intralobar

septa. The thickened septa are often very prominent subpleurally.

5. Hypersensitivity pneumonitis may show an extensive interstitial and air-space infiltrate, giving a ground-glass appearance to large areas of the lung.
6. Parenchymal sarcoidosis has a wide range of appearances. The most characteristic abnormalities are nodular opacities along the bronchovascular bundles and, to a lesser degree, in the interlobular septa and pleura.
7. In lymphangioleiomyomatosis, numerous small cystic air spaces that are distributed widely throughout the lung can be detected, even when the chest roentgenogram is unremarkable.
8. Histiocytosis X is characterized by a combination of pulmonary nodules and cysts, most prominent in the upper lobes.

HRCT helps localize the distribution and severity of emphysema. This may be of importance in the evaluation of patients for lung volume reduction surgery. HRCT can clarify the extent and pattern of intrathoracic disease; if patterns are typical, they can be used in lieu of an open biopsy technique to establish a specific diagnosis of interstitial disease.[23]

Spiral Computed Tomography

Helical, or spiral, CT differs from conventional CT imaging by continuously acquiring imaging data while the patient moves through the CT gantry at a constant rate. Spiral CT has become the standard approach for thoracic imaging in many institutions because imaging time is substantially reduced, often to less than 1 minute. Contrast requirements are also minimized. Reconstructions can be constituted at any level of the thorax, decreasing the likelihood that a small lesion in between tomographic cuts could be missed. The rapidity of image acquisition allows a correlation of lung anatomy and physiology between inspiration and expiration.

Spiral CT is capable of resolving second- to fourth-generation pulmonary arterial branches. It has been shown to be a highly sensitive and specific tool in the diagnosis of central pulmonary embolism that, in most studies, offers performance superior to that of radionuclide imaging [*see Figure 8*]. A major advantage of spiral CT is its ability to demonstrate alternative diagnoses and ancillary findings of pulmonary embolism, such as right ventricular dilatation, pleural-based wedge-shaped infiltrates, linear banding, and increase in the size of affected arteries. Because of these advantages, the number of indeterminate studies is significantly reduced compared with ventilation-perfusion scanning. Spiral CT may be sufficiently sensitive to be used as a basis for withholding anticoagulation for suspected pulmonary embolism if combined with other clinical and laboratory data. However, this point needs confirmation from PIOPED II (see above). Unsuspected pulmonary embolism has been reported as an incidental finding in 5% of inpatient spiral CT examinations; most of these patients had cancer. Whether spiral CT should replace ventilation-perfusion scanning in the standard workup of pulmonary embolism has not been definitively resolved[24] and is currently being assessed in PIOPED II.

Three-dimensional reconstruction is possible from spiral CT data and has been used to create accurate virtual bronchoscopic examinations of the airways. Although these reconstructions do not identify subtle bronchial wall abnormalities, they may prove useful in identification of sites suitable for transbronchial needle sampling of lymphadenopathy and in the assessment of bronchial anatomy distal to high-grade obstructing lesions, which are inaccessible to fiberoptic endoscopes.[25]

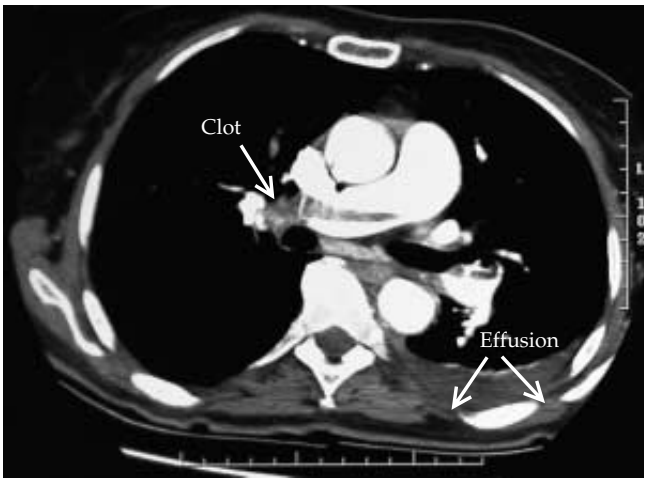

Figure 8 **A large filling defect is seen in the right pulmonary artery in this contrast-enhanced study. Note accompanying pleural effusion.**

MAGNETIC RESONANCE IMAGING

MRI reveals tissue properties by using physical principles different from those used and revealed in standard chest roentgenograms and CT. Because MRIs of the chest can be degraded by motion, thoracic MRIs are usually gated to the heart rate by ECG. MRI produces sagittal and coronal images that are 3 to 10 mm in thickness. Advantages of MRI are its increased soft tissue contrast, multiplanar capability, sensitivity to blood flow, and lack of ionizing radiation. Because of its ability to differentiate between tissues of varying compositions, MRI is particularly suited to evaluation of soft tissue processes. Disadvantages of MRI include inferior spatial resolution, degradation of image with respiratory motion, and the necessity of eliminating metallic objects from the imaging environment, making the method unsuitable for ventilated patients as well as those with metallic implants of any sort. The ability of MRI to differentiate contiguous structures makes it a useful technique for evaluating intrathoracic malignancies in relation to vascular and mediastinal structures. CT and MRI are comparable in accuracy for the evaluation of nodal spread of bronchogenic carcinoma.

MAGNETIC RESONANCE ANGIOGRAPHY

The advent of rapid imaging techniques has made magnetic resonance angiography (MRA) an attractive technology to supplement or supplant pulmonary angiography in the evaluation of pulmonary vascular disorders. MRA has been compared with pulmonary angiography in the diagnosis of pulmonary embolism. For segmental and larger pulmonary embolism, MRA is quite specific and sensitive. In limited studies, magnetic resonance venography has shown high sensitivity and specificity for diagnosis of deep vein thrombosis and may prove an important diagnostic modality.[24]

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) utilizing 18-fluorodeoxyglucose as the positron emitter (to indicate active glucose metabolism) appears to be an accurate noninvasive test for the diagnosis of moderate sized and larger pulmonary focal le-

sions. Fewer data exist for lesions smaller than 1 cm. A sensitivity of 96.8% and a specificity of 77.8% have been reported from a meta-analysis.[26]

ULTRASONOGRAPHY

The normal air-containing lung is poorly visualized by two-dimensional ultrasonography, but in the presence of consolidation, ultrasonography may prove useful in the evaluation of a variety of pleuropulmonary disorders. Pleural effusions present as hypoechoic or nonechoic regions. Pleural lesions in suspected malignant effusion were visualized and biopsies performed with 100% specificity and 88% sensitivity in one study.[27] Consolidation is seen as hypoechoic regions that move with the patient's breathing. Air bronchograms are hyperechoic, whereas liquid-filled airways associated with atelectasis or endobronchial obstruction are hypoechoic. Abscesses are seen as irregularities in density in an otherwise homogeneous region, and tumors may be distinguished within a consolidated area by their relatively homogeneous consistency and by their regular borders. The specificity and sensitivity of the method are insufficient to permit ultrasonography to replace CT or other radiologic methods, but it may be viewed as a complementary technique.

Sampling Techniques

Several techniques are available for obtaining material for microscopic examination or, in the case of infectious agents, growing in culture media. Some sampling techniques are clearly superior in terms of yield, specificity, ease of performance, and safety. In any clinical setting, however, the local experience with, and availability of, specific sampling techniques will dictate the best choice in a given situation. In general, it is advisable to start with the least invasive approaches.

FIBEROPTIC BRONCHOSCOPY

Fiberoptic bronchoscopy has become the standard procedure for exploring the tracheobronchial tree. The fiberoptic bronchoscope possesses excellent optics, is flexible and easily manipulated, and has a small diameter. Topical anesthesia provides adequate comfort, and endotracheal intubation is generally not needed. These factors contribute to ease of performance and the excellent level of patient acceptance associated with this technique. From a diagnostic standpoint, the fiberoptic bronchoscope has virtually replaced the rigid bronchoscope, except in cases involving examination of the tracheobronchial tree during active massive hemoptysis or for extraction of aspirated foreign bodies [*see Table 4*].

In addition to allowing excellent visualization of the bronchi, the fiberoptic bronchoscope provides samples that can be used for smear, culture, cytologic study, and histologic examination.

Direct Vision

Contemporary fiberoptic bronchoscopes allow viewing of the first six generations of the airways from the posterior oropharynx and nasopharynx and the larynx to sub-subsegmental bronchi. Although this corresponds only to the inner third of the lung fields on a chest roentgenogram, a significant proportion of pathologic processes, including many lung tumors, aspirated foreign bodies, inhalation and aspiration injuries, and Kaposi sarcoma, occur in the proximal airways and are amenable to direct inspection. Localization of the source of hemoptysis is made by direct visualization, although it should be noted that in massive hemoptysis, a rigid bronchoscope may be preferable for its superior visualization and ability to maintain a clear airway.

Washings

Washings from the tracheobronchial tree using isotonic saline are useful for cytologic and microbiologic examination. Bronchial washing is particularly helpful in the diagnosis of sputum smear–negative tuberculosis, in which 40% of smears and up to 95% of cultures may be positive.

Bronchoalveolar lavage If the endoscopist wedges the bronchoscope in a segmental or subsegmental orifice before instilling and aspirating saline, the distal airways and air spaces may be sampled. Bronchoalveolar lavage (BAL) has proved extremely useful in the assessment of opportunistic infections in AIDS patients. The sensitivity of BAL for *Pneumocystis carinii* approaches 95% when compared with open lung biopsy and may exceed that of transbronchial biopsy. The yield for other opportunistic infections may be somewhat lower. Culture of BAL specimens has a sensitivity for tuberculosis of up to 88%. BAL has also been used in the evaluation of interstitial lung diseases and in the identification and assessment of rejection of lung transplants. The total number of cells recovered and the differential cell count help categorize alveolitis as neutrophilic or lymphocytic in nature and to gauge its intensity. BAL may be

Table 4 Common Indications and Contraindications for Fiberoptic Bronchoscopy

COMMON INDICATIONS
Inspection of Tracheobronchial Tree
Search for source of bleeding in patient with mild to moderate hemoptysis
Suspected endobronchial lesion (e.g., in patient with lobar collapse)
Search for occult cancer in patient with malignant cells in sputum but normal chest radiograph
Assessment of intractable cough
Staging of known lung cancer
Sampling from Lower Respiratory Tract
Microbiologic
Pulmonary infiltrate in immunocompromised host
Complicated pneumonia in immunocompetent host
Cytologic and histologic
Suspected pulmonary neoplasia
Diagnosis of unexplained pulmonary infiltrates
Aspiration of paratracheal or parabronchial lymph nodes
Cell count and differential
Assessing activity of chronic interstitial pneumonia (investigational)
Therapeutic Interventions
Suctioning mucous plugs
Guided intubation
Removal of foreign bodies (infrequent)
Placement of endobronchial stents
Endobronchial brachytherapy
CONTRAINDICATIONS
Uncooperative patient
Uncorrectable hypoxemia or hypercapnia
Uncorrectable bleeding diathesis
Severe asthma

diagnostic for eosinophilic granuloma when Langerhans cells are recovered in the washings. Milky BAL fluid indicates alveolar proteinosis; such fluid stains positively with the periodic acid–Schiff (PAS) reaction.

Brushings

Specimens obtained from the stiff bristles of a wire brush that can be passed through the bronchoscope may contribute to the cytologic diagnosis of pulmonary malignancies. Bronchial brushings have a much higher diagnostic yield for endobronchially visible proximal lesions but may be positive in 20% to 40% of peripheral lesions when the brushing is fluoroscopically guided. Lesions larger than 2 cm in diameter and lesions located more centrally tend to have higher cytologic yields, as do lesions that directly involve the bronchial tree. Bronchial brushing may contribute material for microbiologic smears and cultures but is unlikely to provide the sole positive result of a diagnostic evaluation.

Biopsy

Bronchoscopic biopsy forceps produce 2 to 3 mm specimens of lung tissue by tearing tissue away from the lung or bronchus. The biopsy is not painful for the patient. It is, however, associated with bleeding, which is usually minor but is occasionally significant or even life threatening.

Endobronchial Endobronchial biopsy of visible lesions through the bronchoscope was shown to be quite sensitive when compared with the aggregate yield of all other available diagnostic modalities, including bronchial brushings and washings, surgical biopsies, bronchoscopic and nonbronchoscopic needle biopsies, pleural fluid cytology, and biopsy of metastases. False negative results are sometimes encountered because a lesion has an overlying necrotic surface or because the process is more than 2 to 3 mm below the mucosal surface. Negative results in a patient who is strongly suspected of having a bronchogenic carcinoma should lead to a repeat procedure and biopsy attempt. CT scanning before the procedure improves the yield (see above).

Transbronchial Transbronchial lung biopsies provide small specimens of lung parenchyma that can be examined histologically and cultured. This technique is commonly used to sample focal and diffuse lesions beyond the range of direct vision. Under fluoroscopic guidance, the biopsy forceps are advanced to a region of interest, and samples are obtained. Usually, four to six individual biopsies provide acceptable diagnostic sensitivity. Transbronchial biopsy for diffuse parenchymal pulmonary disorders is helpful in the diagnosis of granulomatous disorders, such as sarcoidosis, and in infections or metastatic malignancy. However, its value in the evaluation of the nonlymphocytic alveolitides, such as idiopathic interstitial pulmonary fibrosis, is a subject of considerable debate. Chest radiographs are routinely obtained after transbronchial forceps biopsy procedures because pneumothorax complicates 5% to 10% of these cases. Approximately half of patients who experience pneumothorax after transbronchial lung biopsy require chest tube drainage.

Microbiologic Sampling

Quantitative culture methods using bronchoalveolar lavage or a protected catheter brush are useful for documenting bacterial pneumonia and providing guidance for antimicrobial therapy. Careful technique must be observed. Recovery of 10^3 organisms/ml by protected catheter brush, recovery of 10^4 organisms/ml from the fluid obtained from bronchoalveolar lavage, or the presence of intracellular organisms in more than 2% of alveolar cells usually indicates pneumonia, except in patients with chronic bronchitis or bronchiectasis. In an ICU patient, quantitative cultures are reliable if there has been no change in antibiotics for 48 to 72 hours, and they can be used to prove or exclude significant lung infection when infiltrates and fever of uncertain origin are present.[28] The use of invasive techniques for the diagnosis of bacterial pneumonia remains highly controversial, however; there is no evidence that these procedures improve outcome in severe hospital-acquired pneumonia.[29]

Because appropriate management of community-acquired bacterial pneumonia depends on the rapid (and usually empirical) administration of appropriate antibiotics, these techniques have only limited utility for the diagnosis of pneumonia in this setting. In practice, an invasive and expensive procedure, such as bronchoscopy with quantitative culture, is seldom done before first initiating a trial of antibacterial therapy.

Transbronchial Needle Aspiration

Lesions in the pulmonary parenchyma and in the mediastinum may be accessible to bronchoscopic sampling by transbronchial needle aspiration. A 1.3 cm, 22-gauge cytology needle or a 19-gauge cutting needle may be advanced through the sampling channel of a bronchoscope and passed through the bronchial wall to obtain cytologic or histologic material from tumors or adjacent lymph nodes. Transbronchial needle aspiration is particularly useful for the nodal evaluation of intrathoracic malignancy and for pulmonary nodules that are neither central nor peripheral in location. Correlation of endobronchial anatomy with CT findings is advisable before transbronchial needle aspiration is attempted. Percutaneous transthoracic needle aspiration is still better suited for small peripheral nodules, especially when there is a substantial likelihood of a benign diagnosis.

Complications of Fiberoptic Bronchoscopy

When reasonable precautions are taken, the complication rate of fiberoptic bronchoscopy is quite low, and those complications that do occur tend to be minor. Deaths resulting from bronchoscopy are extremely rare. Major complications—chiefly pneumothorax or severe hemorrhage—occur in 0.5% of routine bronchoscopies and about 7% of transbronchial biopsies. Minor complications, including bronchospasm, laryngospasm, epistaxis, and vasovagal syncope, occur in 0.8%.[30] Fever may result when liquid instilled into airways activates alveolar macrophages to release interleukin-1β (IL-1β), IL-6, and tumor necrosis factor–α.[31] Significant hypoxemia, occasionally leading to respiratory failure, may be seen in immunocompromised patients, especially those undergoing BAL for AIDS-related opportunistic infections. Myocardial ischemia has been objectively demonstrated to occur in elderly patients who undergo prolonged bronchoscopies. Careful monitoring and attention to oxygenation are needed in such patients. Because of its favorable safety profile, fiberoptic bronchoscopy is routinely performed as an outpatient procedure.

PERCUTANEOUS TRANSTHORACIC NEEDLE ASPIRATION

Cutting or cytologic needles may be passed through the chest wall under local anesthesia and fluoroscopic, CT, or ultrasound guidance to obtain tissue samples from the lung, mediastinum,

pleura, chest wall, and hila [*see Figure 9*]. Percutaneous transthoracic needle aspiration (PTNA) should be considered when fiberoptic bronchoscopy has been unsuccessful in obtaining diagnostic tissue or when a patient is inoperable or refuses thoracotomy for diagnosis. The major risks of both needle procedures are pneumothorax, severe hemoptysis, and air embolism. The risk of pneumothorax is considerably higher in patients with chronic obstructive pulmonary disease and varies directly with the amount of pulmonary parenchyma that must be traversed to reach the lesion in question. Pneumothorax occurs in 25% to 45% of cases, but only 4% to 15% require chest tube placement. Hemoptysis is seen in 2% to 16% of cases. Because bleeding originates from noncompressible sites, coagulopathy remains an absolute contraindication to PTNA or transbronchial needle aspiration. PTNA should not be attempted in patients with pulmonary hypertension, suspected arteriovenous malformations, or echinococcal cysts.

Depending on their design, percutaneous needles can be used either to aspirate a lesion—thereby providing samples for cytologic examination, smear, and culture—or to obtain a core of tissue that can provide material for histologic examination; their use carries a risk of pneumothorax. PTNA has been reported to have an 88% sensitivity and a 99% specificity for malignant lung lesions and to have a 95% sensitivity and an 81% specificity for benign lesions.[32]

THORACENTESIS

Thoracentesis, the aspiration of liquid from the pleural space, is a standard diagnostic technique. A pleural effusion without known cause should be sampled by thoracentesis for diagnostic purposes. The aspirated liquid can be analyzed for the number of red and white blood cells and the white blood cell differential; concentrations of glucose, lactate dehydrogenase, and total protein; appropriate cultures and smears; and, if indicated, cytology. Additional studies may be indicated in particular clinical circumstances. For example, measurement of pleural fluid amylase levels is helpful when pancreatitis or esophageal rupture is suspected as the etiology of the pleural effusion. Pleural liquid pH is useful in evaluating parapneumonic effusions. A pH of less than 7.29 (or less than 7.22 in the setting of low probability and higher risk) is associated with a complicated effusion that may require drainage.[33] pH paper should not be used; pH should be determined from an aliquot of pleural liquid placed in a heparinized syringe.

The most common complications of thoracentesis are bleeding and pneumothorax. The use of catheter-based thoracentesis kits has led to an increase in the incidence of retained catheters. The risk of complication from thoracentesis is a function of the experience of the operator and may be increased in certain settings, such as in patients with chronic obstructive lung disease or those who have undergone previous radiation therapy. If a single pass is required for the tap, if no air leak is encountered, and if the operator feels the procedure is uncomplicated, the rate of pneumothorax is less than 1%, and a postthoracentesis chest roentgenogram is not necessary.

PLEURAL BIOPSY

In contrast to thoracentesis, pleural biopsy should be performed by a specialist. The technique is employed in the evaluation of patients with unexplained exudative pleural effusions. The technique is performed using a large-bore needle with a cutting edge; small (2 to 3 mm) tissue samples are obtained blindly from the parietal pleura. Some pleural liquid must be present to ensure proper placement of the needle in the pleural space and to minimize the risk of lung puncture. Only 40% of submitted closed pleural biopsy specimens actually contain pleural tissue. It is advisable to submit tissue from at least six separate passes to obtain optimal diagnostic sensitivity. Its value is greatest in establishing the diagnosis of postprimary tuberculous involvement of the pleura: with an adequate number of biopsies submitted for microbiologic and histologic examination, closed pleural biopsy has a sensitivity of 87% for the diagnosis of tuberculous pleurisy (60% culture, 80% histology).[34] The diagnostic yield of biopsy in confirming malignant invasion of the pleura is only slightly greater than that obtained through cytologic examination of the aspirated liquid.

The major contraindication for these techniques is a bleeding disorder, because it is impossible to apply pressure to a pleural bleeding site without performing an open surgical procedure.

THORACOSCOPY

Thoracoscopy is currently employed in the diagnosis of pleural and mediastinal disorders, for the introduction of talc pleurodesis in the management of malignant pleural effusion or recurrent spontaneous pneumothorax, and for the evacuation of partially loculated empyema. Thoracoscopy has been successfully applied as an alternative to open lung biopsy in the evaluation of diffuse interstitial lung disease, for solitary pulmonary nodules, and for lung volume reduction surgery for advanced emphysema.[35] The technique requires access to the pleura through one or more small intercostal incisions, induction of artificial pneumothorax, and examination through a rigid thoracoscope (medical thoracoscopy) or via telescope attached to a video camera (video-assisted thoracoscopic surgery, or VATS). Medical thoracoscopies can be performed in an endoscopy suite under local anesthesia and conscious sedation, whereas VATS usually requires general anesthesia and double-lumen intubation in the operating room. Complication rates are higher than for mediastinoscopy, and hospital stays are longer.

Thoracoscopy should be undertaken for mediastinal disorders only when lesions are inaccessible to the mediastinoscope.

Figure 9 **Under CT guidance, a needle is passed through the chest wall into pleura-based right middle lobe lesions. Peripheral lesions are particularly suitable for this approach, which has a high diagnostic sensitivity.**

Mortality from medical thoracoscopy is reported to be 1% to 5%. Thoracoscopy has a 2% to 3% rate of complications, including prolonged air leak and pleural effusion. Empyema, significant bleeding, and tumor seeding of incisions are also reported. Approximately 10% of thoracoscopies require conversion to open thoracotomy to manage unexpected findings. For this reason, most experts recommend that all thoracoscopic procedures be performed by a thoracic surgeon.

MEDIASTINOSCOPY

Mediastinoscopy and anterior mediastinal exploration through a limited superior parasternal incision (mediastinotomy) are surgical procedures used for diagnostic biopsy of mediastinal masses and the staging of carcinoma of the lung. Mediastinoscopy is performed under general anesthesia and requires a small transverse incision just above the suprasternal notch. Blunt dissection along the pretracheal fascial plane is performed, and paratracheal lymph nodes can be sampled. Mediastinoscopy is especially suited for evaluation of the superior and anterior mediastinum. Mediastinoscopic access to posterior, subcarinal, and some para-aortic nodes is difficult and often necessitates an open exploration through a left-sided second intercostal space incision, the so-called Chamberlain procedure.

Mediastinoscopy is indicated in the nodal staging of lung cancer for superior sulcus tumors; for small cell cancer being considered for resection; for patients with poor ventilatory reserve in whom CT results are discordant with the expected likelihood of nodal metastasis; in evaluation of the superior vena cava syndrome (previously thought to be an absolute contraindication); and in settings of clinical uncertainty.

OPEN LUNG BIOPSY

Noninvasive diagnostic studies are subject to sampling error because of the size of the sample and the frequent nonhomogeneity of the pathologic process of interest. Samples may be crushed or distorted, leading to difficulty in pathologic interpretation. Biopsy by open thoracotomy provides the best obtainable specificity and sensitivity but at the cost of the risk of the open procedure and a painful intercostal incision. Histologic diagnoses are possible in 85% to 95% of cases. New or unexpected diagnoses may be made in almost half of these cases. Surgical mortality is reported in the range of 0% to 13% in immunocompetent patients but as high as 25% to 65% in immunocompromised and mechanically ventilated patients. Mortality is higher when open lung biopsy is performed on an emergent rather than an elective basis.[36] Significant morbidity may occur in another 25% to 50% of patients.[37]

Open biopsy should be considered when the overall prognosis is good, when less invasive modalities have failed to provide a useful diagnosis, and when an empirical therapeutic trial has not resulted in clinical improvement. Decisions for open lung biopsies, however, should give considerable weight as to whether a definitive diagnosis will change therapy and whether that therapy can be expected to lead to improvement in survival. An Israeli study of open lung biopsy in diffuse lung disease reported an 18% benefit, as defined above, at the cost of 13% mortality in immunocompetent patients. For immunocompromised patients, the benefit was 46% but at the cost of 39% operative mortality.[36]

II ASTHMA

Mitchell H. Grayson, m.d.
Michael J. Holtzman, m.d.

Asthma is a major public health issue. It affects nearly 5% of the United States population and is the reason for approximately two million emergency department visits, 470,000 hospitalizations, and 4,500 deaths annually.[1] Mortality has declined over the past 10 years, but rates remain 2.5 to 3 times higher in blacks than in whites.[2] Some evidence indicates that the quality of life of patients with asthma has improved with the development of new medications; however, inappropriate use of medications in the treatment of this disease is widespread. To address these issues, the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health and the World Health Organization (WHO) generated several expert panel reports on the diagnosis and treatment of asthma, including the National Asthma Education Prevention Program (NAEPP).[1] This chapter reviews the current understanding of asthma pathogenesis, diagnosis, and treatment.

Pathogenesis

Asthma has been defined as a chronic inflammatory disorder of the airways that is associated with recruitment of inflammatory cells and the clinical development of wheezing, shortness of breath, chest tightness, and cough. There is widespread but variable airflow obstruction that is often reversible, either spontaneously or as a result of treatment. In addition, asthmatic patients exhibit airway hyperreactivity that can be assessed by measuring the increased bronchoconstrictor response to inhaled agents such as histamine or methacholine. It has been proposed that airway hyperreactivity, as well as the clinical signs and symptoms of asthma, is driven by persistent airway inflammation.

Allergic response

The precise basis for the development of airway inflammation in patients with asthma is not fully defined. One traditional scheme postulates the development of an allergic response in the airways. In this case, the inflammatory cascade may begin when an antigen is inhaled into the airway and is taken up and processed by an antigen-presenting cell, usually a dendritic cell. The dendritic cell then migrates from the airway mucosa to the regional lymph nodes. Upon arrival at the lymph node, the dendritic cell, which has matured along the journey, presents the processed antigenic peptides to T cells. Rare antigen-specific T cells sample the peptides being presented in the lymph node; when an antigen-specific T cell finds a dendritic cell that presents the peptides for which the T cell is specific, it begins to proliferate [*see Figure 1*]. Simultaneously, the dendritic cell, through various signals, attempts to skew the cytokine profile of the developing T cells to cause them to become T helper type 1 (Th1) cells (which primarily produce interferon gamma [IFN-γ]) and interleukin 12 [IL-12]) or Th2 cells (which produce IL-4, IL-5, and IL-13). These cytokine profiles may be found in both $CD4^+$ and $CD8^+$ T cells; both types of T cells have been implicated in causing asthma.

The allergic response in general and the asthmatic allergic response in particular depend on a Th2 response to an antigen.[3] Th2 cells produce IL-4, which causes B cells to switch from usual production of IgM or IgG antibody to production of IgE antibody. Once produced, IgE antibodies bind to the surface of mast cells and basophils, where subsequent antigen cross-linking causes the generation and release of mediators that drive the asthma phenotype.

In an experimental model of the allergic response to inhaled antigen, Th2 cells alone were not sufficient to cause the asthma phenotype, because Th2 cell recruitment to the allergic site depends on help from Th1 cells.[4] Th1 cells are more readily recruited to the airway tissue and are responsible for tumor necrosis factor (TNF)–dependent expression of vascular cell adhesion molecules; the presence of Th1 cells in the airway tissue in turn allows Th2 cells to enter the tissue. The Th1 cells do not need to be of the same antigenic specificity as the Th2 cells.[5] This finding may help explain why inflammatory stimuli, such as respiratory viral infections, may facilitate the allergic response and contribute to flares of allergic asthma.

Allergen itself may also be sufficient to produce airway inflammation. When a sensitized individual is reexposed to allergen, the subsequent cross-linking of IgE on the surface of the mast cells and basophils can lead to the release of immediate-phase reactants such as histamine and TNF. Within 4 to 6 hours after exposure, the activated immune cells produce chemokines and cytokines, proteinases, enzymes, and lipid mediators such as the cysteinyl leukotrienes. Chemokines recruit and help activate additional Th2 cells and eosinophils in the airway. Proteinases and other enzymes may lead to airway damage, which promotes collagen deposition in the subepithelial basement membrane region. Cysteinyl leukotrienes can cause airway smooth muscle constriction and mucous cell secretion that further obstruct the airway lumen.

Leukotrienes in concert with chemokines (e.g., eotaxin) and cytokines (e.g., IL-5) may also recruit and activate eosinophils in the airway. Eosinophils are granulocytes that have a very short life span in the periphery and do not appear in large amounts in the circulation. These cells are produced in the bone marrow under the influence of Th2 cell production of IL-5. Newly produced eosinophils are released into the circulation and home in on the lung tissue, guided by a similar set of cell adhesion molecules that direct Th2 cell traffic. Upon entry into airway tissue, eosinophils and Th2 cells secrete their products, which, in addition to the mast cell/basophil products, are thought to lead to mucous cell metaplasia and smooth muscle hyperplasia. These changes in cellular behavior are the basis for the hypersecretion and hyperresponsiveness that is characteristic of the asthma phenotype. The Th2 cytokines IL-9 and IL-13 are especially effective in driving differentiation of mucous cells. Eosinophil granule constituents such as myelin basic protein, eosinophilic cationic protein, and eosinophil-derived neurotoxin may also contribute to airway inflammation, damage, and remodeling, although recent findings in mouse models and human subjects suggest that the contribution of the eosinophil may not be necessary for the asthma phenotype, at least under some conditions.[6-9] Recently, an additional type of T cell, the regulatory T cell (Tr), was identified. Tr cells produce IL-10 and transforming growth factor–β (TGF-β), which may downregulate the immune response. Studies in experimental models suggest that an inhibition of the Tr function may also drive the asthma phenotype,[10] but whether this phenomenon occurs in humans still needs to be determined.

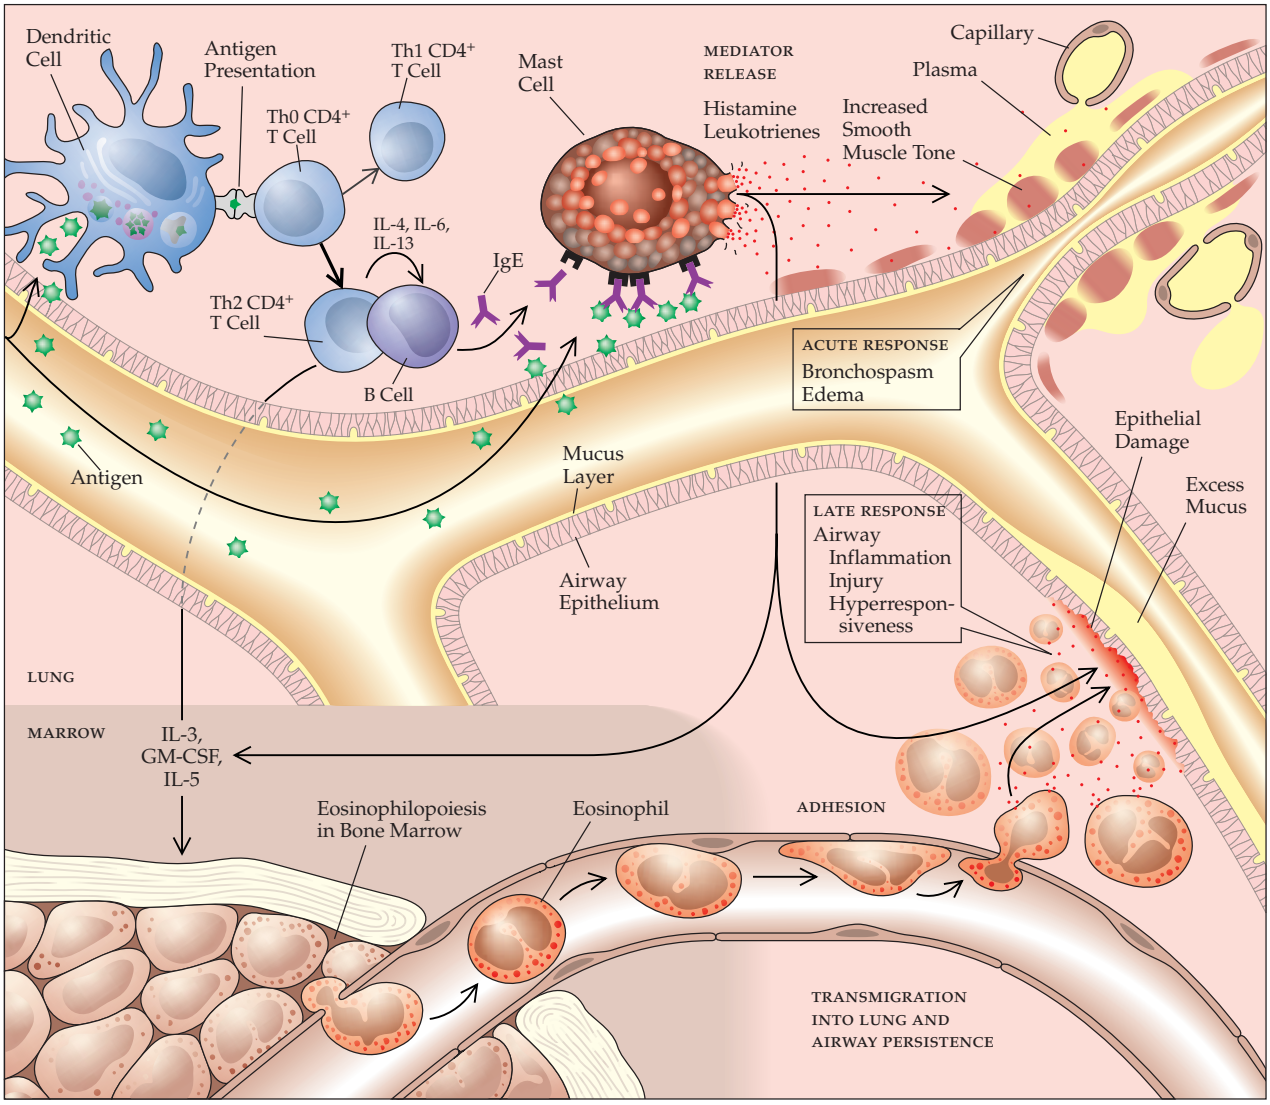

Figure 1 **Pathogenesis of allergic asthma. Inhaled antigen is processed by dendritic cells and presented to Th2 CD4$^+$ T cells. B cells are stimulated to produce IgE, which binds to mast cells. Inhaled antigen binds to IgE, stimulating the mast cell to degranulate, which in turn leads to the release of mediators of the immediate response and the late response. Histamine and the leukotrienes produce bronchospasm and airway edema. Released chemotactic factors, along with factors from the Th2 CD4$^+$ T cells, facilitate eosinophil traffic from the bone marrow to the airway walls. These late responses are proposed to lead to excessive mucus production, airway wall inflammation, injury, and hyperresponsiveness. (GM-CSF—granulocyte-macrophage colony-stimulating factor; IFN-γ—interferon gamma; IL—interleukin)**

GENETIC INFLUENCE

Family and twin studies have clearly shown that asthma is a heritable disease; however, it has proved difficult to identify specific linkage to individual genes. This difficulty likely rests on the fact that asthma is a complex genetic disorder in which multiple genes contribute to the development of the disease. In addition, asthma is a multifactorial disease in which a variety of environmental factors can influence the development of the disease phenotype. Nonetheless, several candidate genes have been linked to the development of asthma, at least in some populations. Genome-wide screens have shown associations between asthma and regions on chromosomes 2p, 4q, 5q23-31, 6p24-21, 11q13-21, 12q21-24, 13q12-14, 16q21-23, and 19q.[11] These chromosomal regions encode genes involved in antigen presentation and activation of T cells (i.e., *CTLA-4 HLA*) and cytokines such as IFN-α, IL-4, IL-5, IL-9, and IL-13, as well as components of the IgE receptor (i.e., FcεRIβ) and the beta agonist receptor. Through use of a candidate-gene approach, IL-13 and associated proteins (i.e., the α chains of the IL-13 and IL-4 receptors and STAT-6) were also found to exhibit linkage to asthma.[12-14] Other investigators have identified novel genes that are associated with asthma. *ADAM33* encodes a metalloproteinase found in airway smooth muscle and fibroblasts and is presumably involved in airway remodeling.[15] The B isoform of *GPRA*, a G protein–coupled receptor, is found in airway smooth muscle cells of asthmatic patients but not in those of nonasthmatic persons.[16] Two additional genes associated with asthma are the dipeptidyl peptidase family member *DPP10* and *PHF11*, which is a member of the family of proteins containing zinc fingers.[17,18] The function of these gene products is unknown. Future studies are likely to provide additional insight into the genetic basis of asthma.

VIRAL INFLUENCE

The cascade of events that surround the generation and acti-

vation of allergen-specific Th2 cells is best demonstrated in persons with allergy. However, many patients with allergy do not develop asthma, and some asthma patients have no demonstrable allergic component. Other than the generation of Th1 cells early in the allergic response, the Th2 hypothesis for asthma does not offer a useful explanation for how certain viral infections may not only exacerbate but initiate the development of asthma. Severe viral infections of the epithelium appear to generate a cascade of events that ultimately leads to the development of both an acute and a chronic asthma phenotype [*see Figure 2*]. Moreover, nearly 25% of children who develop a severe respiratory disease from infection with respiratory syncytial virus (RSV) before 3 years of age will subsequently develop asthma, whereas fewer than 5% of those who develop milder disease from RSV infection will manifest any long-term effects.[19] The basis of the response to RSV infection and the relationship of this response to the development of asthma still need to be defined.

One line of research has focused on the behavior of viral host cells (especially airway epithelial cells).[20] The findings have led to the proposal of an alternative paradigm for asthma pathogenesis that incorporates observed abnormalities in innate immune behavior of airway epithelial cells, viral capacity to initiate and sustain the asthma phenotype, and allergic predisposition of many asthma patients (the so-called Epi-Vir-All paradigm).[21] The contribution of each of these abnormalities to asthma pathogenesis likely varies in different types of asthmatic patients and at different times in the same patients. Moreover, some of the same abnormalities in innate and adaptive airway immunity may also underlie the pathogenesis of other chronic inflammatory airway diseases (e.g., chronic bronchitis) that manifest similar disease traits (e.g., airway hyperreactivity and mucous cell metaplasia). A challenge of current asthma research is to more precisely define these abnormalities and to develop biomarkers that can be used clinically for more accurate diagnosis and treatment of this condition.

Diagnosis

CLINICAL MANIFESTATIONS

The classic symptoms of asthma are wheezing, cough, and shortness of breath. Because of the intermittent nature of asthma symptoms, patients may be entirely asymptomatic between attacks. However, studies suggest that even with essentially normal lung function and an absence of symptoms, patients may still have persistent airway inflammation that requires ongoing therapy.

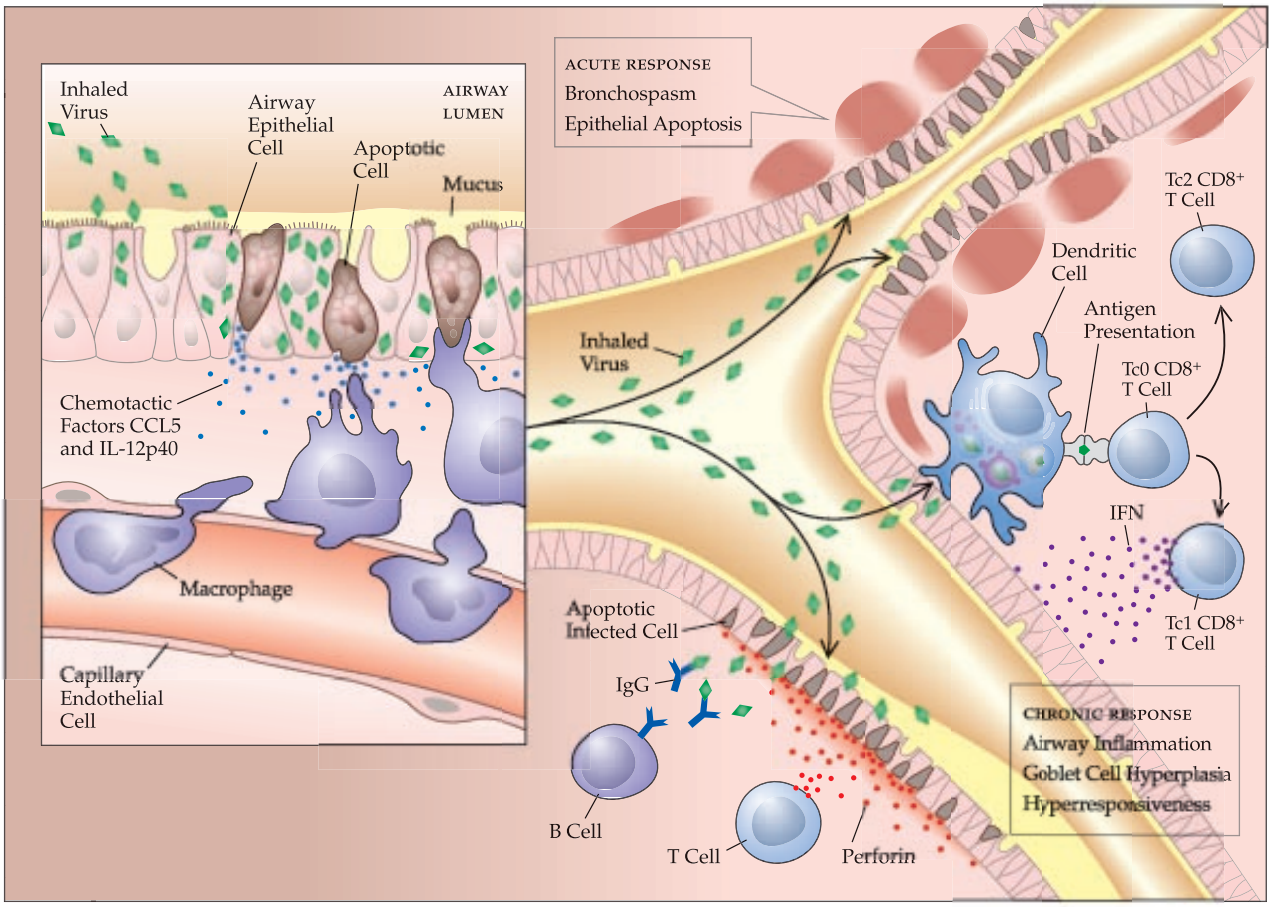

Figure 2 **Pathogenesis of viral-induced asthma. Inhaled virus infects epithelial cells and leads to apoptosis of some of them. The release of chemotactic factors promotes the recruitment of macrophages into the lung parenchyma, where they ingest the dead epithelium. An acute response consisting of bronchospasm occurs at this time. Similar to allergic asthma, the inhaled virus is processed by dendritic cells and presented to Th2 $CD8^+$ T cells. These cells produce copious amounts of IFN-γ. Perforin released from the T cells leads to apoptosis of infected cells. B cells produce IgG, which is capable of neutralizing the virus. These events are thought to be related to the chronic response, which consists of airway inflammation, goblet cell hyperplasia, and airway hyperresponsiveness. (IFN-γ—interferon gamma; IL—interleukin; CCL—chemokine ligand)**

Wheezing

Wheezing is the most common finding during acute airway obstruction, and the chest may be hyperresonant on percussion. As airflow obstruction becomes severe, a number of physical signs may become manifest and may offer clues to the severity of the attack. Tachypnea and tachycardia are common. A fall in systolic blood pressure of more than 10 to 12 mm Hg during inspiration (paradoxical pulse) is found in approximately one half of patients whose forced expiratory volume in one second (FEV_1) is 1 L or less during acute exacerbations. Accessory muscle usage and paradoxical pulse with decreasing intensity of breath sounds also signify severe airway obstruction. The cessation of wheezing in the absence of therapy is an especially ominous sign that may reflect a marked decrease in airflow. Bronchoconstriction can be triggered by a variety of stimuli that have little or no impact on the airways of nonasthmatic persons; these responses can be helpful diagnostically. The stimulus need not be a specific allergen or chemical in the workplace; a nonspecific (i.e., nonantigenic) stimulus, such as strenuous exercise, especially while breathing dry air, may trigger the response.

Cough

The cough of patients with asthma can be nonproductive or can raise copious amounts of sputum. In the absence of infection, sputum is typically mucoid and often tenacious. Eosinophils and their constituents may cause a yellow discoloration of sputum, even when infection is absent. Cough is occasionally the only manifestation of asthma; the term cough-varient asthma has sometimes been used to designate such cases.

Dyspnea

The level of dyspnea tends to vary greatly in individual patients over time, reflecting wide variations in the severity of airflow obstruction. At times, airflow obstruction prevents any significant physical exertion; at other times, strenuous exercise is possible but may trigger wheezing and shortness of breath [*see* Exercise-Induced Asthma, *below*]. During a severe attack, a desperate hunger for air is the overwhelming symptom. Chest tightness commonly occurs with dyspnea and may be confused with angina pectoris. Most patients associate their chest tightness with the sensation of being unable to take in a full and satisfying breath. Older patients are often less aware of airflow obstruction and may therefore require closer monitoring.[22]

STIMULI THAT TRIGGER ATTACKS

The stimuli that trigger asthmatic attacks vary among individual patients. For some patients, attacks of asthma are triggered by allergens such as ragweed or animal dander, house dust containing antigens from dust mites and cockroaches, strong odors or fumes, or ingested substances such as certain foods, sulfite agents, aspirin, and tartrazine [*see* Specific Forms and Complications of Asthma, *below*]. Emotional stress may trigger symptoms in some patients, but the precise role of the central nervous system in regulating airway function is difficult to quantitate. Reflux of gastric acid into the lower esophagus may exacerbate asthmatic symptoms, presumably through vagally mediated parasympathetic nervous reflexes,[23] but the role of gastroesophageal reflux in asthma remains controversial.[24] Persistent posterior drainage of nasal mucus may also be an aggravating factor. Indirect evidence indicates that nasal and sinus disease increases airway responsiveness and thereby exacerbates asthma.[25] Other stimuli are virtually universal precipitants

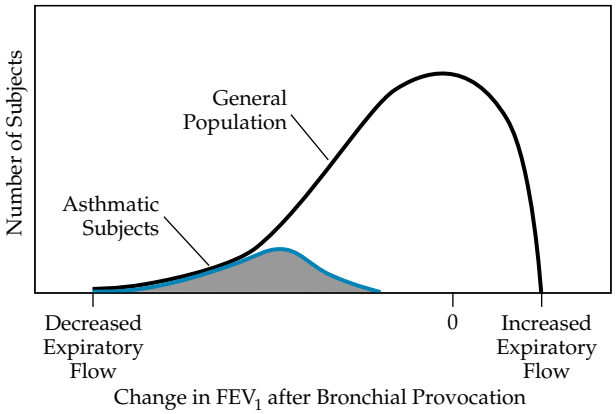

Figure 3 **The change in expiratory flow, as measured by forced expiratory volume in 1 second (FEV_1), after administration of a given concentration of bronchoprovocative agonist is shown for a general population. A large decrease in expiratory flow implies a greater bronchial reactivity. Bronchial reactivity is normally distributed, with a skew toward increased reactivity. The figure indicates that asthmatic persons exhibit varying degrees of bronchial hyperreactivity and that some persons with increased bronchial responsiveness do not manifest clinical signs of asthma.**

of asthma symptoms. Such stimuli include strenuous exercise, particularly if it is performed in cold, dry air; respiratory infections, usually caused by community-acquired viruses; inhaled pollutants and irritants such as ozone, sulfur dioxide, and cigarette smoke; beta blockers, angiotensin-converting enzyme inhibitors, and, in some Asian patients, ingestion of ethanol.[26] Specific antigen responsiveness may be more severe after exposure to environmental pollutants. Some women with asthma have been noted to have a significant increase in exacerbations during the preovulatory and perimenstrual periods.[27] The exact hormonal contributions to asthma flares in these patients are not known; however, increases in progesterone levels have been implicated on the basis of temporal association.

Asthma that is triggered by identifiable inhaled antigens (aeroallergens) is often associated with manifestations of atopic disease (i.e., seasonal allergic rhinitis or eczema). Exceptions to this association include cases of asthma caused by certain sensitizing antigens encountered in the workplace that may not elicit an IgE antibody response [*see* Occupational Asthma, *below*]. Laboratory tests can be used to support a diagnosis of atopic disease. These include increased levels of peripheral blood eosinophils, total serum IgE levels, and specific IgE levels as determined by radioallergosorbent testing (RAST) directed at a particular antigen or by positive wheal-and-flare reactions to antigens pricked or injected into the skin.

Some experts make a distinction between asthma in which there are known allergic precipitants of bronchoconstriction (i.e., extrinsic asthma) and asthma in which there are no known precipants (i.e., intrinsic asthma). In asthma cases in which there is evidence of atopy, lung function may decline at a greater rate than in nonatopic cases.[28] The distinction between extrinsic and intrinsic asthma has probably been overemphasized and may be misleading, because it implies a differentiation of etiology or pathogenesis that is not supported by current data. Categorization into extrinsic or intrinsic asthma groups is difficult: allergic precipitants may not be recognized, symptoms of other atopic diseases may create ambiguity, and laboratory test results may be inconclusive or falsely positive. As a result, it is probably best to avoid the use of the

terms intrinsic and extrinsic asthma. Fortunately, the management of asthmatic patients is not dependent on this distinction.

LABORATORY TESTS

No single laboratory test can establish a diagnosis of asthma, but a test for bronchodilator responsiveness can provide supportive evidence when asthma is suspected on clinical grounds. In patients with baseline airflow obstruction, a significant increase in expiratory airflow (e.g., ≥ 12% increase in FEV_1) after inhalation of a bronchodilator suggests asthma.[29] Unfortunately, as a diagnostic test, bronchodilator responsiveness lacks both sensitivity and specificity. Negative results may be found in asthmatic patients who have near-normal baseline lung function, are tested shortly after self-administration of a bronchodilator, or have obstruction caused by increased mucus secretions. Significant bronchodilator responses may also be observed in other types of chronic obstructive airway diseases, such as chronic bronchitis.

Because asthma is episodic, a diagnosis of asthma may be suspected on the basis of recurrent symptoms, even if there is normal pulmonary function. Measurement of airway reactivity may be a useful diagnostic test in this setting. In clinical practice, airway reactivity is defined by increased airway resistance or decreased maximal expiratory airflow (e.g., FEV_1) after a challenge with an inhaled nonspecific stimulus, such as methacholine or histamine. In asthmatic patients, airflow obstruction occurs with nonspecific stimuli that do not alter the airway mechanics of patients without asthma. The degree of nonspecific reactivity is often expressed as the dose required to reduce the FEV_1 by 20% from the measured baseline. This variable, the PD_{20} FEV_1, does not absolutely distinguish asthmatic patients from patients with other respiratory disorders (e.g., allergic rhinitis); however, as the degree of reactivity increases (with a decrease in the PD_{20} FEV_1), the confidence that asthma is present increases.

Other, less frequently used stimuli for bronchoprovocation include cold air, exercise, eucapnic hyperventilation, and adenosine 5′-monophosphate. Although bronchoprovocation tests are very sensitive, they are not specific for asthma [*see Figure 3*]. An alternative approach for the diagnosis of asthma is to demonstrate lability of maximal airflow. This can be demonstrated by having the patient periodically monitor his or her condition with a self-operated peak flowmeter and by keeping a diary of the results or by using a device that electronically collects and stores the information. A diurnal variation in peak expiratory airflow (PEF) of 15% or more is highly suggestive of a diagnosis of asthma.[30]

In an adult with asthmatic symptoms of new onset, a chest radiograph is also warranted to exclude alternative diagnoses (e.g., pneumonia, congestive heart failure, and pulmonary fibrosis). In patients with asthma, the chest radiograph is usually normal; occasionally, subtle changes indicative of bronchial wall thickening are detected, and during an episode of severe airflow obstruction, radiographic signs of hyperinflation may be present. Chest radiographs of patients treated for asthma exacerbations reveal unsuspected pulmonary infiltrates, atelectasis, pneumothorax, or pneumomediastinum only 2% of the time; therefore, radiographs are not routinely indicated in patients with documented asthma who are experiencing a flare of disease.

Differential Diagnosis

Acute respiratory illness can mimic the signs and symptoms of asthma, and it can exacerbate existing asthma. Commonly, adults and children with tracheobronchitis or bronchiolitis that is associated with respiratory viral infection present with signs of cough, wheezing, dyspnea, and increased secretions that are all driven by underlying airway inflammation and consequent airway hyperreactivity. Common viral pathogens include adenovirus, rhinovirus, influenza virus, metapneumovirus, and parainfluenza virus. In immunocompromised hosts, other less common pathogens (e.g., herpes simplex virus, respiratory syncytial virus, and possibly metapneumovirus) may be responsible [*see 7:XXV Respiratory Viral Infections*]. Much less commonly, asthmatic symptoms are caused by the Churg-Strauss syndrome [*see 14:IV Focal and Multifocal Lung Disease*], which is a form of vasculitis characterized by asthmalike airflow obstruction and wheezing.

In addition to acute conditions, flares of chronic obstructive airway diseases (especially chronic bronchitis but sometimes bronchiectasis or cystic fibrosis) [*see 14:III Chronic Obstructive Diseases of the Lung*] can cause transient increases in obstruction and lead to episodic wheezing similar to that seen in asthma. Other chronic lung diseases may also affect the airway in a manner that can be mistaken for asthma. For example, sarcoidosis may cause endobronchial granuloma formation with resultant airflow limitation, as well as cough, wheezing, and dyspnea that are refractory to the usual bronchodilator medications. In addition, rheumatoid arthritis may be associated with bronchiolitis, producing findings that mimic refractory asthma.

Congestive heart failure and pulmonary embolism can also cause dyspnea and wheezing. Wheezing in association with interstitial pulmonary edema is common enough to have been designated cardiogenic asthma. Improvement after administration of an inhaled bronchodilator does not exclude cardiogenic asthma as the cause of wheezing. Wheezing is a rare manifestation of pulmonary embolism. Although in the acute setting either pulmonary edema or pulmonary embolism may be mistaken for asthma, the discovery of rales, peripheral edema, and chest radiographic findings of pulmonary edema should allow for a quick distinction. Pulmonary emboli rarely cause wheezing or airflow obstruction sufficient enough to be confused with asthma exacerbations, and the sudden onset of dyspnea in a cancer patient or in a patient with an immobilized extremity should prompt additional diagnostic testing, such as an extremity ultrasound, perfusion lung scanning, computed tomography, or pulmonary angiography.

The conditions most likely to be confused with asthma over a more protracted period are those that cause partial upper airway obstruction [*see Table 1*]. In this context, the term upper airway refers to the single lumen airway from the carina upward. Dyspnea and wheezing associated with upper airway obstruction may be continuous and may fail to respond to bronchodilators—a pattern that suggests focal anatomic obstruction. However, in other cases, signs and symptoms may be intermittent and may be brought on by exercise (because of the increased airflow across the narrowed orifice) or by certain postures. Epinephrine or glucocorticoids occasionally relieve symptoms of upper airway obstruction by decreasing edema—a result that may lead one to mistake the cause of the symptoms as being asthma. Findings that suggest the correct diagnosis are the patient's perception that the problem is in the throat, wheezes that are heard loudest over the neck and transmitted with less intensity to the lung periphery, hoarseness, a cough that sounds unusual, and a normal arterial to alveolar oxygen difference ($A\text{-}aD_{O_2}$ gradient). A helpful diagnostic clue is a history of trauma, surgery, or prolonged intubation of the upper airway. Upper airway obstruction produces characteristic abnormalities in

flow-volume curves [*see 14:I Lung Function Assessment and Thoracic Diagnostic Techniques*]. An imaging test that may occasionally prove helpful in the diagnosis of upper airway obstruction is tracheal tomography, especially when performed with the latest generation of CT scanners. Laryngoscopy or fiberoptic bronchoscopy may also be useful in selected cases.

One particularly common type of upper airway obstruction that is frequently misdiagnosed as asthma is vocal cord dysfunction. Patients with vocal cord dysfunction can present with a change in vocal quality, wheezing, stridor, shortness of breath, or dyspnea on exertion. In patients with vocal cord dysfunction who do not have asthma, results of pulse oximetry, blood gas measurements, and chest radiography will be normal, and these patients will not exhibit altered airway reactivity. Flow-volume curves obtained during attacks typically show decreased inspiratory airflow consistent with an extrathoracic site of airway obstruction. Observing the vocal cords by endoscopy during an episode of vocal cord dysfunction can establish the diagnosis. The classic pattern consists of adduction of the anterior two thirds of the vocal cords with a posterior diamond-shaped chink. This occurs during inspiration but can be present during the entire respiratory cycle. It should be stressed that vocal cord dysfunction can exist alone or in combination with asthma; therefore, a diagnosis of vocal cord dysfunction does not rule out the existence of underlying asthma.

Table 1 Causes of Upper Airway Obstruction

Specific Forms and Complications of Asthma

EXERCISE-INDUCED ASTHMA

Exercise-induced asthma is distinct from exercise limitation caused by other forms of cardiopulmonary disease in which breathlessness develops after a certain level of exercise and gradually resolves with rest.[31] In contrast, an asymptomatic person with asthma and normal or near-normal lung function may exercise for several minutes without experiencing any symptoms. Five to 10 minutes after exercise, pulmonary obstruction develops (often accompanied by wheezing, shortness of breath, and chest tightness); the magnitude of obstruction is a function of drying and cooling of the airway mucosa and is thus a function of minute ventilation and of the temperature and humidity of the inspired air. The obstruction spontaneously resolves 30 to 60 minutes after onset.

The crucial determinants of exercise-induced asthma are the level of ventilation during exercise and the temperature and relative humidity of the inspired air. The higher the minute ventilation during exercise and the colder and drier the inspired air, the greater the airflow obstruction that develops after exercise. The intrathoracic airways become cooled and lose water as they condition large volumes of inspired air. It has been postulated that the fall in airway temperature and evaporative drying of the mucosa are the initiating stimuli for bronchoconstriction. The second step in this sequence is unknown; evidence is available regarding the possible activation of mast cells and the release of mediators. Another hypothesis attributes the airflow obstruction to a greater degree of reactive hyperemia of asthmatic airways in the postexercise period.[32]

NOCTURNAL ASTHMA

During periods of heightened disease activity, it is common for patients with asthma to experience symptoms at night.[33] They may awaken at 2:00 to 4:00 A.M. with cough, wheezing, and dyspnea. Measurements of pulmonary function before and after sleep usually document a significant worsening of obstruction in the morning, a phenomenon referred to as morning dipping. This phenomenon may contribute to the observed clustering of asthmatic deaths in the hours between midnight and 8:00 A.M. The precise cause of nocturnal asthma is uncertain, but possible mechanisms include sleep-related changes in airway tone, lung volumes, and airway inflammation; circadian variations in circulating histamine, cortisol, and epinephrine levels; prolonged exposure to allergens or irritants in the bedroom; late asthmatic reactions to daytime allergens or other inciting stimuli; gastroesophageal reflux related to the supine posture; retained airway secretions resulting from depressed cough reflex; and an increase in the intervals between antiasthmatic medication use.

NEAR-FATAL AND HYPERACUTE ASTHMA

There are data to suggest that patients at risk for near-fatal or fatal asthma differ histologically and pathophysiologically from other patients with asthma.[34] Advanced age, greater airway reactivity, previous use of mechanical ventilation, and long-term steroid therapy are important risk factors for mortality. Additional risk factors are previous hospitalizations for asthma, problems with compliance, major psychiatric diagnoses, use of major tranquilizers, reduced chemosensitivity to hypoxemia, and decreased perception of dyspnea. Patients with sudden attacks that worsen rapidly (referred to as hyperacute attacks) are at the greatest risk for mortality.

Histologically, patients who die less than 1 hour after the onset of symptoms have a larger proportion of neutrophils and fewer eosinophils than patients who die more than 2.5 hours af-

ter the onset of an attack, suggesting that pathogenesis may be different in those who have hyperacute attacks; such hyperacute attacks may possibly represent infection. The central airways of asthmatic patients who die during an attack have greater amounts of smooth muscle and submucosal glands than the central airways of patients in nonfatal cases and may be more responsive to bronchoconstrictive stimuli and less responsive to bronchodilators.

In some studies, regular use of beta agonists was associated with an unfavorable outcome in asthma patients. However, observations of patients with near-fatal asthma have shown that severe asphyxia and not cardiac arrhythmias may be the cause of near-fatal episodes, suggesting that undertreatment with anti-inflammatory medications, such as steroids, rather than overtreatment with beta agonists is the problem.

ASTHMA CAUSED BY ASPIRIN, SULFITES, OR TARTRAZINE

Current estimates are that 10% to 20% of patients with asthma exhibit an idiosyncratic reaction to ingested acetylsalicylic acid (aspirin).[35] Within 15 minutes to 4 hours after ingestion of as little as 10 mg of aspirin, susceptible patients may experience significant worsening of airflow obstruction and nasal or ocular symptoms (e.g., nasal congestion, rhinorrhea, and conjunctival injection). Nasal polyps are common in aspirin-sensitive asthmatic patients; the term aspirin triad has been used to describe the combination of asthma, nasal polyps, and idiosyncratic reactions to aspirin.

The most likely mechanism by which aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) trigger bronchoconstriction in susceptible asthmatic patients is the blockade of the cyclooxygenase-mediated conversion of arachidonic acid to prostaglandins (particularly prostaglandin E_2 [PGE_2], a potent anti-inflammatory prostaglandin). This causes shunting of arachidonic acid toward the lipoxygenase pathway, where, possibly on the basis of genetic polymorphisms, there is increased expression of LTC4 synthase.[36] This in turn facilitates the formation of this bronchoconstrictor and proinflammatory leukotrienes.[37] The hypothesis does not account for the idiosyncratic nature of the reaction in only a minority of asthmatic persons or for the peculiar finding that, in rare cases, a patient with asthma actually exhibits improvement in lung function after administration of aspirin. Further, there have been conflicting data regarding leukotriene levels in these patients; however, at least some studies indicate an elevation in cysteinyl leukotrienes. This finding would help explain why leukotriene antagonists have shown good clinical efficacy in these patients. Another proposed mechanism for aspirin sensitivity is that endogenous prostaglandins normally inhibit inflammatory mediator release, especially from mast cells, and that prostaglandin blockade allows the disinhibition of this proinflammatory mechanism.

A history of asthmatic worsening or of nasal or conjunctival symptoms after aspirin ingestion is usually sufficient to identify aspirin-sensitive patients. Such patients should avoid any product containing aspirin or other NSAIDs that inhibit cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Acetaminophen and salsalate are weak COX-1 inhibitors, but with high doses, reactions can occur in a minority of aspirin-sensitive patients. Sodium salicylate, salicylamide, choline magnesium trisalicylate, benzydamine, chloroquine, azapropazone, and dextropropoxyphene do not inhibit COX enzymes and can be used safely. Selective COX-2 inhibitors have been shown to be safe in aspirin-sensitive patients.[38]

Sulfiting agents, including sodium and potassium bisulfite and metabisulfite, are used in the food-processing industry as sanitizing agents, preservatives, and antioxidants. These agents are also found in a great number of medications, including some bronchodilator solutions. Restaurant food, almost all wines and certain beers, fresh and dried fruits, peeled potatoes (including French fries), avocado dip, and shrimp and other shellfish are common sources of sulfites. The asthmatic reactions may be severe and life threatening, but they usually respond rapidly to bronchodilator therapy. An estimated 5% of persons with asthma are thought to have sulfite sensitivity, which currently can be properly diagnosed only by a controlled sulfite challenge.

Tartrazine, a food dye approved by the Food and Drug Administration, is a coal tar derivative widely used in prepared foods and drinks, medications, and mouth care products. Worsening of airflow obstruction in asthmatic patients has been reported in double-blind, placebo-controlled oral challenges with tartrazine. In most instances, positive responses occurred only in aspirin-sensitive asthmatic patients. Other reports have called into question the existence of tartrazine sensitivity. Tartrazine-free diets are so restrictive that careful documentation of sensitivity in a controlled fashion should always precede the imposition of such a diet on a patient.

ASTHMA IN PREGNANCY

Asthma is a potentially serious medical problem during pregnancy.[39] Pregnant women with asthma have higher rates of complications, such as hyperemesis gravidarum, uterine hemorrhage, preeclampsia, placenta previa, and the need for cesarian section; these complications are especially prevalent in patients with severe asthma. There is little evidence of an increase in maternal mortality associated with asthma.[39] Prematurity and intrauterine growth retardation of the fetus are associated with poor asthma control in the mother.[39] Improved control of asthma is associated with improvement in fetal outcome.[39] Of pregnant patients with asthma, one third will experience improvement in their asthma, one third will remain stable, and one third will experience a worsening of their asthma. Unfortunately, at this time it is not possible to accurately predict what will happen to a given patient. In fact, there is no evidence to suggest that the level of severity seen in one pregnancy will be seen in the next pregnancy of the same patient.

OCCUPATIONAL ASTHMA

Persons with asthma who are exposed to irritant dusts or fumes in the work environment are susceptible to exacerbations.[40] Occupational asthma, however, refers to asthma of new onset that is caused by prolonged exposure to a specific inhaled substance in the workplace. Occupational exposures may be involved in the development or worsening of as much as 10% of asthma cases.[40] The particular gas, dust, or vapor seems to sensitize the airways; continued exposure causes reversible airway narrowing and the development of nonspecific bronchial hyperreactivity. A typical history is that of a worker who after a few months (but sometimes up to several years) at a job notices cough, wheezing, and chest tightness shortly after arriving at the workplace, especially after a brief absence over the weekend (so-called Monday-morning asthma). Symptoms persist while the patient is at work but often abate after the patient returns home. Continued occupational exposure may lead to more persistent symptoms, more continuous airflow obstruction, and susceptibility to the typical spectrum of precipitants of asthma

in addition to the offending agents encountered in the work environment. Some persons with occupational asthma report a delayed onset of asthmatic symptoms: symptoms begin hours after the patient leaves the workplace, making recognition of an association with the offending agent more difficult. Occasionally, workers experience recurrent nocturnal asthmatic symptoms for several nights after a work-related exposure.

More than 200 substances have been linked to occupational asthma, and the list of agents continues to grow [*see Table 2*]. Major categories of offending agents include laboratory animals, birds, insects, and various animal products; plants and wood dust; biologic enzymes; isocyanates; anhydrides; metals; fluxes; latex; and drugs and other chemicals. For some of these agents, an immunologic mechanism involving the immediate hypersensitivity reaction has been demonstrated; for other substances, atopy does not predispose persons to the development of disease, and evidence of an IgE-mediated pathogenesis is lacking. Genetic factors also probably play a role in susceptibility among workers. The prevalence of disease varies with the sensitizing agent. For example, asthma develops in approximately 5% to 10% of workers exposed to toluene diisocyanate, in an estimated 20% of bakers exposed to wheat flour or rye flour, and in as many as 50% of people who work with platinum salts or proteolytic enzymes. Reducing concentrations of offending agents by better control of dust lowers the incidence of asthma exacerbations and may decrease sensitization.

Exposure to irritant gases can range from contact with pure chlorine gas in industrial or environmental spills to inhalation of smoke (which contains several toxic gases, as well as particulate matter and carbon monoxide). Such exposure can result in a wide spectrum of syndromes, ranging from acute tracheobronchitis to diffuse alveolar damage that results in acute respiratory distress syndrome. An intermediate response, termed reactive airway dysfunction syndrome, is a severe and persistent asthmatic state that can be difficult to treat and may result in long-term impairment of function.[41] Preexisting lung disease and long-term cigarette smoking are risk factors for more severe reactions.

Variations in lung function related to occupational exposures can be confirmed by the use of simple portable devices for recording PEF. Definitive diagnosis entails isolating the offending agent and then having the patient inhale carefully controlled concentrations of it while pulmonary function is sequentially recorded for several hours. Skin testing with the appropriate soluble extracts and RAST tests for specific IgE antibody assess only the presence of sensitization to the agent. Many workers exhibit positive skin-test or RAST results but have no evidence of asthma.

LATE ASTHMATIC REACTIONS

The airflow obstruction that develops after inhalation of certain allergens or industrial agents may follow one of several patterns [*see Figure 4*]. An immediate response typically occurs within 5 to 10 minutes after inhalation and usually resolves spontaneously over a period of 30 to 60 minutes, much like the airflow obstruction that develops after bronchoprovocation with histamine, methacholine, or exercise. This early asthmatic reaction often responds rapidly to inhaled bronchodilators. A delayed response to inhaled allergens and industrial agents is sometimes observed. Typically, this late asthmatic reaction occurs 6 to 8 hours after the inhalational challenge; it is often more severe than the immediate response, and it may resolve slowly

Table 2 Causes of Occupational Asthma

Potential Hazard	*Persons at Risk*	*Sensitizing Agent*
Laboratory animals, birds, insects, other animal products	Laboratory workers, animal handlers, veterinarians	Rats, mice, rabbits, guinea pigs
	Pigeon breeders, poultry workers, bird fanciers	Pigeons, chickens, budgerigars (shell parakeets)
	Grain workers	Grain mites
	Entomologists	Moths and butterflies
	Crab and prawn processors	Crabs and prawns
Plants, wood dust	Bakers	Wheat flour, rye flour
	Food processors	Coffee beans, castor beans
	Tea workers	Tea leaves
	Tobacco manufacturers	Tobacco leaves
	Carpenters, sawmill operators, cabinetmakers	Wood dust, including western red cedar dust
Biologic enzymes	Detergent industry workers	*Bacillus subtilis*
	Pharmaceutical industry workers, biomedical researchers	Pepsin, trypsin, bromelain
Isocyanates	Workers with polyurethane, plastics, and varnish	Toluene diisocyanate
	Automobile spray painters	Hexamethylene diisocyanate
Anhydrides	Workers with epoxy resins and plastics	Phthalic, trimellitic, and other anhydrides
Metals	Tanners	Chromium
	Platinum refiners	Platinum
	Metal platers	Nickel
Fluxes	Aluminum solderers	Aminoethylethanolamine
	Electronics workers	Colophony
Drugs, other chemicals	Pharmaceutical workers	Penicillins, cephalosporins, methyldopa, spiramycin, tetracycline
	Workers with plastics and rubbers	Azodicarbonamide
	Insulators	Urea, formaldehyde
	Refrigeration workers	Freon
	Hairdressers	Persulfate salts, henna

over a period of 12 to 24 hours. Treatment with glucocorticoids may prevent the occurrence of late asthmatic reactions and may be especially useful if the late response is relatively refractory to bronchodilators. Persons exhibiting both early and late responses are said to have dual reactions; occasionally, recurrent nocturnal airflow obstruction continues for several days after a single exposure.

Late reactions are important to our basic understanding of asthma, because often the clinical manifestations of asthma, particularly during subacute exacerbations, more closely mimic late asthmatic reactions than early reactions in terms of both timing and responsiveness to medications. Evidence from bronchoalveolar lavage specimens indicates that the late response correlates temporally with an influx of eosinophils and neutrophils into the airways.[42] Release of previously made factors by mast cells and basophils is thought to account for the immediate response and for the subsequent cellular infiltration. The release of a secondary wave of de novo synthesized mediators accounts for the delayed development of inflammation and obstruction. In animal models of the late asthmatic reaction, the development of bronchial hyperreactivity is coincident with the late response and is prevented by its inhibition.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis (ABPA), a hypersensitivity reaction to the colonization of the airways by *Aspergillus* species, rarely occurs except in patients with asthma. This disorder typically develops in patients with atopy and long-term asthma and is marked by fever, flulike symptoms, myalgias, and lassitude. The chest radiograph reveals pulmonary infiltrates, often with associated atelectasis of the involved segments or lobes caused by tenacious mucous plugs that occlude the proximal airways. Although this entity is frequently mistaken for bacterial pneumonia, sputum cultures are negative for pathogenic bacteria. Clues to the proper diagnosis include the presence of sputum and blood eosinophilia, the volume loss that accompanies the pulmonary infiltrates, and failure of the infiltrates to respond to antibiotics.

Abundant *Aspergillus* organisms are found in the bronchial lumina of patients with allergic bronchopulmonary aspergillosis, but significant tissue invasion does not occur. An exuberant inflammatory response involves both the bronchial wall and the surrounding lung. Acute and chronic inflammation in the walls of central bronchi, accompanied by necrosis, leads to bronchiectasis and large mucous plugs (mucoid impaction). At times, a granulomatous response results in the replacement of bronchial and peribronchial tissue (bronchocentric granulomatosis). An eosinophilic pneumonia commonly affects the surrounding lung tissue.

The pulmonary infiltrates may resolve spontaneously but commonly recur, leading to the appearance of migratory pulmonary infiltrates on chest x-ray [*see Figure 5*]. Chronic disease commonly involves the upper lobes; typical features include bronchiectasis (usually involving central airways)[43] and fibrosis with retraction. Chronic ABPA may be readily mistaken for tuberculosis, especially because hemoptysis occurs in one third to one half of cases. ABPA can occur in patients with cystic fibrosis, and a minority of patients with ABPA have mutations in the cystic fibrosis transmembrane regulator (*CFTR*) gene.[44]

The diagnosis of allergic bronchopulmonary aspergillosis can be confirmed by the following test results: (1) positive immediate skin-test reaction to *Aspergillus* antigen, (2) elevated total serum IgE level (usually > 1,000 ng/ml), (3) elevated levels of specific IgE and IgG antibodies against *Aspergillus* (levels are usually twice those of allergic asthmatic patients who do not have allergic bronchopulmonary aspergillosis), (4) the presence of precipitating antibodies against *Aspergillus*, and (5) peripheral blood eosinophilia together with the recurrent appearance of pulmonary infiltrates on chest x-ray.[45]

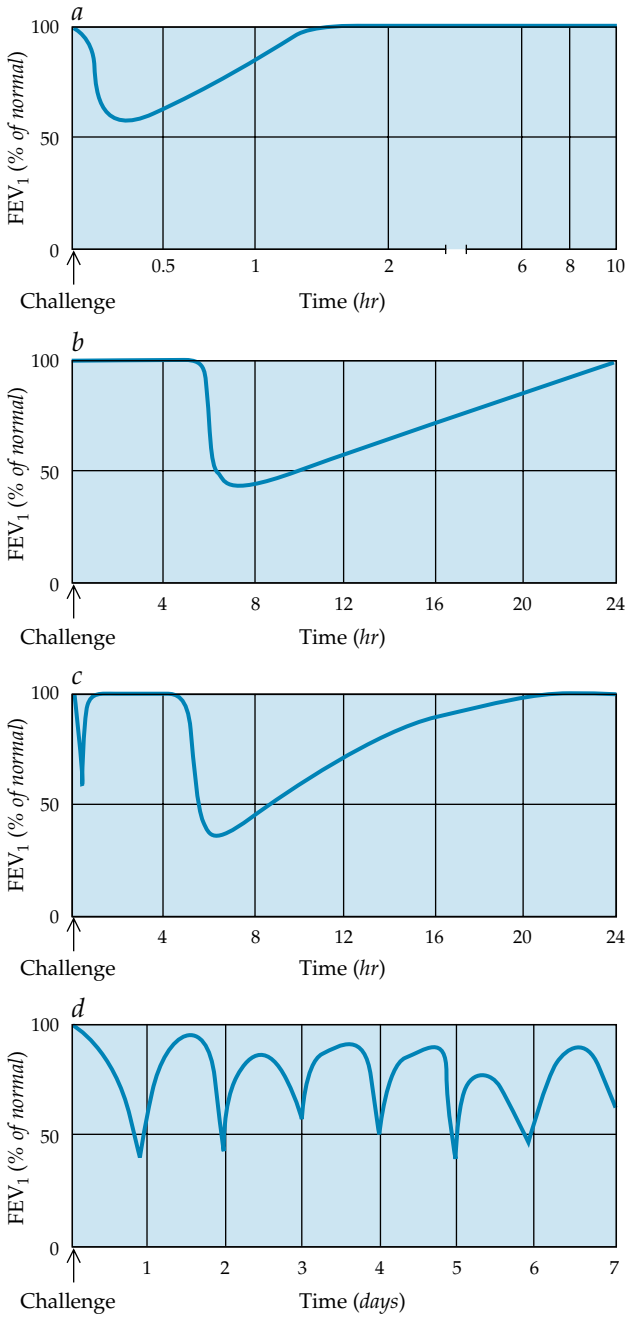

Figure 4 **Four patterns of bronchial response to an inhaled antigen are depicted. (*a*) An early response occurs within a few minutes after administration of the stimulus and resolves without treatment over the next 30 to 60 minutes. (*b*) A late response develops several hours after the bronchoprovocative challenge and resolves gradually over the next 12 to 24 hours. (*c*) A dual response combines features of both the early and the late reaction. (*d*) Occasionally, decreases in expiratory flow recur on several nights after a single challenge test. Note that different time scales are used.**

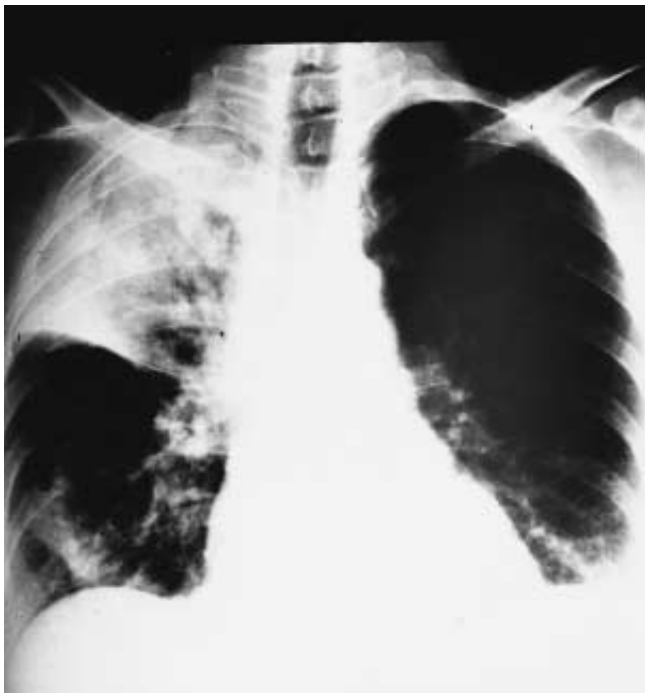

Figure 5 **This posteroanterior chest radiograph shows an asthmatic patient with allergic bronchopulmonary aspergillosis. Characteristic radiographic findings include the migratory nature of the infiltrates, the predominant upper lobe involvement, and the associated atelectasis. The minor fissure forms the lower border of the upper right lobe infiltrate; the minor fissure is displaced cephalad, indicating loss of volume in the right upper lobe.**

Management

In the United States, the total cost incurred because of asthma, including the direct costs of care and the indirect costs from lost productivity, is estimated to be $10.7 billion a year.[46] Almost half the costs arise from hospital care, and 80% of the costs are incurred by 20% of the patients.[46,47] Studies of patients hospitalized for exacerbations of asthma have documented deficiencies in the care that patients had been receiving before admission, which suggests that published guidelines[1,48] are not understood[49] and are not being used by primary care physicians.[50] In addition, many patients with asthma are not satisfied with their treatment regimen.[51] Education of the patient is a critical and often neglected aspect of care that has the potential to improve outcomes.[52] Self-monitoring with the use of inexpensive peak flowmeters may improve a patient's ability to judge disease severity and may reduce morbidity.[52] A specialist can provide more therapeutically effective[53] and more cost-effective treatment[54] and should be involved in the care of all patients with moderate to severe asthma.

ASTHMA THERAPIES

Medications used to treat asthma can be classified into two groups in accordance with their principal actions. The first group comprises bronchodilators that act primarily to relax airway smooth muscle; these agents include beta agonists and anticholinergic agents, although theophylline and its derivatives also have mild bronchodilator activity. The second group comprises anti-inflammatory drugs that act mainly as inhibitors and modifiers of airway inflammation; these agents include glucocorticoids, leukotriene modifiers, theophylline, and anti-IgE antibody [*see Table 3*].

The mainstay of therapy for asthma is the long-term use of medications to downregulate the airway inflammatory process and thereby control abnormal airway behavior. [*For treatment of specific presentations, see* Management Strategies, *below*.] Currently available drugs allow for adequate control of asthma in most patients, but there is significant need for—and ongoing effort to develop—agents that more fully and permanently correct the asthmatic condition.[55]

Bronchodilators

Beta agonists The most effective bronchodilators function by selectively and potently stimulating the $beta_2$ receptors on airway smooth muscle. Receptor activation causes adenylate cyclase to increase the levels of intracellular cyclic adenosine monophosphate (cAMP). Epinephrine is short-acting (30 to 60 minutes) when inhaled and activates both alpha receptors and beta receptors. Beta-adrenergic stimulation predominates in the airways, resulting in bronchodilatation, but dominant peripheral alpha-adrenergic stimulation results in vasoconstriction and may cause an increase in blood pressure. In clinical practice, epinephrine is given primarily as a subcutaneous or intramuscular injection for acute relief of severe airflow obstruction. It is also sold without prescription as an inhalant in metered-dose canisters. In general, epinephrine should not be used for the management of asthma; it is only useful in acute bronchospastic situations—although even then, an inhaled selective $beta_2$ agonist is preferred. Similarly, isoproterenol, a powerful nonselective beta agonist, has a short duration of action and is available as an inhalant for the treatment of asthma, but it has largely been replaced by newer, more selective $beta_2$ agonists.

Selective $beta_2$ agonists have structural modifications that make them effective when taken by inhalation. The duration of action of these compounds varies from 4 to 6 hours. Examples are metaproterenol, terbutaline, and albuterol [*see Table 4*]. Bitolterol has a slightly extended duration of action of 6 to 8 hours; it is currently available only in a metered-dose delivery system. A preparation that contains only the R isomer of albuterol (levalbuterol) has been reported to have reduced side effects and complications, but these claims are still being studied.[56] Salmeterol, an even longer-acting $beta_2$ agonist with a slow onset of action, can be given twice a day as maintenance therapy (not rescue therapy); it has resulted in better asthma control and quality of life than is seen with albuterol. Salmeterol does not compromise the bronchodilator response to the short-acting $beta_2$ agonists[57] and may have mild anti-inflammatory effects.[58] Formoterol, also a long-acting selective $beta_2$ agonist, has a duration of action similar to that of salmeterol, but it has a more rapid onset of action; formoterol thus has potential for use as a long-acting maintenance medication and a long-acting rescue medication in place of the short-acting $beta_2$ agonists.[59] Because of their potential to mask underlying inflammation, long-acting $beta_2$ agonists (i.e., salmeterol and formoterol) should not be used as monotherapy. In the United States, a combination dry-powder inhaler is available with salmeterol and the inhaled glucocorticoid fluticasone dipropionate. In most countries other than the United States, a combination of formoterol and the glucocorticoid budesonide is available for inhaled use. It is anticipated that this combination will soon be available in the United States as well.

The frequency and severity of side effects from the $beta_2$ agonists depend not only on the dose but also on the route of administration. Side effects are most prominent with parenteral admin-

Table 3 Summary of Drugs for Asthma

Drug	*Initial Dose*	*Maintenance Dose*	*Relative Efficacy*	*Cost*	*Comments*
Bronchodilators					
$Beta_2$ agonists	*See Table 4*		First choice for rescue		Oral or parenteral therapy associated with significant side effects; use short-acting drugs/inhaler p.r.n. rather than on regular schedule; use long-acting drugs regularly
Anticholinergic agents	*See Table 5*		Only for exacerbations		Can worsen prostatism, glaucoma; can be combined with beta agonists
Anti-inflammatory agents					
Systemic glucocorticoids					
Prednisone	0.5–1.0 mg/kg/day	None or minimal	Usual oral agent	$5.00/mo	q.d. initially, then wean off, if possible, or switch to q.o.d.
Methylprednisolone, oral	24–48 mg/day	None or minimal	Less commonly used oral agent	$9.00–43.00/mo	q.d. initially, then wean off, if possible, or switch to q.o.d.
Methylprednisolone, I.V.	60–125 mg q. 6–8 hr	None	Usual I.V. agent	$24.00–26.99/day	Oral therapy as effective
Inhaled glucocorticoids	*See Table 4*		First choice of anti-inflammatory agents		Various inhaled corticosteroid agents differ in potency [*see Table 5*]
Cromolyn sodium	2 puffs q.i.d.	Same	Much less potent than inhaled steroids	$30.00–39.99/canister	Used more in children; no steroid side effects; no longer preferred treatment
Nedocromil	2 puffs q.i.d.	Same	Much less potent than inhaled steroids	$50.00–59.99/mo	No longer preferred treatment
Leukotriene modifiers					As a group, less effective than inhaled corticosteroids; help with associated allergic rhinitis; should be used in aspirin-sensitive patients
Montelukast	10 mg q.h.s.	Same	First choice of leukotriene modifiers	$60.00–69.99/mo	No lab monitoring or restrictions related to meals
Zafirlukast	20 mg b.i.d.	Same		$50.00–59.00/mo	Should be taken at least 1 hr before or 2 hr after meals
Zileuton	600 mg q.i.d.	Same		$79.00–89.99/mo	Must monitor LFTs
Theophylline	100–200 mg b.i.d.	Adjust to serum level 10–20 μg/ml	Third choice	$10.00–19.99	Relatively weak bronchodilator; only used when all other agents optimized; significant toxicity, must monitor levels
Other anti-inflammatory agents					
Omalizumab	150–375 mg q. 2–4 wk	150–375 mg q. 2–4 wk	Only as add-on therapy in severe persistent asthma	$1,000/mo	Given S.C.; dosage based on pretreatment IgE levels and body mass
Methotrexate	7.5 mg/wk	Adjust to effect; maximum, 25 mg/wk	Efficacy controversial	$10.00–19.99/mo	Toxic drug, must monitor blood counts and LFTs closely; should only be given by asthma expert

LFT — liver function test

istration, are of intermediate prominence with oral administration, and are least prominent with inhaled administration. Common side effects are those of sympathetic stimulation, including nervousness and agitation, muscle tremors, and palpitations. Cardiac stimulation may lead to tachycardia and cardiac arrhythmias. Intracellular shifts of potassium can cause hypokalemia, although the clinical significance of this finding is uncertain. Long-term administration of beta agonists may be associated with the development of tolerance[60]—possibly caused by the decrease in the number and responsiveness of membrane beta receptors related to polymorphisms of the beta receptor genes[61]—and with increased airway responsiveness to allergen and nonspecific stimuli.

Over the years, $beta_2$ agonists given by inhalation have been

Table 4 Estimated Comparative Doses of Inhaled Bronchodilators for Asthma[38]

Drug	*Maintenance Dosage*	*Exacerbation Dosage*	*Relative Efficacy*	*Cost*	*Comments*
Inhaled Short-Acting Beta$_2$ Agonists			Inhaled short-acting beta$_2$ agonists are first-line p.r.n. therapy; no significant differences in efficacy among inhaled short-acting beta$_2$ agonists	$30.00–39.99/mo	Dilute aerosols to minimum of 4 ml at gas flow of 6–8 L/min
Albuterol					
Nebulizer, 5 mg/ml	1.25–5.0 mg q. 4–8 hr p.r.n.	5.0 mg q. 2 hr			
MDI, 84 μg/puff	2–4 puffs q. 6 hr p.r.n.	3–8 puffs q. 2 hr			MDI as effective as nebulizer when used with spacer
DPI, 200 μg/capsule	1–2 capsules q. 6 hr p.r.n.	Not studied in exacerbations			—
Bitolterol					
Nebulizer, 2 mg/ml	0.5–3.5 q. 4–8 hr p.r.n.	Not studied in exacerbations	—	N/A	—
MDI, 370 μg/puff	2–4 puffs q. 6 hr p.r.n.	—	—		—
Levalbuterol Nebulizer, 0.63 mg/3 ml	0.31–0.63 mg q. 6–8 hr p.r.n.	0.63–1.25 mg q. 6–8 hr p.r.n.	Similar to albuterol, slightly fewer side effects	$110.00–130.00/mo	—
Inhaled Long-Acting Beta$_2$ Agonists			Inhaled long-acting beta$_2$ agonists first-line scheduled bronchodilator therapy	$50.00–69.99/mo	Salmeterol has slower onset of action; not used as a rescue bronchodilator; should only be used with an inhaled glucocorticoid
Salmeterol					
MDI, 21 μg/puff	2 puffs q. 12 hr	Not recommended			
DPI, 50 μg/blister	1 blister q. 12 hr	—			
Formoterol DPI, 12 μg/capsule	1 capsule q. 12 hr	Not recommended	—	N/A	Faster onset of action than salmeterol; may be used as a rescue bronchodilator
Inhaled Anticholinergics			Indicated in combination with inhaled short-acting beta$_2$ agonists for exacerbations	$30.00–34.99/mo	
Ipratropium bromide					
Nebulizer, 0.25 mg/ml	Not recommended	0.5 mg q. 2–8 hr			May mix with albuterol in same nebulizer
MDI, 18 μg/puff	Not recommended	3–8 puffs q. 3–4 hr			MDI as effective as nebulizer when used with spacer
Combined Short-Acting Beta$_2$ Agonist and Anticholinergic			When both are indicated	$30.00–39.99/mo	When both are indicated
Albuterol + ipratropium bromide					
MDI albuterol (90 μg/puff) + ipratropium bromide (18 μg/puff)	Not recommended	3–8 puffs q. 2 hr			

DPI—dry-powder inhaler MDI—metered-dose inhaler

the mainstay of treatment for asthma because of their rapid onset of action, their effectiveness, and their convenience. In the mid-1980s, an increase in asthma deaths occurred in New Zealand after the introduction of the beta$_2$ agonist fenoterol. A study based in Saskatchewan, Canada, however, suggested that all beta$_2$ agonists, especially if used heavily, are associated with an increased risk of fatal and near-fatal asthmatic episodes, but a meta-analysis suggested that the risk is very small and may be confined to beta$_2$ agents given by nebulizer.[62] A recent case-control study found increased mortality in patients treated with short-acting beta$_2$ agonists for 1 to 5 years, but shorter courses were not associated with death.[63] In other studies, nebulized and oral beta$_2$ agonists were associated with increased risk of cardiovascular death, ischemic heart disease, and cardiac failure.[64,65] The most obvious question concerning these studies is whether the increased mortality occurred because of the administration of excessive amounts of the therapeutic agent or because of the severity of illness in those patients given the drug. Further studies have suggested that the regular use of beta$_2$ agonists leads to a mild increase in the degree of airway responsiveness to allergens.

Investigators have applied genetic analysis of the beta$_2$ receptor to try to determine whether certain patients are more susceptible to the detrimental effects of bronchodilator treatment. Initial retrospective studies indicated that a subgroup of patients with a specific polymorphism (homozygosity for arginine [Arg/Arg]) in the beta$_2$-adrenergic receptor gene (*beta$_2$ AR*) exhibited less improvement with long-term albuterol treatment than with intermittent therapy. Further, these patients experienced a significant decline in respiratory function when treatment with long-term beta-agonist therapy was discontinued.[66] A more recent prospective trial found a similar trend; in that study, patients with a homozygosity for glycine (Gly/Gly) experienced improvement of symptoms from albuterol therapy, whereas patients with a homozygosity for arginine (Arg/Arg) experienced improvement when albuterol therapy was discontinued.[67] Ongoing studies aim to define the risk associated with the use of long-acting beta$_2$

agonists; these studies also seek to determine the specific haplotypes that appear most susceptible to detrimental actions of $beta_2$ agonists. Early studies have found the greatest risk associated with Arg/Arg at 16th amino acid in the $beta_2$ receptor.[66] This haplotype is found at highest frequency in the African-American population,[68] but studies are under way to further define the association of additional mutations.

At present, these observations must be added to the list of potentially negative effects associated with the regular use of these beta agents. Currently, it is recommended that short-acting $beta_2$ agonists be used only on an as-needed basis.[1] This strategy not only avoids the potential negative side effects of the drug but also allows the clinician to detect an increase in asthmatic symptoms—as indicated by the patient's increased need for the $beta_2$ agonist—and a worsening of the underlying inflammation. When patients begin to feel the need to use inhaled $beta_2$ agonists more frequently and at increased doses, they should be seen by a physician and evaluated for factors that may be aggravating their asthma; the addition of other treatments should be considered to better control the asthma. Excessive reliance on inhaled bronchodilators, without sufficient attention to the underlying inflammatory component of the disease, continues to be a problem in the way asthma is managed. Inhaled glucocorticoids, rather than scheduled doses of $beta_2$ agonists, should be considered as first-line therapy for asthmatic patients with daily symptoms.[1]

Anticholinergic agents For hundreds of years, the anticholinergic agents atropine and stramonium, which are alkaloid derivatives of plants of the *Datura* species, have been used as bronchodilators. Because atropine is well absorbed into the blood across the respiratory tract mucosa, it causes significant systemic side effects, even when administered by inhalation. The atropinic congeners ipratropium bromide and methylatropine nitrate are poorly absorbed into the circulation when inhaled and therefore have limited side effects. Atropine and its derivatives compete with acetylcholine at muscarinic receptors, which are adjacent to the parasympathetic, postganglionic nerve endings.

Ipratropium bromide requires 60 minutes to reach peak effect—a slightly longer time than seen with inhaled $beta_2$ agonists—but it lasts 4 to 6 hours. It has a somewhat smaller bronchodilatory effect in patients with asthma. Potential advantages are (1) its minimal cardiac stimulatory effects, which make it particularly desirable for use in patients with coronary artery disease or cardiac arrhythmias, and (2) its additive bronchodilatory effect when used in combination with submaximal doses of $beta_2$ agonists. No benefit is gained by adding ipratropium bromide to a regimen of $beta_2$ agonists given at maximal doses in long-term therapy. There is a modest benefit for patients with acute asthma exacerbations.[69] The primary indication for anticholinergic agents is chronic obstructive pulmonary disease.

Anti-inflammatory Drugs

Systemic glucocorticoids The precise mechanism or mechanisms by which glucocorticoids downregulate asthmatic inflammation (or other types of inflammation) are yet to be defined. Nonetheless, considerable evidence indicates that glucocorticoids act at least in part by inhibiting the production of proinflammatory cytokines. Cellular targets of glucocorticoid action include T cells and eosinophils. The eosinophil, in particular, is especially sensitive to glucocorticoid treatment; it rapidly undergoes apoptotic cell death upon exposure to glucocorticoids. Glucocorticoids also exhibit a slight bronchodilatory effect, which is perhaps related to alterations in airway smooth muscle receptors; however, this action is a relatively minor component of glucocorticoid action in asthma.

The optimal dose, dosing schedule, preparation, and duration of therapy for the treatment of asthma with glucocorticoids are uncertain. As a consequence, physicians have widely varying preferences for glucocorticoid treatment regimens. Available studies suggest that lower dosages of intravenously delivered hydrocortisone (200 mg/day) are as effective as higher dosages (2,000 mg/day) in hospitalized patients[70] and that a prolonged taper of oral prednisone may not be necessary to prevent late exacerbations of asthma. Systemic glucocorticoids are commonly employed for short courses (e.g., 1 to 3 weeks) to treat exacerbations of asthma.

Therapy for less than 3 weeks is not associated with adrenal axis suppression; longer courses require tapering doses and measurement of A.M. cortisol levels to determine when it is safe to stop therapy. Prednisolone and prednisone, which is metabolized to prednisolone in the liver, are the most widely used oral preparations in the treatment of asthma; these two agents are equally effective in patients who do not have severe liver disease. Long-term maintenance therapy should be avoided because of the well-known side effects of extended use of systemic glucocorticoids. In those few cases in which relief of symptomatic airflow obstruction cannot be achieved by other means, orally administered glucocorticoids are given at the lowest effective dose. Alternate-day administration minimizes side effects and hypothalamic-pituitary-adrenal axis inhibition and may provide sufficient control of chronic symptoms.

A subset of asthmatic patients either are unresponsive to glucocorticoids or require persistently high doses of glucocorticoids for adequate control.[71] This phenomenon has led to the possibility that some patients develop "steroid-resistant" asthma, but the precise basis for defining this group remains uncertain. Some reports have indicated that these patients might have abnormalities of the intracellular mechanisms of glucocorticoid action.[72] Other studies have indicated that resistance may be reversed by high-dose glucocorticoid therapy. In either case, a proportion of these patients may simply have more severe disease; however, evidence of steroid-resistant asthma may suggest that use of other anti-inflammatory agents is indicated (see below).

Inhaled glucocorticoids Inhaled glucocorticoids are the primary long-term maintenance therapy aimed at preventing recurrent exacerbations of asthma. Regular use of inhaled glucocorticoids, even in low doses, has been shown to effectively prevent a major portion of asthma hospitalizations and deaths.[73] These benefits are realized, however, only when the proper dose is prescribed and the patient takes the medication on a regular basis and with proper technique of inhalation.[74] The particular advantages of inhaled glucocorticoids are that the agent is deposited locally in the airway and that it is poorly absorbed into the circulation; this results in a decrease in systemic side effects.

Five preparations of inhaled glucocorticoids are available in the United States: beclomethasone, triamcinolone, flunisolide, fluticasone, and budesonide[75] [*see Table 5*]. Formulations using the propellant hydrofluoroalkane instead of the chlorofluorocarbons, which harm the ozone layer, are available. Because these inhalers generate aerosols with smaller-size particles, more of the inhaled glucocorticoid is delivered into the small airways, resulting in improved therapeutic response.[76] A particularly popular combination of salmeterol and fluticasone is available

in this form; its increased efficacy may be related to better deposition of the combination or improved patient compliance.

Inhaled glucocorticoids effectively inhibit the late-phase response even when given after antigen challenge; if taken long term, they reduce airway inflammation and remodeling.[77] After a period of days to weeks of regular use of inhaled glucocorticoids, many patients manifest a decrease in airway hyperreactivity.[78] Conversely, a subset of patients who are withdrawn from therapy exhibit flares of asthma that appear linked to airway infiltration of $CD4^+$ and $CD8^+$ T cells.[9] These findings appear to fit with the capacity of glucocorticoids to suppress at least partially allergic or viral-induced airway hyperreactivity in experimental models of asthma.

High doses of inhaled glucocorticoids may be as effective as moderate doses of prednisone in the treatment of asthma exacerbations.[79] Long-term oral glucocorticoid therapy can be discontinued in some patients, and the frequency of bronchodilator administration can often be reduced. Inhaled glucocorticoids are often particularly effective during periods of increased exposure to aeroallergens. Local side effects include glossitis, sore throat, hoarseness, dysphonia, and oral candidiasis. Oral candidiasis occurs in 5% to 15% of patients who use inhaled glucocorticoids; rinsing the mouth with water after each use, utilizing a spacer device (if using a metered-dose inhaler), or both can decrease the incidence of this side effect. Despite extended use of inhaled glucocorticoid preparations, histologic changes in the bronchial mucosa and alterations in oropharyngeal flora do not occur. In adults, systemic side effects are usually seen only with high doses of inhaled glucocorticoids; these side effects include skin atrophy, reduction in bone density, cataracts, and suppression of the hypothalamic-pituitary-adrenal axis.[80]

Cromolyn and nedocromil Cromolyn (sodium chromoglycate) exhibits properties that are distinct from other antiasthmatic medications. It does not act as a bronchodilator and does not directly antagonize the action of inflammatory mediators or reverse established inflammation. Instead, this agent appears to inhibit inflammation by preventing the release of chemical mediators from mast cells, even in the presence of cell-bound IgE antibody and appropriate antigen. The mechanism by which cromolyn capacity stabilizes mast cells remains uncertain. Two effective delivery systems are available: a solution for nebulization and an aerosol delivered by a metered-dose pressurized canister. Controlled trials have shown that cromolyn is minimally beneficial for patients with asthma.[81] As a result of this modest effect and the development of safer inhaled glucocorticoids, the use of cromolyn and nedocromil is limited. Nonetheless, because these agents cause few if any side effects and exhibit efficacy in mast cell–dependent events, they may be useful for the pretreatment of patients at risk for allergen- or exercise-induced asthma.

Leukotriene modifiers Leukotriene modifiers have been developed to directly antagonize the capacity of leukotrienes to mediate airway smooth muscle contraction, mucus secretion, and inflammatory cell recruitment; they have been especially useful for the treatment of asthma induced by exercise, aspirin, and allergens.[82] The class of leukotrienes that contribute to asthma pathogenesis is derived from the action of the 5-lipoxygenase pathway that metabolizes arachidonic acid to biologically active lipid mediators, especially leukotriene D_4 (LTD_4). LTD_4 produces bronchospasm by binding to a specific receptor, cysteinyl leukotriene type 1 receptor (CysLT1R), on airway smooth muscle. Another leukotriene, LTB_4, is a potent chemotaxin, especially for neutrophils, but its role—as well as that of other lipoxygenase products—for producing the asthma phenotype remains uncertain.

Two types of leukotriene modifiers are available for the treatment of asthma. Zileuton inhibits 5-lipoxygenase itself and therefore blocks all leukotriene formation. The other type includes montelukast, zafirlukast, and pranlukast (available in Japan); these agents inhibit the binding of cysteinyl leukotriene to CysLT1R. The specific indications for these drugs in the treatment of asthma are still being established; however, patients with aspirin-induced and exercise-induced asthma respond well to either a 5-lipoxygenase or CysLT1R inhibitor. Leukotriene antagonists have been shown to be effective in patients

Table 5 Estimated Comparative Daily Dosages of Inhaled Glucocorticoids

Drug	*Low Dosage*	*Medium Dosage*	*High Dosage*	*Relative Efficacy*	*Cost*	*Comments*
Beclomethasone 42 μg/puff 84 μg/puff	168–504 μg 4–12 puffs/day 2–6 puffs/day	504–840 μg 12–20 puffs/day 6–10 puffs/day	> 840 μg > 20 puffs/day > 10 puffs/day	Third highest potency	$30.00–39.99/mo	Now available in HFA MDI, possibly improving effectiveness
Budesonide 200 μg/puff	200–400 μg 1–2 inhalations/day	400–600 μg 2–3 inhalations/day	> 600 μg > 3 inhalations/day	Second highest potency	$30.00–39.99/mo	DPI inhaler
Flunisolide 250 μg/puff	500–1,000 μg 2–4 puffs/day	1,000–2,000 μg 4–8 puffs/day	> 2,000 μg > 8 puffs/day	Lowest potency	$50.00–59.00/mo	
Fluticasone 44 μg/puff 110 μg/puff 220 μg/puff	83–264 μg 2–4 puffs/day 2 puffs/day —	264–660 μg — 2–6 puffs/day 1–2 puffs/day	> 660 μg — > 6 puffs/day > 3 puffs/day	Highest potency	$40.00–49.99/mo	Also formulated in combination with salmeterol in DPI
Triamcinolone 100 μg/puff	400–1,000 μg 4–10 puffs/day	1,000–2,000 μg 10–20 puffs/day	> 2,000 μg > 20 puffs/day	Lowest potency	$30.00–39.99/mo	Provided with spacer

DPI—dry-powder inhaler HFA—hydrofluoroalkane MDI—metered-dose inhaler

with allergic rhinitis.[83] Therefore, they may be considered useful in patients who have symptoms of both allergic rhinitis and asthma. These medications are effective in approximately 50% of patients with mild, persistent asthma or moderate asthma; they may be added to or substituted for inhaled or oral anti-inflammatory drugs,[84,85] but they are not as effective as inhaled glucocorticoids with or without long-acting beta$_2$ agonists.[86,87]

Because of associated liver dysfunction, patients taking zileuton must undergo frequent liver function testing. Doubling of liver transaminases necessitates the discontinuance of the drug. Zafirlukast has been reported to induce elevations in transaminase levels in rare situations; however, most authorities do not recommend regular monitoring of liver function in patients taking this drug. These side effects have not been found to occur with montelukast therapy. Leukotriene antagonists allow for the reduction of systemic glucocorticoids; in rare instances, patients have been noted to develop a vasculitis—the Churg-Strauss syndrome—once treatment with systemic glucocorticoids was reduced.[88] This phenomenon has also been reported with the use of potent inhaled glucocorticoids. In both cases, the development of Churg-Strauss syndrome was attributed to preexisting disease that was masked by glucocorticoid treatment and that became exacerbated when this treatment was reduced [*see 14:4 Focal and Multifocal Lung Disease*].

Theophylline Theophylline is a methylxanthine that is closely related in structure to caffeine.[89] It was thought that theophylline acted by increasing cAMP levels by inhibiting the activity of phosphodiesterase, an enzyme that facilitates the conversion of cAMP to the noncyclic adenosine 5′-monophosphate. Other modes of action for theophylline have been explored, including antagonism of adenosine at its receptor. Theophylline may also have anti-inflammatory effects that include reduction in the number of inflammatory cells, expression of cytokines, and acceleration of neutrophil apoptosis.[90,91] Recent studies suggest that theophylline may even influence transcription of genes in the airway tissue and thereby downregulate inflammation.[92]

When given orally, theophylline is almost completely absorbed from the gastrointestinal tract. The rate of absorption, however, can vary greatly, depending on the formulation. A rapid onset of action can be achieved with the elixir of theophylline (peak effect is seen at approximately 60 minutes), whereas a long duration of action results from slow-release preparations (peak effect occurs at 6 to 8 hours), making once- or twice-daily dosing schedules possible. Aminophylline (the ethylenediamine salt of theophylline) and oxtriphylline (the choline salt of theophylline) are more water soluble than theophylline. Aminophylline is the preparation used for I.V. administration; its bronchodilator activity is solely attributable to theophylline, which by weight constitutes 85% of aminophylline.

Oxidation and demethylation of theophylline take place in the liver; hepatic metabolites, along with a small amount of unaltered theophylline, are excreted in the urine. The average serum half-life of theophylline in nonsmoking adults is approximately 7 to 9 hours, but differences in metabolic rates among people and in the same person over time lead to considerable variability in theophylline serum concentrations after a given dose. Clearance of theophylline is accelerated in children, in cigarette smokers, and in persons receiving phenytoin; its clearance is delayed by numerous influences, including primary liver disease, right ventricular failure, and the use of certain drugs (e.g., cimetidine, erythromycin, ciprofloxacin, and oral contraceptives).

In mild to moderate asthma, the bronchodilator response varies directly with the theophylline serum concentration. Significant bronchodilation occurs at theophylline concentrations as low as 5 to 8 mg/L; at concentrations exceeding 20 mg/L, side effects become increasingly common. Traditionally, a therapeutic range of 10 to 20 mg/L has been recommended; however, lower levels may be effective against inflammation, and many experts recommend a dose range of 5 to 15 mg/L.[93] At levels greater than 40 mg/L, serious toxic reactions can be observed, including seizures and ventricular arrhythmias. Occasionally, life-threatening toxic reactions occur at lower serum levels (i.e., 25 to 40 mg/L). This relatively narrow therapeutic index, along with highly variable clearance rates, has necessitated measurement of serum theophylline concentrations in many clinical circumstances—especially in patients with severe airflow obstruction, in whom maximal bronchodilator effect is desired.

Side effects are common with theophylline and may occur at serum concentrations at or below the therapeutic target range. GI complaints include nausea and vomiting, abdominal pain, and diarrhea. Headache, nervousness, insomnia, and tremors are the most common neurologic side effects. Cardiac stimulation may lead to sinus tachycardia, extrasystoles, and atrial arrhythmias. In cases of severe theophylline toxicity caused by overdosage (i.e., theophylline concentration > 40 mg/L, especially > 60 mg/L), clearance of theophylline can be accelerated by the administration of activated charcoal, either orally or by nasogastric tube; this will remove any theophylline remaining in the stomach or intestine. On rare occasions, charcoal hemoperfusion is necessary to reduce theophylline concentrations rapidly.

The risk of life-threatening toxicity depends not only on the drug level but also on whether intoxication is acute or chronic. A theophylline level between 40 and 50 mg/L in an acutely intoxicated patient carries a very low risk of seizures; however, the same level in a patient receiving long-term theophylline therapy whose ability to clear the drug is impaired carries a significant risk of seizures and represents a potentially life-threatening intoxication. Moreover, when a toxic level is attributable to reduced clearance rather than to acute intoxication, the duration of risk is greater because of the long half-life of theophylline. Because of the multiple side effects, the need to monitor blood levels of the drug, the potential severity of toxicity, and the availability of newer classes of more effective drugs, theophylline is no longer considered a primary choice of therapy for patients with asthma.

Other Anti-inflammatory Agents

Additional anti-inflammatory agents are under development, but at least one has been approved by the Food and Drug Administration and is available in the United States for asthma therapy: a humanized monoclonal antibody (mAb) against IgE (omalizumab). This agent removes circulating IgE but is unable to bind to cell-bound antibody; this prevents the possibility of therapy-induced anaphylaxis. Omalizumab is administered subcutaneously on a biweekly or monthly schedule on the basis of pretreatment serum IgE levels and body mass index. Once therapy is begun, IgE levels should not be monitored (they will actually increase because of the formation of an IgE–anti-IgE complex). No significant side effects have been noted with omalizumab; however, the high cost of therapy is a significant obstacle to its use. This therapy, which has been shown to reduce asthma exacerbations and glucocorticoid dosage, is indicated for severe, persistent asthma; studies suggest that patients with markedly decreased lung function, those who have recently vis-

ited the emergency department, and those who require high-dose inhaled glucocorticoids are most likely to respond to treatment with omalizumab.[94,95]

Other agents have shown little effectiveness in the treatment of asthma. Antihistamines have not been recommended as part of the usual treatment of asthma. Newer-generation drugs, however, are more potent inhibitors of in vivo histamine effects and show some promise, possibly in combination with other mediator blockers, such as the leukotriene modifiers.[96] Methotrexate may have a glucocorticoid-sparing effect in glucocorticoid-dependent asthmatic patients.[97] However, most patients referred to specialists for methotrexate therapy can be managed with higher doses of inhaled glucocorticoids, long-acting $beta_2$ agonists, theophylline administered at therapeutic levels, or inhaled anticholinergic agents; in addition, precipitating problems, such as rhinosinusitis and gastroesophageal reflux, need to be eliminated. One study found that auranofin, an oral gold preparation, had glucocorticoid-sparing effects in asthmatic patients.[98] Cyclosporine, an inhibitor of T cell activation, has been shown to have efficacy in some patients with severe asthma.[99] Other treatments that have been found to be of possible benefit to these patients include hydroxychloroquine,[100] keliximab (a chimeric monoclonal antibody to $CD4^+$),[101] and high-dose intravenous immunoglobulin.[102] None of these agents have been accepted as being useful for asthma treatment.

Immunotherapy

Immunotherapy for asthma remains controversial.[103,104] The strategy involves repeated administration of an allergen in gradually increasing amounts to reduce sensitivity to the allergen. Immunotherapy has clearly been shown to be effective in allergic rhinitis and, thus, may be effective in some patients with specific types of allergic asthma. However, the role of immunotherapy in the majority of patients with asthma has not been determined and remains of limited use.

MANAGEMENT STRATEGIES

Outpatient Care

In newly diagnosed asthma patients, the identification of avoidable precipitants of airway obstruction should be sought by history, and whenever possible, precipitants should be removed from the environment.[105] Common sources of allergens and irritants in the home include pets, insects, dust mites, cigarette smoke, dust and mold, feather pillows, down comforters, and shag rugs. Because patients may be exposed to multiple allergens in their home, skin testing is useful in demonstrating hypersensitivity to a suspected allergen; this in turn allows for targeted and appropriate avoidance measures. Exposure to allergens may not always cause immediate symptoms; rather, it may induce a state of enhanced bronchial hyperreactivity to many nonspecific stimuli. The relation between allergen exposure and worsening of asthma may not be immediately apparent.

An air filter or air conditioner may be helpful during periods of heavy outside air contamination. Beta-blocking drugs, including ophthalmic solutions, should be avoided; if such a drug is absolutely necessary, a selective $beta_1$ blocking agent should be given in the lowest possible dose. Treatment of postnasal drip or esophageal reflux of gastric acid may ease asthmatic symptoms in some patients. Weight loss in obese patients with asthma may also improve symptoms and lung function.[106]

Several new types of devices have been developed to directly deliver medication to the airways.[107] Breath-actuated metered-dose inhalers, dry-powder inhalers, and metered-dose inhalers with nonchlorofluorocarbon (hydrofluoroalkane) propellants are now on the market. The dry-powder inhalers seem to be easier for patients to use than the other types of delivery devices, because no coordination of hand action and breath taking are required. However, most patients who use the new types of delivery devices still require a metered-dose inhaler (usually for their short-acting $beta_2$ agonist) as part of their regimen.

Some patients have difficulty using metered-dose aerosol systems, either because of a lack of coordination or because of a physical handicap. Spacer devices or reservoir bags (into which the medication is sprayed from the metered-dose canister and from which the patient then inhales) may greatly assist patients who have poor coordination; an adapter is available for patients with arthritic hands. Use of a spacer results in greater delivery of the drug to the airway[108] and a reduction in complications. The principal mechanisms underlying these effects are a reduction of larger particles that would otherwise adhere to the posterior pharynx and a slowing of the rate of inhalation (most devices have warning signals when inspiration is too fast), allowing the intermediate-sized particles to make the turn from the mouth into the airway.

On the basis of symptom frequency and measurements of airway function, the NAEPP guidelines divide asthma into four categories: mild intermittent, mild persistent, moderate persistent, and severe persistent. Although this section discusses discrete therapeutic options, it should be noted that asthma is an ever-changing disease. Therefore, a patient may have moderate persistent asthma at one visit, but with appropriate treatment, the asthma may become only mildly intermittent. The practitioner should be aware of this fact and continually adjust therapy to match the current level of disease severity. In this manner, patients will be exposed to the lowest possible dose of medication to adequately treat their disease; this will in turn lead to a lower incidence of unwarranted side effects and to better quality of life.

Mild intermittent asthma Patients with mild intermittent asthma have daily symptoms no more than twice a week or nocturnal symptoms no more than twice a month. Because airway function is not significantly compromised, these patients achieve an FEV_1 (or PEF) of at least 80% of predicted value/personal best value with less than 20% variability. These individuals have no symptoms between attacks. Although not proved, it is assumed that patients with mild intermittent asthma have no ongoing lung inflammation and therefore can be treated with only intermittent bronchodilator therapy for occasional symptoms.[1] However, there are scant data supporting or refuting the presence of inflammation in the airways of mild asthmatics, and some experts have begun to suggest the use of anti-inflammatory therapy even in patients with mild intermittent asthma. Short-acting $beta_2$ agonists delivered by metered-dose inhalers are preferred on the basis of rapid onset, potent bronchodilator effect, and few side effects. In addition, patients should attempt to avoid exposure to any known triggers in their environment.

Mild persistent asthma When symptoms are more frequent than twice a week but not yet daily or when nocturnal symptoms occur more than twice a month but not weekly, the patient is regarded as having mild persistent asthma. Although some slight increase in airway variability (20% to 30%) may be

seen, these patients do not have much loss of airway function at baseline (i.e., FEV_1 and PEF of at least 80% of predicted value/personal best value). These patients are regarded as having continuous airway inflammation, and long-term drug therapy should be employed to control this process. The NAEPP guidelines recommend use of a low-dose inhaled glucocorticoid as the preferred treatment.[1] However, alternative therapies may also be used in these patients, including leukotriene antagonists and theophylline. Appropriate environmental-control measures should be taken to limit the patients' exposure to known triggers of their symptoms.

Moderate to severe persistent asthma Because airway inflammation is the primary problem in moderate to severe asthma, the fundamental therapy is glucocorticoids, administered primarily by inhalation.[1] Some studies of patients with asthma have reported a slowing of the decline in lung function after the addition of inhaled glucocorticoids to a regimen of inhaled bronchodilators. Use of bronchial hyperreactivity as an additional indicator of the need for anti-inflammatory therapy has been reported to result in more aggressive treatment and improved outcomes.[108]

Patients with daily symptoms and persistent airflow obstruction should use inhaled glucocorticoids regularly. Inhaled $beta_2$ agonists should continue to be used on an as-needed basis. In patients receiving low-dose inhaled glucocorticoids, the addition of a long-acting selective $beta_2$ agonist at its regular dose may provide improved control.[109] Although long-acting selective $beta_2$ agonists should not be used in place of low-dose inhaled steroids,[110] their use can often lead to a reduction in the dose of inhaled steroids.[111] When inhaled glucocorticoids do not adequately control the patient's symptoms, a long-acting $beta_2$ agonist should be added to the regimen. This form of combination therapy (e.g., salmeterol and fluticasone) has been extremely useful in patients with moderate to severe persistent asthma, as well as in patients with less severe disease. Alternatively, in patients with moderate persistent asthma (i.e., those with FEV_1 values between 60% and 80%), the NAEPP guidelines allow for increasing the inhaled corticosteroid dose or for the addition of a leukotriene antagonist or theophylline in place of a long-acting $beta_2$ agonist.[1]

Severe persistent asthma (characterized by constant symptoms and an FEV_1 value of 60% or less than the predicted value) should be treated with a combination of a high-dose inhaled glucocorticoid and a long-acting $beta_2$ agonist. If this approach fails to fully control the patient's symptoms, the addition of a leukotriene antagonist, theophylline, or both can be considered. However, there are scant data pertaining to the use of these medications in the treatment of severe persistent asthma; as such, these agents are not included in the NAEPP recommendations. More severe and acute symptoms often warrant a short course of oral glucocorticoids. Often, patients show dramatic improvement with oral glucocorticoids but experience a relapse of symptoms shortly after the medication is discontinued. Relapses can be managed by reinstituting the oral glucocorticoids and by tapering the regimen to alternate-day therapy at the minimal dose necessary to maintain the patient's symptoms at an acceptable level.

An asthma specialist should evaluate all patients with moderate to severe persistent asthma. A specialist can verify the diagnosis, identify the specific allergens that trigger symptoms, and establish strategies by which the patient can avoid the triggers that cause the asthma to flare.

Exercise-induced asthma Exercise-induced asthma can be a significant source of morbidity in asthmatic patients, particularly in those who are physically active. This form of asthma is of particular concern in the treatment of athletes and children. Inhaled $beta_2$ agonists are active as prophylactic agents; they are also used therapeutically after an attack has occurred. One successful approach to controlling exercise-induced asthma is through the daily use of a leukotriene modifier.[112] The symptoms of exercise-induced asthma often can be reduced through the use of a warm-up routine before exercise and a cool-down routine after exercise. As with nocturnal asthma, overall treatment of the asthma will often relieve the exercise-induced component.

Aspirin-induced asthma Patients with aspirin-induced asthma should avoid aspirin and other NSAIDs. Otherwise, these patients should be treated in accordance with the guidelines outlined (see above), with leukotriene modifiers being a useful agent for disease control.[113]

Asthma in pregnancy Treatment of asthma during pregnancy is similar to the treatment of asthma in nonpregnant patients and should occur in consultation with an asthma specialist.[114] Education of the patient about asthma and the appropriate use of medications, regular peak flow monitoring in patients with moderate to severe asthma, and a self-management plan are important.

The short-acting $beta_2$ agonists metaproterenol, terbutaline, and albuterol have been found to be safe during pregnancy and should be used on an as-needed basis. The long-acting $beta_2$ agonists have not been studied adequately to determine their safety and should only be used after other medications have been optimized.

The inhaled glucocorticoids beclomethasone and budesonide have proved to be safe in pregnancy. There are few studies of safety of the other inhaled glucocorticoids in pregnancy. Use of inhaled glucocorticoids during pregnancy is a very useful therapy for reducing exacerbations of asthma and should be used in all patients who require as-needed short-acting $beta_2$ agonists more than once or twice weekly. In patients whose asthma is not well controlled with low doses of inhaled glucocorticoids, an increase in the dose of inhaled glucocorticoids or the addition of theophylline, which has been found to be safe in pregnancy, should be considered. Use of a long-acting $beta_2$ agonist in this situation should only occur after consideration of the risk. If these measures fail to control the asthma or if a severe exacerbation occurs, use of systemic glucocorticoids may be necessary. Prednisone and prednisolone have been found to be safe for the fetus in the vast majority of studies. Systemic glucocorticoid use may, however, be associated with an increase in the risk of the maternal complications of pregnancy. Once control is established, the doses of glucocorticoids should be gradually lowered at a rate that is well tolerated by the patient.

Occupational asthma Treatment of the milder airway responses may include the use of inhaled glucocorticoids, bronchodilators, and, if there are signs of airway infection, antibiotics. In most cases, removal of the offending agent or transfer of the patient from the site of the offending agent cures occupational asthma. Transfer of the patient to a job that merely reduces rather than eliminates exposure does not effectively relieve symptoms. In a few cases, asthma continues for years after the patient has left the workplace.

Allergic bronchopulmonary aspergillosis Systemic administration of glucocorticoids is a mainstay of treatment for asthmatic patients who have ABPA. Although antifungal therapy and inhaled glucocorticoids have not been thought to be useful, the combination of itraconazole—an antifungal with enhanced activity against *Aspergillus* species[115]—and high-dose inhaled beclomethasone[116] may be helpful. Besides symptomatic and radiographic evidence of a response to therapy, the total serum IgE concentration has been used to follow the course of the disease; in some instances, an increase in IgE concentration heralds an exacerbation.

Emergency Therapy

On arrival of the patient in the emergency department, oxygenation should immediately be assessed by pulse oximetry, and controlled doses of oxygen should be provided to increase the O_2 saturation to greater than 90%.[117] An arterial blood gas measurement should be obtained as soon as practical. Patients with severe hypoxemia should be rapidly evaluated for hypercapnia, pneumothorax, atelectasis, or pneumonia, because many patients with uncomplicated asthma do not have hypoxemia.

The most effective emergency treatment is repeated administration of a shorter-acting $beta_2$ agonist by inhalation. There is no advantage to giving $beta_2$ agonists systemically, and the inhaled route is preferred for initial therapy, even in severe exacerbations. Administration of a $beta_2$ agonist by metered-dose inhaler and a spacer device is as effective as administration by nebulization and requires less time with a respiratory therapist, making this approach potentially more cost-effective. In patients younger than 45 years, $beta_2$ agonists can be administered every 15 to 20 minutes for up to three or four doses without adverse hemodynamic consequences, although unpleasant side effects from adrenergic overstimulation are universal. Intravenous aminophylline has been found to be only a weak bronchodilator in this setting and adds little benefit. Systemic glucocorticoids should be given early for severe attacks because the glucocorticoids will not take effect for as long as 12 hours.[118] High doses are no more effective than routine doses of hydrocortisone (i.e., 200 mg I.V. bolus every 6 hours), methylprednisolone (40 to 60 mg I.V. bolus every 6 to 8 hours), or prednisone (40 to 60 mg orally every 6 to 8 hours).[118]

Evaluation of lung function through spirometry or measurement of peak expiratory airflow is useful in assessing the severity of the asthmatic attack and the response to treatment. Patients whose FEV_1 or PEF is decreased to 25% of normal or less are at risk for hypercapnia, and their arterial blood gas values should be obtained. Patients who have hypercapnia despite initial bronchodilator therapy should receive further treatment in an intensive care unit. Hypercapnia signals very severe and potentially life-threatening airway obstruction; if not reversed, intubation and mechanical ventilation will be required [*see 14:VIII Respiratory Failure*]. Some patients respond rapidly to an intensive bronchodilator regimen and can be discharged from the emergency department promptly. Because some degree of persistent airflow obstruction is likely to remain in such patients despite the resolution of their dyspnea and wheezing, most patients should be placed on an intensified home treatment program at the time of release. For most patients, this program should include a brief course of glucocorticoids. The routine use of oral glucocorticoids for 1 week after discharge from the emergency department reduces the rate of relapse in patients treated for an acute asthma exacerbation.[119] Other patients experience only slight, gradual improvement despite repeated administration of potent bronchodilators. In these cases, the airway obstruction may be accompanied by inflammation and edema of the airways, as well as by excessive mucus secretions.

All patients discharged from the emergency department should have a follow-up examination with their primary care provider or asthma specialist within 1 week of discharge. Although the patient may still be on a systemic glucocorticoid, it is important to remember that the asthma exacerbation occurred because of ineffective control of the underlying airway inflammation. Thus, an increase in anti-inflammatory medication would be warranted, as well as intensive asthma education, which is not often given during the emergency department visit.

In-Hospital Therapy

The most common indication for hospitalization because of asthma is the failure of signs and symptoms of obstruction to resolve after 3 or 4 hours of emergency therapy. Respiratory failure with hypercapnia severe enough to require endotracheal intubation or significant barotrauma requires immediate hospitalization. In-hospital therapy for asthma to a large extent is simply a continuation of the measures that were begun in the emergency department. Development of protocols for hospital care of asthma patients has resulted in improved outcomes.[120]

Inhaled bronchodilators continue to be a mainstay of asthma therapy. In severe, life-threatening attacks of asthma, short-acting inhaled $beta_2$ agonists can be given as often as every 1 to 2 hours if necessary. As the obstruction resolves, administration can be less frequent. A long-acting $beta_2$ agonist may be useful in reducing the need for frequent use of inhaled short-acting $beta_2$ agonists.[121] Glucocorticoid treatment is indicated in virtually all patients admitted for severe asthma. Two regimens commonly employed for the treatment of such patients are (1) hydrocortisone, 2 mg/kg by I.V. bolus, followed by 0.5 mg/kg/hr by continuous infusion, and (2) methylprednisolone, 60 to 125 mg by I.V. bolus every 6 hours. Some experts recommend giving a total daily dose of prednisone of 0.5 to 1 mg/kg orally. The optimal dosage and route of administration for glucocorticoids remain to be defined.

Most patients will improve with treatment, though progress may require several days. Serial determinations of pulmonary function are useful for monitoring the response to therapy. When the FEV_1 or PEF reaches 50% to 60% of normal, patients usually have minimal or no symptoms, and the wide fluctuations in airflow that often characterize the initial course are no longer present. The frequency and intensity of the bronchodilator regimen can then be decreased, I.V. medications can be switched to oral preparations, and the patient can be started on a program that can be continued after hospital discharge.

Occasionally, a patient deteriorates despite appropriate therapy. In this situation, it is necessary to monitor arterial blood gases closely. Intubation and mechanically assisted ventilation are needed in cases involving progressive hypercapnia and significant respiratory acidosis. For all intubated patients, lung function should be assessed. Lung compliance should be assessed by recording the airway pressure required to deliver a tidal volume (calculated by dividing tidal volume by plateau pressure). Flow resistive pressure should be determined (peak pressure minus plateau pressure). The presence and degree of intrinsic positive end-expiratory pressure (auto-PEEP) should be assessed. Baseline measurements can be compared to subsequent values as a means of assessing response to therapy or the need for accelerated treatment. If initial values reflect only modest obstruction in a

hypercapnic asthmatic patient, a substantial contribution of respiratory muscle fatigue or weakness to the respiratory failure is likely [*see 14:VIII Respiratory Failure*]. Extreme measures, such as I.V. administration of isoproterenol, bronchial lavage to remove mucous plugs, and general anesthesia, are potentially dangerous and are rarely indicated. Ancillary measures include use of controlled supplemental oxygen for patients with arterial oxygen desaturation (O_2 saturation < 90%) and empirical broad-spectrum antibiotic therapy (e.g., ampicillin, tetracycline, erythromycin, or trimethoprim-sulfamethoxazole) for patients with fever and sputum purulence that is not caused by eosinophils. Rapid diagnosis of viral infections is becoming more widely available through the use of real-time polymerase chain reaction and immunofluorescence staining, but treatment options are limited. Similarly, there is at best only marginal benefit from vigorous hydration, use of inhaled saline mists, mucolytic therapy (e.g., acetylcysteine), and chest physiotherapy.

Mitchell H. Grayson, M.D., receives grants for clinical research from Genentech, Inc., and Novartis AG, and he serves on the speakers' bureau of Merck & Co, Inc.

Michael J. Holtzman, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III CHRONIC OBSTRUCTIVE DISEASES OF THE LUNG

Gerald W. Staton, Jr., m.d., f.a.c.p.

Chronic Obstructive Pulmonary Disease

definitions

Chronic obstructive pulmonary disease (COPD) is defined as a disease state characterized by airflow limitation that is not fully reversible. The airflow obstruction is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles and gases.[1] COPD, chronic obstructive lung disease, and chronic airflow obstruction (CAO) are synonyms used to describe the minimally reversible airflow obstruction caused by chronic bronchitis, emphysema, or both. These conditions are distinguished from asthma in that the abnormalities limiting airflow are for the most part irreversible, although irreversible airflow obstruction can develop in some patients with asthma[2] [*see 14:II Asthma*]. The inclusiveness of these terms stems from the fact that chronic bronchitis and emphysema usually occur together as the consequences of a common etiology (e.g., cigarette smoking). Chronic bronchitis and emphysema must be distinguished not only from asthma but also from bronchiectasis and obstructive bronchiolar disorders, which are covered in this chapter, and from upper airway obstruction and interstitial lung diseases that have an obstructive component (e.g., sarcoidosis and pulmonary lymphangioleiomyomatosis [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]).[3]

Chronic Bronchitis

Chronic bronchitis follows prolonged exposure of the tracheobronchial tree to nonspecific irritants and is characterized by hypersecretion of mucus and structural changes in the bronchi, including inflammation, metaplasia of the epithelium, and enlargement of the mucous glands. The inflammation and hypersecretion of mucus usually cause daily cough and sputum production, which help to identify the disease clinically. For epidemiologic purposes, chronic bronchitis is defined by the presence of cough and sputum on most days for at least 3 months of the year for a minimum of 2 years in succession.

Some cigarette smokers with chronic productive cough (often called smoker's cough) do not have dyspnea, and in fact, pulmonary function testing reveals no detectable obstruction of airflow in these patients. In other smokers, however, clinically significant narrowing of the airways develops. Because of these differing features, many physicians use the term chronic mucus hypersecretion or chronic bronchitis without airway obstruction to identify the former presentation and the term chronic obstructive bronchitis or chronic bronchitis with airway obstruction to identify the latter. The validity of such a distinction is supported by the fact that the two forms of chronic bronchitis have different natural histories.

In contrast to chronic bronchitis, acute bronchitis is a self-limited condition of the bronchi that is most often caused by viral infections in association with an upper respiratory tract illness or acute exposure to a nonspecific irritant (e.g., ammonia). Acute bronchitis, however, may also occur as a transient complication of chronic bronchitis.

Emphysema

Emphysema is a destructive process involving the lung parenchyma. It is defined in pathologic terms on the basis of findings of abnormal permanent enlargement of air spaces distal to the terminal bronchiole, accompanied by the destruction of the alveolar walls without obvious fibrosis. At autopsy, some areas of emphysema are found in the lungs of most persons older than 60 years.

epidemiology

Chronic bronchitis and emphysema are by far the most common causes of CAO; other causes include bronchiectasis and bronchiolitis. In the United States, an estimated 10 million adults report physician-diagnosed COPD; data suggest that 24 million adults have abnormal lung function, which points to significant underdiagnosis of COPD.[4] In 2000, COPD caused 119,054 deaths, representing a 128% increase since 1980.[4] COPD is the fourth leading cause of death in the United States and the fifth leading cause of death worldwide. From 80% to 90% of cases of COPD can be attributed to cigarette smoking. The risk of death from chronic bronchitis or emphysema is 30 times greater for heavy smokers (i.e., those who smoke 25 or more cigarettes a day) than for nonsmokers.

In cigarette smokers, the prevalence of chronic bronchitis increases with age (and, thus, with the increase in the total cumulative amount of cigarette smoke inhaled) and the number of cigarettes smoked. More than 50% of middle-aged men who smoke at least one pack of cigarettes a day report having chronic productive cough. Cigar and pipe smokers, as well as former cigarette smokers, have a rate of chronic bronchitis higher than the general population but lower than current cigarette smokers. Although occupational dust exposure is also associated with the development of chronic bronchitis, the effect of cigarette smoking overwhelms the occupational effect.

Some degree of emphysematous changes can be found in the autopsied lungs of 65% of men and 15% of women. Severe involvement, leading to a clinical diagnosis of emphysema, occurs in slightly less than 1% of the population. However, prevalence statistics are more relevant for cigarette smokers, who constitute the major population at risk. In a series involving more than 1,800 autopsies, the prevalence of emphysema judged to be advanced to far advanced was 0% in nonsmokers, 12% in smokers of less than one pack of cigarettes a day, and 19% in those who consumed one or more packs a day.[5]

Forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 to forced vital capacity (FEV_1/FVC) can be used to assess the prevalence of CAO. If an FEV_1 value of less than 80% of predicted and an FEV_1/FVC of less than 70% is defined as abnormal, 7.4% of men and 5.8% of women in the general adult population would be considered to have obstructive lung disease.[3] There is a normal, or bell-shaped, distribution of FEV_1 values in the nonsmoking population. In cigarette smokers, this distribution curve is shifted toward lower FEV_1 values [*see Figure 1*]. The prevalence of abnormal values increases with increasing years of cigarette smoking. For instance, after 40 to 60 pack-years of cigarette smoking (number of pack-years = packs of ciga-

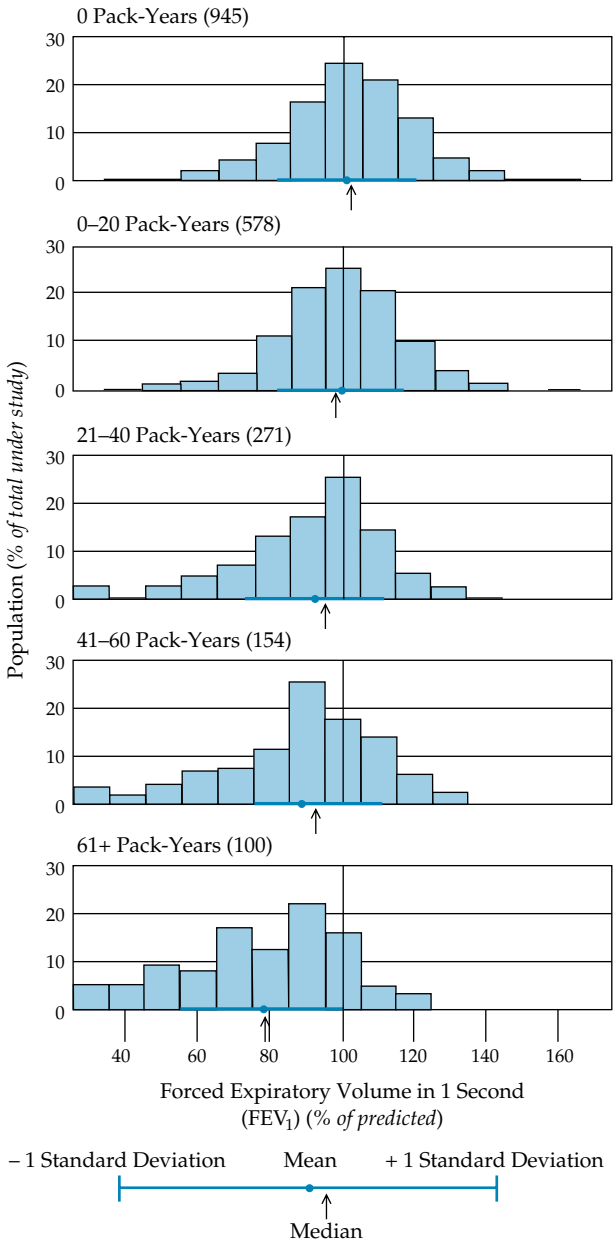

Figure 1 **There is a normal distribution of expiratory flow values, as measured by percent of the predicted forced expiratory volume in 1 second (FEV_1), among nonsmokers. Among cigarette smokers, the distribution is shifted toward lower FEV_1 values, with a larger skew at the lower range, as the number of pack-years of smoking increases.[182]**

rettes/day × number of years the person has smoked), most smokers have slightly reduced expiratory flow, and approximately 10% manifest CAO.

ETIOLOGY

Chronic bronchitis and emphysema are usually caused by cigarette smoking of at least 10 years' duration. The specific pathogenic substances in cigarette smoke have not been identified with certainty. It is likely that particle size and gas solubility determine which of the hundreds of noxious substances found in cigarette smoke are deposited in the trachea and the large bronchi, causing bronchitis, and which are deposited in the bronchioles and the gas exchange units, causing narrowing of the small airways and emphysema.

Cigarette smoking is such a dominant factor in the pathogenesis of COPD that it has been difficult to identify any causative or contributing factors other than α_1-antitrypsin deficiency [see α_1-Antitrypsin Deficiency, *below*]. Prolonged exposure to respirable dusts in the work environment has long been recognized as a cause of so-called industrial or occupational bronchitis in nonsmoking workers engaged in occupations such as coal or gold mining, textile manufacturing, and cement and steel making. An analysis of the accumulated data over the past 25 years suggests that these exposures are associated with the development of significant COPD.[6] Chronic HIV or hepatitis C infection,[7,8] low body mass,[9] and low intake of dietary antioxidants may be cofactors in some cigarette smokers.[10]

In otherwise healthy adults, passive cigarette smoking (i.e., indoor exposure of nonsmokers to cigarette smoke) and outdoor air pollution may cause nonspecific respiratory symptoms such as cough and may induce subtle abnormalities in pulmonary function, but they have not been shown to lead to the development of COPD.[11] A major unknown in the etiology of COPD is why clinically significant airway obstruction develops in only 10% to 15% of smokers. Hypotheses for the unique susceptibility of some cigarette smokers to the development of severe airflow obstruction suggest the presence of host factors and exposure factors. Host factors include preexisting airway hyperresponsiveness[12]; impaired lung growth; smaller size of terminal bronchioles; and genetic determinants favoring increased elastase activity, impaired antiprotease function, or other factors.[13,14] Exposure factors include deeper and more frequent inhalation of tobacco smoke, occupational dust and chemical exposure, indoor (including possible effects of passive smoking) and outdoor air pollution, and chronic bacterial or viral infection.[15]

NATURAL HISTORY

The dominant feature of the natural history of chronic bronchitis and emphysema is the development and progression of airflow obstruction. In healthy nonsmokers, FEV_1 begins declining at about 20 years of age at an average rate of about 0.02 to 0.04 L/yr. In smokers with obstructive lung disease, FEV_1 decreases, on average, two to three times faster than normal [*see Figure 2*]. A person with an FEV_1 of 2.0 L (50% of normal) at 45 years of age who continues to smoke cigarettes heavily is apt to be breathless on light exertion at 55 years age; for such a smoker, the FEV_1 would be expected to have fallen to about 1.2 L, or 30% of normal, at 55 years of age. At 60 years of age, the expected FEV_1 would be about 0.8 L (20% of normal). The person would probably be breathless at rest or on minimal exertion and would be at risk for recurrent episodes of acute respiratory failure. At the same estimated rate of lung function loss, this person would not be expected to live past 65 years of age.

Other factors may modify the development and progression of COPD. In addition to advanced age, variables that appear to confer a worse prognosis include frequent exacerbations,[16] persistent airway bacterial colonization,[17] hypoxemia, hypercapnia, cor pulmonale, and, possibly, increased airway responsiveness and eosinophilia (asthmatic bronchitis).[12] When smokers with mild to moderate airflow obstruction stop smoking, the rate of decline in expiratory flow reverts to that observed in nonsmokers, and there may be a slight improvement in FEV_1 during the first year.[18] Cough and phlegm production usually decrease, as well.[19] Unfortunately, when obstruction is already severe, smok-

ing cessation may not be as effective in altering future deterioration. There remains considerable variability among individuals, so that no single factor or group of factors can be used to predict the outcome in a given patient.

PATHOLOGY

Early Pathologic Changes

Pathologic changes are apparent in the lungs of smokers even before the appearance of COPD.[20] Breaks in the alveolar septal walls are seen, possibly representing a precursor to more generalized emphysema and inflammation of the bronchioles. The lungs of cigarette smokers, even in those as young as 25 years, can be distinguished from those of nonsmokers by the abnormal accumulation of pigmented macrophages in respiratory bronchioles, often accompanied by edema, epithelial hyperplasia, and fibrosis in adjacent bronchiolar and alveolar walls. The significance of these early findings is threefold. First, peripheral airways (i.e., bronchioles and small bronchi less than 2 mm in diameter) are an important site of airflow obstruction, both in asymptomatic cigarette smokers and in patients with advanced COPD. Second, the pathologic changes that occur in patients with the centriacinar form of emphysema [*see* Established Emphysema, *below*] initially develop in the respiratory bronchioles. Third, evidence suggests that the early abnormalities observed in cigarette smokers are for the most part reversible with cessation of smoking.

Airflow through healthy lungs is limited primarily by the resistance of the central airways (i.e., the trachea and the major bronchi) and the upper airways (i.e., the larynx and the pharynx) but also, to some degree, by the resistance of the small airways of the lung periphery. As COPD worsens, there is a marked increase in airflow resistance; almost all of this increase is in the peripheral airways. The degree of pathologic narrowing of the terminal bronchioles is strongly correlated with all physiologic indices of airflow obstruction, including the reduced FEV_1. The small airways either are directly narrowed by inflammatory changes or, as in emphysema, lose the tethering effect provided by the surrounding lung parenchyma, which normally limits narrowing during expiration.

Lungs of asymptomatic young smokers show clusters of macrophages in and around respiratory bronchioles. Other early pathologic lesions include squamous cell metaplasia of the epithelium, chronic inflammation of airway walls, small foci of peribronchiolar fibrosis, and muscular hypertrophy of the bronchiolar wall.[21] As COPD progresses, mural connective tissue, pigment, and muscle become more prominent. In addition, goblet cell hyperplasia develops,[22] and mucosal ulcerations appear.

Mild bronchiolitis is probably a universal finding in young smokers. The degree to which these terminal airways are narrowed by the inflammation has a strong correlation with obstruction, as measured by spirometry.[23]

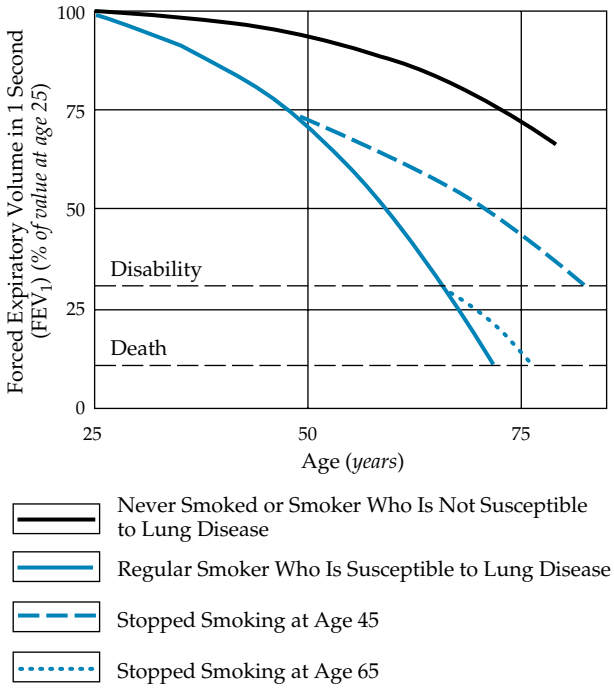

Figure 2 **Expiratory flow, as measured by FEV_1, declines up to two to three times faster in cigarette smokers who are susceptible to obstructive lung disease than in nonsmokers or in those who smoke but are not susceptible to lung disease. Smoking cessation can decrease the rate of fall in FEV_1 in susceptible cigarette smokers, delaying the onset of disability or death.[183]**

Late Pathologic Changes

Established chronic bronchitis The pathologic hallmark of chronic bronchitis is enlargement of the mucous glands in the major bronchi. The diameter of the mucous glands relative to the thickness of the bronchial wall is greater in patients with chronic bronchitis.

Although excess mucus in the airways is common in patients with chronic bronchitis, it has physiologic significance only when it obstructs the lumina of small airways. The small number and irregular distribution of goblet cells among the epithelial cells lining the airways make quantification difficult. It is possible that the mucus found plugging small airways is not produced locally but originates in the central airways. Functional disorders that may contribute to mucous plugging include secretion of mucus with altered viscoelastic properties and impaired ciliary clearance mechanisms.

It has not been established whether the volume of bronchial smooth muscle is increased in patients with chronic bronchitis, as it is in those with asthma. Smooth muscle hyperplasia has been found in the main and lobar bronchi in those patients with chronic bronchitis who have intermittent attacks of wheezing.

Bronchoscopic findings include generalized erythema, edema, and friability of the tracheobronchial mucosa. Mucous gland pits, which are depressions in the mucosa approximately 1 to 2 mm in diameter that represent the orifice of one or more mucous glands, are also present. Often, the most striking finding is dynamic expiratory collapse of large central airways; however, this is the result of obstruction of small peripheral airways rather than the cause of the expiratory airflow limitation.

Established emphysema The terminology commonly used by pathologists to describe pulmonary emphysema makes reference to two distinct units of lung structure: the acinus and the lobule. The acinus is an anatomic subdivision that consists of a respiratory bronchiole together with all the alveolar ducts and alveoli extending from it [*see Figure 3*]. A lobule is defined as the smallest discrete portion of the lung surrounded by connective tissue septa. Emphysema may involve the acinus and the lobule uniformly in a pattern called panacinar or panlobular emphyse-

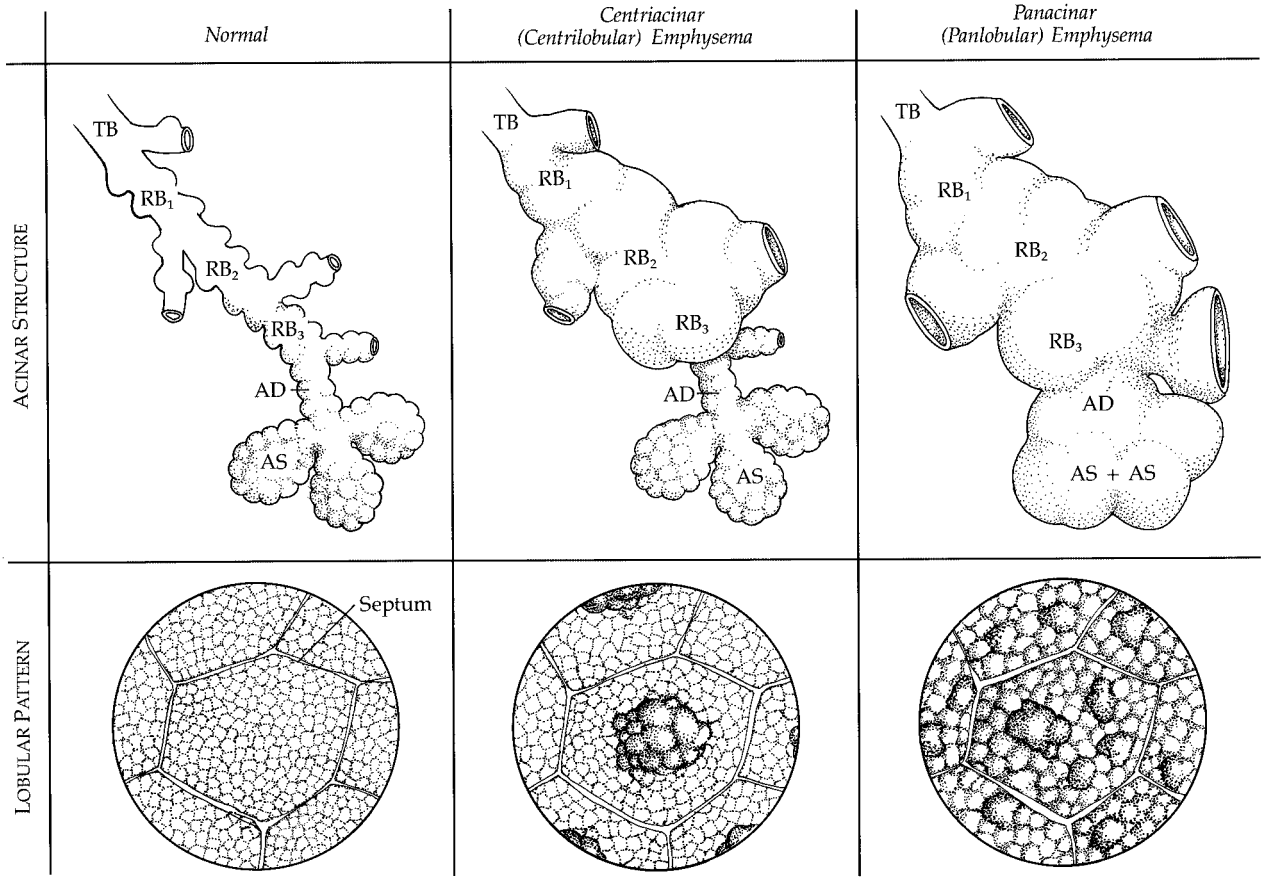

Figure 3 **In the top row, the acinar structure of normal lungs is compared with that of lungs in patients with centriacinar (centrilobular) emphysema or panacinar (panlobular) emphysema. The normal acinus has a clearly defined structure consisting of the terminal bronchiole (TB); first-, second-, and third-order respiratory bronchioles (RB_1, RB_2, and RB_3, respectively); alveolar ducts (AD); and alveolar sacs (AS). In centriacinar emphysema, there is selective enlargement and destruction predominantly of the respiratory bronchioles. In contrast, panacinar emphysema is defined by universally enlarged and destroyed air spaces throughout the acinus. Patterns of lobular destruction are depicted in the bottom row. The normal pulmonary lobule is a macroscopic structure, the borders of which can be identified by the presence of connective tissue septa. In centriacinar emphysema, the predominant site of overdistention is in the center of the lobule, with relative sparing toward the periphery—hence the name centrilobular emphysema. In contrast, there are uniform destructive changes throughout the lobule in panlobular emphysema.**

ma. Alternatively, it may involve primarily the respiratory bronchioles; this form of the disease is termed centriacinar, centrilobular, or, perhaps most correctly, proximal acinar emphysema.[24]

Panacinar emphysema is common in patients with α_1-antitrypsin deficiency [*see* α_1-Antitrypsin Deficiency, *below*]. Pathologic examination reveals enlargement of the alveolar ducts and sacs with loss of distinguishing features. Holes, or fenestrae, develop in the alveolar walls and progressively enlarge. The process of destruction ultimately leaves only strands of tissues containing supportive structures such as vessels, bronchi, and septa. The emphysematous spaces are spread uniformly across the lobule. Typically, the lower lobes show more involvement than the upper lobes.

Centriacinar emphysema is commonly found in cigarette smokers and is rare in nonsmokers. This form of emphysema primarily affects the respiratory bronchioles. The destroyed respiratory bronchioles enlarge and coalesce, forming emphysematous spaces surrounded by relatively normal alveolar ducts and alveoli. The emphysematous spaces are situated in the midportion of the lobule, separated from the septa by normal alveolar tissue. The small airways supplying these emphysematous spaces typically show signs of inflammation and are often narrowed. Centriacinar emphysema is usually more extensive and severe in the upper lobes.

Pure centriacinar emphysema is not a common finding at autopsy. In most cigarette smokers, a mixture of centriacinar and panacinar emphysema develops. This mixture may take the form of predominant centriacinar emphysema in the upper lung zones and panacinar emphysema in the lower zones or centriacinar emphysema that extends to the alveolar ducts and alveoli to varying degrees. Distinction between these two forms of emphysema is often difficult in advanced cases and is of no clinical significance. However, there may be subtle differences in the altered lung function between the two forms, possibly related to greater abnormalities of small airways and more fibrosis in centriacinar emphysema.

Other abnormalities found at autopsy in patients with COPD include atrophy of cartilage in the walls of segmental and subsegmental bronchi, obliteration of small airways (i.e., loss of bronchioles 0.4 to 0.6 mm in diameter), increased longitudinal smooth muscle in the intima of pulmonary arterioles and small arteries, and dilatation of bronchial arteries and veins.

Inflammatory cells are an important host factor in the development of COPD.[24-26] Activated macrophages, lymphocytes with a predominance of $CD8^+$ T cells, and neutrophils are found in increased numbers in the respiratory bronchioles of smokers. These activated macrophages release the neutrophil chemotactic factors leukotriene B_4 and interleukin-8 (IL-8), which are amplified by tumor necrosis factor–α (TNF-α). Complex interactions between these cells and mediators lead to increased amounts of proteases and oxidants in the lung parenchyma, airways, and possibly adjacent lung vessels.[27] Two interrelated causes—an imbalance of proteases and antiproteases and an imbalance of oxidants and antioxidants—are hypothesized to produce the chronic bronchitis and emphysema seen in cigarette smokers.

Protease-Antiprotease Imbalance

One current theory of the pathogenesis of emphysema holds that the disease may develop because of an imbalance between protease and antiprotease activities in the lungs.[24-26,28] The origins of this theory date to 1963, when the Scandinavian researchers Laurell and Eriksson identified a group of patients with a deficiency in α_1-antitrypsin (also called α_1-proteinase inhibitor), a major serum antiprotease [*see* α_1-Antitrypsin Deficiency, *below*]. Emphysema developed in a remarkably high percentage of these patients, typically at an unusually young age.

Most cigarette smokers have normal serum α_1-antitrypsin concentrations. In fact, cigarette smoking may cause a small (approximately 20%) rise in serum α_1-antitrypsin concentrations. (Increased amounts of α_1-antitrypsin often can be retrieved from the lungs of smokers by means of lavage.) Nonetheless, long-term inhalation of cigarette smoke has a number of effects that can lead to an excess of protease activity in the lung parenchyma [*see Figure 4*]. First, cigarette smoke activates alveolar macrophages to secrete proteases (multiple cathepsins and matrix metalloproteinases) and mediators that attract neutrophils; these or additional mediators also stimulate neutrophils to release more than the usual amount of cathepsin G and neutrophil elastase. Second, several oxidants that are present in cigarette smoke or are generated from products of cigarette smoke, such as the oxides of nitrogen, interact with hydrogen peroxide released from activated alveolar macrophages and neutrophils to oxidize and inactivate α_1-antitrypsin and other antiproteases.[29] Third, cigarette smoke may inhibit the synthesis of elastin, thereby retarding repair of damaged elastin fibers.

Oxidant-Antioxidant Imbalance

A number of studies have found evidence of an increased oxidative burden in cigarette smokers.[29] Sources of oxidants include cigarette smoke and the inflammatory cells (macrophages and neutrophils). In addition, the antioxidant system appears to be inadequate for dealing with the increased oxidants, producing an imbalance. Adverse effects of the oxidant stress include inactivation of antiproteases, membrane lipid peroxidation, DNA and matrix damage, epithelial injury, and stimulation of transcription of inflammatory cytokines, amplifying the inflammation.

Obviously, these two hypotheses are intertwined, suggesting that both mechanisms have a role in the production of COPD. As a consequence of the excesses of proteases and the inhibition of antiproteases, the walls of the respiratory bronchioles and the alveoli are damaged and the altered repair mechanisms prevent remodeling and fibrosis, resulting in emphysema. The oxidative imbalance damages the walls of the airway

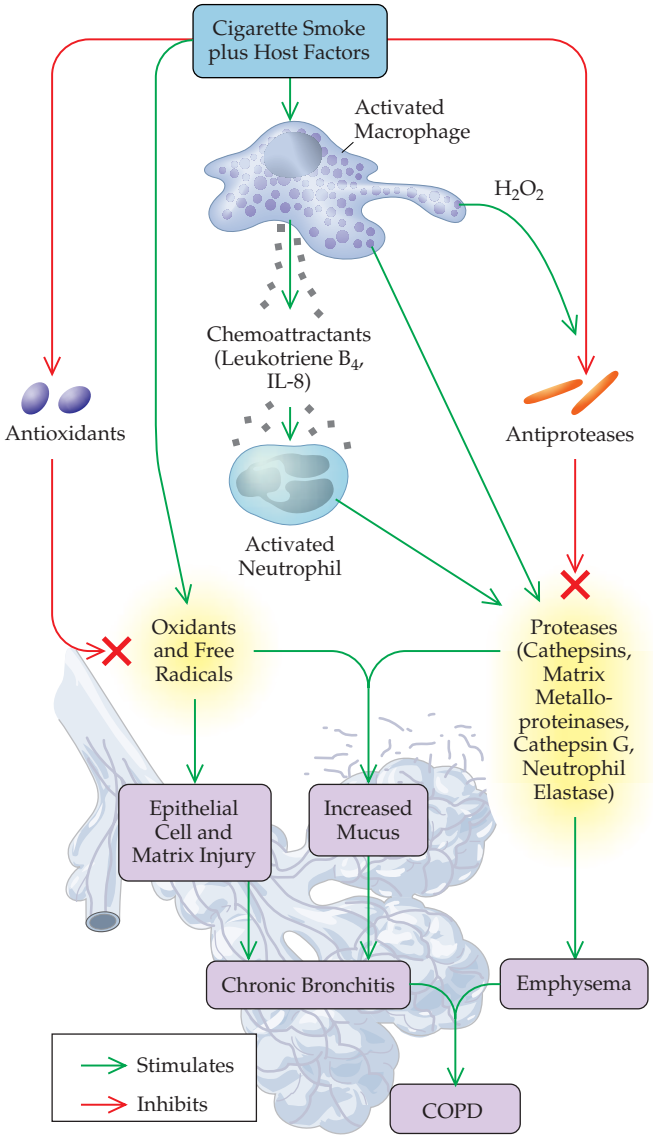

Figure 4 **Host factors play a role in the development of chronic obstructive pulmonary disease (COPD) in smokers. Cigarette smoke activates alveolar macrophages to secrete proteases (i.e., multiple cathepsins and matrix metalloproteinases). The activated macrophages release the neutrophil chemoattractants leukotriene B_4 and interleukin-8 (amplified by tumor necrosis factor–α [TNF-α]), and the chemoattractants also stimulate neutrophils to release more than the usual amount of cathepsin G and neutrophil elastase. Several oxidants that are present in cigarette smoke or are generated from products of cigarette smoke interact with hydrogen peroxide released from activated alveolar macrophages and neutrophils to oxidize and inactivate α_1-antitrypsin and other antiproteases. Cigarette smoke may inhibit the synthesis of elastin, thereby retarding repair of damaged elastin fibers. There is an increased oxidative burden from cigarette smoke and the inflammatory cells (macrophages and neutrophils), and the antioxidant system appears to be inadequate for dealing with the increased oxidants, producing an imbalance. Adverse effects of the oxidant stress include inactivation of antiproteases, membrane lipid peroxidation, DNA and matrix damage, and epithelial injury. As a consequence of the excesses of proteases and the inhibition of antiproteases, the walls of the respiratory bronchioles and the alveoli are damaged, and the altered repair mechanisms prevent remodeling and fibrosis, resulting in emphysema. The oxidative imbalance damages the walls of the airway and, along with the excess proteases, stimulates mucus hypersecretion, producing chronic bronchitis.**

Table 1 Differentiating Features in Advanced Chronic Airflow Obstruction

Features	*Type A—Pink Puffer (Predominant Emphysema)*	*Type B—Blue Bloater (Predominant Chronic Bronchitis)*
Symptoms and Signs	Dyspnea (first and predominant symptom); patients are usually thin, weight loss is common; minimal or no cough; hyperinflated lung fields; no signs of cor pulmonale	Cough and sputum production with frequent chest infections; stocky build; recurrent or persistent signs of right heart failure
Routine Laboratory Studies		
Chest radiograph	Hyperinflation; decreased vascular markings, bullae	Normal or increased markings at lung bases (so-called dirty-chest appearance)
Arterial blood gases	Mildly reduced P_aO_2; normal or decreased P_aCO_2	Marked reduction in P_aO_2; increased P_aCO_2
Total lung capacity	Increased	Normal or slightly increased
D_{LCO}	Decreased	Normal
Hematocrit	Normal	Increased
Specialized Laboratory Studies		
Inspiratory resistance	Normal	Increased
Pulmonary compliance	Increased	Normal
Ventilation-perfusion distribution	Increased V_D/V_T	Increased regions of low $\dot{V}_A/\dot{Q}$
Hemodynamics	Normal or decreased cardiac output Mild pulmonary hypertension	Normal cardiac output Marked pulmonary hypertension
Ventilatory Performance and Gas Exchange during Exercise	More wasted ventilation D_{LCO} fails to increase normally Decreased P_aO_2; small rise in P_aCO_2	Less wasted ventilation D_{LCO} increases normally P_aO_2 may increase; moderate rise in P_aCO_2
Gas Exchange during Sleep	Moderate degree of oxygen desaturation	Frequent periods of profound oxygen desaturation

D_{LCO}—diffusing capacity of lung for carbon monoxide P_aCO_2—arterial carbon dioxide tension P_aO_2—arterial oxygen tension V_D/V_T—ratio of dead space to tidal volume $\dot{V}_A/\dot{Q}$—ventilation/perfusion distribution

and, along with the excess proteases, stimulates mucus hypersecretion, producing chronic bronchitis.

DIAGNOSIS

Clinical Manifestations

The hallmarks of COPD are chronic productive cough and persistent, progressive exercise limitation because of breathlessness. Although these two symptoms are nonspecific, they usually point to the correct diagnosis of COPD in the context of prolonged cigarette smoking. Patients with predominant chronic bronchitis present with chronic productive cough, whereas patients with predominant emphysema complain of dyspnea [*see Table 1*]. Cough with expectoration develops 10 to 12 years after smoking begins. The symptom is often dismissed as a simple smoker's cough. However, persons with established chronic bronchitis commonly produce 2 oz or more of mucoid sputum a day. Transient periods of sputum discoloration caused by purulence commonly occur, often in association with respiratory tract infections. A small amount of hemoptysis may accompany a superimposed acute tracheobronchitis.

Wheezing is also common. It can occur transiently as mucus accumulates in airways and resolve suddenly with the expectoration of phlegm; however, some patients with chronic bronchitis experience prolonged and severe attacks of wheezing that mimic those of asthma. This combination of chronic bronchitis and reversible bronchospasm is commonly referred to as asthmatic bronchitis. These patients tend to respond more strongly to anti-inflammatory and bronchodilator drugs.

Shortness of breath, rather than cough, is more often the reason that patients in whom emphysema predominates seek medical attention. Although exertional dyspnea correlates in general with the degree of airflow obstruction, wide variability among individuals makes it impossible to predict the extent of respiratory impairment on the basis of any single value or set of values for expiratory flow. Nevertheless, as a broad guideline, only minimal limitation is imposed until the value for FEV_1 falls below 65% of normal. As airflow obstruction progresses, dyspnea develops with more moderate levels of exertion. When the FEV_1 value drops below 35% to 40% of normal, the patient may become breathless during activities of daily living such as making the bed or bathing.

Orthopnea is often present in patients with advanced airway disease, especially in cases in which increased airway secretions accompany significant airflow limitation. The orthopnea of COPD must be differentiated from the paroxysmal nocturnal dyspnea of chronic heart failure. This differentiation is based on the rapidity of onset of dyspnea with the patient lying supine: dyspnea is said to develop almost immediately in those with COPD but to be delayed for as long as a few hours in those with congestive heart failure. However, the distinction is not clear-cut, because patients with florid heart failure often refuse to lie supine even for brief periods, and patients with COPD may awaken after several hours of sleep with cough, shortness of breath, and chest congestion—symptoms that mimic paroxysmal nocturnal dyspnea. Relief is obtained by coughing up secretions. To further complicate matters, the two processes most often occur together.

COPD may have systemic effects. Possibly as a consequence of systemic inflammation,[30] nutritional abnormalities, and weight loss, COPD may be accompanied by skeletal muscle dysfunction (contributing to exercise limitations), coronary artery disease,[31] low serum testosterone levels (in males),[32] and osteoporosis.[33] Patients with COPD are also at increased risk for developing lung cancer.[34]

Physical Examination

Physical findings vary with the severity of disease and the relative contributions of chronic bronchitis and emphysema [*see*

Table 1]. In the early stages, physical examination may yield entirely normal results. With more advanced disease, tachypnea and a prolonged expiratory phase of the respiratory cycle are usually present. Emphysematous hyperinflation of the lungs may cause a hyperresonant percussion note and an unusually low position of the diaphragm. Breath sounds may be reduced by decreased airflow, and wheezes are heard in 40% or more of patients, especially if patients are in the supine position when examined. Rales are heard in some patients, particularly at the posterior lung bases, in the absence of heart failure. These are usually heard during the entire inspiratory phase, rather than solely at end-inspiration, which is the usual finding in interstitial lung disease (e.g., asbestosis or idiopathic pulmonary fibrosis). Clubbing of the digits is not a manifestation of COPD.

Laboratory Tests

In most patients who present with the symptoms and signs of COPD [*see* Clinical Manifestations, *above*], the order of testing should be as follows: (1) pulmonary function tests (including measurement of arterial blood gases), (2) chest radiography, and, in rare instances, (3) computed tomography of the chest.

Pulmonary function tests In the dyspneic patient, routine pulmonary function tests depict the characteristic pattern of volume-dependent airway obstruction [*see 14:I Lung Function Assessment and Thoracic Diagnostic Techniques*].[35] Spirometry, which should be performed in all smokers with any respiratory symptoms and all smokers older than 45 years,[36] reveals a reduction in FEV_1/FVC and an even greater relative decline in the forced expiratory flow between 25% and 75% of vital capacity (FEF_{25-75}). As the airflow obstruction worsens, a normal volume of gas can no longer be exhaled in the time available, and vital capacity also declines.

Measurement of lung volumes uniformly reveals an increased residual volume (RV) and a normal to increased functional residual capacity (FRC). RV may be two to four times higher than normal because of slowing of expiratory flow and trapping of gas behind prematurely closed airways. FRC increases by two mechanisms: dynamic hyperinflation and activation of inspiratory muscles during exhalation. As a result, tidal breathing may take place at lung volumes as high as 1 to 2 L above normal levels. The advantage of an increased FRC to the patient with significant airflow obstruction is enlarged airway diameter with greater radial support (which means less airway resistance) and increased driving pressure (i.e., elastic recoil) for exhalation. The cost to the patient is the greater work of breathing incurred at higher lung volume. Total lung capacity (TLC) is normal or increased in COPD. As would be predicted, there is a correlation between the extent of emphysematous lung destruction found at postmortem examination and the TLC. However, the correlation is not close, so that only a markedly increased TLC would be used to gauge the severity of emphysema.

Pulmonary function tests are useful in patients with COPD to confirm the obstructive abnormality, to quantify the severity of the defect, to assess the reversibility of the airflow obstruction in response to therapy,[37] and to monitor the course of the disease. A low FEV_1/FVC and a decrease in expiratory flow rates prove obstruction, but the best measurement for assessing the severity of the obstruction is the FEV_1. A scheme for determining severity of COPD has been proposed [*see Figure 5*]. Construction of flow-volume loops may be useful if upper airway obstruction is a diagnostic consideration.

Abnormalities in gas exchange It has long been recognized that the pattern of gas-exchange abnormalities in COPD may differ greatly among patients with airflow obstruction of identical severity. Early in the course of disease, when expiratory flow is only slightly reduced, mild hypoxemia may be the only blood gas abnormality. However, in advanced stages of COPD, two distinct patterns emerge [*see Table 1 and Figure 6*]. Patients in one group (type A) exhibit dyspnea with only mild to moderate hypoxemia (arterial oxygen tension [P_aO_2] levels are usually > 65 mm Hg) and maintain normal or even slightly reduced arterial carbon dioxide tension (P_aCO_2) levels. These patients are some-

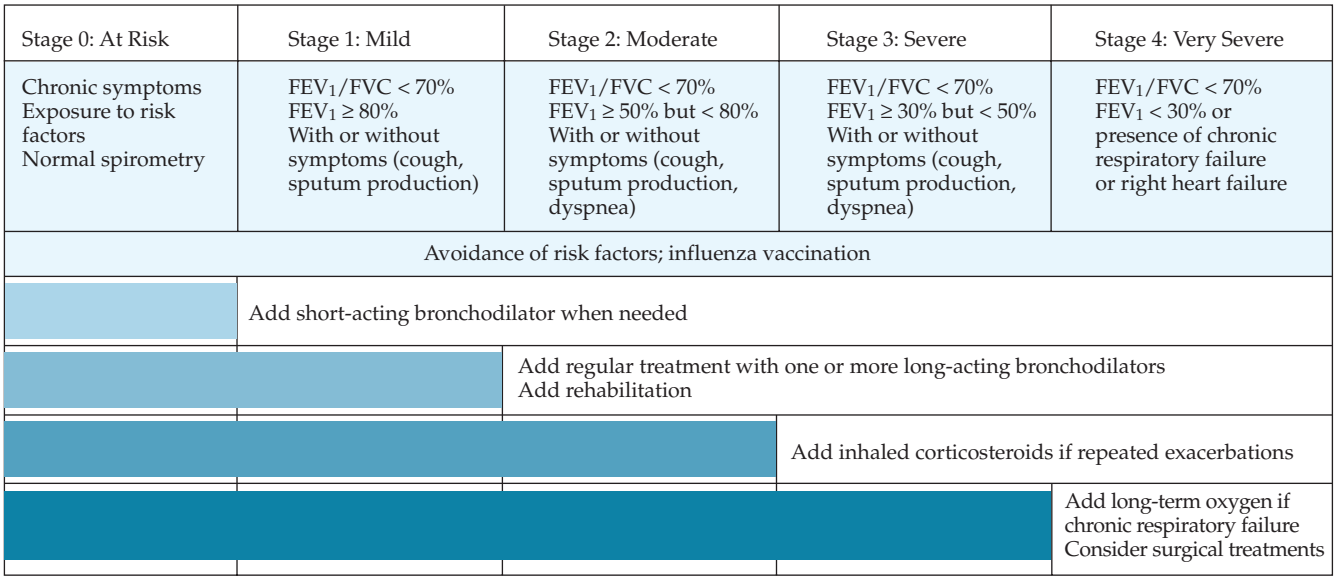

Figure 5 **Staging of COPD based on data derived from spirometry and recommended therapy for each stage. Therapy escalates as disease becomes more severe.[43]**

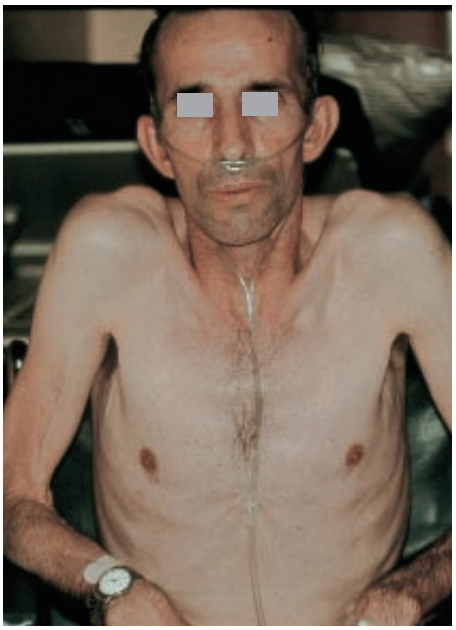

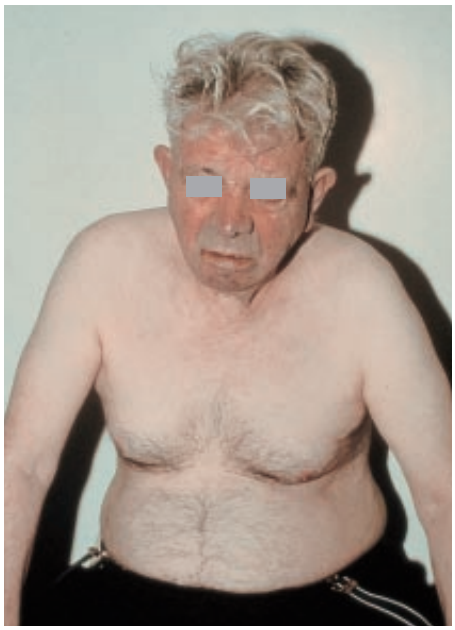

Figure 6 **In the advanced stages of chronic airflow obstruction, two distinct clinical types may emerge. Emphysema patients (so-called pink puffers, left) exhibit dyspnea without significant hypoxemia and tend to be thin, to have hyperinflated lung fields at total lung capacity, and to be free of signs of right heart failure. Chronic bronchitis patients (so-called blue bloaters, right) are characterized by marked hypoxemia with cyanosis and peripheral edema resulting from right heart failure.**

times referred to as pink puffers; they tend to be thin, to experience hyperinflation at total lung capacity, and to be free of signs of right heart failure. The pink puffer usually has severe emphysema. The other clinical group (type B) is characterized by marked hypoxemia and peripheral edema resulting from right heart failure. These patients, sometimes called blue bloaters, typically exhibit cough and sputum production. They have frequent respiratory tract infections, experience chronic carbon dioxide retention (P_aCO_2 > 45 mm Hg), and have recurrent episodes of cor pulmonale. The blue bloater may also have pathologic evidence of severe emphysema but, in addition, suffers from inflammation of large and small airways and possible defects in ventilatory control. These patients usually meet the criteria for chronic bronchitis. Many patients will demonstrate features of both types, giving rise to either mixed or intermediate clinical presentations.

Several explanations have been proposed for this disparate response to severe airflow obstruction, including differences in pulmonary mechanics, in the central control of ventilation, and in respiratory disturbances during sleep. Type A patients appear to have advanced emphysema with relatively little evidence of airway disease. These patients have abnormally compliant lungs, and airflow obstruction is related primarily to a loss of lung elastic recoil. In contrast, type B patients typically have intrinsic airway disease that manifests clinically as cough and sputum production (i.e., chronic bronchitis) and physiologically as increased resistance to airflow during both expiration and inspiration (airflow resistance during inspiration is not as apparent in patients with emphysema and loss of lung elastic recoil). Type B patients may compensate for the increased work of breathing imposed by this inspiratory resistive load by limiting their total amount of ventilation, causing P_aCO_2 levels to rise. Patients with both reduced elastic recoil and increased inspiratory resistance (i.e., those with a mixed type of clinical presentation) would be predicted to have chronic hypercapnia, and this is indeed the case.

It is also possible that patients with severe COPD in whom hypercapnia ultimately develops have intrinsic defects that cause relatively depressed ventilatory responses to acute rises in P_aCO_2 levels, falls in P_aO_2 levels, or both. This hypothesis is supported by the finding that the healthy first-degree relatives of patients with COPD and chronic carbon dioxide retention have blunted ventilatory responses to hypercapnia and hypoxia, as compared with the first-degree relatives of patients with COPD but no chronic hypercapnia.

Alternatively, arousal responses during sleep may be abnormally depressed in type B patients. Failure to arouse and resume normal ventilation may explain why, during sleep, type B patients experience more severe and prolonged decreases in P_aO_2 levels and increases in P_aCO_2 levels than normal persons or type A patients. Over time, repeated periods of hypercapnia during sleep may diminish the potency of hypercapnia as a stimulus to increase ventilation, eventually leading to fixed carbon dioxide retention.[38]

The more profound hypoxemia observed in type B patients, as compared with type A patients, is in part a result of overall alveolar hypoventilation. In addition, ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching in type B patients involves a greater number of alveoli receiving low levels of ventilation for the amount of blood flow delivered (i.e., a low ratio of alveolar ventilation to perfusion [$\dot{V}_A/\dot{Q}$]).

These two different patterns of abnormal gas exchange have very different consequences for the cardiovascular system in patients with advanced COPD. In the type B patient, both alveolar hypoxia and acidosis (secondary to chronic hypercapnia) stimulate pulmonary arterial vasoconstriction, and hypoxemia stimulates erythrocytosis. Increased pulmonary vascular resistance, increased pulmonary blood volume, and, possibly, increased blood viscosity from secondary erythrocytosis all contribute to pulmonary arterial hypertension.[39] In response to long-term pulmonary hypertension, cor pulmonale generally develops. In cor pulmonale, the right ventricle becomes hypertrophic; to increase cardiac output, abnormally high right ventricular filling pressures then occur. Additional hemodynamic loads may cause the right ventricle to fail, with the consequent development of systemic venous hypertension, manifested by jugular venous dis-

tention, peripheral edema, passive hepatic congestion, and, sometimes, ascites. (Pleural effusion is not a manifestation of cor pulmonale in the absence of left heart failure.) Echocardiographic evaluation of right heart function and estimation of pulmonary arterial systolic pressure are useful in quantifying the degree of pulmonary hypertension.[39]

The emphysematous lung destruction characteristically seen in type A patients leads to a restricted vascular bed because of the loss of pulmonary capillaries from the destroyed alveolar walls. This condition is reflected in the reduced diffusing capacity of the lung for carbon monoxide ($D_{L_{CO}}$) observed in type A (but not in type B) patients.[40] However, because P_aO_2 levels are only mildly depressed in type A patients, pulmonary vasoconstriction is minimal, and secondary erythrocytosis does not develop. Cardiac output may be slightly reduced. As a result, pulmonary hypertension in type A patients is milder than in type B patients, and cor pulmonale develops infrequently, usually only in the terminal phase of the illness.

Differences in gas exchange during exercise also distinguish the two clinical types. Type A patients have abnormally high levels of ventilation for a given workload (expressed in terms of oxygen consumption, $\dot{V}O_2$), but nevertheless, the P_aO_2 falls with exercise. The $D_{L_{CO}}$ in type A patients rises minimally and remains low during exercise, reflecting inadequacies in the alveolar-capillary surface area available for gas exchange. Patients with COPD who have $D_{L_{CO}}$ levels less than 55% of normal can be expected to have oxygen desaturation with exercise. In contrast, type B patients have subnormal increases in ventilation for a given level of work (decreased ratio of minute ventilation to oxygen consumption [$\dot{V}_E/\dot{V}O_2$]) and a greater rise in P_aCO_2 levels with exercise than type A patients, and yet, P_aO_2 levels may increase during exercise. This increase in P_aO_2 levels must reflect improved matching of ventilation to perfusion during exercise.

Chest Imaging

Radiographic abnormalities may be minimal, even in cases of advanced COPD.[41] When correlations are made between radiographic and pathologic findings in advanced COPD, the results of chest radiography suggest a diagnosis of emphysema in fewer than half of the cases, even among those with the highest emphysema scores pathologically.

Three types of radiographic abnormalities, when paired with the appropriate clinical history, suggest the diagnosis of emphysema [*see Table 1*].[41] The first abnormality is arterial deficiency in the lung periphery; on chest radiograph, narrowed or absent vessels in the lung periphery are associated with hyperlucency, usually in a symmetrical, bilateral distribution. The second abnormality relates to hyperinflation and is evident in the standard posteroanterior and lateral chest radiographs, which are obtained at TLC; radiographic signs of hyperinflation in these films include a low position of the diaphragm (i.e., at or below the seventh rib anteriorly), increased depth of the retrosternal air space, and a narrow, vertically oriented cardiac silhouette. Perhaps the most useful sign of hyperinflation is a flattening of the diaphragmatic contour and loss of the diaphragm's normal domed appearance, especially as visualized on the lateral film. The third abnormality is bullous disease. The presence of a bulla together with either of the other two radiographic findings is virtually diagnostic of emphysema, although only a small percentage of patients afflicted with emphysema have bullae [*see* Bullous Lung Disease, *below*].

Chronic bronchitis is rarely recognized on a chest radiograph [*see Table 1*].[41] On occasion, the diagnosis may be suspected because of visualization of thickened bronchial walls, particularly in a parahilar bronchus viewed end-on. In other patients, bronchovascular markings at the lung bases may be accentuated—a pattern that has been dubbed the dirty chest of chronic bronchitis. A similar radiographic appearance has been referred to as the increased-markings pattern of emphysema, especially when increased vascular markings are observed in the presence of pulmonary hypertension and cor pulmonale. The precise pathologic correlate of this radiographic image is unknown.

CT of the chest can be useful in the differential diagnosis of COPD.[41] Patients without abnormalities in pulmonary function may have extensive upper lobe emphysema, as demonstrated by CT. Occasional smokers who have normal airflow on spirometry but diminished $D_{L_{CO}}$ may have emphysema that can be detected only by high-resolution CT scanning.

TREATMENT

Reviews and guidelines on the treatment of COPD have been published,[25,35,42-44] but the various guidelines do not agree on recommendations.[45] Suboptimal prescription of and adherence to appropriate therapies further complicate management of COPD.[46] Of the therapeutic measures available for patients with chronic bronchitis and emphysema, only smoking cessation and long-term administration of supplemental oxygen to the chronically hypoxemic patient have been definitively shown to alter the natural history of the disease favorably. Data suggest, however, that the combination of a long-acting $beta_2$ agonist and inhaled corticosteroids may also improve survival of patients with COPD.[47]

Helping a patient to quit smoking is probably the single most important intervention; effective methods include counseling by physicians and nurses, use of nicotine replacement therapy, behavior intervention (e.g., individual or group therapy), and several pharmacologic interventions (e.g., bupropion and nortriptyline)[48] [*see CE:III Reducing Risk of Injury and Disease*]. Spirometric evidence of airway obstruction in patients who smoke, when combined with advice to stop smoking, may contribute to increased smoking-cessation rates.[49] Smoking cessation generally causes the symptoms of chronic bronchitis to diminish or entirely remit,[19] and it stops the accelerated loss of lung function observed with continued cigarette smoking.[18,50]

Reduction in morbidity and mortality in patients with COPD can be achieved with yearly vaccinations against influenza.[51] Administration of the pneumococcal vaccine is also advisable, although its efficacy is less well documented in this patient population.[52] In the future, immunization with *Haemophilus influenzae* vaccine may be recommended.[53]

A variety of other therapies offer potential relief of symptoms in patients with COPD. These include the use of bronchodilators; anti-inflammatory therapy; administration of antibiotics during acute purulent exacerbations; pulmonary rehabilitation programs, including physical exercise and respiratory muscle training; and, for patients with cor pulmonale, the use of diuretics. Based on the GOLD (*G*lobal Initiative for the Diagnosis, Management, and Prevention of Chronic *O*bstructive *L*ung *D*isease) staging system, a stepwise plan for management of patients with COPD has been proposed [*see Figure 6*].[43]

Management of Chronic Disease

Bronchodilators COPD has been considered a disorder of irreversible airflow obstruction, in contradistinction to asthma.

Table 2 Estimated Comparative Doses of Inhaled Bronchodilators for COPD

Category (Relative Efficacy)	*Drug*	*How Available*	*Maintenance Dosage*	*Exacerbation Dosage*	*Comment*
Inhaled long-acting anticholinergics (first-line therapy)	Tiotropium	DPI, 18 µg/puff	1 capsule q. day	Not recommended	Anticholinergic of choice for maintenance therapy
Inhaled short-acting anticholinergics	Ipratropium bromide	Nebulizer, 0.25 mg/ml	0.5 mg q. 6 hr	0.5 mg q. 2–8 hr	May mix with albuterol in same nebulizer
		MDI, 18 µg/puff	2–6 puffs q. 6 hr	3–8 puffs q. 3–4 hr	MDI as effective as nebulizer when used with spacer
Inhaled long-acting beta$_2$ agonists (may replace anticholinergic)	Salmeterol	MDI, 21 µg/puff	2 puffs q. 12 hr	Not recommended	Slower onset of action than short-acting beta$_2$ agonists
		DPI, 50 µg/blister	1 blister q. 12 hr	Not recommended	
	Formoterol	DPI, 12 µg/capsule	1 capsule q. 12 hr	Not recommended	Faster onset of action than salmeterol
Inhaled short-acting beta$_2$ agonists (second-line therapy)	Albuterol	Nebulizer, 5 mg/ml	1.25–5.0 mg q. 4–8 hr p.r.n.	5.0 mg q. 2 hr	Dilute aerosols to minimum of 4 ml at gas flow of 6–8 L/min
		MDI, 84 µg/puff	2–4 puffs q. 6 hr p.r.n.	3–8 puffs q. 2 hr	MDI as effective as nebulizer when used with spacer
		DPI, 200 µg/capsule	1–2 capsules q. 6 hr p.r.n.	Not studied in exacerbations	—
	Bitolterol	Nebulizer, 2 mg/ml	0.5–3.5 q. 4–8 hr p.r.n.	Not studied in exacerbations	—
		MDI, 370 µg/puff	2–4 puffs q. 6 hr p.r.n.	Not studied in exacerbations	—
	Pirbuterol	MDI, 200 µg/puff	2–4 puffs q. 6 hr p.r.n.	Not studied in exacerbations	—
Combined short-acting beta$_2$ agonist and anticholinergic (when both are indicated)	Albuterol + ipratropium bromide	MDI; albuterol, 90 µg/puff + ipratropium, 18 µg/puff	2–4 puffs q. 6 hr p.r.n.	3–8 puffs q. 2 hr	—

DPI—dry powder inhaler MDI—metered-dose inhaler

Nevertheless, most patients with COPD who are given a sufficiently strong bronchodilating medication will exhibit at least a 10% increase in maximal expiratory airflow.[37] Dyspneic patients should be given a trial of bronchodilators even if pulmonary function testing shows that they do not manifest significant bronchodilation, because bronchodilator responsiveness may vary over time.[37] Additionally, some of the symptomatic benefit from bronchodilators in COPD patients may come from reduction in exercise-induced dynamic hyperinflation, a change that may not be detected by spirometry.[25,54]

Bronchodilator therapy should be administered on the basis of the patient's symptoms and in a stepwise fashion on the basis of disease stage. For COPD patients in stages 1 through 4, a short-acting inhaled bronchodilator such as albuterol should be used as needed for treatment of symptoms [*see Figure 5 and Table 2*]. For symptomatic patients in stages 2 through 4, long-acting bronchodilators should be prescribed and used on a regular basis[55] [*see Figure 5 and Table 2*]. Current recommendations suggest the long-acting bronchodilator of choice is tiotropium, an approved anticholinergic drug that is inhaled once daily [*see Table 2*]. Alternatively, a long-acting beta$_2$ agonist (i.e., salmeterol or formoterol) may be used[55] [*see Table 2*]. An additional benefit of either type of long-acting bronchodilator therapy may be a reduction in the frequency of exacerbations.[55]

If the patient's symptoms are incompletely controlled with one long-acting inhaled bronchodilator, a second long-acting inhaled bronchodilator should be added. Whether the combination of anticholinergic and beta$_2$-agonist therapies will result in additive or synergistic bronchodilation and a reduction in exacerbations is unknown. When a combination of a long-acting beta$_2$ agonist and inhaled corticosteroid is required, a single an inhaler containing salmeterol and fluticasone can be used, potentially improving compliance.[56]

If the patient remains symptomatic on optimized inhaled medication, a trial of theophylline is indicated.[57] Because of theophylline's narrow therapeutic window, dosing must be individualized; serum levels from 8 to 12 mg/dl are optimal for COPD patients.

Bronchodilators may be delivered by three types of devices: nebulizers, metered-dose inhalers (MDIs), and dry-powder inhalers (DPIs). Nebulizers are useful in patients who cannot operate MDIs or DPIs, but they are bulky and messy to use. MDIs are familiar to many patients but require excellent coordination or the use of a spacer. DPIs come in several forms, some easier to use than others. Patients must be instructed in the use of each apparatus, and the technique of their use must be reviewed with the patient periodically. All three types of devices can be used to deliver medication to spontaneously breathing patients. Only nebulizer systems and MDIs can be used in intubated patients. There is no evidence that nebulized bronchodilators are of

greater benefit than properly administered dry-powder or metered-dose inhaled medications used with a spacer.[58] Use of bronchodilators in the setting of acute exacerbations is discussed elsewhere [*see* Management of Acute Exacerbations, *below*].

Corticosteroids The role of corticosteroids in the treatment of COPD is controversial; however, the current understanding that all forms of COPD are associated with a tissue inflammatory response [*see Figure 4*] suggests that anti-inflammatory therapy may alter disease progression and symptoms.

Patients who have recurrent attacks of wheezing, a significant acute response to inhaled bronchodilators (> 20% increase in FEV_1), and sputum eosinophilia may have COPD with an asthmatic component (asthmatic bronchitis); these patients may respond well to corticosteroids.[59]

Oral corticosteroid therapy should be avoided in COPD except in the setting of acute exacerbations [*see* Management of Acute Exacerbations, *below*]. Oral steroids required on a regular basis should be given in the lowest possible dose, preferably on alternate days.

Inhaled corticosteroids may have significant beneficial effects on airway inflammation [*see Table 3*].[60] In randomized trials, inhaled steroids did not arrest decline in lung function in patients with COPD[61]; however, their use was associated with reductions in respiratory symptoms, in acute exacerbations, and in use of health care services.[62] Medium to high doses of inhaled corticosteroids may be of greater benefit than lower doses [*see Table 3*].[47] Analyses of large databases have suggested that inhaled corticosteroids, especially when used with long-acting $beta_2$ agonists, may also increase survival.[47,63] The most recent guidelines recommend inhaled corticosteroids for COPD patients with stage 3 or 4 disease who have frequent exacerbations [*see Figure 5*].[43,64]

The main issue in corticosteroid therapy for COPD, as in any therapy, is how to achieve maximal benefit with minimal toxicity. If prolonged oral corticosteroid therapy is given to patients who do not show objective improvement in pulmonary function, the net effect will be negative. Complications associated with prolonged oral corticosteroid therapy include weight gain, osteoporosis,[33] hypertension, diabetes, cataracts, and myopathy. Serious pulmonary infections, including locally invasive aspergillosis, can ensue.

Side effects from inhaled corticosteroids in COPD patients are much less than those associated with oral corticosteroid use: osteoporosis[65] and adrenal suppression[66] have not been detected, and weight gain, hypertension, diabetes, and myopathy are not seen. Inhaled corticosteroids may carry a small risk for the development of cataracts.

Antibiotics In the 1950s and 1960s, clinical trials of daily antibiotic use in patients with mild COPD demonstrated that this intervention did not significantly alter either the degree of disability or the rate of disease progression. Only patients with very frequent purulent exacerbations (so-called chronic purulent bronchitis) derived some symptomatic benefit from regular antibiotic use.

Management of Acute Exacerbations

Acute exacerbations are short-term deteriorations of clinical and functional status of COPD patients.[67,68] Acute exacerbations of COPD are associated with worsening dyspnea (often at rest), increased cough (often with purulent sputum), and the development of wheezing, fatigue, fever, tachypnea, cyanosis, edema, and alteration of consciousness.

Symptoms that suggest an exacerbation of COPD can be caused by other diseases or complications of COPD. Examples of the diseases that can mimic a COPD exacerbation include pneumothorax, pneumonia, congestive heart failure, cardiac arrhythmia, pulmonary embolism, drug toxicity, metabolic disorders, stroke, and myopathy.

The immediate decision in the management of an acute worsening of COPD is whether the exacerbation is severe enough to require emergent evaluation and possible hospitalization. Criteria for immediate evaluation include a requirement of maximum therapy to control symptoms, alteration of consciousness, dyspnea at rest, a respiratory rate greater than 25 breaths/min, a pulse rate greater than 110 beats/min, increased cyanosis, and use of accessory muscles. As COPD becomes more advanced, patients are more likely to require emergent care when exacerbations occur. Other factors that should be considered include comorbidities; the medical sophistication, judgment, and reliability of the patient and caregivers; and the distance to the medical center or clinic.

Table 3 Estimated Comparative Daily Dosages of Inhaled Corticosteroids[184]

Drug	*Low Dosage*	*Medium Dosage*	*High Dosage*	*Relative Efficacy*
Beclomethasone 42 µg/puff 84 µg/puff	168–504 µg 4–12 puffs/day 2–6 puffs/day	504–840 µg 12–20 puffs/day 6–10 puffs/day	> 840 µg > 20 puffs/day > 10 puffs/day	Third-highest potency
Budesonide 200 µg/puff	200–400 µg 1–2 inhalations/day	400–600 µg 2–3 inhalations/day	> 600 µg > 3 inhalations/day	Second-highest potency
Flunisolide 250 µg/puff	500–1,000 µg 2–4 puffs/day	1,000–2,000 µg 4–8 puffs/day	> 2,000 µg > 8 puffs/day	Lowest potency
Fluticasone 44 µg/puff 110 µg/puff 220 µg/puff	 88–264 µg 2–6 puffs/day 1–2 puffs/day	 264–660 µg 6–15 puffs/day 2–6 puffs/day	 > 660 µg > 15 puffs/day > 6 puffs/day	Highest potency
Triamcinolone 100 µg/puff	400–1,000 µg 4–10 puffs/day	1,000–2,000 µg 10–20 puffs/day	> 2,000 µg > 20 puffs/day	Lowest potency

Antibiotics Exacerbations are often precipitated by respiratory infection, which may be caused by viral[69] or bacterial pathogens or a combination of the two. In patients with symptoms of infection, the duration of symptoms and the risk of serious deterioration in lung function can be reduced by a 7- to 10-day course of broad-spectrum antibiotics. Recent guidelines suggest that with advancing age, severity of disease, and the presence of comorbidity, the pathogens encountered in exacerbations tend to be more resistant, necessitating use of broader-spectrum antibiotics; sputum culture is required in the most severe illnesses.[70] For patients with simple chronic bronchitis (i.e., those with an $FEV_1 > 50\%$), in the absence of pneumonia, empirical treatment with ampicillin, tetracycline, or trimethoprim-sulfamethoxazole is satisfactory. In patients whose FEV_1 is less than 50%, many of the isolates of *H. influenzae, Moraxella* (*Branhamella*) *catarrhalis,* and *Streptococcus pneumoniae* are β-lactam resistant; and other organisms, such as members of the Enterobacteriaceae family and *Pseudomonas* species, become more common.[69] In these patients, a quinolone, a β-lactam–β-lactamase inhibitor combination, a second-generation oral cephalosporin, or a second-generation macrolide may be needed.

Bronchodilators The bronchodilator of choice in exacerbations of COPD is a short-acting $beta_2$ agonist (e.g., albuterol), mainly because of its rapid onset of action. The initial dose is four puffs every 4 hours. In patients who do not respond, doses can be increased and the frequency of dosing decreased to three to eight puffs every 2 hours [*see Table 2*].

Once short-acting $beta_2$-agonist therapy is started, inhaled anticholinergic therapy (e.g., ipratropium) should be initiated or increased. The dosage is usually three or four puffs but can be increased to five to eight puffs every 3 to 4 hours [*see Table 2*]; the onset of action is slower than that of beta agonists, but the duration of action is longer.

A nebulizer has no advantage over an MDI used with a large-volume spacer. The only instances in which a nebulizer is preferred to an MDI is in patients who have extreme dyspnea or altered consciousness. There are no data suggesting that the addition of theophylline to bronchodilator therapy is beneficial for exacerbations of COPD.[71] In patients already on theophylline, measurement of theophylline level is indicated because acute illness and some of the medications used to treat exacerbations can precipitate theophylline toxicity.

Corticosteroids Corticosteroids are beneficial in exacerbations of COPD,[72] but they are associated with side effects of varying severity. Patients should be considered for prednisone therapy (1) if they are currently on oral or inhaled steroids, (2) if they have recently finished a regimen of oral steroids, (3) if they previously responded to oral or inhaled steroids, or (4) if they are not responding to initial bronchodilator therapy. The dosage of prednisone is 0.6 to 1.0 mg/kg/day. In addition, patients whose oxygen saturation is 90% or less or whose peak expiratory flow rate is 100 L/min or less should be considered for treatment with corticosteroids regardless of their current therapy.

Exacerbations are often associated with hypercapnia and worsening of hypoxemia. Oxygen supplementation should be adjusted to keep oxygen saturation around 90% to 92% to maintain tissue oxygenation while minimizing the risk of worsening hypercapnia. In patients whose hypercapnia increases and whose blood pH values are less than 7.35 despite initial bronchodilator therapy, ventilatory support should be considered [*see 14:VII Respiratory Failure*].[73]

Management of Advanced Disease

In patients with far-advanced COPD who have cor pulmonale and right heart failure, therapies are often directed specifically at the hemodynamic consequences of the disease [*see 14:XI Pulmonary Hypertension, Cor Pulmonale, and Primary Pulmonary Vascular Diseases*].[74] Diuretics are administered for symptomatic relief of peripheral edema; they may also reduce pulmonary arterial pressure by decreasing intrapulmonary blood volume. Care must be taken to avoid chloride depletion from long-term diuretic use because the resultant hypochloremic metabolic alkalosis depresses respiratory drive and may aggravate CO_2 retention. Digoxin and aminophylline are only weak inotropic stimulants of the right ventricle. The increases in right ventricular output produced by these medications are not clinically significant.

A variety of arterial vasodilators, including hydralazine and nifedipine, have been used in an attempt to reduce pulmonary arterial hypertension secondary to severe COPD. A limited number of studies have demonstrated that long-term (i.e., 6 to 12 month) vasodilator administration produces persistent reductions in pulmonary arterial pressures, but there is no evidence that such therapy produces sustained symptomatic improvement or prolongs survival.[74] A potential risk of vasodilator therapy, particularly in the patient with fixed (i.e., anatomic) pulmonary hypertension, is the development of systemic hypotension and renal hypoperfusion. In general, relief of hypoxemia with long-term supplemental oxygen administration has proved to be more effective than drug therapy in reducing pulmonary arterial resistance.

Pulmonary Rehabilitation

Physical-training programs, such as treadmill walking, significantly increase the exercise capacity of patients with even far-advanced chronic bronchitis and emphysema.[75] These results have been achieved despite the fact that lung function, as reflected in such measurements as vital capacity and FEV_1, is not affected and maximal heart rate is generally not reached during the training sessions.

Much interest has focused on the possibility that resistive or endurance exercises aimed at strengthening the inspiratory muscles might increase respiratory muscle strength and endurance and thereby improve exercise capacity, at least in cases in which respiratory muscle fatigue contributes to exercise limitation. For instance, it was shown that patients with severe COPD who breathed through an inspiratory resistor (with the amount of resistive load carefully tailored to the particular patient) for 15 minutes twice daily for 1 month derived a number of benefits. Such a regimen not only increased the endurance of the inspiratory muscles but also enabled patients to walk farther during a fixed period, and it increased their endurance during submaximal exercise on a bicycle. However, it is not clear whether the benefit derived from respiratory muscle training exceeds that derived from general physical conditioning. As with other forms of physical training, deconditioning occurs within a few weeks of cessation of the exercise program.

Long-term Oxygen Administration

Probably the single most important advance in recent years in the treatment of advanced COPD has been the widespread

home use of supplemental oxygen.[76] Chronic hypoxemia causes secondary erythrocytosis and contributes to exercise limitation, pulmonary hypertension, right heart failure, and impaired neuropsychiatric function. Each of these consequences of chronic hypoxemia can be ameliorated or even corrected by the administration of oxygen at levels that are sufficient to maintain the arterial oxygen saturation at values exceeding approximately 90%. This target value, which corresponds to a P_aO_2 of 60 to 80 mm Hg, can usually be achieved with oxygen supplementation delivered at a rate of 2 L/min via nasal cannulas, but the rate of oxygen administration should be titrated to the individual patient's needs according to arterial blood gas measurements taken when the patient is breathing supplemental oxygen.

Supplemental oxygen administration for a minimum of 15 hr/day may suffice to ameliorate some of the adverse consequences of chronic tissue hypoxia, particularly secondary erythrocytosis and pulmonary hypertension. However, survival is significantly improved when supplemental oxygen is given for 24 hr/day.

In general, patients should receive long-term home oxygen supplementation if the P_aO_2 is 55 mm Hg or less or if the P_aO_2 is 59 mm Hg or less and one or more of the following conditions are present: peripheral edema (a sign of cor pulmonale), a hematocrit of 55% or greater, and P pulmonale on the electrocardiogram. The resting P_aO_2 should be assessed when the patient is free of an exacerbation and has received intensive bronchodilator therapy. With adequate oxygen therapy, phlebotomy for polycythemia (i.e., hematocrit > 50%) is rarely necessary.

Oxygen for home use can be stored in cylinders as compressed gas or as liquid oxygen, or it can be generated from ambient air by machines called oxygen concentrators that are the size of a bedside table. Portable tanks of oxygen, filled from a liquid oxygen reservoir tank, can provide supplemental oxygen for several hours of use outside the home. Newer methods to conserve oxygen consumption and prolong the time spent outside the home while using portable oxygen tanks include devices that release oxygen only during the inspiratory phase of the respiratory cycle and direct transtracheal administration of oxygen via an indwelling tracheal catheter.[77]

Long-term Ventilatory Support

Intermittent application of negative pressure or noninvasive positive pressure ventilation has been used in the treatment of patients with chronic hypercapnia caused by advanced chronic bronchitis and emphysema.[78] During periods of mechanical ventilation, the respiratory muscles are rested and gas exchange improves. Trial results in a limited number of patients suggested that daytime symptoms, arterial blood gas levels, and exercise performance may be improved when only a few hours of ventilation are applied nightly or even less frequently.

Surgery

Interest in surgical therapy for diffuse emphysema has been revived because of advances in the operative technique. Emphysematous lung tissue is removed by one of several approaches and techniques.[79] The rationale is to remove overdistended, poorly functioning emphysematous regions, thereby allowing more-normal or less-affected regions to expand with a decrease in the FRC and an improvement in inspiratory muscle function.[80] The surgery produces a 13% to 96% improvement in FEV_1 and a reduction in RV; many patients who previously required supplemental oxygen are able to discontinue it or reduce their use after surgical therapy. However, results vary enormously among patients.[81] Operative mortality is 5% to 7%. Patients usually stay in the hospital 7 to 10 days; the main morbidity is prolonged air leaks.[82] Decreases in TLC, increases in elastic recoil pressures, and lengthening of inspiratory muscles have been shown to be directly related to functional improvement.[83] The surgery can be performed on many patients who are not candidates for lung transplantation, or it may be performed instead of lung transplantation or as a bridge to transplantation.[84] By 5 years after surgery, only 8% of the patients continue to have a significant improvement in FEV_1.[85] In two small randomized trials, patients treated with pulmonary rehabilitation plus surgery, compared with patients treated with pulmonary rehabilitation alone, were shown to have improvement in lung function, exercise capacity, and quality of life.[86,87]

A randomized, multicenter clinical trial comparing lung volume reduction surgery with continued medical treatment in 1,218 patients with severe emphysema found that the surgery increased the chance of improved exercise capacity but did not confer a survival advantage, except in patients who had both predominantly upper lobe emphysema and low exercise capacity after rehabilitation.[88] Patients with an FEV_1 20% or less than predicted and either homogeneous emphysema on high-resolution CT scanning or a diffusion capacity 20% or less than predicted had a higher 30-day postoperative mortality than the medically treated group.[89] Patients with non–upper lobe emphysema and high baseline exercise capacity proved to be poor candidates because of operative mortality and negligible functional gains.[88]

In younger patients with far-advanced COPD, lung transplantation is a therapeutic option. Criteria for referral for lung transplantation include an FEV_1 less than 20% of predicted value, hypercapnia, homogeneous emphysema on high-resolution CT scan, and pulmonary hypertension.[90] In patients with pure emphysema, single-lung transplantation has been performed successfully despite the concern that the remaining emphysematous lung would become further overexpanded because of the normal recoil of the transplanted lung.[91] In patients with chronic bronchitis who have any evidence of concomitant bronchiectasis, bilateral lung transplantation is performed at many centers to eliminate the potential risk of persistent infection in the remaining lung. Heart-lung transplantation is not needed even by patients with cor pulmonale, because the right ventricle rapidly recovers when pulmonary vascular resistance is reduced. The 5-year survival rate after lung transplantation is 57%.[92]

Other Conditions Associated with CAO

α_1-ANTITRYPSIN DEFICIENCY

Degradation of interstitial elastin fibers by elastolysis is a central pathologic process in the development of emphysema [*see* Protease-Antiprotease Imbalance, *above*].[93] The main defense of normal lung tissue against this enzymatic destruction is alveolar α_1-antitrypsin, which inactivates elastase by forming a stable complex with it. α_1-Antitrypsin is synthesized predominantly in the liver and is present in the serum of normal persons at concentrations of 83 to 200 mg/dl if measured by nephelometry and 150 to 350 mg/dl (20 to 50 μM) if measured by radial immunodiffusion.

Genetic Variants Affecting α_1-Antitrypsin Levels

The genetic model describing inheritance of α_1-antitrypsin

Figure 7 **This chest radiograph of a patient with homozygous α_1-antitrypsin deficiency reveals hyperinflation and hyperlucent lung fields with bilateral basilar bullae. Other findings include prominent central pulmonary arteries and rapid pruning of the pulmonary arterial branches, consistent with pulmonary arterial hypertension.**

genes invokes multiple autosomal codominant alleles at a single locus.[94] The locus on chromosome 14 has been designated Pi, which stands for protease inhibitor system. The most prevalent α_1-antitrypsin allele, found with a frequency of 0.95 in whites in the United States, is labeled Pi^M. Variant α_1-antitrypsin molecules are denoted with letters on the basis of their electrophoretic mobility. The variant protein molecule with the lowest rate of electrophoretic mobility is Pi^Z.

Most of the various Pi phenotypes are associated with normal amounts of serum α_1-antitrypsin.[93] However, in persons homozygous for the Pi^Z allele, serum concentrations of α_1-antitrypsin are only 10% to 15% of normal. In the United States, the prevalence of α_1-antitrypsin deficiency caused by a homozygous Pi^Z genotype is one in 3,000 persons[62]; it is less common in African Americans.[95] The substitution of a single amino acid in the normal M α_1-antitrypsin protein leads to the formation of polymers of the protein in the endoplasmic reticulum and impairs the release of the Z protein from hepatocytes into the circulation.[94] The protein appears as periodic acid–Schiff–positive and diastase-resistant granular cytoplasmic inclusions in the livers of patients heterozygous or homozygous for Pi^Z. The secreted Pi^Z α_1-anti-trypsin is also a less potent inhibitor of neutrophil elastase than Pi^M.[94]

Because of the deficient and less potent α_1-antitrypsin, endogenous proteases are not effectively inhibited, resulting in a breakdown of elastin and the development of emphysema.[93,94] This hypothesis is supported by studies that found evidence for uninhibited elastase activity in patients with α_1-antitrypsin deficiency.[96] Uninhibited elastase may stimulate macrophages to release IL-8 and leukotriene B_4, which is a chemoattractant for neutrophils that perpetuates the local inflammation and increased amounts of neutrophil elastase.[97]

Emphysema Caused by α_1-Antitrypsin Deficiency

Emphysema develops in at least 80% of patients with homozygous Pi^Z α_1-antitrypsin deficiency. The mean age at onset of dyspnea is 45 to 50 years in nonsmokers and approximately 10 years earlier in those who smoke. Remarkably, some nonsmoking patients with homozygous Pi^Z α_1-antitrypsin deficiency never manifest symptomatic emphysema.[98] There is no escape for smokers with this deficiency, however: all such patients have symptomatic airflow obstruction at a young age.

Diagnosis The typical pathologic picture is panacinar emphysema, but as many as 25% to 30% of nonsmoking patients and 60% of cigarette smokers report symptoms of chronic bronchitis as well. Many of the patients have evidence of enhanced airway reactivity.[99] High-resolution CT scanning has also detected a significant incidence of bronchiectasis.[100] Involvement of the lower lobes often predominates, perhaps because of increased neutrophil traffic and release of neutrophil elastase in the lower lung fields. The radiographic manifestation of this phenomenon is most commonly attenuation of the pulmonary vasculature to the lower lobes; in more advanced cases, basilar bullae may be seen [*see Figure 7*]. Features that would suggest α_1-antitrypsin deficiency as the cause of a particular patient's emphysema would thus include a family history of emphysema (especially among nonsmokers), the onset of symptoms at 30 to 50 years of age, the development of significant emphysema in a nonsmoker, and basilar predominance of the radiographic abnormalities.[98]

Serious liver disease, usually in the form of cirrhosis, occurs in 5% to 10% of adults with α_1-antitrypsin deficiency and may provide a clue to the underlying enzyme deficiency in some patients. Symptomatic liver disease is more common in children, who may present with neonatal hepatitis. Many infants and children recover, but 10% to 20% of those with hepatitis progress to cirrhosis and liver failure during childhood or early adulthood. It is not certain why some Pi^Z patients have symptomatic liver disease in childhood and others do not and acquire emphysema later in life. Other possible complications of α_1-antitrypsin deficiency include vasculitis, aneurysms, panniculitis, and pancreatitis.[93]

In persons who are heterozygous for the Z variant (Pi^{MZ}), serum α_1-antitrypsin concentrations are approximately 70% of normal.[86] Whether increased respiratory symptoms and airflow obstruction are greater in persons with the Pi^{MZ} phenotype than in matched Pi^M control subjects is not certain. Two long-term studies found greater deterioration in lung function in Pi^{MZ} patients than in Pi^{MM} patients.[101,102] The uncertainty might be explained by different degrees of deficiency in antiprotease levels. It is thought that α_1-antitrypsin levels higher than 40% of normal afford protection against the development of emphysema.

Treatment For patients with homozygous Pi^Z deficiency, smoking cessation and prevention of passive-cigarette-smoke exposure are essential. Consideration should be given to administration of purified α_1-antitrypsin, which is commercially available for replacement therapy.[93] Weekly infusions (60 mg/kg) can elevate serum levels above the hypothetical minimum protective level (50 mg/dl, 11 μM) for the entire week. Alternatively, a higher dose (250 mg/kg) can be given every 4 weeks. Clinical data support this longer interval, but unlike the weekly infusion, this regimen has not been approved for the product label. Studies of both dosing regimens using bronchoalveolar lavage have shown that adequate levels of α_1-antitrypsin are achieved

not only in the serum but also in the lung, where they are crucial. Preliminary data suggest reduction in the breakdown of elastin in patients on replacement therapy.[103]

There are numerous unresolved questions about antiprotease replacement therapy. The most important question is whether it will actually retard the progression of emphysema. Preliminary data from uncontrolled trials suggest a reduction in progression of disease with weekly replacement therapy.[104,105] For the present, individual treatment decisions have to be made without full information, with cost[106] and potential risk weighed against potential benefit. Replacement therapy probably is not indicated for patients who have normal pulmonary function; careful follow-up should be sufficient in such cases. Patients with mild to moderate airflow obstruction might benefit from replacement therapy. Smokers with CAO who have similar degrees of obstruction do benefit at this stage of the illness if the protease burden is reduced by the cessation of smoking. Patients with very severe airflow obstruction ($FEV_1 < 1$ L) may be beyond the point at which the natural course of the disease can be favorably altered by replacement therapy, much like smokers with very severe CAO, whose clinical course may not be altered by smoking cessation if there is little lung function left to preserve. In the future, it may be feasible to use antiprotease therapy[107] or gene therapy to restore normal production of α_1-antitrypsin.[108]

For homozygous Pi^Z patients with very severe airflow obstruction, lung volume reduction surgery[109] or single-lung transplantation offers hope for improved function and prolonged survival. Survival after transplantation is similar to that in patients with COPD.[110]

BULLOUS LUNG DISEASE

A bulla is defined pathologically as an emphysematous space greater than 1 cm in diameter; it is recognized radiographically as a localized hyperlucent area of lung demarcated by a curved hairline rim. Formation of bullae may complicate either panacinar or centriacinar emphysema. As many as one third of patients with radiographic evidence of emphysema have bullae on chest radiographs, although large, clinically significant bullae develop in only a small percentage of such patients.

Pathophysiology

Bullae may also form in the presence of normal surrounding lung tissue. The pathologic picture in this circumstance is most often described as paraseptal, or periacinar, emphysema. This condition involves destructive enlargement of predominantly the acinar ducts and the alveoli and primarily affects the periphery of the lobule adjacent to the surrounding septa. These subpleural bullae may produce a so-called soap-bubble appearance along the margin of the lung or may coalesce into a single bulla or multiple large bullae, typically in the lung apices. The perimeter of a bulla is formed by a thin layer of fibrous tissue and collapsed adjacent lung parenchyma. By contrast, the wall of congenital lung cysts (i.e., bronchogenic cysts) consists of bronchial epithelium.

For the most part, bullae behave as space-occupying lesions in the lung. Although bullae are inflated with gas, they participate minimally in overall ventilation. The virtual absence of ventilation of bullae in vivo can be demonstrated by (1) the absence of a change in the size of a bulla on an expiratory chest radiograph, (2) the large discrepancy between total lung capacity as measured by body plethysmography and as measured by helium dilution techniques, and (3) diminished or absent ventilation on radionuclide lung scanning with xenon-133. Perfusion scans reveal that bullae are also underperfused or nonperfused, and angiography demonstrates that large pulmonary vessels are not present within bullae. Thus, if a bulla contributes to hypoxemia in a patient, it is usually as a result of ventilation-perfusion imbalance (low $\dot{V}/\dot{Q}$) in the surrounding atelectatic lung tissue.

Diagnosis

Bullae that are surrounded by normal lung tissue are often asymptomatic. Until more than one third of the radiographic volume of a lung is occupied by a bulla, no clinically significant change in measured vital capacity occurs. Dyspnea may develop if the bulla is massively enlarged, or the patient may come to medical attention because of such complications as pneumothorax or infection. A bulla may be present with emphysema. Tests that may be useful for assessing the severity of associated emphysema in patients with bullae include CT of the chest, radionuclide lung scans, measurement of the $D_{L_{CO}}$, expiratory chest radiographs, and static pressure-volume curves of the lungs.

Treatment

Although a bulla may remain stable in size for many years, there is usually growth over time. Surgical resection of a large, symptomatic bulla may markedly increase vital capacity and P_aO_2 by allowing the surrounding normal lung to expand fully.[111]

A more difficult decision regarding the management of bullous lung disease is encountered in patients who have concomitant generalized emphysema throughout their lungs. In these patients, bullae simply represent a local exaggeration of a widespread process, and lung function does not normalize after resection of a bulla. Nevertheless, some patients with mild to moderate emphysema benefit from bullectomy. Improvement may be disappointingly brief, however, because bullae tend to recur.

However, there are no established guidelines for the management of bullous lung disease in patients with emphysema, and the decision to operate on a giant bulla is ultimately based on various subjective factors.

BRONCHIECTASIS

Bronchiectasis is a chronic suppurative disease of the airways that if sufficiently widespread may cause CAO.[112] In the preantibiotic era, it was a relatively frequent sequela of pulmonary infections in childhood, typically leading to chronic respiratory disability and death by 40 years of age. In modern practice, bronchiectasis is far less common and carries a much less dire prognosis. Nevertheless, it continues to be an important cause of chronic productive cough with sputum purulence, and it accounts for a significant percentage of cases of massive hemoptysis.

Etiology

Bronchiectasis is a localized, irreversible bronchial dilatation caused by a destructive inflammatory process involving the bronchial walls. Necrotizing bacterial or mycobacterial infection is thought to be responsible for most cases of bronchiectasis. A typical history is that of a childhood respiratory infection, such as whooping cough or bacterial superinfection complicating a viral pneumonia, followed by recurrent or persistent so-called chest colds.

Adult-onset bronchiectasis may result from an untreated or

inadequately treated bronchopneumonia that is caused by virulent organisms such as staphylococci or gram-negative bacilli. Mycobacterial infection frequently causes bronchiectasis, but because reactivation tuberculosis usually involves the upper lobes of the lungs, the clinical consequences differ considerably from the clinical consequences of other forms of bronchiectasis, which usually involve the right middle lobe, the lingula, or the lower lobes.

Generalized bronchiectasis may develop when systemic or pulmonary defense mechanisms are impaired in such a way as to predispose the patient to recurrent or chronic bacterial infections involving the airways. Rare congenital abnormalities of lung structure such as bronchial cartilage deficiency (Williams-Campbell syndrome) and tracheobronchomegaly (Mounier-Kuhn syndrome) may lead to generalized bronchiectasis, as may inherited deficiencies of immunoglobulins, impaired phagocytosis, complement deficiency, and α_1-antitrypsin deficiency.[113] In adults, widespread bronchiectasis occurs in association with hypogammaglobulinemia,[114] including isolated IgG subclass deficiencies[115]; cystic fibrosis [*see* Clinical Variants of Bronchiectasis, Cystic Fibrosis, *below*]; primary ciliary dyskinesia [*see* Clinical Variants of Bronchiectasis, Primary Ciliary Dyskinesia, *below*]; and several systemic diseases,[116] including rheumatoid arthritis,[117] other connective tissue diseases, inflammatory bowel disease, sarcoidosis, yellow nail syndrome, and HIV infection.[118]

Pathogenesis

Bronchiectasis results from the destruction of airways. The continued progression of disease over time likely results from continued infection, often with destructive organisms such as *P. aeruginosa,*[119] and the continued presence of tissue inflammation[120] with release of cytokines that are chemotactic for neutrophils.[121] These neutrophils locally release proteolytic enzymes such as elastase and other neutrophil enzymes[122] that may be involved in further airway and parenchymal damage and also may have an enhancing effect on mucus hypersecretion.[123]

The most important consequence of bronchiectatic damage to a portion of the airways is an increased susceptibility to recurrent or persistent bacterial infections. Normal defense mechanisms against infection are breached: ciliary function is disrupted by squamous metaplasia or by ulceration of the epithelial lining; excess mucus is secreted and pools in dilated spaces; and cough becomes less effective in clearing mucus from dilated bronchial segments. Once bacterial superinfection is established, it is virtually impossible to eradicate, and daily expectoration of purulent sputum is the end result in advanced cases. In bronchiectasis involving the upper lobes, stasis of mucus is prevented by gravitational drainage, resulting in the dry bronchiectasis of tuberculosis, in which cough and sputum production are usually absent but hemoptysis may occur.

Diagnosis

Three types of bronchiectasis have been described on the basis of bronchographic-pathologic findings: cylindrical, varicose, and cystic. Distinction between these three types of bronchiectasis is not useful clinically, however, because the manifestations and course of bronchiectasis are not correlated with the bronchographic pattern.

Clinical manifestations In most cases, the clinical presentation and a plain chest radiograph suffice for a presumptive diagnosis of bronchiectasis. Factors in the history, such as chronic cough and sputum purulence originating from a serious respiratory tract infection, often in childhood, strongly suggest the diagnosis. In addition, chronic sinusitis frequently accompanies bronchiectasis, and its presence should raise the suspicion of concomitant chronic lower respiratory tract infection.

In other patients, the clinical picture is one of frequent lower respiratory tract infections limited to the same area or areas of the lungs. Symptoms, physical findings, and abnormalities on the chest radiograph may not clear completely between each episode of pneumonia. Some patients have a mucoid sputum that becomes intermittently infected; disease course mimics that of chronic bronchitis with episodic infectious exacerbations. In this case, the local findings on chest examination and on the chest radiograph usually point to the diagnosis of bronchiectasis.

Clubbing of the digits occurs in the majority of patients with significant bronchiectasis and is a valuable diagnostic clue, especially because clubbing of the digits is not a manifestation of COPD [*see* Chronic Bronchitis and Emphysema, Diagnosis, *above*]. Auscultation of the chest usually reveals localized findings. Typically, paninspiratory, coarse crackles are heard over the involved region, and there may also be variable low-pitched wheezes if secretions are present in the airways.

Chest imaging Bronchiectasis may be seen on the plain chest radiograph in a number of different patterns. Cystic bronchiectasis is most readily recognized because of the distinctive appearance of a collection of thin-walled cystic spaces, sometimes accompanied by air-fluid levels, arranged in a segmental distribution. A localized increase in interstitial markings that follow the general orientation of the bronchovascular bundles may indicate milder degrees of ectasia. Occasionally, the thickened walls of a dilated bronchus can be visualized as the bronchus courses with its longitudinal axis perpendicular to the x-ray beam. These parallel lines are approximately 1 mm thick and are referred to as tramlines. Atelectasis often accompanies extensive bronchiectasis, in which case the radiographic appearance may mimic a postobstructive pneumonia. In approximately 7% of patients with bronchiectasis, the plain chest radiograph is entirely normal.

The current generation of CT machines provide excellent magnified images of bronchiectatic airways. CT scanning can be used to confirm a clinical suspicion of bronchiectasis, to suggest the specific cause,[124] and to evaluate the extent of disease[125] [*see Figure 8*].

Sputum examination Examination of purulent sputum produced by a patient with bronchiectasis may suggest the underlying diagnosis in two ways. First, if sputum is collected in a container for several hours until a sufficient volume is obtained, the sputum may settle into a characteristic three-layered pattern: foamy on top, purulent in the middle, and liquid at the bottom. Occasionally, the same pattern is observed in sputum from patients with chronic bronchitis or suppurative lung abscess. Second, routine bacterial culture of the sputum may grow *Pseudomonas* species. In an immunocompetent host, *Pseudomonas* species are almost never isolated from the sputum unless the host has bronchiectasis, is receiving broad-spectrum antibiotics, has a long-term tracheostomy, or is in the intensive care unit. *Staphylococcus aureus,* gram-negative bacilli other than *Pseudomonas* (especially *H. influenzae*), and *Mycobacterium avium* complex[126] may also infect the airways of patients with bronchiectasis. Bronchiec-

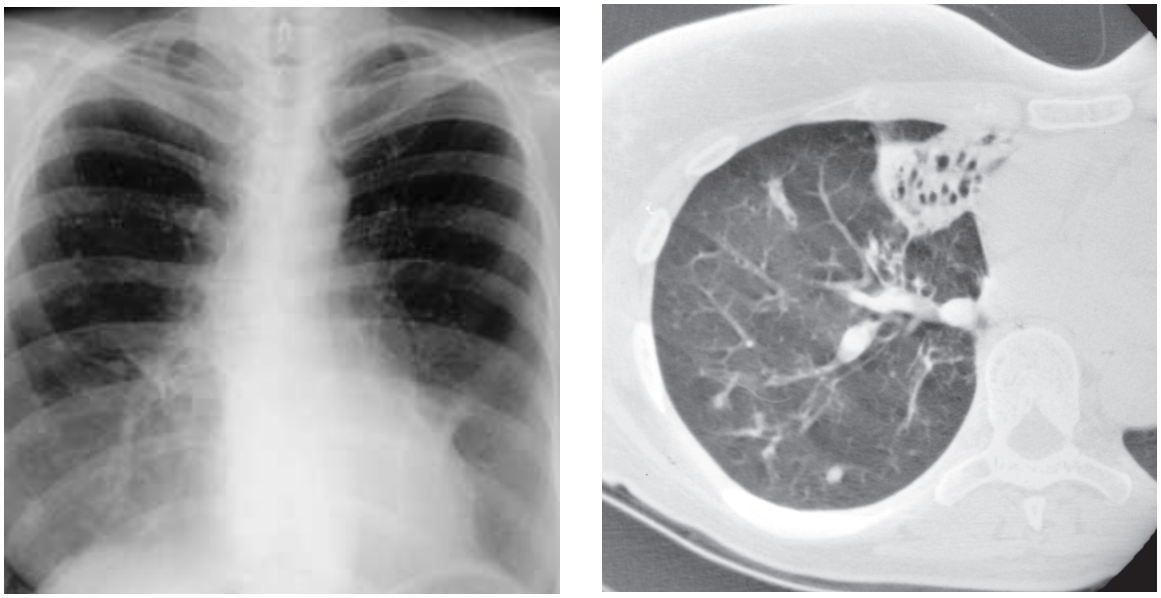

Figure 8 **In a comparison of a frontal chest radiograph with a CT scan of a patient with hemoptysis, the radiograph (left) suggests only an infiltrate in the right middle lobe; the CT scan (right) shows bronchiectasis in the right middle lobe that was the source of the bleeding.**

tasis is also a feature of allergic bronchopulmonary aspergillosis [*see 14:II Asthma*].

Pulmonary function tests Pulmonary function tests may remain normal if only a small portion of the tracheobronchial tree is affected. Widespread bronchiectasis causes chronic obstruction of expiratory airflow and may also cause a restrictive deficit if there is sufficient associated atelectasis or involvement of lung parenchyma by the infectious process. However, airflow obstruction is generally the main abnormality.

Treatment

The mainstays of therapy for bronchiectasis (including cystic fibrosis and primary ciliary dyskinesia), as for any chronic suppurative disease, are administration of antibiotics and drainage.

Antibiotics The use of antibiotics in the treatment of bronchiectasis has not been subjected to careful scientific investigation, and no one method of administration has proved to be superior in clinical experience. It is reasonable to culture the sputum periodically, because in patients from whom *S. aureus* or *H. influenzae* has repeatedly been isolated, antibiotics with appropriate spectra of activity can be selected. Oral antibiotics with effective antipseudomonal activity, such as the quinolones, show promise; however, because of the potential emergence of resistant strains of *Pseudomonas,* these drugs probably should not be used as single agents for long-term suppressive therapy. Nevertheless, many patients seem to benefit from broad-spectrum oral antibiotics, even when *Pseudomonas* is the only pathogen in the sputum and in vitro sensitivity testing shows that the antibiotics lack activity against *Pseudomonas*. In a patient who has daily purulent sputum production and is not allergic to sulfonamides, trimethoprim-sulfamethoxazole (one double-strength tablet twice daily) can be given continuously. Alternatively, antibiotics may be given intermittently or on a schedule in which different antibiotics are rotated.[127] Nebulized antibiotics may also be effective.[128]

If oral antibiotic therapy has failed, serious infectious complications (such as persistent fever with new areas of infiltration detected on the chest radiograph or the development of pleuritic chest pain) are generally best treated with a 10- to 14-day course of intravenous antibiotics. Two synergistic antibiotics with appropriate in vitro activity should be used for *Pseudomonas* infection.

Drainage Drainage of secretions is partially achieved by coughing and expectoration of sputum. However, because the diseased airways collapse during coughing and forced exhalation and because there is pooling of secretions distal to the areas of collapse, it is useful to include postural drainage as part of the management of bronchiectasis. Chest physiotherapy (e.g., the use of chest percussion and vibration) is often used to aid bronchopulmonary drainage, although it is difficult to demonstrate that physiotherapy produces benefits beyond those that are produced by postural drainage alone. There is no role for aerosolized recombinant human deoxyribonuclease (DNase) in bronchiectasis not associated with cystic fibrosis.[129]

Bronchodilator therapy Many patients with bronchiectasis will have significant airflow obstruction, manifested clinically by wheezing and detected by pulmonary function testing. Theophylline, beta$_2$ agonists, and anticholinergic bronchodilators can be used in this setting, although the evidence for their effectiveness is limited.[130-133] Bronchodilator therapy may promote the clearance of airway secretions if the bronchodilating agents are administered before each postural drainage session.

Anti-inflammatory therapy During episodes of exacerbation, oral corticosteroids may help improve the patient's condition, although the benefit of this approach has not been established in randomized trials.[134] High-dose inhaled corticosteroids have been shown to reduce markers of airway inflammation[135] and improve lung function,[136] but the potential role of long-term therapy is uncertain. Leukotriene modifiers have no role in the

treatment of bronchiectasis, except in the setting of allergic bronchopulmonary aspergillosis.[137]

Therapy for hemoptysis Significant hemoptysis can also usually be controlled with appropriate antibiotic therapy. Massive hemoptysis (> 200 ml of blood over a 24-hour period) that occurs as a complication of bronchiectasis was traditionally managed with surgical resection of the involved lung. Now, however, massive hemoptysis caused by bronchiectasis is often effectively treated with bronchial arterial embolization, an invasive radiologic procedure involving catheterization of the bronchial arteries. The dilated bronchial arteries that perfuse the airways in bronchiectasis are particularly suited for the application of this technique. The procedure requires a skilled angiographer.

Surgery In the modern antibiotic era, the role of surgery in the management of bronchiectasis has been declining.[138] In patients with widespread bilateral disease, diseased lung tissue is better able to support gas exchange than no lung tissue at all. In patients with only limited localized disease, symptoms can usually be well controlled with the measures described above. In addition, experience indicates that after lobar resections for localized bronchiectasis have been performed, clinically evident recurrences of the disease are common in parts of the lung that had previously been thought to be uninvolved. In the rare instance in which severe symptoms or recurrent complications in a young patient lead to consideration of resection, the localized nature of the bronchiectasis must first be demonstrated radiographically. If there is bronchiectasis distal to an obstructing bronchial lesion, surgery is indicated to remove the obstruction along with the diseased lung tissue.

CLINICAL VARIANTS OF BRONCHIECTASIS

Cystic Fibrosis

Although cystic fibrosis is an inherited disease that usually manifests itself in early childhood, a discussion of the condition in the context of general adult medicine is worthwhile for two reasons. First, increasing numbers of children with cystic fibrosis are now surviving into young adulthood: the median survival in the United States is 32 years.[139] Second, some patients have a variant form of the disease in which symptoms first appear during adolescence or adulthood.

Pathogenesis The genetic defects responsible for cystic fibrosis have been identified.[139] The cystic fibrosis locus is on the long arm of chromosome 7; it codes a polypeptide comprising 1,480 amino acids that has been named the cystic fibrosis transmembrane regulator (CFTR).[139] In 70% of patients with cystic fibrosis, the 508th amino acid of this sequence is missing (ΔF508 mutation). The abnormal protein derived from the altered sequence is not glycosylated; it is retained in the endoplasmic reticulum and is not transferred to the cell membrane. The result is a defective membrane with decreased apical chloride conductance and increased sodium absorption.[140] Excessive dehydration of respiratory secretions may alter the character of the sol phase, in which the cilia normally beat, making it thicker and more viscous. Patients who are homozygous for the ΔF508 mutation have a more severe form of the disease than those who are heterozygous.[141] A number of other defects of the cystic fibrosis gene have also been identified, and the resultant defects in the production of CFTR can be grouped into five classes [*see Figure 9*]. Because these defects cause the CFTR to function differently, phenotypic severity differs among the classes.[142] Several of these defects are associated with mild lung disease and even normal sweat chloride concentrations.[143] As a result, patients may present at a later age, and diagnosis may be difficult. In addition, polymorphisms of other genes involved in the immune response may alter the phenotypic severity.[144]

It is likely that impaired tracheobronchial clearance of the abnormal secretions leads to widespread mucous plugging of airways, resulting in secondary bacterial infection, persistent inflammation, and consequent generalized bronchiectasis.[145] The bacterial flora in the airways are highly stereotyped: early in the course of the disease, *S. aureus* is found in the sputum; subsequently, mucoid strains of *P. aeruginosa* are isolated (mucoid in this context refers to a slimy substance secreted by the colony of organisms growing on a culture plate). Despite the presence of these highly virulent pathogens in the lower respiratory tract, infection remains confined to the airways. Although lung abscess and empyema are common complications of *Staphylococcus* or *Pseudomonas* pneumonia, they very rarely develop in patients with cystic fibrosis.

Diagnosis CAO is present in virtually all adult patients with cystic fibrosis and follows a relentlessly progressive course. Thus, cough, chronic purulent sputum production, and exertional dyspnea are cardinal symptoms of cystic fibrosis. Increased airway reactivity is found in approximately 20% to 25% of patients with this disease; in this subgroup, episodic wheezing may be a prominent manifestation, leading to a misdiagnosis of asthma.[146] Nasal polyposis and chronic sinusitis are common upper respiratory tract findings in patients with cystic fibrosis and may be mistaken for signs of allergic disease. Even findings consistent with allergic bronchopulmonary aspergillosis are observed in as many as 9% of patients.[145] A small number of patients become colonized, although they are rarely infected, with atypical mycobacteria.[145,147] Two important complications of lower respiratory tract disease in patients with cystic fibrosis are hemoptysis and pneumothorax. Minor hemoptysis occurs intermittently in a majority of patients. In approximately 7% of adult patients, rupture of dilated bronchial arteries leads to massive, potentially fatal hemoptysis. Pneumothoraces may complicate the course of advanced obstructive lung disease in approximately one sixth of adult patients and are frequently recurrent.[148] Hypoxemia and hypercapnia, occurring initially during exercise and sleep,[149] are prominent complications and can be associated with the development of pulmonary hypertension.[150] Osteoporosis producing significant kyphosis is frequent in adult patients with cystic fibrosis.[151]

The chest radiograph may strongly suggest the diagnosis of cystic fibrosis. The generalized bronchiectasis manifests itself as a diffuse increase in interstitial markings, and discrete bronchiectatic cysts are often visible; typically, involvement of the upper lobes predominates. The obstructive aspect of the disease is reflected in the typical finding of pulmonary hyperinflation. This combination of diffusely increased markings with cystic spaces, upper lobe predominance, and hyperinflation is highly characteristic of cystic fibrosis; rare alternative radiographic diagnoses include eosinophilic granuloma and lymphangiomyomatosis [*see 14:V Chronic Diffuse Infiltrative Lung Diseases*]. In the late stages of the disease, cardiomegaly and signs of pulmonary arterial hypertension appear on the chest radiograph as cor pulmonale develops.

Extrapulmonary manifestations may also suggest the diagnosis of cystic fibrosis. Prominent among these findings are pancreatic insufficiency with consequent steatorrhea, recurrent partial intestinal obstruction caused by abnormal fecal accumulation (so-called meconium ileus equivalent), heat prostration, hepatic cirrhosis, and aspermia in males.

The diagnosis of cystic fibrosis should therefore be suspected in the adolescent or young adult who has widespread bronchiectasis and *Staphylococcus* or *Pseudomonas* infection of the airways. The diagnosis should also be considered in the young patient with so-called refractory asthma, especially if the asthma symptoms are accompanied by clubbing of the digits, chronic sputum purulence, a persistently abnormal chest radiograph, or symptoms of pancreatic insufficiency. The diagnosis can be established by a finding of abnormal results on a sweat test performed in a qualified laboratory using pilocarpine iontophoresis.[152] In persons younger than 20 years, a sweat chloride level exceeding 60 mEq/L confirms the diagnosis; a value exceeding 80 mEq/L is required for diagnosis in persons 20 years of age or older. The diagnosis can be confirmed by genotyping for the most common CFTR mutations. Genotyping should also be used when the sweat chloride tests results are equivocal or normal and cystic fibrosis is strongly suspected.

With the identification of the gene for cystic fibrosis, genetic screening has become available. A National Institutes of Health panel suggested that genetic testing for cystic fibrosis be offered to adults with a positive family history of the disease, to partners of people with the disease, to couples currently planning a pregnancy, and to couples seeking prenatal care, but not to the general population or newborns.[153]

Treatment Treatment of the pulmonary aspects of cystic fibrosis is similar to that of bronchiectasis [*see* Bronchiectasis, Treatment, *above*] and includes management of infections and the use of respiratory therapy modalities that are designed to mobilize secretions, including regular percussion and postural drainage, and to reduce airway obstruction.[139,145,154] A pneumatic bronchial drainage vest or a flutter device makes it easier to vibrate the chest so as to enhance the removal of thick secretions.[155,156] No randomized, controlled trials have established the efficacy of any airway clearance regimen in cystic fibrosis, however.[157] Aerosolized antibiotics such as tobramycin may have a role in reducing the burden of infection in those who have become chronically infected with *P. aeruginosa*.[145,158] Treatment with intravenous antibiotics is usually required for episodes of symptomatic infection with *P. aeruginosa*[145,159] or other organisms. Chronic treatment with macrolide antibiotics may have beneficial effects related to mechanisms other than antibacterial activity—namely, reduction in biofilm formation and anti-inflammatory properties.[160] Because the viscosity of the mucus in cystic fibrosis is partially caused by DNA released from cells, recombinant human DNase administered by inhalation is effective.[161] In patients with reversible airflow obstruction, treatment with bronchodilators (e.g., beta agonists), anticholinergics, and theophylline and with low-dose alternate-day oral or daily inhaled corticosteroids may be of benefit.[162-164] Strategies to reduce airway inflammation and to reduce the burden of neutrophil proteases are also being evaluated.[165,166] Attention to nutrition, physical conditioning, and emotional health must be part of an effective care plan. Bronchial artery embolization is useful in patients with significant hemoptysis.[167] Mechanical ventilatory support at night using noninvasive techniques may be useful in patients with chronic respiratory failure.[168] Lung transplantation is now being performed with good results in cystic fibrosis patients whose FEV_1 is less than 30% of predicted value.[169,170]

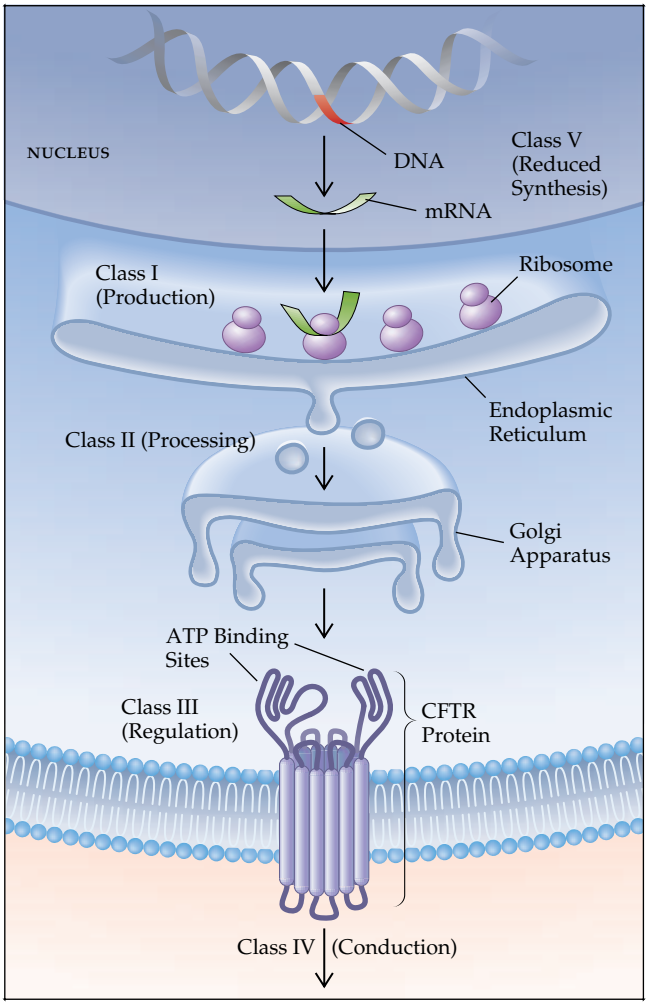

Figure 9 **Categories of cystic fibrosis transmembrane conductance regulator (CFTR) mutations. Cystic fibrosis can be produced by abnormalities at several points in the pathway from gene to functional protein on the cell surface. Class I mutants are associated with decreased transcription of the DNA or translation of the RNA. Class II mutants are attributable to abnormalities in processing of the protein in the endoplasmic reticulum, resulting in the degradation of the protein. Class III mutants are associated with abnormal regulation of the protein. Class IV mutants are associated with abnormal function of the CFTR protein on the cell surface. Class V mutants are associated with decreased synthesis of the CFTR protein. Some mutants (e.g., ΔF508, class II and class III) can be associated with more than one defect.**

The discovery of a specific genetic defect raises the possibility of more specific and perhaps more effective therapy. Therapy could be either pharmacologic (aimed at altering transport through involved or uninvolved ion channels) or genetic (aimed at replenishing the CFTR). In pilot studies, inhalation of amiloride, an epithelial sodium channel blocker, led to objective improvement in sputum character. Other sodium channel blockers that are more potent and longer-acting may be available in the future. Triphosphate nucleotides (adenosine triphosphate and uridine triphosphate) have been found to be effective chloride secretagogues in vivo but have not been tested in long-

term therapy.[171] Another approach is to rescue the mutant CFTR protein from the endoplasmic reticulum and improve the function of the abnormal channel when it is delivered to the plasma membrane.[172] Strategies aimed at correcting the genetic defect are advancing, albeit slowly.[108] An altered adenovirus (incapable of replication) has been used to introduce the cystic fibrosis gene into patients, and phase II trials of this therapy are under way.[108] Several other approaches are being taken and may be successful in the near future.[173]

Primary Ciliary Dyskinesia

In 1933, Dr. Manes Kartagener identified a group of patients with bronchiectasis who also suffered from chronic sinusitis and situs inversus. This triad of findings came to be known as Kartagener syndrome. Approximately 40 years later, it was recognized that male infertility was associated with this syndrome: men with Kartagener syndrome were found to have live sperm with absent or ineffective motility. Sperm tails and the cilia of respiratory tract epithelial cells share an ultrastructure, and in 1975, it was recognized that an inherited abnormality in that ultrastructure (i.e., an absence of the adenosine triphosphatase [ATPase]–containing dynein arms of the outer microtubular doublets) led to nonfunctioning respiratory tract cilia and immotile spermatozoa[174] [*see Figure 10*].

The consequences of congenital nonfunctioning cilia of the upper and lower respiratory tracts are chronic sinusitis, secretory otitis media, and daily productive cough dating from birth or early childhood; bronchiectasis develops during childhood in the majority of patients. With respect to situs inversus, it is speculated that the normal asymmetrical positioning of body organs is dependent on normal functioning of cilia on embryonic epithelium. In the absence of normal ciliary function, placement of organs to either the left or the right is random, and as expected, about one half of patients with congenitally nonfunctioning cilia manifest situs inversus. Thus, the term immotile cilia syndrome was coined to include all patients with chronic sinusitis and bronchiectasis resulting from ultrastructural abnormalities of cilia. Fertility is reduced not only in men but also in women with this syndrome, because of deficient cilia in the oviducts and fimbriae.

Primary ciliary dyskinesia highlights the importance of normal ciliary function in clearing airway mucus, as well as the importance of other mechanisms, especially cough, in defending against disease. Ciliary dysfunction in the lower respiratory tract leads to the retention of secretions, bacterial superinfection, and bronchiectasis. Other protective mechanisms appear to prevent more serious sequelae, including acute pneumonias and progressive airflow obstruction.

Pathogenesis A variety of abnormalities in addition to absent or deficient dynein arms may impair the structure and function of cilia and sperm tails.[175] Many of these abnormalities involve derangement of the normal configuration of microtubules. In each case, in vitro microscopic studies of ciliary motility have demonstrated a pattern of decreased, uncoordinated, or ineffective beating. Because at least some movement of the cilia is observed, the term primary ciliary dyskinesia has been proposed as a more accurate description of this condition than the term immotile cilia syndrome. Inheritance is thought to be autosomal recessive. Any given ultrastructural abnormality is found consistently in the cilia of the upper and lower respiratory tract (as well as in sperm tails in men), and all affected members of the same family have the same defect. The clinical syndrome that results is a common expression of impaired ciliary motility independent of the specific ultrastructural defect.

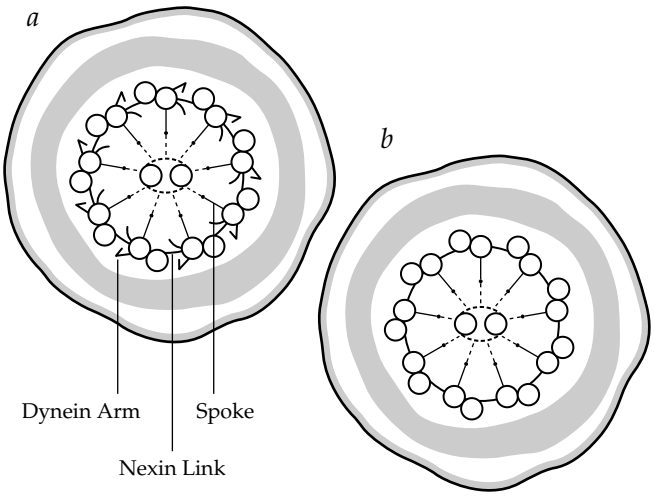

Figure 10 **A cross section (*a*) of the tail of a normal sperm reveals dynein arms. In a cross section of the tail of a sperm from a patient with Kartagener syndrome (*b*), dynein arms are missing; such a cell would be immotile. Similar changes have been noted in the cilia in the respiratory tract and paranasal sinuses in these patients.**

Diagnosis The diagnosis of primary ciliary dyskinesia can be made clinically in all patients with Kartagener syndrome.[176] A clinical diagnosis can also be made on the basis of the following criteria: a history of chronic sinusitis; a productive cough since childhood; and either the presence of live but immotile spermatozoa or a family history in which the patient has a sibling with Kartagener syndrome. In patients who have had chronic sinusitis and productive cough since childhood but who meet neither of the two additional criteria, three types of specialized laboratory studies can be employed to support the diagnosis of primary ciliary dyskinesia: (1) electron microscopic examination of sperm tails or of cilia from bronchial or nasal biopsy specimens, (2) in vitro light microscopic examination of the motility of cilia, and (3) measurement of mucociliary clearance in the nose or the tracheobronchial tree. An example of the last technique listed is inhalation of an aerosol of radiolabeled particles followed by external scanning over the thorax for at least 2 hours. Normal values for the ciliary structural and functional studies have been established.[177] These studies should be performed during periods of clinical stability, because acute inflammation can reversibly alter ciliary function.[178]

Differential diagnosis The respiratory disease associated with primary ciliary dyskinesia may be contrasted with that associated with cystic fibrosis. In cystic fibrosis, in the absence of acute infectious exacerbations, ciliary function is normal and mucociliary transport only modestly decreased. In primary ciliary dyskinesia, however, mucociliary transport along nasal or tracheobronchial mucosa is virtually absent. Nevertheless, disease of the lower respiratory tract is usually far milder in patients with primary ciliary dyskinesia than in those with cystic fibrosis. Bronchiectasis in primary ciliary dyskinesia usually involves the lower or the middle lung zones and is less widespread than in cystic fibrosis. Also, in primary ciliary dyskinesia,

bacterial infection of the airways is more commonly caused by *Haemophilus, Neisseria,* or *Streptococcus* organisms than by *Staphylococcus* or *Pseudomonas* organisms, and acute pneumonias are relatively infrequent. Finally, airflow obstruction is usually mild in primary ciliary dyskinesia, and progression to cor pulmonale is uncommon. Patients with primary ciliary dyskinesia usually can remain fully active and may survive to old age.

Treatment Treatment with postural drainage and antibiotics for infections aids in maintaining stable lung function [*see* Bronchiectasis, Treatment, *above*].[179]

BRONCHIOLITIS

Disorders of the bronchioles can be divided into three categories: (1) primary bronchiolar disorders, which are covered in this section; (2) parenchymal disorders with prominent bronchiolar involvement, and (3) bronchiolar involvement in large airway diseases.[180] Parenchymal disorders with prominent bronchiolar involvement such as hypersensitivy pneumonitis, respiratory bronchiolitis/interstitial lung disease, and bronchiolitis obliterans organizing pneumonia are covered in another chapter [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. The larger airway diseases associated with bronchiolar involvement are COPD, bronchiectasis [*see* Bronchiectasis, *above*], and asthma [*see 14:II Asthma*].

The primary bronchiolar disorders can be further divided into five types: acute bronchiolitis, constrictive bronchiolitis (obliterative bronchiolitis or bronchiolitis obliterans), diffuse panbronchiolitis, mineral dust airway disease, and follicular bronchiolitis.[180]

Etiology

Acute bronchiolitis is mostly a disease of childhood.[180] One form of the disease, an acute bronchiolitis that occurs in infants, is often the result of infection with respiratory syncytial virus. Adenovirus infection may cause a more serious necrotizing form of bronchiolitis in children; in some of these children, the healing process is characterized by exuberant inflammation and fibrosis that obliterate the bronchiolar lumen. If only one lung is affected, the obstructive disease may appear on radiography as a unilateral hyperlucency of the lung field because of distal alveolar overdistention (i.e., air trapping) and decreased vascularity in the affected lung. This syndrome of a unilateral hyperlucent lung in a patient with bronchiolitis bears two eponyms: Swyer-James syndrome, named for the two physicians who first described the disease in children, and Macleod syndrome, named after the physician who reported the first adult case.

Constrictive bronchiolitis is a rare cause of CAO in adults, occurring after viral pneumonia (e.g., pneumonia caused by measles, influenza, or adenovirus infection), after inhalation of toxic gases (e.g., chlorine or nitrogen dioxide), and as an idiopathic phenomenon.[180] Constrictive bronchiolitis has been documented as a complication of collagen vascular diseases, particularly rheumatoid arthritis, and as a sequela of stem cell transplantation in the setting of graft versus host disease. A possible association with the drug penicillamine has also been suggested.[180]

Diffuse panbronchiolitis has been seen primarily in Asia, particularly in Japanese adults. The cause is unknown, although a genetic predisposition is suspected.[180]

Mineral dust airway disease is associated with exposure to a number of inorganic dusts, including asbestos, iron and aluminum oxide, talc, mica, silica, silicate, and coal.[180]

Follicular bronchiolitis can be idiopathic; it can also be associated with collagen vascular diseases (particularly rheumatoid arthritis) or immunodeficiency syndromes such as HIV infection.[180]

Diagnosis

Clinical manifestations In patients with an acute infection or who have had a toxic exposure, fever, nonproductive cough, and dyspnea may develop 2 to 4 weeks after the initial event, often after an asymptomatic interval. In other patients, the gradual onset of dyspnea and dry cough are the presenting symptoms. Chest examination typically reveals high-pitched inspiratory crackles, wheezing, and a highly characteristic midinspiratory squeak.

Pulmonary function testing shows marked airflow obstruction and little or no reversibility of obstruction in response to bronchodilators.

Chest radiograph The characteristic chest radiographic finding is a pattern of diffuse, nodular densities, sometimes with a fine nodularity mimicking miliary tuberculosis. Although these findings are typical of bronchiolitis, a spectrum of presentations is possible. Radiographically, hyperinflation and vascular attenuation mimicking emphysema may be the only findings, or there may be scattered nonhomogeneous patchy infiltrates. High-resolution CT scanning of the chest, particularly if performed on inspiration and expiration, may show nodular lesions, regions of ground-glass attenuation, bronchocentric infiltrates, and small regions of lucency, denoting obstruction and air trapping at a small airway level.[181]

Treatment

Treatment of constrictive bronchiolitis is usually ineffective, although corticosteroids are often tried. Initially, high-dose corticosteroids (e.g., prednisone given in an oral dosage of 1 mg/kg/day) are used in an attempt to suppress the inflammatory reaction within and around the bronchioles. Although corticosteroids often benefit patients with idiopathic bronchiolitis obliterans organizing pneumonia, they are rarely effective against other forms of bronchiolitis.

Prognosis

In some patients with bronchiolitis, the disease progresses to severe airflow obstruction, respiratory failure, and death. In others, the inflammation remits, and chest x-ray and pulmonary function test results return to normal.

Gerald W. Staton, Jr., M.D., F.A.C.P., has received grants for educational activities from GlaxoSmithKline and Boeringer Ingleheim and serves as an advisor to GlaxoSmithKline.

Inhaled steroids have not been approved by the FDA for use in COPD.

IV FOCAL AND MULTIFOCAL LUNG DISEASE

Gerald W. Staton, Jr., m.d., f.a.c.p.

Chest physicians, when consulted, most often begin their consultation by examining the results of imaging studies—standard posteroanterior and lateral chest radiographs, computed tomography scans of the chest, or both. In doing so, they assess the differential diagnostic probabilities and possibilities on the basis of the radiographic patterns. This approach serves to focus their efforts on history taking and the physical examination, and it facilitates their defining of proper diagnostic measures, which in turn guide therapeutic and management advice. In this chapter, the approach taken by chest physicians is used to discuss and categorize a wide range of lung diseases.

Assessment of Chest Radiographs

Focal and multifocal lung diseases are classified into seven categories on the basis of chest radiography and CT: (1) focal pulmonary infiltrates, (2) multifocal pulmonary infiltrates, (3) true segmental infiltrates, (4) cavitary infiltrates, (5) single small nodules, (6) large masses, and (7) multiple nodules. These radiographic patterns may be caused by infectious diseases; neoplastic diseases; or noninfectious, nonneoplastic disorders. The differential diagnoses for the seven categories are dissimilar but by no means mutually exclusive. Many diseases that usually cause focal infiltrates can produce multifocal infiltrates [*see* Focal Pulmonary Infiltrates, *below*]. Other disorders nearly always present as multiple infiltrates, and the pathology only rarely localizes to one area [*see* Multifocal Pulmonary Infiltrates, *below*]. Infiltrates that conform perfectly to the segmental anatomy of the lung usually result from an abnormality of the bronchus or pulmonary artery leading to the infiltrate [*see* True Segmental Infiltrates, *below*]. Cavitary infiltrates, single small nodules, large masses, and multiple nodules have distinct differential diagnoses.

Diagnosis of a focal or multifocal lung disorder starts with the abnormal chest radiograph or with abnormal findings on chest CT. In many instances, the chest CT scan may be abnormal when the chest radiograph is normal or shows very indistinct changes. In each category of radiographic pattern, the clinical features of the illness, the presence or absence of associated pleural or mediastinal abnormalities, and ancillary laboratory tests all serve to narrow the differential diagnosis. In some disorders, the combined radiographic, clinical, and laboratory presentation is virtually specific. In other disorders, cytologic, histopathologic, or microbiologic information is necessary to make a specific diagnosis.

In each of the seven categories, infectious diseases and neoplastic diseases are more common than noninfectious, nonneoplastic disorders. Many of the infectious and neoplastic entities, however, are discussed in great detail in other chapters; this chapter focuses on the noninfectious, nonneoplastic disorders that are relatively common.

Focal Pulmonary Infiltrates

When a focal infiltrate is dense, it is likely that pus, blood, water, or tissue is filling alveolar spaces. A focal infiltrate that is patchy and less dense suggests a less advanced stage of disease process. Many conditions can cause a focal infiltrate that is visible on the chest radiograph [*see Table 1*].

Infectious Diseases

Bacterial Pneumonia

The most common cause of a focal infiltrate is bacterial pneumonia.[1] Five clinical features in combination strongly suggest the diagnosis: (1) acute onset, (2) a new or increasing infiltrate on the chest radiograph [*see Figure 1a*], (3) fever, (4) purulent sputum, and (5) a white blood cell count that is either high, low, or shifted to the left. Absence of one or more of these features does not eliminate the possibility of bacterial pneumonia but does increase the probability of an alternative diagnosis.

Because many different types of bacteria can cause pneumonia, a precise etiologic diagnosis cannot be made either on clinical grounds or by a chest radiograph. Positive blood cultures have near-perfect specificity but low sensitivity, whereas positive sputum cultures can only suggest a specific etiology. *Streptococcus pneumoniae* is the most common cause of bacterial pneumonia, accounting for perhaps 85% of all cases in otherwise healthy young adults. However, many other bacteria also cause pneumonia, with a higher incidence in patients with chronic medical conditions and advanced age. These include *Haemophilus influenzae, Klebsiella pneumoniae, Staphylococcus aureus,* and *Legionella pneumophila* [*see 7:XX Pneumonia and Other Pulmonary Infections*]. An even wider range of pathogens cause pneumonia in patients in intensive care units. These include virulent gram-negative bacilli with high potential for antibiotic resistance, such as *Pseudomonas aeruginosa* and *Enterobacter, Serratia,* and *Proteus* species. Other infectious causes of focal infiltrates include *Mycoplasma pneumoniae, Chlamydophila pneumoniae,* tuberculosis (especially in patients with advanced-stage HIV infection and other immunosuppressed patients), viruses, rickettsiae, fungi, and parasites.

Neoplastic Diseases

Alveolar cell carcinoma and lymphoma commonly present as focal pulmonary infiltrates, though they also cause multifocal in-

Table 1 Major Causes of Focal Pulmonary Infiltrates

Cause	*Examples*
Infectious	Bacterial pneumonia Tuberculosis
Neoplastic	Primary lung cancer Alveolar cell carcinoma Lymphoma
Noninfectious, nonneoplastic	Radiation pneumonitis Lipoid pneumonia Lung contusion Pulmonary embolism Lobe torsion

Figure 1 **(*a*) This chest radiograph demonstrates a focal left lower lobe infiltrate caused by bacteremic pneumococcal pneumonia in a 22-year-old man. (*b*) A focal right upper lobe infiltrate caused by alveolar cell carcinoma is revealed in this chest radiograph of a 71-year-old woman. (*c*) The focal right lower lobe infiltrate in this chest radiograph is the result of lipoid pneumonia in a 68-year-old woman.**

filtrates. Bronchogenic lung cancer usually produces a nodule or a mass but can cause a focal dense infiltrate. The absence of fever and purulent secretions (unless there is a postobstructive pneumonia) and the longer duration of symptoms suggest a noninfectious cause.

Alveolar Cell Carcinoma

Alveolar cell carcinoma may result in one or more areas of airspace opacity, presenting as an area of focal indistinct infiltrate or, sometimes, mimicking lobar pneumonia [*see Figure 1b*]. Chest CT often shows areas of "ground-glass opacity"; less commonly, the infiltrates are consolidative.[2] Patients cough and produce mucoid sputum; a few patients produce large volumes of sputum (bronchorrhea) that in rare instances has a salty taste. Weight loss and malaise are common. Fever and chills are absent. Metastases are less common than with other primary lung neoplasms, and the course of the illness is longer. Alveolar cell carcinoma is not related to smoking. Diagnostic tests should begin with sputum cytology, followed by fiberoptic bronchoscopy with bronchoalveolar lavage and transbronchial biopsy or, if needed, open lung biopsy by a traditional or a video-assisted thoracoscopic approach. Localized disease can sometimes be resected; radiation therapy and chemotherapy have no important role.

Lymphoma

Lymphoma can also produce a focal, dense consolidation. With Hodgkin disease, there may be multiple contiguous areas of tumor involvement that grow and merge, resulting in a dense infiltrate with irregular borders. Hilar and mediastinal adenopathy are nearly always present. Pleural effusions occur in as many as 30% of patients. Diagnostic strategies include fiberoptic bronchoscopy, aspiration biopsy of the infiltrate or of the mediastinal nodes (using needles that obtain a tissue core), mediastinoscopy, and pleural biopsy. Biopsy of associated cervical nodes or of the bone marrow is helpful in some cases. In non-Hodgkin lymphoma, the chest radiograph may show a dense infiltrate with regular margins, similar to the infiltrate seen in bacterial pneumonia or alveolar cell carcinoma. Mediastinal and hilar node involvement may be absent. Pleural effusion occurs in one third of patients [*see 12:XI Lymphomas*].

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Pulmonary embolism can cause a focal infiltrate or focal atelectasis; in other cases, the chest radiograph is normal or shows multifocal infiltrates or multiple nodules.[3] Pulmonary infarcts are always based at a visceral pleural surface, including fissures [*see 1:XVIII Venous Thromboembolism*]. Several other noninfectious, nonneoplastic disorders typically present as a focal pulmonary infiltrate. In making a diagnosis, the clinical history is very important because these disorders occur in specific clinical settings.

Radiation Pneumonitis

Radiation pneumonitis follows pulmonary irradiation after a lag time that is somewhat dose dependent.[4] Symptoms include nonproductive cough, dyspnea, and fever. These symptoms develop approximately 8 weeks after completion of a course of radiation therapy consisting of 4,000 cGy; they develop 1 week earlier for each additional 1,000 cGy administered.[1] Chemotherapeutic agents such as dactinomycin, doxorubicin, bleomycin, and busulfan can potentiate the effects of radiation. Onset is usually subacute. There may be rales and signs of consolidation. Hyperpigmentation of the skin overlying the irradiated lung is common but does not correlate with the severity of lung injury. Laboratory findings include leukocytosis and hypoxemia. Bronchoalveolar lavage may rule out tumor and infection—a determination that is most important in making a differential diagno-

Table 2 Major Causes of Multifocal Pulmonary Infiltrates

Cause	*Examples*
Infectious	Bacterial pneumonia *Pneumocystis jiroveci* pneumonia Influenza Tuberculosis Endemic fungal pneumonias Invasive aspergillosis
Neoplastic	Alveolar cell carcinoma Lymphoma
Noninfectious, nonneoplastic	Drug reactions Simple eosinophilic pneumonia Chronic eosinophilic pneumonia Bronchiolitis obliterans organizing pneumonia Allergic granulomatosis and angiitis Sarcoidosis

sis—and may demonstrate dysplastic type II cells, the presence of which suggests radiation injury. Lavage also reveals excess lymphocytes in both involved and uninvolved areas. Drug-induced lung injury causes similar cytopathic changes in type II cells, but usually, neutrophilic inflammation is also present.

The chest radiograph shows an infiltrate of variable density. A highly characteristic infiltrate has sharp edges and conforms exactly to the radiation port. Occasionally, high-resolution CT shows regions of air-space consolidation that are not visible on routine chest radiography. Many patients gradually improve over a few weeks. When the disease is severe, glucocorticoid therapy is often used, with uncertain benefit. Because of fever and fear of superinfection, antibacterial therapy is often given, also with uncertain benefit. Typically, the involved area of the lung scars and contracts with time, and the chest radiograph shows progressive volume loss.

Lipoid Pneumonia

Lipoid pneumonia is a noninfectious, inflammatory lung disorder caused by the aspiration of mineral oil or other oily substances. It is most common in elderly patients and others with impaired swallowing. Whether or not swallowing is impaired, lipoid pneumonia can result from the use of petroleum jelly or other oily substances applied to the lips or nose to relieve chronic dryness or mineral oil taken by mouth for relief of constipation. The most common symptom is a chronic cough, which may be caused by coexisting lung disease rather than lipoid pneumonia; fever is uncommon. Often, the disease is discovered on a routine chest radiograph that shows a focal, dense infiltrate, usually in a lower lobe or in the right middle lobe [*see Figure 1c*].[5] The radiographic appearance of such an infiltrate in a relatively asymptomatic patient suggests chronic pneumonia or lung cancer. CT scanning may show an extremely low density infiltrate produced by accumulated lipid; the density typically ranges from –60 to –150 Hounsfield units (water is 0). In contrast, the density of lung cancers usually ranges from +60 to +150 Hounsfield units. Lipid-laden macrophages can be demonstrated with the oil red O stain, which colors lipid droplets bright red. The stain can be applied to bronchoalveolar lavage specimens or transthoracic aspirates. A positive test supports the diagnosis, but some caution is necessary. Endogenous lipoid pneumonia may occur distal to an obstructed bronchus, and in such cases, the lipid is derived from the breakdown of cell membranes. Thus, bronchoscopy is still needed to rule out an obstructed bronchus even after demonstration of lipid-laden macrophages by needle aspiration. A variety of other lung disorders, such as pulmonary hemorrhage and primary and metastatic cancers, can also be associated with lipid-laden macrophages. To establish the diagnosis of exogenous lipoid pneumonia, it is necessary to analyze carefully all the clinical, cytopathologic, and radiographic findings, including the results of CT scanning. Many cases are diagnosed only after thoracotomy for resection of a presumed malignancy. The only specific therapy is avoidance of exposure to mineral oil and other lipid-containing agents. Lipoid pneumonia usually improves slowly after exposure to the agent is eliminated, though complete clearing of the infiltrate does not always occur.

Lung Contusion

Lung contusion is an important cause of focal, usually dense infiltrate. It results from blunt chest trauma, most often from falls or motor vehicle accidents. Usually within hours after trauma, an infiltrate develops deep beneath the impact point, representing blood and edema in the lung. Associated injuries, such as rib fractures and traumatic pneumothorax, may be present. Focal shunting through the area can cause refractory hypoxemia. If the injury is severe enough, the entire area may become necrotic and form a large cavity with irregular inner margins.

Lobe Torsion

Torsion of a lobe of the lung is rare and usually occurs postoperatively, particularly after resection of the left upper lobe. The vascular pedicle of the remaining left lower lobe twists and is compromised, and the lobe increases in density as it fills with blood and edema fluid. The diagnosis is often made by radiography but can be difficult. The differential diagnosis includes unilateral lung infection, edema, and hemorrhage. Treatment involves surgical relief of the torsion in early cases or resection of the lobe if it is no longer viable.

Multifocal Pulmonary Infiltrates

Most disorders that cause single infiltrates can also cause multiple infiltrates [*see Table 2*]. Pneumococcal pneumonia and other bacterial pneumonias are occasionally multifocal [*see Figure 2a*]; viral pneumonias are commonly multifocal or diffuse.[1] Clinical features of pneumonia with multiple infiltrates are similar to clin-

Figure 2 **(*a*) Bacteremic pneumococcal pneumonia caused the extensive bilateral multifocal infiltrates revealed in this chest radiograph of a 27-year-old man. (*b*) Alveolar sarcoidosis is the cause of the extensive bilateral multifocal infiltrates shown in this chest radiograph. The patient is a 22-year-old woman. (*c*) Alveolar cell carcinoma often presents as multifocal infiltrates, as seen in this chest radiograph of a 65-year-old man.**

ical features of pneumonia with one infiltrate, except that severity increases with extent of disease. Pulmonary thromboemboli can also produce multifocal infiltrates; a normal chest radiograph, unilateral or bilateral pleural effusions, and focal infiltrate or atelectasis are other possible radiographic patterns for pulmonary thromboemboli.[3] Septic pulmonary emboli often cause multiple infiltrates [*see* Multiple Nodules and Masses, *below*]. Finally, sarcoidosis is perhaps the most protean of all the noninfectious and nonmalignant lung disorders [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. A diffuse infiltrate with or without hilar adenopathy is the usual presentation [*see Figure 2b*].

INFECTIOUS DISEASES

Pneumocystis jiroveci *Pneumonia*

Pneumocystis jiroveci (formerly *P. carinii*) is an organism that was previously thought to be a protozoan but, on the basis of genetic studies, is currently considered to be a fungus. *Pneumocystis* pneumonia (PCP) typically occurs in patients who are immunocompromised, most commonly those with HIV/AIDS. Radiographically, PCP presents as multifocal infiltrates, usually hazy opacities in the perihilar regions.[6] These infiltrates can become diffuse and associated with severe respiratory compromise. CT shows ground-glass attenuation that may be diffuse or in a mosaic pattern. Less commonly, PCP presents as solitary or multiple, solid or cavitary opacities. Cysts, often associated with pneumothorax, can also be seen.

Tuberculosis

Primary tuberculosis is often focal and often associated with ipsilateral hilar adenopathy, especially in children. Most diagnosed adult cases of tuberculosis, however, result from reactivation of latent infection. Reactivation tuberculosis is often multifocal [*see 7:II Tuberculosis*].[7] Bilateral infiltrates in the upper lung zones are most characteristic. The upper lung zones are favored sites, because a higher ratio of ventilation to perfusion results in higher local oxygen tension, which enhances growth of *Mycobacterium tuberculosis.* The apical and posterior segments of the upper lobes are most commonly involved, followed by the apical-posterior segments of the lower lobes. The lingula, the middle lobe, and the basal segments of the lower lobes can all be involved by bronchogenic spread. Concomitant pleural disease occurs in a minority of patients.

Cavitation is frequent, but even in the absence of cavitation, the diagnosis of tuberculosis should be considered when multifocal infiltrates are present. Atypical radiographic patterns, including isolated lower lobe infiltrates, are particularly common in elderly, debilitated patients. These patterns can complicate and delay diagnosis. Atypical radiographic features, including midlung or lower lung field infiltrates, hilar adenopathy, and absence of cavitation, can be seen in immunocompromised patients, especially in patients with AIDS [*see 7:XXXIII HIV and AIDS*].

Endemic Fungal Pneumonias

Endemic fungal pneumonias are acquired by inhalation of aerosolized particles (usually small respirable spores) rather than by microaspiration of pharyngeal organisms—the mechanism of infection for most pyogenic bacterial pneumonias. Severe cases of endemic fungal pneumonia usually involve multiple areas; blastomycosis and coccidioidomycosis often cause multiple dense alveolar infiltrates [*see 7:XXXVII Mycotic Infections*].

Melioidosis

Melioidosis is an indolent bacterial pneumonia caused by the gram-negative bacillus *Burkholderia pseudomallei*. It is most common in Southeast Asia and may appear in patients months or even years after they have migrated to nonendemic areas. Multifocal infiltrates are characteristic. The clinical illness resembles tuberculosis except that upper lobe predominance is not as striking in melioidosis.

Invasive Aspergillosis

An opportunistic fungal infection that is also acquired by inhalation, invasive aspergillosis occurs in patients who experience a decrease in the number or function of phagocytes.[8] Prolonged neutropenia from cytotoxic chemotherapy for acute leukemia is the most common predisposing factor. High-dose glucocorticoid therapy also predisposes to this infection, as do several immunosuppressive regimens used for solid-organ transplantation and, especially, for bone marrow transplantation. Clinical features include fever, dyspnea, pleuritic chest pain, hemoptysis, and hypoxemia. The chest radiograph shows characteristic multiple dense infiltrates, which may be nondescript, wedge shaped and peripheral, or even nodular. Individual lesions may cavitate, particularly as the number of neutrophils begins to rebound after chemotherapy. During this recovery time, the patient is at the highest risk for major hemoptysis [*see 7:XXXVIII Mycotic Infections in the Compromised Host*]. CT shows a characteristic pattern of nodules surrounded by ground-glass attenuation (halo sign).

Diagnosis is difficult because actual tissue invasion must be determined. However, any positive culture for *Aspergillus* from sputum or bronchoscopic specimens has high predictive value in the patient with profound neutropenia. Such cultures are valuable but less specific in transplant recipients or other moderately immunosuppressed patients and are often not helpful in patients with chronic bronchitis, who are frequently colonized with this organism. Negative cultures never rule out the diagnosis of invasive aspergillosis.

NEOPLASTIC DISEASES

Two neoplasms that present as focal infiltrates [*see* Focal Pulmonary Infiltrates, *above*] also commonly present as multifocal infiltrates: alveolar cell carcinoma[2] [*see Figure 2c*] and Hodgkin disease. Hodgkin disease, however, almost always has associated hilar and mediastinal adenopathy, whereas alveolar cell carcinoma almost never does. Lymphomatoid granulomatosis, an angiocentric T cell lymphoma of variable grade, usually presents as multiple pulmonary nodules [*see* Multiple Nodules and Masses, *below*] but can also present as multifocal pulmonary infiltrates.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Several noninfectious, nonneoplastic pulmonary diseases may produce multiple areas of lung infiltration.

Drug Reactions

Multifocal infiltrates can occur as a manifestation of drug toxicity, especially acute methotrexate, nitrofurantoin-related, and amiodarone-related pulmonary toxicity [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. With amiodarone-related lung disease, the infiltrates may be bilateral and more prominent in upper lung zones. The drug profile must be reviewed carefully in any patient with unexplained multifocal pulmonary infiltrates.

Simple Eosinophilic Pneumonia

Patients with simple eosinophilic pneumonia, often called Löffler syndrome, have nonproductive cough and fever [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. The chest radiograph shows patchy infiltrates, typically in the lower lung fields; the infiltrates resolve within 1 to 2 weeks. The main clue to the diagnosis is an increase in the number of peripheral eosinophils, often to 60% or more of the total white blood cell count. Bronchoalveolar lavage is seldom indicated, because patients are only mildly ill; when lavage is done, it reveals pulmonary eosinophilia. The main causes of this pneumonia are drugs and worms—usually nematodes such as *Ascaris* and *Strongyloides,* which migrate through the lung during one phase of infection [*see 7:XXXV Helminthic Infections*]. Drugs that cause the syndrome include but are not limited to carbamazepine, chlorpromazine, cocaine, imipramine, isoniazid, naproxen, nitrofurantoin, penicillins, sulfonamides, and tetracycline.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia, which is caused by immunologic hyperreactivity to microfilariae, is characterized by dyspnea, wheezing, and coughing, all of which are worse at night, as well as fever, weight loss, and fatigue [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. The chest radiograph reveals interstitial micronodular lesions that may be diffuse or multifocal. Peripheral blood eosinophilia is in excess of 3,000/mm^3; the serum IgE levels are extremely high, and antibodies to microfilariae are present. Two filarial parasites, *Wuchereria bancrofti* and *Brugia malayi,* are causative agents [*see 7:XXXV Helminthic Infections*]. Blood eosinophilia is less prominent in patients with chronic forms of the disease. Patients who have lived in areas where tropical pulmonary eosinophilia is endemic can present with restrictive or obstructive lung disorders that are the residua of episodes of tropical eosinophilia that occurred earlier in life.

Chronic Eosinophilic Pneumonia

Chronic eosinophilic pneumonia is more serious than simple eosinophilic pneumonia[9] [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. It primarily affects women between 20 and 40 years of age; however, it has been reported in patients of both sexes and of all ages. Most patients have moderate to severe illness lasting from 1 month to several months, with fever, night sweats, nonproductive cough, shortness of breath, and weight loss. About one third of patients have a history of asthma, and up to one half have some atopic history, including allergic rhinitis and nasal polyps. About one half of patients have wheezing as part of their clinical presentation, some for the first time. The chest radiograph may show dense peripheral infiltrates that are often referred to as reverse pulmonary edema or the photographic negative of pulmonary edema. When the clinical presentation and chest radiograph are highly typical, the diagnosis can be made clinically. About two thirds of patients have peripheral eosinophilia; a minority have an elevated serum IgE level. Bronchoalveolar lavage shows increased eosinophils and increased lymphocytes. Open lung biopsy, which is seldom required, shows lymphocytes and eosinophils in alveolar walls and spaces, as well as bronchiolitis obliterans in up to one third of specimens.

The etiology of chronic eosinophilic pneumonia is unknown. The disease may represent a hypersensitivity response to unknown antigens or may be an idiopathic immunologic activation.

Acute Eosinophilic Pneumonia

Idiopathic acute eosinophilic pneumonia (AEP) is another syndrome that presents as multifocal infiltrates[10] [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. Blood eosinophilia is usually absent, and the onset is acute, generally within several days. Patients may have a fever and severe hypoxemia and may progress to respiratory failure. There is usually no history of atopy. There are rales on physical examination, but there is rarely any wheezing. The prime diagnostic consideration is severe community-acquired pneumonia. The chest radiograph shows bilateral infiltrates that may progress to diffuse infiltrates. Unlike the case with chronic eosinophilic pneumonia, there is no tendency for peripheral subpleural localization. CT shows multifocal air-space opacities, often with an interstitial component. Increased septal markings (Kerley B lines) are seen in about one third of cases. Diagnosis of AEP is usually made by bronchoalveolar lavage, which shows over 25% eosinophils (mean, 37 ± 2.5). Culture for respiratory pathogens is negative.

The etiology of this immune disorder is unknown. In addition to the increase in pulmonary eosinophils, pathobiologic features include an increase in the number of helper T cells and neutrophils in the lung and elevated concentrations of interleukin-5 (IL-5) in lavage fluid.

Bronchiolitis Obliterans Organizing Pneumonia

Bronchiolitis obliterans alone is a distinct pathologic process in which distal airways are filled with plugs of loose connective tissue containing fibroblasts and inflammatory cells [*see 14:III Chronic Obstructive Diseases of the Lung*]. Clinical manifestations in patients with this pathology include severe airflow obstruction and poor response to bronchodilator therapy; chest radiographs show no infiltrates. Some cases are idiopathic, but others are associated with specific immunologic abnormalities, such as rheumatoid arthritis, graft versus host disease (GVHD) in bone marrow transplant recipients, and chronic rejection in lung transplant recipients.

Bronchiolitis obliterans organizing pneumonia (BOOP) is a pathologic entity that is also (and perhaps more descriptively) called cryptogenic organizing pneumonia [*see 14:V Chronic Diffuse Infiltrative Lung Disease*].[11] The lung parenchyma is involved, and alveolar spaces are filled with loose connective tissue that contains fibroblasts and mixed inflammatory cells. The process also involves contiguous distal airways, so the characteristic plugs of bronchiolitis obliterans are also seen. The chest radiograph often shows multiple dense peripheral infiltrates.[9] A less common pattern of idiopathic BOOP is a dense lobar infiltrate, which resembles bacterial pneumonia in radiographic appearance. Because of the long course of the illness, clinical suspicion often focuses on chronic pulmonary infections, such as blastomycosis or even alveolar cell carcinoma. The most common features on CT scanning, which shows the extent of disease better than a chest radiograph, include patchy bilateral air-space consolidation, small nodular opacities (sometimes with a reversed halo sign), and bronchial wall thickening and dilatation. In half of cases, these abnormalities are mainly subpleural; in the other half of cases, they are distributed throughout the affected lobes.[12]

The diagnosis of BOOP can often be made on transbronchial lung biopsy. In cases in which an open lung biopsy is needed, the video-assisted thoracoscopic technique has become the established procedure.

Allergic Granulomatosis and Angiitis

Also known as Churg-Strauss syndrome, allergic granulomatosis and angiitis is rare [*see 15:VIII Systemic Vasculitis Syndromes*].[13] Almost all patients with allergic granulomatosis and angiitis have a strong history of atopic allergy with preexisting bronchial asthma for an average of 5 to 10 years before diagnosis of the vasculitis. Patients present with fever, shortness of breath, and a variety of complaints related to skin and nerve involvement (e.g., purpura, painful skin nodules, skin infarction, footdrop, wristdrop, or painful neuropathy). Myocardial involvement occurs in a minority of patients but on occasion can dominate the clinical presentation. Wheezing is common. Clinically significant renal involvement is uncommon. In 25% of cases, the chest radiograph shows peripheral infiltrates or nodules that seldom cavitate. Pleural effusion, pericardial effusion, or both may occur with or without infiltrates. Churg-Strauss syndrome, though rare, most often occurs in patients with bronchial asthma. There is an association between Churg-Stauss syndrome and treatment of asthma with leukotriene inhibitors.[14] Onset of the vasculitis usually occurs as glucocorticoids are tapered during leukotriene inhibitor therapy, and it is possible that some of these cases represent occult Churg-Strauss disease that is initially suppressed with glucocorticoids and then flares with glucocorticoid withdrawal. However, at least one case has been reported in a patient with no recent glucocorticoid use.[15]

Other Noninfectious, Nonneoplastic Multifocal Disorders

Other immunologic lung diseases can produce multifocal infiltrates. Wegener granulomatosis is the most common lung vasculitis. The radiographic spectrum of illness includes infiltrates and nodules that are usually multiple and often cavitate [*see* Cystic and Cavitary Infiltrates, *below*].

Collagen vascular disease can be associated with multifocal lung involvement.[16] Pneumonitis associated with systemic lupus erythematosus (SLE) may be diffuse but may also appear as dense lower lobe infiltrates. Other clinical and serodiagnostic features of SLE are present. Systemic sclerosis and mixed connective tissue disease usually present as diffuse interstitial infiltrates, often with basilar predominance [*see 14:V Chronic Diffuse Infiltrative Lung Disease* and *15:IV Systemic Lupus Erythematosus*].

Lung disease associated with rheumatoid arthritis takes many forms, including pulmonary fibrosis, pleural effusions, and necrobiotic pulmonary nodules, the pathologic appearance of which is similar to that of subcutaneous rheumatoid nodules [*see 14:V Chronic Diffuse Infiltrative Lung Disease* and *15:II Rheumatoid Arthritis*]. Peripheral dense, masslike infiltrates may also occur. Some lesions may cavitate; such lesions are most common in men with high-titer rheumatoid factor and subcutaneous rheumatoid nodules.

Other noninfectious, nonmalignant disorders that can cause multifocal infiltrates include silicosis and other diseases caused by inorganic dust inhalation.[17] With extensive disease, progressive massive fibrosis may develop, producing large opacities. These opacities begin in peripheral areas of the lung and migrate centrally as lung volume is lost. The chest radiograph almost always shows a background of small nodules that are most prominent in the upper lobe. Patients have productive cough and dyspnea on exertion. The physiologic findings are typical of restrictive disease, but many patients also have airflow obstruction resulting from cigarette smoking or from airway damage caused by massive dust overload.

Table 3 Major Causes of True Segmental Infiltrates

Cause	*Examples*
Infectious	Bacterial pneumonia Tuberculosis Invasive aspergillosis, *Mucor* pneumonia, *Pseudomonas* pneumonia Bronchiectasis
Neoplastic	Primary lung cancer Carcinoid tumors Cylindromas, mucoepidermoid carcinomas
Noninfectious, nonneoplastic	Foreign body Amyloidosis and sarcoidosis Asthma with mucous plugging Allergic bronchopulmonary aspergillosis Pulmonary infarction Bronchial fracture Postoperative atelectasis

Caplan syndrome occurs in patients with rheumatoid arthritis who have been occupationally exposed to coal dust or other particulates, such as silica, asbestos, aluminum dust, and iron dust. The tendency to form large, masslike infiltrates is more pronounced in these patients than it is in other patients with rheumatoid arthritis. The infiltrates are multiple and may be more than 5 cm in diameter. They are often somewhat nodular and may cavitate and even calcify. Histologically, they resemble other rheumatoid necrobiotic nodules except that the foreign particulate matter can be easily demonstrated. The occupational history and the nodules and fibrosis evident on the chest radiograph are diagnostic clues.

In ankylosing spondylitis, a spondyloarthritis that leads to a stiff spine, calcification of spinal ligaments results in a characteristic radiographic appearance, the so-called bamboo spine [*see 15:III Seronegative Spondyloarthritis*]. Chest wall expansion is impaired, and lung volumes are somewhat reduced. Patients may develop characteristic dense fibrous or fibrobullous infiltrates that are often limited to the upper lung zones. These chest radiographic findings mimic those of tuberculosis, and cavitation may occur. Once cavities have developed, abnormal air spaces may become colonized with *Aspergillus* species, causing fungus balls and even a locally invasive disease termed chronic necrotizing aspergillosis. CT studies of groups of patients with ankylosing spondylitis have found interstitial lung disease that is more diffuse and not confined to the apexes of the lung.[18] The lung disease associated with ankylosing spondylitis does not progress to respiratory insufficiency. Dyspnea on exertion and nonproductive cough are the usual symptoms. Once *Aspergillus* colonization or infection has occurred, symptoms from the local fungal infection may predominate; such symptoms include hemoptysis, productive cough, and mild to moderate constitutional symptoms. Locally invasive *Aspergillus* infection may extend directly to the pleura but almost never spreads hematogenously to distant sites.

Exogenous lipoid pneumonia may also cause multifocal infiltrates. These infiltrates are dense and are usually seen in both lower lobes.[5]

True Segmental Infiltrates

A chest radiograph that shows nearly complete involvement of a single lung segment, especially if associated with volume

loss, should raise suspicion that there is disease in the bronchus or in the pulmonary artery supplying that segment [*see Table 3*].[19]

INFECTIOUS DISEASES

Common bacterial pneumonias caused by *S. pneumoniae* and *H. influenzae* are usually not truly segmental unless an entire lobe is involved. In contrast, involvement of one or more discrete segments, often at the lung bases, is common in *Mycoplasma* pneumonia [*see Figure 3a*].[1]

Three types of pneumonia exhibit a strong tendency for angioinvasion and cause dense, wedge-shaped peripheral infiltrates resulting from combined infection and infarction of a lung segment. Patients may have fever and purulent sputum from the infection, and they may have hemoptysis and pleural pain from lung infarction. *Aspergillus* and *Mucor* species are important causes of this syndrome in immunosuppressed patients, particularly patients with neutropenia or those receiving high-dose glucocorticoid therapy [*see 7:XXXVIII Mycotic Infections in the Compromised Host*], and *Pseudomonas* pneumonia is an important cause of this syndrome in debilitated patients [*see 7:X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas*].

Bronchiectasis is a disease of the airways that can present as a peripheral segmental infiltrate, from dilated bronchi filled with mucus and infiltrate, and as an associated volume loss. Air-fluid levels may be seen in dilated saccular airways. Because CT scanning is more sensitive and specific than chest radiography in documenting bronchiectasis, it has replaced bronchography in the diagnosis of this process. The usual clinical presentation is a chronic cough that produces purulent sputum [*see 14:III Chronic Obstructive Diseases of the Lung*].

Tuberculosis is a parenchymal lung disease but may also involve the airways heavily. Bronchiectasis is a common late sequela. Because it occurs most often in bronchi of the upper lobes, it is well drained; hence, little or no sputum is produced (so-called dry bronchiectasis). Hemoptysis, often massive, can occur in patients who have no history of chronic cough and sputum. True segmental infiltrates may be seen early or late in the course of this chronic infection.

Pulmonary aspergillosis is an uncommon and, usually, very late complication of AIDS. Endobronchial aspergillosis is one manifestation of AIDS that often presents as true segmental infiltrates of the involved segment or segments. Pulmonary aspergillosis in AIDS may also present as multiple nodules and single or multiple infiltrates.

NEOPLASTIC DISEASES

Lung tumors that arise in the lung parenchyma present as nodules or masses. Tumors that arise in central airways block a segment of the lung, leading to distal infection, atelectasis, or both; the infection or atelectasis conforms perfectly to the obstructed segment, lobe, or lung. Symptoms include cough and hemoptysis or purulent sputum, as well as fever from the postobstructive pneumonia.

Carcinoid Lung Tumors

Carcinoid tumors of the lung are low-grade adenocarcinomas [*see 12:VIII Lung Cancer*].[20] Most carcinoid tumors arise in central airways, so they present as segmental infiltrate or atelectasis more often than do primary lung cancers [*see Figure 3b*]. Carcinoid tumors grow more slowly and metastasize less often than primary lung cancers, and they are not related to cigarette smoking. Although the mean age of incidence is 55 years, carcinoid tumors are almost evenly distributed across adulthood; in contrast, the incidence of primary lung cancer increases markedly with age. Despite their relative infrequency, carcinoid tumors account for a high percentage of lung tumors in patients in their third and fourth decades but only a tiny percentage of tumors in patients of advanced age.

Other Lung Tumors

Several other lung tumors typically grow in central airways and also present as segmental infiltrate, atelectasis, or both. Adenoid cystic carcinomas, known as cylindromas, and mucoepidermoid carcinomas are low-grade cancers of the mucous glands that usually occur in the trachea or central bronchi. The clinical presentation is similar to that of carcinoid tumors, but mucous gland tumors occur less than one tenth as often as carcinoid tumors. The histopathologies of cylindromas, mucoepidermoid carcinomas, and carcinoid tumors differ.

Figure 3 **(*a*) Unlike common bacterial pneumonias, *Mycoplasma* pneumonia frequently involves one or more specific segments. In this chest radiograph of a 42-year-old man, *Mycoplasma* pneumonia involves the anterior basal segment of the right lower lobe. (*b*) This chest radiograph of a 24-year-old man demonstrates a carcinoid tumor obstructing the medial basal segment of the right lower lobe. (*c*) Allergic bronchopulmonary aspergillosis may cause a segmental infiltrate or segmental atelectasis. In this chest radiograph of a 40-year-old man, the infiltrate revealed in the medial basal segment of the right lower lobe is the result of allergic bronchopulmonary aspergillosis.**

Benign lung tumors are uncommon. Most are hamartomas, which present peripherally as nodules [*see* Single Small Nodules, *below*]. Benign tumors presenting in the central airways are extremely rare; most are fibromas or lipomas.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Foreign Bodies

Aspiration of a foreign body is an important cause of a segmental infiltrate. However, only 10% of foreign bodies are radiodense. When they are, they can often be identified immediately on the radiograph. When the foreign body is invisible on the radiograph, the diagnosis requires a bronchoscopic examination. Bronchoscopy should be performed if the clinician can combine the clinical history (e.g., altered consciousness, choking spell, irritative cough, repeated infections, or hemoptysis) with the finding of a true segmental infiltrate on the chest radiograph.

Amyloidosis and Sarcoidosis

Pulmonary amyloidosis exhibits many different radiographic patterns, including diffuse infiltrates and single or multiple nodules or masses. Amyloid deposition in a central airway may cause obstruction, leading to segmental infiltrates. Sarcoidosis also displays many patterns [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. It commonly presents as diffuse interstitial disease with or without enlarged hilar and mediastinal lymph nodes, but it also has many uncommon presentations, including multiple nodules and endobronchial sarcoidosis with a segmental infiltrate.

Asthma

Simple mucous plugging during an acute exacerbation of asthma can lead to a segmental or lobar infiltrate and atelectasis. This pattern frequently occurs as the patient is improving, perhaps because hyperinflation is resolving and the airways are no longer so widely dilated. Bronchoscopy is not indicated and may be dangerous during an acute exacerbation [*see 14:II Asthma*].

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis, which is also associated with asthma, is a hypersensitivity disease that primarily affects the central bronchi [*see 14:II Asthma* and *7:XXXVIII Mycotic Infections in the Compromised Host*]. Immediate hypersensitivity and delayed hypersensitivity are involved in pathogenesis. Onset of disease occurs most often in the fourth and fifth decades, and virtually all patients have long-standing atopic asthma. Even those few patients who do not have a history of documented asthma exhibit airflow obstruction when they present with this disorder. The typical patient has a long history of intermittent wheezing, after which the illness evolves into a more chronic and more highly symptomatic disorder with fever, chills, pulmonary infiltrates, and productive cough.

The chest radiograph may show a segmental infiltrate or segmental atelectasis, most commonly in the upper lobes [*see Figure 3c*]. One infiltrate may clear, only to be followed by another infiltrate in a different location. When the patient presents with typical symptoms, the branching, fingerlike shadows from mucoid impaction of dilated central bronchi are pathognomonic of allergic bronchopulmonary aspergillosis. CT scans showing typical central bronchiectasis are highly supportive of the diagnosis of allergic bronchopulmonary aspergillosis.[21]

Pulmonary Infarction

Obstruction of a segmental artery by thromboembolism can cause pulmonary infarction [*see 1:XVIII Venous Thromboembolism*]. The infiltrate is often peripheral and wedge shaped and occasionally has a clearly defined central limit that forms a pleurally based truncated cone, the so-called Hampton hump. Dyspnea, pleuritic chest pain, and, occasionally, hemoptysis are the clinical features of pulmonary infarction. An associated pleural effusion is commonly seen.

Bronchial Fracture

Segmental, lobar, or lung atelectasis can occur after trauma as a result of displacement of the fractured ends of bronchi. Pneumothorax, pneumomediastinum, and subcutaneous emphysema are often seen in this clinical setting.

Postoperative Atelectasis

Segmental or lobar infiltrates are common after surgery. In some instances, mucous plugging produces obstruction with volume loss. More commonly, particularly after cardiac surgery, atelectasis of the left lower lobe without bronchial obstruction occurs, in association with pleural effusion and diaphragmatic elevation.

Table 4 Major Causes of Cystic and Cavitary Pulmonary Infiltrates

Cause	*Examples*
Infectious	Necrotizing bacterial pneumonia Tuberculosis Blebs and bullae with secondary infection Other chronic suppurative infections Parasitic infections
Neoplastic	Primary lung cancer Metastatic lung cancer
Noninfectious, nonneoplastic	Wegener granulomatosis Sarcoidosis Rheumatoid nodules Pulmonary laceration

Cystic and Cavitary Infiltrates

Cavitation of the lung results from a suppurative infection, a rapidly growing neoplasm, or a destructive immune process such as vasculitis [*see Table 4*]. As with other focal and multifocal infiltrates, infections and neoplasms are most common and must be considered first.

INFECTIOUS DISEASES

Pyogenic bacteria can cause necrosis and thus cavitation of the lung. *S. pneumoniae* pneumonia rarely cavitates; when cavitation occurs, it usually indicates a mixed infection with anaerobic bacteria. Gram-negative aerobic pneumonias, including those caused by *K. pneumoniae* or *P. aeruginosa*, cavitate more frequently. A gram-negative pneumonia may produce a large, dense infiltrate, with multiple cavities appearing as the illness progresses. Staphylococcal pneumonia acquired from microaspiration may complicate influenza or may occur de novo [*see 7:I Infections Due to Gram-Positive Cocci*]. Multiple small cavities are frequent. Pyemic staphylococcal infection, often caused by right-sided endocarditis, typically causes scattered, round infiltrates, which often enlarge and then cavitate. Parapneumonic effusions and

Figure 4 **(*a*) This chest radiograph of a 40-year-old man shows a large cavity and extensive infiltrate in the right upper lobe, caused by tuberculosis. (*b*) Central necrosis of a large cell carcinoma in a male smoker who is 65 years of age has left a large, thick-walled cavity in the upper lobe, as this chest radiograph reveals. (*c*) In 70% of cases of Wegener granulomatosis, the chest radiograph reveals that at least one of the lesions is cavitary. A large, thick-walled cavity caused by Wegener granulomatosis can be seen in the left upper lobe of this 37-year-old man.**

empyema are fairly common with either form of staphylococcal pulmonary infection.

A mixed anaerobic infection often produces a single, rounded, putrid lung abscess, which can be as large as 10 cm in diameter and frequently has an air-fluid level. Mixed infections may also cause a focal infiltrate with multiple small cavities. In lung gangrene (a rare entity), vascular compromise, focal vasculitis, and thrombosis of the involved lobe occur. The entire lobe cavitates, leaving chunks of necrotic lung floating in liquid pus. Anaerobic bacteria are probably involved in the etiology of most cases of lung gangrene, either alone or as part of a mixed infection with aerobic organisms. Diagnosis of this entity is based on the radiographic findings. Other infections complicated by cavitary infiltrates include *Pneumocystis* infections, septic thromboembolism, and bronchiectasis.

Blebs and bullae are thin-walled structures that may be congenital but usually result from emphysema. When bacterial superinfection is present, these cystic spaces may develop air-fluid levels and surrounding infiltrates. In the absence of old chest radiographs, it may be difficult to differentiate true cavitation from superinfection of bullae, or so-called bullitis.

Suppurative Infections

Chronic suppurative infections typically cause necrosis. Tuberculosis usually involves the upper lobes [*see 7:II Tuberculosis*]. Cavities are generally small to medium in size, have thick walls, and do not exhibit air-fluid levels [*see Figure 4a*]. There are often associated nodular infiltrates and fibrosis. Atypical mycobacterial infections, especially those caused by *M. avium* complex, often present as larger and more dramatic cavities, partly because such infections tend to occur in patients with underlying bullous lung disease. Infected, preexisting, abnormal air spaces caused by the underlying disease are difficult to distinguish from new necrosis of the lung caused by *M. avium* complex.

Histoplasmosis is a granulomatous infection that rarely cavitates in normal hosts. Blastomycosis and coccidioidomycosis have a mixed granulomatous and pyogenic histopathology, and lung necrosis is more common [*see 7:XXXVII Mycotic Infections*]. *Aspergillus* and *Mucor* infections lead to lung necrosis and infarction and frequently cavitate [*see 7:XXXVIII Mycotic Infections in the Compromised Host*]. *Nocardia* infections are subacute but also suppurative and may present as single or multiple cavitary lesions. Individual lesions tend to be round and well circumscribed; air-fluid levels are common [*see 7:IV Infections Due to Gram-Positive Bacilli*].

Parasitic Infections

Parasitic infections with cavities include echinococcal cysts, which are located in the lower lobes; the cysts are thin walled and have an irregular liquid level caused by collapse of the cyst wall [*see 7:XXXV Helminthic Infections*].[22] Although uncommon in the United States, echinococcosis is very common in parts of Africa and Asia. Paragonimiasis is most often acquired in East and Southeast Asia; infiltrates, pleural effusions, and impressive eosinophilia are sometimes seen [*see 7:XXXV Helminthic Infections*]. A more chronic form of the disease may present as fibrous nodules. Small, thin-walled cysts and cavities can also be created when small nodules soften and then cavitate as the contents are expectorated. Cysts and cavities average 2 to 4 cm in diameter.

Amebic lung abscesses, which are also uncommon in the United States, usually occur in the right lower lobe and generally have thick, irregular walls; they are frequently associated with hepatic abscesses.

NEOPLASTIC DISEASES

Any rapidly growing primary lung cancer can cavitate [*see 12:VIII Lung Cancer*]. Squamous cell carcinoma cavitates most frequently; adenocarcinoma and large cell cancers cavitate less frequently [*see Figure 4b*]; and despite having rapid growth rates, small cell cancers cavitate least often. Cavities are thick walled, as would be expected, because they result from central necrosis of a growing mass.

Hematogenous metastases can also cavitate. Cavitation has been reported in many different types of metastatic disease but occurs more frequently in squamous cell cancers that originate in the head and neck, cervix, or skin than in adenocarcinomas.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Cavitation in noninfectious, nonneoplastic disease is usually caused by a destructive immunologic process, such as vasculitis or rheumatoid necrobiosis.

Wegener Granulomatosis

Wegener granulomatosis is the most common lung vasculitis and is characterized by necrotizing granulomas of the upper and lower respiratory tracts, necrotizing glomerulonephritis, and

other features of systemic vasculitis [*see 15:VIII Systemic Vasculitis Syndromes*]. The mean age at onset is 40 years, but Wegener granulomatosis may occur at any age; it is slightly more prevalent in men. Clinical features vary greatly and relate to the sites of involvement. Systemic symptoms include fever, malaise, and weight loss. Upper airway findings include rhinorrhea, sinus pain and drainage, nasal and nasopharyngeal ulcers, and otitis media. Respiratory symptoms include cough, dyspnea, and hemoptysis. Skin, eye, or joint involvement is common, and renal involvement is extremely common. The chest radiograph or CT scan shows nodules or infiltrates, which are multiple about 90% of the time. About 70% of the time, at least one lesion is cavitary [*see Figure 4c*].[23]

Other Noninfectious, Nonneoplastic Multifocal Disorders

Other immunologically mediated processes such as sarcoid and rheumatoid nodules can cavitate [*see* Multiple Nodules and Masses, *below*]. Uncommonly, closed chest trauma results in one or more cysts in the lung that can be air filled or can be completely or partly filled with blood.

Single Small Nodules

Single small nodules, often called coin lesions, are usually primary lung cancers or granulomas [*see Table 5*].[24] It is important to detect and thoroughly evaluate such lesions because over 90% of cancers discovered at this stage can be cured. In general, given the high frequency of lung cancer, nodules—even small nodules detected only by CT—must be assumed to be malignant and must be removed unless they can be proved to be benign; unless they can be assumed to be benign on the basis of their having remained unchanged or on the basis of the young age of the patient; or unless the patient cannot tolerate a surgical procedure.

A benign etiology can be assumed if a chest radiograph taken 2 or more years earlier shows the lesion to have been the same size as or larger than it is currently. Such a situation could arise if the lesion went unrecognized on the initial film. (Unless the patient is younger than 35 years, it is inappropriate simply to follow a coin lesion.) There are also classic benign patterns of calcification that obviate further assessment of single small nodules. For granulomas, such patterns include dense, perfectly central targets of calcium; ring calcification; and solid, dense calcification of the whole nodule. For pulmonary hamartomas, patterns include the so-called popcorn calcification pattern. (It should be noted that small specks of calcium and eccentric clumps of dystrophic calcium are often seen in malignant tumors). Thin-section CT with contrast enhancement is another way to prove that a nodule is benign. Lesions of about –20 Hounsfield units that do not enhance with contrast are always benign; lesions that do enhance are either tumors or active granulomas.[25] A fine-needle biopsy may provide a specific benign diagnosis by histopathologic examination, cytologic examination, or culture of a microorganism.

If a patient with a pulmonary nodule is younger than 35 years, the chance of malignancy is low enough to justify serial follow-up every 6 months for 2 years. For patients of any age with a proven malignancy or a growing nodule and for all patients older than 35 years in whom the nodule cannot be proved benign, the lesion should be resected unless the patient cannot tolerate the required surgery. The patient's tolerance is largely determined by cardiopulmonary reserve and associated illnesses. Video-assisted thoracoscopic surgery decreases the morbidity of nodule resection.

Table 5 Major Causes of a Single Small Nodule

Cause	*Examples*
Infectious	Granuloma Parasites
Neoplastic	Primary lung cancer Hamartoma Carcinoid Metastasis
Noninfectious, nonneoplastic	Arteriovenous malformation Bronchogenic cysts Intrapulmonary lymph node Rounded atelectasis

INFECTIOUS DISEASES

Most infectious lung nodules are granulomas. Histoplasmomas are by far the most common, especially in the vast areas of the central United States drained by the Ohio and Mississippi rivers. Histoplasmomas rarely cause harm; the problem they pose, however, is in proving that they are not cancerous [*see above and Figure 5a*]. In the deserts of the southwestern United States, coccidioidomycosis is a common cause of a peripheral nodule [*see 7:XXXVII Mycotic Infections*]. Tuberculomas are uncommon in the United States but are frequent in countries with a high incidence of tuberculosis [*see 7:II Infections Due to Mycobacteria*]. Cryptococcomas can be small nodules or large masses [*see* Large Masses, *below, and 7:XXXVIII Mycotic Infections in the Compromised Host*].

A rare cause of a lung nodule that is almost always discovered after resection for presumed lung cancer is infection with *Dirofilaria immitis,* the dog heartworm [*see 7:XXXV Helminthic Infections*].[26] In areas of the world endemic for *D. immitis*, echinococcus is a common cause of a solitary pulmonary nodule.[22]

A lesion cannot be presumed to be benign just because there is immunologic evidence of infection by a particular pathogen remote to the lung, such as a positive skin test or positive serodiagnostic titers. To exclude the diagnosis of cancer, the organism must be identified directly or by culture from the sputum or from material obtained by needle aspiration.

NEOPLASTIC DISEASES

Lung cancers of each cell type can produce solitary nodules. This presentation is most characteristic of adenocarcinoma [*see Figure 5b*], but squamous cell, large cell, small cell, and even alveolar cell cancers can present as nodules. A single nodule is seldom a metastatic lesion. About 25% of carcinoid tumors present as solitary nodules.

Hamartomas are the most frequent benign tumors presenting as a nodule; they constitute 5% of all nodules. A nodule with scattered clumps of calcium throughout the whole lesion, termed popcorn calcification, is very likely a hamartoma. Unless such calcification is evident, hamartomas are often resected when cancer cannot otherwise be ruled out.[27] Other benign pulmonary tumors are very rare and are much more commonly present either intratracheally or intrabronchially.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Nodules are rarely noninfectious and nonneoplastic. Bronchogenic cysts[28] and arteriovenous malformations can present as a single nodule [*see Figure 5c*]. Pulmonary sequestrations are usually larger [*see* Large Masses, *below*]. Rheumatoid nodules, We-

Figure 5 **(*a*) A histoplasmoma presents as a solitary nodule in the upper right lower lobe (arrow) in this chest radiograph of a 50-year-old man. (*b*) This solitary nodule in the apex of the left lung (arrow) proved to be an adenocarcinoma. The patient is a 63-year-old woman who has a history of heavy smoking. (*c*) In this chest radiograph of a woman who is 24 years old, the solitary nodule of a bronchogenic cyst can be seen in the left lower lobe, behind the cardiac shadow (arrow).**

gener granulomatosis, and pulmonary amyloidosis are rare disorders that seldom present as a single nodule.

Intrapulmonary lymph nodes can also present as small, solitary lung nodules. In one series, 17 of 96 patients who underwent excision of well-circumscribed peripheral pulmonary nodules had this pathology.[29] All the intrapulmonary lymph nodes were located within 20 mm of a visceral pleural surface and were in the lower lobes or middle lobe. They could not be distinguished radiographically from neoplasm or granuloma; however, improved radiologic image quality and use of CT will likely increase the number of intrapulmonary lymph nodes detected as small nodules.

A relatively uncommon cause of a solitary lesion is rounded atelectasis, which can produce a lesion of up to 5 cm in diameter. Rounded atelectasis is always adjacent to the pleura and may have a comet-tail appearance, with the "tail" pointing toward the hilum. The nodular density represents the curling up of atelectatic lung tissue adjacent to a chronic pleural process. A more common pseudotumor is found with pleural effusions caused by congestive heart failure. Collections of liquid appear as rounded lesions on the posteroanterior radiograph, most often in the major fissure. Lateral films often show fissural loculation of liquid.

Large Masses

Neoplasms are the most common cause of lesions larger than 6 cm in diameter. Other conditions only rarely cause such large masses [*see Table 6*].

Table 6 Major Causes of Large Pulmonary Masses (> 6 cm)

Cause	*Examples*
Infectious	Bacterial pneumonia (round pneumonia) Blastomycosis Cryptococcosis Invasive aspergillosis, mucormycosis
Neoplastic	Primary lung cancer Alveolar cell carcinoma Lymphoma
Noninfectious, nonneoplastic	Sequestration Bronchogenic cyst Progressive massive fibrosis

INFECTIOUS DISEASES

Bacterial pneumonia occasionally presents as a round infiltrate. An anaerobic lung abscess can also produce a homogeneous round infiltrate before cavitation. This can occur when the bronchi associated with an anaerobic lung abscess are occluded, thereby preventing pus from escaping and air from entering.

Cryptococcal infection can produce a solitary mass of up to 10 cm in diameter, often with few inflammatory symptoms. Blastomycosis, however, is the fungal infection that most frequently causes a rounded mass. It is often found in the superior segment of the lower lobe, projecting over the hilum on a standard posteroanterior chest radiograph. Blastomycosis is one of the more common benign conditions that are discovered at thoracotomy for presumed lung cancer [*see 7:XXXVII Mycotic Infections*].

Invasive pulmonary aspergillosis[8] and pulmonary mucormycosis occur in patients with neutropenia or in patients with depressed neutrophil function, usually caused by high-dose glucocorticoid therapy. Although each of these diseases most often presents as multifocal infiltrates [*see* Multifocal Pulmonary Infiltrates, *above*], these entities can also produce a focal infiltrate or a large, rounded mass [*see Figure 6a*].

NEOPLASTIC DISEASES

Large masses are most often large cell carcinoma [*see Figure 6b*] but are not uncommonly adenocarcinoma or squamous cell carcinoma. Alveolar cell carcinoma commonly presents as a slowly growing mass, often occupying most of a lobe or lung. Hodgkin and non-Hodgkin lymphoma may present as masses [*see 12:XI Lymphomas*]. The former, but not the latter, almost always displays hilar adenopathy, mediastinal adenopathy, or both.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Bronchopulmonary sequestration may be intralobar or extralobar and typically presents as a large mass with well-defined edges [*see Figure 6c*]. Intralobar sequestrations are located in the posterior basal segment adjacent to the diaphragm, and two of three sequestrations are located on the left. Extralobar sequestrations are contiguous with the diaphragm, and 90% are located on the left; they are not as limited as intralobar sequestrations to the posterior segment.

Lipoid pneumonia and pulmonary contusion usually present as infiltrates [*see* Focal Pulmonary Infiltrates, *above*] but can sometimes mimic round masses. Bronchogenic cysts can also present as large masses.[28] Progressive massive fibrosis in silicosis

Figure 6 **(*a*) Mucor infection caused the large dense mass revealed in the right lung on this chest radiograph. The patient is a 74-year-old man who has had prolonged neutropenia, caused by myelofibrosis. (*b*) A large mass, the most common presentation of large cell carcinoma, can be seen in the right upper lobe in the chest radiograph of a male smoker who is 66 years of age. (*c*) This chest radiograph of a 31-year-old woman shows a large mass in the right lower lobe adjacent to the diaphragm. The mass is an intralobar sequestration.**

and coal workers' pneumoconiosis can have the appearance of a large mass.[17]

Multiple Nodules and Masses

Hematogenous metastases are the most likely cause of multiple nodules, especially if the patient is not febrile and the nodules vary widely in size. Because hematogenous spread to the lung usually occurs over time, different nodules have shorter or longer growth intervals before discovery. Other causes of multiple nodules are uncommon [*see Table 7*]. The differential diagnosis for multiple nodules is different from that for single small nodules or large masses.

INFECTIOUS DISEASES

Endocarditis and Endovascular Infections

Pyemic abscesses[30] are most commonly caused by right-sided endocarditis [*see 7:XVIII Infective Endocarditis*] or by other endovascular infections; *S. aureus* is the most common pathogen. Most patients have high fever and shaking chills. The white blood cell count is usually elevated and shifted toward neutrophils and neutrophil precursors, and blood cultures are usually positive. If the cause is endocarditis, a tricuspid murmur may be heard, and brisk venous pulsations in the neck (large V waves with rapid Y descent) may provide evidence of a leaky valve. Transthoracic echocardiography reveals vegetations in about half of cases; transesophageal echocardiography reveals vegetations in more than 80% of cases. The chest radiograph demonstrates multiple small nodules, which are usually 1 to 3 cm in diameter [*see Figure 7a*]. With time, the lesions may grow and cavitate. Subpleural nodules are frequently associated with pleural effusions, which may be sterile but often are highly inflammatory parapneumonic effusions or even frank empyema.

Other Infections

Multiple pulmonary nodules may also be caused by subacute or chronic infections. Melioidosis, for example, can present as multiple nodules [*see* Multifocal Pulmonary Infiltrates, *above*]. Patients often have chronic symptoms that are similar to those of tuberculosis. Nodules may be grouped in one area of the lung and may grow, coalesce, and cavitate as the disease progresses. *Nocardia* infections can also produce multiple nodules, which frequently cavitate [*see 7:IV Infections Due to Gram-Positive Bacilli*]. Over half of the patients who have *Nocardia* infections are immunosuppressed; sometimes, low-grade fever is the only symptom. Other patients have productive or nonproductive cough. Patients may also have associated subcutaneous nodules or brain abscesses, both of which are the result of hematogenous spread from the lung.

Cryptococcosis,[31] coccidioidomycosis, and paragonimiasis can produce scattered nodules. Often, the disease is relatively inactive and the only clinical finding is an abnormal chest radiograph. Individual lesions may soften and then be evacuated by expectoration of central necrotic areas, leaving thin-walled cavities. Histoplasmosis is a very frequent cause of multiple asymptomatic lung nodules. There are usually fewer than five nodules, and the lesions rarely if ever cavitate. Calcification is common but takes many years—at least 10 years in adults and somewhat less time in children. Dense, nearly total calcification is generally a strong indicator of a benign lesion. Small amounts of eccentric calcification, however, are frequently seen in rapidly growing primary and metastatic tumors, perhaps as a result of necrosis and subsequent calcification.

Extensive echinococcal infection can produce multiple large masses in the lung.[22] One or more of the lesions may be cavitary. The patient may be afebrile, and the initial diagnosis is often metastatic cancer. However, a CT scan will show that the density of echinococcal lesions in Hounsfield units is close to zero. In this way, metastatic cancer can be eliminated as a diagnosis. Other echinococcal lesions may be found in the liver, kidneys, or

Table 7 Major Causes of Multiple Pulmonary Nodules and Masses

Cause	*Examples*
Infectious	Septic emboli Multiple granulomas Fungal and parasitic infections
Neoplastic	Metastatic carcinoma Lymphoma
Noninfectious, nonneoplastic	Arteriovenous malformations Wegener granulomatosis Sarcoidosis and amyloidosis Rheumatoid nodules

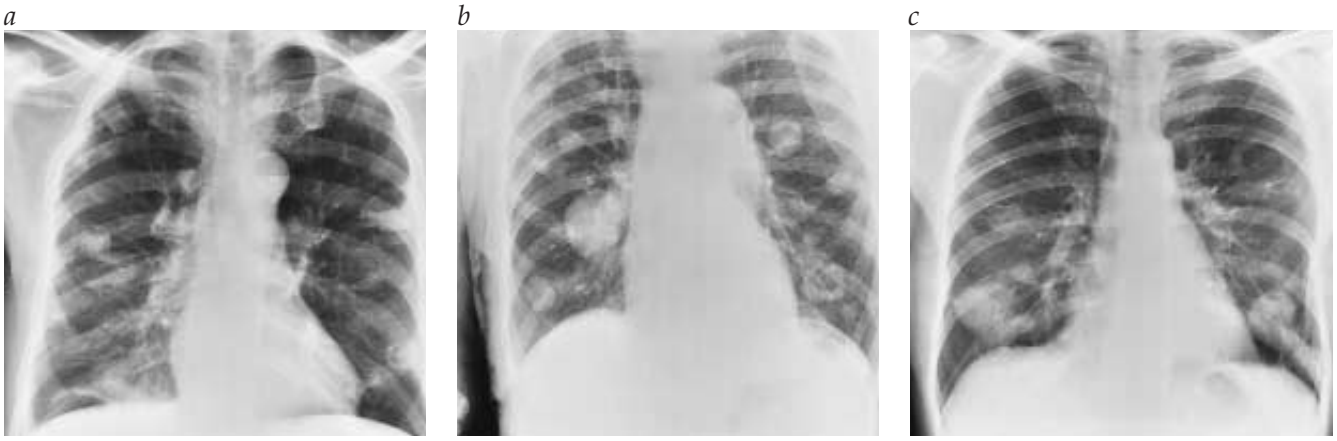

Figure 7 **(*a*) Multiple nodules, some with cavitation and some with air-fluid interfaces, are visible in this chest radiograph of a male I.V. drug abuser who is 34 years of age. The nodules are the result of tricuspid valve endocarditis caused by *Staphylococcus aureus*. (*b*) This chest radiograph of a 37-year-old woman with primary laryngeal cancer reveals metastatic squamous cell carcinoma. As is characteristic, the nodules vary widely in size, and some demonstrate cavitation. (*c*) This radiograph shows a 49-year-old man with Wegener granulomatosis, characterized by multiple nodules that vary widely in size and that have cavitated in some cases.**

other viscera. Surgery is impossible because of the extent of the disease (e.g., bilateral and extrapulmonary), but prolonged courses of antiparasitic therapy can be surprisingly effective.

NEOPLASTIC DISEASES

Metastatic carcinoma is the single most important cause of multiple pulmonary nodules [*see Figure 7b*]. Diagnosis is made by presumption if there are extensive metastases and an obvious primary cancer or by transthoracic needle aspiration biopsy if there is clinical uncertainty.

Lymphomatoid granulomatosis is a rare pulmonary disorder that usually presents as multiple pulmonary nodules or as multiple or diffuse infiltrates.[32] The radiographic presentation mimics metastatic carcinoma or pulmonary vasculitis—particularly Wegener granulomatosis. Immunohistochemical methods have established that lymphomatoid granulomatosis is an angiocentric T cell lymphoma of variable grade. The disease is extranodal, involving the lung and, in a substantial minority of cases, the skin and the central nervous system. It is most common in men in their sixth and seventh decades. In untreated cases, survival is less than 1 year, but survival may be prolonged by the use of combination therapy with prednisone and cyclophosphamide or, if that fails, by more aggressive combination chemotherapy as employed against T cell lymphoma.

Posttransplant lymphoproliferative disorders (PTLDs) often present as multiple well-circumscribed pulmonary nodules.[33] These disorders are related to infection with Epstein-Barr virus and may have polymorphic or monomorphic populations of lymphocytes, the latter being more aggressive and frankly malignant. AIDS-related lymphoma is a non-Hodgkin B cell lymphoma, also related to Epstein-Barr virus infection; it is similar to the monoclonal type of PTLD and often presents as multiple pulmonary nodules. Patients with other types of intensive immunosuppression also may occasionally develop multinodular pulmonary lymphoma. A feature that is shared by all of these disorders is the absence of associated mediastinal adenopathy. Pulmonary Kaposi sarcoma in patients with AIDS and other immunosuppressive conditions can also present as multiple pulmonary nodules.[34]

Two other related neoplastic entities, found exclusively in women, produce multinodular lung lesions that are most often asymptomatic: multiple pulmonary fibroleiomyomatous hamartomas, which are thought to arise within the lung, and so-called benign metastasizing uterine leiomyomas, which are thought to arise in the uterus. The two neoplasms are identical histopathologically and have often been shown to have estrogen receptors. These hamartomas and leiomyomas are most often benign and may regress spontaneously. Hysterectomy, oophorectomy, and antihormone therapy have been tried in rare cases of progression, without much effect.

NONINFECTIOUS, NONNEOPLASTIC DISORDERS

Only a few noninfectious, nonneoplastic conditions present as multiple pulmonary nodules. Pulmonary arteriovenous malformations are multiple in as many as one third of cases; half of these are associated with hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) [*see 5:XIII Hemorrhagic Disorders*]. Sometimes, the chest radiograph is so suggestive of this disorder that it is virtually diagnostic, especially when a feeding artery and a draining vein are visualized. To prove the diagnosis and to identify all the lesions, however, pulmonary angiography is always necessary. Patients may present with a number of clinical syndromes, including hemoptysis, hypoxemia, congestive heart failure, and systemic embolization. Invasive radiologic procedures have been developed to embolize the fistulas. These procedures are usually preferable to resection. Even if a large symptomatic lesion is resected, smaller lesions may grow and become symptomatic, leading to a series of resections and extensive loss of lung.

Wegener granulomatosis often causes multiple lung nodules [*see* Cystic and Cavitary Infiltrates, *above, and Figure 7c*]. Rheumatoid nodules [*see* Multifocal Pulmonary Infiltrates *and* Cystic and Cavitary Infiltrates, *above*] should also be included in the category of multiple pulmonary nodules. The infiltrates are multiple, are frequently discrete and well circumscribed (i.e., nodular), and sometimes cavitate. Temporal arteritis can produce multiple nodular lesions with fever, cough, and weight loss and should be considered in elderly patients. Pulmonary hyalinizing granuloma is an obscure cause of multiple bilateral pulmonary nodules.[35]

Sarcoidosis[36] and amyloidosis may produce multiple well-defined nodules, mimicking metastatic carcinoma. The nodules may be the only manifestations of these diseases. Histopatholog-

ic diagnosis is required, either by transthoracic needle aspiration biopsy or by open lung biopsy. There is no specific treatment for nodular amyloidosis, which has a better prognosis than other forms of pulmonary amyloidosis (e.g., diffuse interstitial infiltrates or endobronchial amyloidosis).

Additional Information

Additional information on focal and multifocal lung disease may be obtained from the National Heart, Lung, and Blood Institute (http://www.nhlbi.nih.gov) and the American Thoracic Society (http://www.thoracic.org).

V CHRONIC DIFFUSE INFILTRATIVE LUNG DISEASE

Gerald W. Staton, Jr., m.d.
Roland H. Ingram, Jr., m.d.

Chronic diffuse infiltrative lung disease encompasses a wide variety of disorders that primarily affect the alveoli and lung interstitium; involvement of the airways and the pulmonary vasculature is secondary to the interstitial process.

Chronic diffuse infiltrative lung disease affects approximately 70 per 100,000 population.[1] Postinflammatory pulmonary fibrosis and idiopathic pulmonary fibrosis (IPF) are the most common diagnoses.[1] Other common diseases are sarcoidosis, intersititial lung disease associated with collagen vascular disorders, and infiltrative lung disease secondary to occupational or environmental exposures or to drugs and radiation. In the United States, some of these disorders are more common in African Americans, though data are incomplete.[2]

A combination of environmental exposures and genetic susceptibility may play a significant role in the development of diffuse infiltrative lung disease.[3] Despite the diversity of contributing factors, the different forms of the disease appear to share a common pathogenetic pathway. The steps involved include initiation of tissue injury, maintenance of inflammation, and either resolution or development of remodeling and fibrosis.[4] In animal studies, several causative agents (e.g., bleomycin, paraquat, radiation, and cyclophosphamide) have been shown to produce a pattern of injury that resembles common idiopathic varieties of the disorder. In these models, there is initial damage to type I epithelial cells (which form the air-blood barrier) and capillary endothelial cells. After a phase of edema and mild hemorrhage, sometimes with extravascular fibrin accumulation, there is an influx of neutrophils. Newly recruited lymphocytes and macrophages appear later. Under the influence of various growth factors, type II epithelial cells (which normally proliferate in response to injury) replicate and spread out, replacing the damaged type I cells. Within 2 weeks, collagen, elastin, and other extracellular matrix components are present, and eventually, extensive lung fibrosis becomes evident. Variations in this common pathway lead to the specific diseases discussed in this subsection.

Approach to the Patient with Suspected Chronic Diffuse Infiltrative Lung Disease

Although more than 100 causes of diffuse infiltrative lung disease have been described, a smaller group of causes accounts for the vast majority of cases. Given the nonspecificity of the clinical, radiographic, and sometimes even pathologic features, the differential diagnosis should be approached carefully.[5] In all cases, a history and physical examination should be performed, a chest radiograph should be taken, and pulmonary function should be evaluated. Although such measures often do not lead to a definitive diagnosis, they help determine the most likely causes in a given case and thus serve to markedly limit the diagnostic possibilities, thereby reducing costs and effort of further studies.

presenting symptoms and patient history

The most common presenting complaints in diffuse infiltrative lung disease are dyspnea of gradual onset—initially with extreme exertion—and nonproductive cough. Chest pain and hemoptysis are uncommon except in specific disorders.

The history should include careful questioning as to the duration of symptoms—usually cough or dyspnea. Often, symptoms have been present for many months or even years, which would render an infectious cause very unlikely. In contrast, a more rapidly evolving course, over days to weeks, increases concern about infection. Exclusion of infection as the cause of diffuse infiltrative lung disease is of paramount importance because of the need for specific antimicrobial therapy and because many noninfectious causes of this disorder are treated with glucocorticoids. Fever may be observed in several noninfectious types of diffuse infiltrative lung disease (e.g., sarcoidosis, hypersensitivity pneumonitis, collagen vascular disease, and drug-induced disease), but its presence should always alert the clinician to the possibility of infection. Infectious diffuse infiltrative lung disease that evolves subacutely over weeks to months is rarely caused by common viral or bacterial organisms. On the other hand, mycobacterial and pathogenic fungal infections (e.g., histoplasmosis, coccidioidomycosis, and blastomycosis) can present subacutely and are usually associated with fever. Perhaps the most common infectious cause is *Pneumocystis carinii* pneumonia (PCP) in a patient with AIDS. AIDS-related PCP may present as dyspnea that evolves slowly over many weeks, occasionally without fever or other evidence of systemic toxicity; this pattern may resemble that of common noninfectious causes of diffuse infiltrative lung disease. A careful history regarding risk factors for HIV infection is a critical part of the evaluation of all patients with recent-onset diffuse infiltrative lung disease.

In addition to establishing the duration of illness and the presence or absence of fever and other systemic complaints, the history should focus on the patient's occupation and medications. Many different occupational exposures can lead to diffuse infiltrative lung disease, but most are rarely encountered in clinical practice. Occupation-related varieties are caused by exposure to the inorganic dusts, such as asbestos and silica, or to organic dusts that cause hypersensitivity pneumonitis. Asbestosis typically becomes evident many years after exposure, so in taking the history, it is important to note the patient's prior occupations. The most common form of occupation-related hypersensitivity pneumonitis is farmer's lung, which primarily affects dairy farmers. A farmer should be questioned carefully about any relation between respiratory or systemic symptoms and exposure to organic material (moldy hay or grain) that may contain thermophilic actinomycetes. The history should also include questions about possible exposure to pigeons or pet birds and to humidifiers, because such exposure can result in hypersensitivity pneumonitis [*see Table 1*].

Many drugs have been reported to cause diffuse infiltrative lung disease. The history should focus on both prescribed and over-the-counter medications and should include questions about medications taken during the preceding weeks or months [*see Table 2*].

Table 1 Common Causes of Hypersensitivity Pneumonitis

Disease	*Antigen Source*	*Probable Antigen(s)*
Farmer's lung	Moldy hay	Thermophilic actinomycetes, *Micropolyspora faeni, Thermoactinomyces vulgaris*
Bagassosis	Moldy pressed sugarcane (bagasse)	Thermophilic actinomycetes, *T. sacchari, T. vulgaris*
Multiple bird handler's diseases	Bird droppings, products, and feathers	Bird proteins
Laboratory worker's lung	Rat fur	Rat urine proteins
Diisocyanates and trimellitic anhydrides	Chemical exposures	Altered proteins
Ventilator lung	Contaminated humidifiers, dehumidifiers, air conditioners, and heating systems	Thermophilic actinomycetes, *T. candidus, T. vulgaris, Penicillium* species, *Amoeba* species, *Klebsiella* species, and *Candida* species

Finally, the clinician should ask about symptoms consistent with an underlying collagen vascular disease or vasculitis. A past history of Raynaud phenomenon, photosensitivity, skin rashes, or arthritis carries great diagnostic relevance.

physical examination

The physical examination has less diagnostic utility than the history but is important nonetheless. Collagen vascular disorders may be suggested by detection of synovitis, telangiectasia, sclerodactyly, or a malar rash. Sarcoidosis also involves extrapulmonary organs and should be suspected in patients with uveitis, erythema nodosum, or plaquelike skin lesions consistent with cutaneous sarcoidosis. Malignant diffuse infiltrative lung disease (i.e., lymphangitic spread) may be associated with findings relevant to the primary tumor, such as an abdominal or breast mass, hepatomegaly, or guaiac-positive stools. Finally, cardiovascular examination is very important because on occasion, chronic pulmonary venous congestion resulting from occult mitral stenosis or left ventricular failure may present as diffuse infiltrative lung disease.

laboratory examination

The laboratory examination comprises both routine studies (e.g., complete blood count, biochemical screening) and those that are more specialized. Sarcoidosis may be suggested by cytopenias if the bone marrow is involved or by hypercalcemia or elevated serum liver enzyme levels. Collagen vascular disease and malignancy may also result in cytopenias. Peripheral eosinophilia would suggest chronic eosinophilic pneumonia. Uncommonly, eosinophilic granuloma presents as a diffuse pulmonary disorder; these patients may have laboratory evidence of diabetes insipidus.

Additional laboratory tests, such as autoimmune serology and determination of angiotensin-converting enzyme (ACE) level, may prove useful, depending on the clinical and radiographic features in a given case. Antinuclear antibodies or rheumatoid factor is usually present in the serum of patients with collagen vascular disorders, but both are also found in low titer in up to 50% of patients with IPF. Increased serum levels of ACE are suggestive of sarcoidosis, but ACE can also be elevated in miliary tuberculosis, berylliosis, asbestosis, and silicosis. Hypersensitivity pneumonitis is nearly always associated with the presence of serum antibody against the offending antigen. However, the presence of antibody against one of the causative agents of hypersensitivity pneumonitis in serum does not prove that hypersensitivity pneumonitis is the cause of diffuse infiltrative lung disease but only that there has been sufficient exposure to the antigen to elicit an immunologic response. Resolu-

Table 2 Drugs That Commonly Induce Chronic Parenchymal Lung Disease

Category	*Drugs*	*Notes*
Chemotherapeutic agents	Bleomycin	Dose related, worse with O_2
	Busulfan	Induces pulmonary fibrosis, with high mortality and occasionally alveolar proteinosis
	Cyclophosphamide	Variable onset and course
	Vinblastine	Synergistic with mitomycin-C
	Nitrosoureas	Dose related, delayed onset
Cardiovascular drugs	Amiodarone	Long half-life, induces ARDS after procedures
	Hydralazine, others	Induce systemic lupus erythematosus (SLE)
Anti-inflammatory drugs	Methotrexate	Produces granulomas, as found on biopsy
	Penicillamine	Induces Goodpasture-like syndrome, SLE, bronchiolitis obliterans
	Gold	Injectable only; induces BAL lymphocytosis
Antibiotics	Nitrofurantoin	Induces acute and chronic parenchymal lung disease
	Sulfasalazine	BOOP, PIE, or pulmonary fibrosis
Illicit drugs	Methylphenidate	I.V. injection produces talc granulomas
	Cocaine	Induces BOOP, alveolar hemorrhage

ARDS—acute respiratory distress syndrome BAL—bronchoalveolar lavage BOOP—bronchiolitis obliterans organizing pneumonia PIE—peripheral eosinophilia

tion of pneumonitis with disappearance of antibody after stopping the exposure provides a more conclusive association.

chest radiography

Radiographic features are for the most part nonspecific. Diffuse infiltrative lung disease may be characterized by bilaterally symmetrical interstitial, alveolar, or mixed alveolar-interstitial radiographic patterns. In some cases, the lung fields appear completely normal on the chest radiograph despite the presence of significant clinical and physiologic abnormalities. There are certain ancillary radiographic clues that, if present, may help in narrowing the list of possible causes [*see Table 3*].

high-resolution computed tomography

The use of high-resolution computed tomography (HRCT) represents a significant advance in the evaluation of diffuse parenchymal lung disease. With the use of HRCT, the extent, location, and pattern of lung involvement can be determined with great accuracy [*see Figure 1*]. HRCT can often detect abnormalities in patients who have symptoms of interstitial lung disease but whose chest radiographs are normal. When combined with clinical data and chest radiography, HRCT of the chest can lead to a specific diagnosis in 60% to 80% of cases.[6] When HRCT indicates a specific diagnosis (e.g., eosinophilic granuloma), the need for a lung biopsy is eliminated.[5]

pulmonary function testing

Pulmonary function testing provides diagnostic clues to diffuse infiltrative lung disease, helps in establishing disease severity and defining prognosis, and is useful for monitoring response to therapy and disease progression.[7] The hallmarks of the disorder include a restrictive ventilatory pattern (reduced lung volume), a normal or increased ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC), a reduction in the diffusing capacity of the lung for carbon monoxide ($D_{L_{CO}}$), and a reduction in arterial oxygen tension (P_aO_2) associated with normal or reduced arterial carbon dioxide tension (P_aCO_2). In addition, there is usually significant exercise limitation resulting from a fall in P_aO_2, abnormalities in respiratory mechanics, associated pulmonary vascular disease, or a combination of these factors.

bronchoalveolar lavage

In most cases, the cause of lung disease remains uncertain despite careful clinical, radiographic, laboratory, and physiologic evaluation. The next step is usually to perform bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial lung biopsy. Certain causes can be diagnosed solely by BAL, others only by biopsy, and some by either technique. BAL is most useful for diagnosing infectious causes, especially PCP. The diagnostic sensitivity of this procedure for AIDS-related PCP is approximately 90% to 95%. Thus, it is the procedure of choice for diagnosing the 20% to 50% of cases of AIDS-related PCP that cannot be diagnosed by induced sputum examination. Other opportunistic infections, such as cytomegalovirus pneumonia and disseminated fungal or tuberculous infection, can also be diagnosed by BAL. Noninfectious causes that can be diagnosed by this technique include alveolar proteinosis, lymphangitic carcinomatosis, and alveolar cell carcinoma. In addition, BAL may provide helpful information by revealing one of the following changes: (1) increased numbers of eosinophils in chronic eosinophilic pneumonia, (2) asbestos bodies in asbestosis, (3) so-

a

b

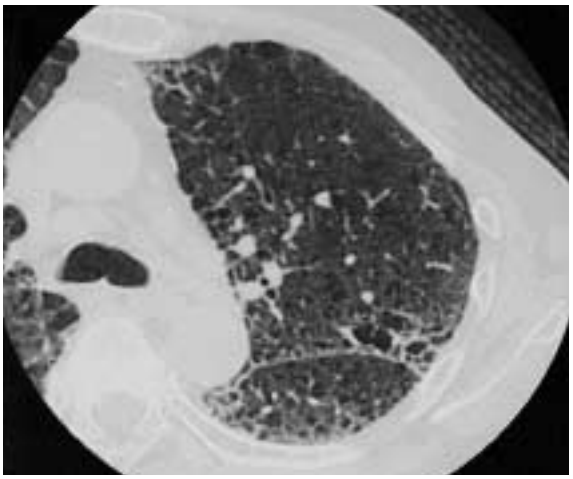

Figure 1 **High-resolution computed tomography (HRCT) in patients with chronic diffuse interstitial lung disease can occasionally suggest a specific diagnosis. (*a*) Posteroanterior radiography demonstrates a diffuse interstitial process, but differential diagnosis is lengthy. (*b*) HRCT shows a combined interstitial and cystic process that is virtually diagnostic of eosinophilic granuloma of the lung.**

Table 3 Radiographic Clues to Diagnosis of Diffuse Infiltrative Lung Disease

Associated Radiographic Finding	*Primary Diagnostic Considerations*
Hilar adenopathy	Sarcoidosis, lymphoma, carcinoma, granulomatous infection
Pleural effusion	Collagen vascular disease, asbestosis, lymphangiomyomatosis (chylous), tuberculosis
Pneumothorax	Eosinophilic granuloma, *Pneumocystis carinii* pneumonia, lymphangiomyomatosis
Upper lung zone predominance	Silicosis, eosinophilic granuloma, sarcoidosis
Peripheral predominance	Eosinophilic pneumonia, bronchiolitis obliterans organizing pneumonia, drug-induced injury

Table 4 Diagnostic Efficacy of Transbronchial Lung Biopsy

Diseases Frequently Diagnosed by TLB Findings
Infectious diffuse infiltrative lung disease
Sarcoidosis
Lymphangitic carcinoma
Alveolar cell carcinoma
Talc-induced diffuse infiltrative lung disease
Diseases Suggested by TLB Findings
Cytotoxic-induced disease
Bronchiolitis obliterans organizing pneumonia (occasionally)
Eosinophilic pneumonia
Hypersensitivity pneumonitis
Not Diagnosable by TLB Findings
Idiopathic pulmonary fibrosis
Diseases commonly misdiagnosed as idiopathic pulmonary fibrosis
Eosinophilic granuloma
Lymphangiomyomatosis
Bronchiolitis obliterans organizing pneumonia
Hypersensitivity pneumonitis
Sarcoidosis (occasional cases)
Lymphangitic carcinoma (occasional cases)

TLB—transbronchial lung biopsy

called foamy cells with lamellar inclusions in amiodarone-induced disease, (4) hyperplastic and atypical type II pneumocytes in cytotoxic drug-induced lung injury, (5) Langerhans cells in eosinophilic granuloma, and (6) a bloody effluent with abundant hemosiderin in alveolar macrophages in diffuse alveolar hemorrhage. Quantitating the number and distribution of inflammatory cells (e.g., macrophages, lymphocytes, and neutrophils) may suggest a specific diagnosis.[8] The alveolar lavage liquid of healthy nonsmokers typically contains 84% to 99% macrophages, 1% to 14% lymphocytes, and 0% to 1% neutrophils. The common causes of nongranulomatous diffuse infiltrative lung disease (e.g., IPF, some of the collagen vascular disorders, and asbestosis) are often characterized by a neutrophilic alveolitis, whereas sarcoidosis and hypersensitivity pneumonitis are associated with increases in lymphocytes. However, overlap exists (e.g., IPF with an increased number of lymphocytes or sarcoidosis with a normal number of lymphocytes).

lung biopsy

In many cases, the diagnosis of chronic diffuse infiltrative lung disease remains unknown until a lung biopsy is obtained. Pathologically, these disorders may be characterized by variable degrees of involvement of alveolar septa or alveoli by inflammatory cells, mesenchymal cells, fibrosis, granuloma, or neoplastic cells. In rare instances, the abnormal substance that accumulates in the lung parenchyma is blood, proteinaceous material (alveolar proteinosis), amyloid, smooth muscle (lymphangiomyomatosis or tuberous sclerosis), or an abnormal material that is deposited as a result of an inherited storage disorder (Gaucher disease, Niemann-Pick disease [*see 5:VII Nonmalignant Disorders of Leukocytes*]).

Lung tissue may be obtained either by transbronchial lung biopsy during bronchoscopy [*see Table 4*] or by one of two open biopsy techniques: traditional open lung biopsy or video-assisted thoracoscopy.[9] Transbronchial lung biopsy is most useful in diagnosing infectious diffuse infiltrative lung disease and sarcoidosis. Noncaseating granulomas can be demonstrated on transbronchial lung biopsy specimens in 70% to 90% of patients with sarcoidosis. The diagnostic yield is highest (approximately 90%) in patients with radiographically apparent lung disease (stages II and III) and lowest (approximately 70%) in patients with hilar adenopathy alone (stage I). Whether one proceeds to open lung biopsy after obtaining a nonspecific transbronchial lung biopsy depends on the particular clinical and radiographic features in an individual case, the impact that a more precise diagnosis would have on therapy, and an assessment of the risk of open lung biopsy in a given case[5] [*see Figure 2*]. The frequency with which open lung biopsy is performed to better define the histopathologic features of noninfectious forms of the disease varies greatly among different centers. Use of video-assisted thoracoscopy rather than open lung biopsy has not resulted in the anticipated decrease in morbidity and cost.[10]

treatment

The treatment recommendations for the lung diseases addressed in this subsection are based on small, nonrandomized series (often without control groups), case reports, and clinical experience. There are very few randomized, controlled trials of treatment for these diseases.

Even before a specific diagnosis is known, preventive and nonspecific measures can be initiated. Immunization against pneumococcal antigens (every 5 years) and yearly immunizations against influenza are indicated. There may be an increased risk of gastroesophageal reflux in patients with certain interstitial lung diseases (e.g., IPF and scleroderma), which should be treated appropriately if present.[11] Patients who have a reversible obstructive defect may benefit from bronchodilators. Many patients will be treated with corticosteroids, so the usual side effects and complications of such agents should be anticipated and treated.[12] Supplemental oxygen given at rest and with exercise will often improve patients' tolerance of activities of daily living.[13] Pulmonary hypertension and cor pulmonale occurring in patients with far advanced disease can be ameliorated with appropriate treatment [*see 14:XI Pulmonary Hypertension, Cor Pulmonale, and Primary Pulmonary Vascular Diseases*]. In patients with the most severe disease, referral for consideration of lung transplantation is appropriate.[14]

Chronic Diffuse Infiltrative Lung Disease of Known Etiology

drug-induced disease

Many different drugs have been reported to cause diffuse infiltrative lung disease [*see Table 2*].[15] Updated information on drug-induced lung disease is available on the Internet at http://www.pneumotox.com. Estimates are that drug-induced lung disease affects several hundred thousand patients each year and accounts for approximately 3% of cases of infiltrative lung disease.[1] To minimize the morbidity and mortality of drug-induced disease, early recognition is critical. Discontinuance of the offending agent is often followed by spontaneous improvement, whereas failure to appreciate the causal relation between the drug and the pulmonary disease can lead to irreversible lung injury. Unfortunately, certain aspects of drug-induced disease can hinder the recognition of this cause-and-ef-

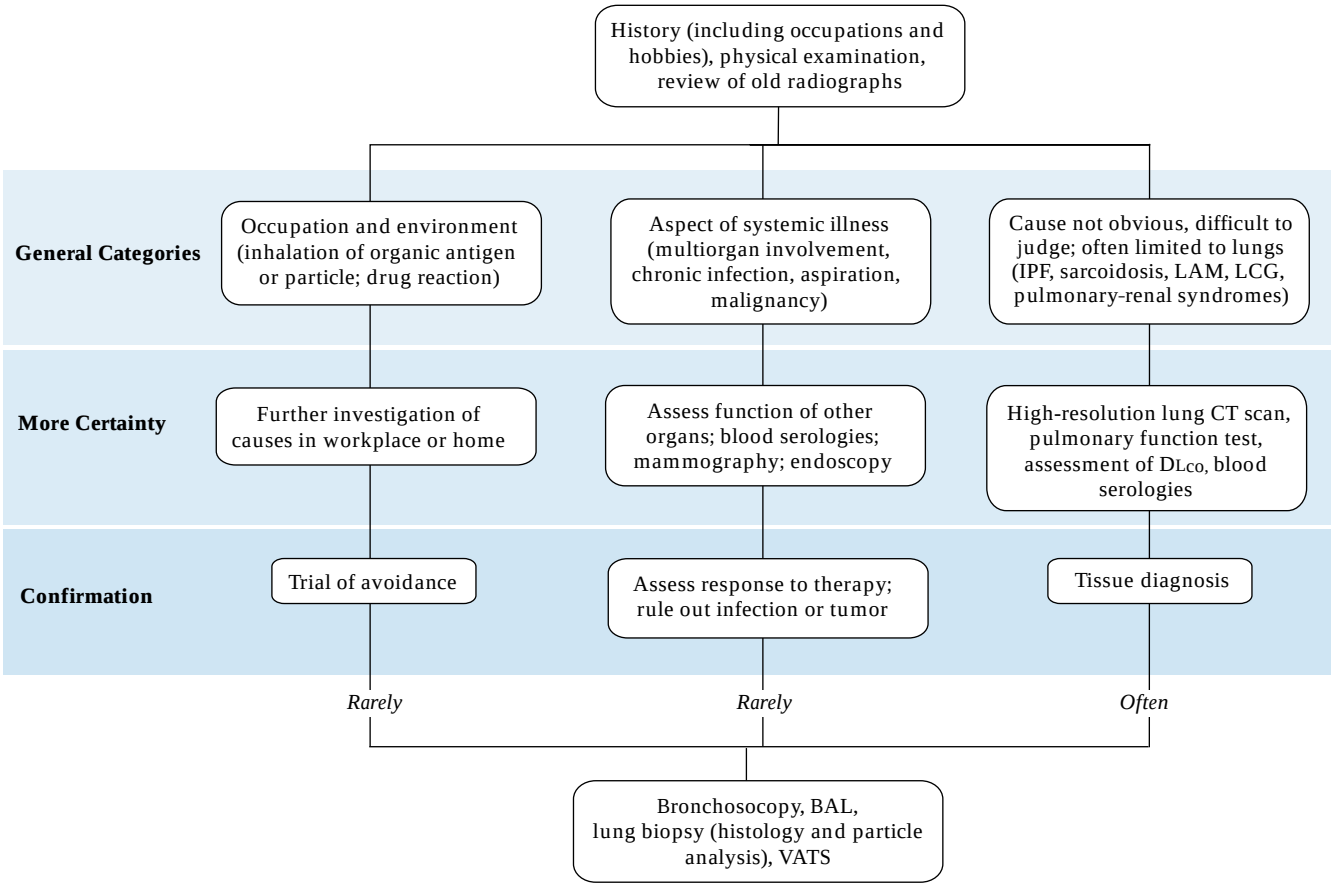

Figure 2 **Algorithm for the evaluation of diffuse interstitial lung disease.[5] (BAL—bronchoalveolar lavage; IPF—idiopathic pulmonary fibrosis; LAM—lymphangioleiomyomatosis; LCG—Langerhans cell granulomatosis; $D_{L_{CO}}$—diffusing capacity of the lung for carbon monoxide; VATS—video-assisted thoracoscopic surgery)**

fect relation. First, although many drugs can cause diffuse infiltrative lung disease, very few of the patients who receive such drugs experience this disease. Second, the onset of the pulmonary disease may occur weeks to months after the drug is begun. In the case of cytotoxic drug–induced disease, the onset of respiratory symptoms can occur many weeks after the last exposure to the offending agent. Finally, the drugs that cause diffuse infiltrative lung disease are often prescribed for conditions that are themselves associated with an increased risk for the disease. For example, a patient who receives an anticancer chemotherapeutic agent is at risk for infection and tumor infiltration of the lung. Similarly, the anti-inflammatory drugs that cause parenchymal lung disease are often prescribed for one of the collagen vascular disorders that can have diffuse infiltrative lung disease as one of its features. For all these reasons, the physician must have a heightened awareness of the possibility of a drug-induced etiology in patients with diffuse infiltrative lung disease.

Disease Induced by Cytotoxic Drugs

Diffuse infiltrative lung disease is a major cause of morbidity and mortality in patients undergoing treatment for an underlying malignancy. In some cases, the drug that is used to treat the malignancy is the direct cause of the pulmonary lesions. Some patients die of cytotoxic drug–induced pulmonary toxicity, and others experience permanent impairment of lung function after being cured of their malignancy. Most of the drugs used in the treatment of malignancy have the potential to cause diffuse infiltrative lung disease. The major offending agents are bleomycin, cyclophosphamide, methotrexate, and the nitrosoureas. Cyclophosphamide and methotrexate are also being used increasingly for nonmalignant conditions, though they are administered at much lower doses in the treatment of these disorders than in the treatment of malignancy. Drug-induced pulmonary disease is less common at these lower doses, but it can occur.

Clinical manifestations The clinical features of cytotoxic drug–induced disease are nonspecific. Cough and dyspnea are often prominent, and fever is not uncommon. The chest radiograph usually reveals bilateral and symmetrical interstitial infiltrates, though asymmetry may be seen early in the course of disease. The pace of the disease, both clinically and radiologically, is variable. Most often the onset is subacute, with cough and dyspnea occurring over several weeks. A more explosive onset, with features of acute respiratory distress syndrome (ARDS) and an urgent need for mechanical ventilatory support, can also be seen.[16] Lung fibrosis resulting from therapy with bleomycin and other agents can occur insidiously over many months.

Pathologic features The pathologic features of cytotoxic drug–induced disease are distinctive but not pathognomonic. Interstitial inflammatory cell infiltration and fibrosis may be

observed. However, the most characteristic finding of cytotoxic drug–induced disease is an increase in type II pneumocytes that show marked atypia. This pathologic feature is highly suggestive of cytotoxic drug–induced disease, but similar changes in type II cells can be seen with severe viral infections and during the reparative phase of ARDS.

A somewhat different pathologic picture is seen with disease induced by cytarabine or methotrexate. Cytarabine has been associated with an often fatal form of noncardiac pulmonary edema. Methotrexate-induced disease has been associated with granulomas, lymphocytic alveolitis, and a significant increase in helper T cells or with a diffuse alveolar damage pattern.[17]

Diagnosis Diagnosis of cytotoxic drug–induced lung disease is established by identifying a previous exposure to the offending agent, excluding infection as the cause of the lung damage, and demonstrating pathologic features that are consistent with drug-induced injury. The temporal relation between drug exposure and the onset of lung disease is variable. An interval of a few weeks between the last exposure to the drug and the onset of symptoms is not unusual; in rare cases, this interval can be as long as several months. The clinical and radiographic features of lung disease induced by a cytotoxic drug are indistinguishable from those caused by opportunistic infection. Thus, an aggressive approach to diagnosis is required. Failure to detect an infectious etiology by bronchoscopy increases the likelihood of drug-induced disease, especially if the characteristic type II cell changes are observed in a transbronchial lung biopsy specimen. However, open lung biopsy may be required to confidently exclude infection and to better define the histopathologic features of cytotoxic drug–induced injury. Even with open lung biopsy, the diagnosis of cytotoxic drug–induced disease remains inferential because there are no pathognomonic features.

Treatment Elimination of further drug exposure is essential in managing cytotoxic drug–induced lung disease. Anecdotal reports indicate that glucocorticoid therapy has been associated with rapid improvement in gas exchange and reversal of chest radiograph abnormalities. If the cytotoxic drug–induced disease is very severe or appears to progress despite elimination of further drug exposure, an empirical course of glucocorticoids is advisable.

Prevention Cytotoxic drug–induced lung disease is not easily prevented, because cytotoxic drugs are often necessary for optimal treatment of a potentially fatal malignancy. For patients with testicular carcinoma who receive bleomycin, the risk of pulmonary lesions appears to be dose related. Monitoring of the $D_{L_{CO}}$ and spirometry during therapy may in some cases permit detection of lung injury early enough to allow discontinuance of the drug and lessen the likelihood of permanent and severe lung impairment. However, therapy for non-Hodgkin lymphoma with bleomycin in combination with doxorubicin, cyclophosphamide, vincristine, and prednisone causes diffuse infiltrative lung disease in a non–dose-dependent fashion, thereby impeding efforts to prevent it. Perhaps the most effective strategy to reduce morbidity and mortality from cytotoxic drug–induced disease is not to prevent it altogether but, rather, to diagnose it as early as possible; further drug exposure can then be avoided by switching to alternative chemotherapy regimens whenever feasible.

Disease Induced by Noncytotoxic Drugs

Diffuse infiltrative lung disease may result from exposure to a variety of noncytotoxic agents, including antibiotics, anti-inflammatory agents, antiarrhythmics, and illicit drugs. In addition, this disorder may be one of the manifestations of drug-induced systemic lupus erythematosus (SLE).

Nitrofurantoin-induced disease Nitrofurantoin, an antibacterial agent used primarily for the treatment of urinary tract infection, is one of the most common causes of drug-induced lung disease. Both acute and chronic pulmonary toxicity can occur, but the acute syndrome is much more common. The acute pleuropulmonary reaction begins 2 to 10 days after initial drug exposure and is manifested by dyspnea, cough, and often fever. Pleurisy occurs in one third of patients. The chest radiograph shows a pattern of alveolar or interstitial infiltrates, sometimes accompanied by a pleural effusion. Peripheral blood eosinophilia may be observed. The disorder is diagnosed on the basis of a history of recent exposure to nitrofurantoin and spontaneous resolution of the clinical and radiographic changes 1 to 4 days after discontinuance of the drug. This rate of resolution is much faster than would occur with infection and serves to establish the diagnosis with a high degree of certainty. Chronic toxicity is not associated with systemic symptoms and has a clinical and radiographic picture that is indistinguishable from that of IPF. If there is no improvement within 2 to 3 months after withdrawal of the drug, corticosteroid therapy is indicated.

Amiodarone-induced disease Amiodarone is an antiarrhythmic agent that is used in the treatment of many types of tachyarrhythmia. This drug has a variety of dose-dependent toxic effects on different organs, but the major limitation to its use is pulmonary toxicity, which occurs in 5% to 7% of cases. Amiodarone-induced pulmonary toxicity is usually heralded by the onset of cough and dyspnea that may initially be attributed to heart failure. Systemic symptoms, including low-grade fever, are not uncommon. The chest radiograph may show a bilateral, symmetrical interstitial process similar to that observed in other types of diffuse infiltrative lung disease. However, more unusual radiographic patterns occur, including unilateral disease and isolated upper lobe disease; the latter finding may suggest tuberculosis. Pleural effusion occurs occasionally.

A diagnosis of amiodarone-induced lung disease is established primarily by excluding other likely causes of the pulmonary disorder, especially infection and heart failure. Bronchoscopy with BAL and biopsy helps exclude infection and reveals the presence of so-called foamy macrophages with lamellar inclusions (visualized by electron microscopy). These changes within macrophages are indicative of exposure to amiodarone but do not prove that the drug is the cause of the pulmonary process, because similar changes are seen in asymptomatic persons who are receiving the drug.

Interestingly, there have been several reports of acute amiodarone-induced lung disease in patients who have undergone relatively minor surgical procedures, such as placement of an automatic defibrillator, or in those who have undergone pulmonary angiography. Often, the disease follows a fulminant course, and sometimes the outcome is fatal. Because the half-life of amiodarone is several weeks, patients who undergo these procedures are still at risk for acute lung injury if the drug was discontinued 1 to 2 months before the procedure.

Withdrawal of the drug is the cornerstone of treatment for

amiodarone-induced lung disease. Glucocorticoids seem to be useful in more severe or persistent cases.

Disease induced by gold and penicillamine Gold and penicillamine, used primarily for the management of rheumatoid arthritis and other collagen vascular disorders, can lead to diffuse infiltrative lung disease. Even with an open lung biopsy, it may be difficult to determine whether the pulmonary damage is caused by the therapeutic agent or by the underlying disorder. Discontinuance of the drug, along with empirical corticosteroid therapy if symptoms are severe, is advisable. Penicillamine has also been implicated in cases of diffuse alveolar hemorrhage with glomerulonephritis, drug-induced SLE, and panbronchiolitis with severe airflow obstruction.

Disease induced by illicit drugs Illicit drugs can also cause diffuse infiltrative lung disease. Talc-induced granulomatosis and pulmonary fibrosis can result from injection of crushed and dissolved amphetamine or narcotic pills that have talc as the filler. The disease can progress years after the last exposure, because the talc persists in the lungs and continues to elicit an inflammatory response. Open lung or transbronchial lung biopsy reveals a granulomatous inflammation with abundant talc particles, which can be visualized with polarizing microscopy. Failure to evaluate granulomas with a polarizing microscope may lead to an erroneous diagnosis of sarcoidosis. The diagnosis can also be made by detecting talc in the retina. Heroin use can lead to acute pulmonary edema but does not in itself cause a chronic diffuse infiltrative lung disease. Cocaine has been associated with acute pulmonary edema and has been reported to cause diffuse alveolar hemorrhage and a syndrome of pulmonary infiltrates with eosinophilia. Cocaine-related pulmonary reactions do not lead to chronic lung lesions.

pneumoconioses

Environmental or occupational exposure to particulate matter can cause several pneumoconioses, including asbestosis, silicosis, coal worker's pneumoconiosis (CWP), and berylliosis. Whether a person develops disease after exposure to such agents is determined by (1) differences in delivery and the persistence of the agent in the lung, (2) genetic and acquired differences in enzymatic and nonenzymatic defense systems, and (3) genetically determined differences in the propensity to develop inflammation in response to the agent.[18]

Pneumoconioses manifest as asthma, chronic bronchitis, or diffuse parenchymal (mostly interstitial) disease. Complications that may be common to a wide variety of pneumoconioses include carcinoma of the lung, especially in patients with diffuse interstitial fibrosis,[19] and chronic necrotizing pulmonary aspergillosis.[20]

Asbestosis

Exposure to asbestos, a fibrous silicate used in insulation, in friction-bearing surfaces, and to strengthen materials, is associated with the development of pleural changes (plaques and effusions), an increased incidence of malignancy (bronchogenic carcinoma and mesothelioma), and diffuse interstitial fibrosis. Only diffuse interstitial fibrosis is called asbestosis. The specific form of asbestos is important in the subsequent development of fibrosis: short-fiber chrysotile asbestos disappears from the lung in a short time and is associated with a lower frequency of disease, whereas amphibole asbestos (amosite or crocidolite) contains longer fibers that persist in the lung and is associated with a higher frequency of disease.[21]

Asbestosis is characterized by the gradual onset of dyspnea 20 to 30 years after exposure to asbestos. Cough is usually present but is nonproductive unless the patient has been a smoker and has complicating chronic bronchitis. Fine end-inspiratory rales can be heard before the chest radiograph becomes abnormal, and digital clubbing is common. In the late stages of asbestosis, signs of cor pulmonale may develop.

Early in the course of disease, the chest radiograph may be normal, but small, irregular linear shadows gradually develop in the lower lung zones. Pulmonary function tests may show restriction, decreased $D_{L_{CO}}$, and exercise-induced hypoxemia.[22] Diagnosis of asbestosis is made when a patient has a history of exposure to asbestos, pleural plaques (an objective indicator of exposure), and, in uncertain cases, excess asbestos in specimens obtained from the lung (by BAL, transbronchial lung biopsy, or open lung biopsy).

There is no specific treatment for patients with asbestosis.

Silicosis

Silicosis is a chronic fibrotic lung disease caused by exposure to crystalline free-silica.[21] The occupational settings in which significant free-silica exposure may occur include certain types of mining; the cutting, polishing, and carving of stone; foundry work; and abrasive cleaning (sandblasting). Exposure of approximately 5 years' duration is usually required for the development of silicosis unless the exposure is very heavy. There are two forms of silicosis: simple nodular silicosis and progressive massive fibrosis (PMF). Many patients with simple nodular silicosis are asymptomatic or suffer only from chronic bronchitis secondary to tobacco use, whereas patients with PMF may develop disabling dyspnea.

Physical findings are often absent. Radiographically, simple nodular silicosis is characterized by diffuse, small, rounded opacities that tend to be more prominent in the upper lobes. Hilar node enlargement may be seen, sometimes with concentric (eggshell) calcifications. In patients with PMF, the opacities coalesce into large, irregularly shaped masses. In patients with simple nodular silicosis, pulmonary function may be normal or may exhibit a mixed pattern of obstruction and restriction.[22] Severe restriction and hypoxemia, as well as pulmonary hypertension, develop in patients who have PMF.

Diagnosis of silicosis can usually be made if the patient has a history of exposure and the chest radiograph is consistent with silicosis (see above). In atypical cases, the presence of silica in BAL liquid or in lung biopsy specimens (often guided by CT scan of the chest) can establish the diagnosis and exclude tuberculosis and carcinoma.

Tuberculosis and infection with atypical mycobacteria occur with increased frequency in patients with silicosis and may be confused with the progression of the silicosis, making conclusive diagnosis difficult. Because cell-mediated immunity appears to be normal in patients with silicosis, the tuberculin skin test can be helpful in identifying patients in whom diagnosis of tuberculosis should be explored.

Silicosis is generally considered an untreatable disease, though one report suggests that oral glucocorticoids reduce lung inflammation and improve lung function.[23] Prevention of further exposure to silica and prevention and treatment of active tuberculosis are important aspects of care.

Coal Worker's Pneumoconiosis

CWP is an uncommon cause of pulmonary fibrosis in workers who are exposed to coal dust and graphite.[21] Most of these patients are miners.

Many patients with CWP have a chronic cough that is sometimes productive of gray or black sputum, which may be caused by chronic bronchitis that is related to tobacco use or exposure to coal dust. Much like silicosis, CWP comprises simple CWP and PMF. PMF is characterized by severe dyspnea, whereas simple CWP is associated with less dyspnea.[22] The radiographic changes characteristic of simple CWP are small, rounded opacities; opacities that are larger than 1 cm are arbitrarily classified as PMF. Simple CWP does not progress if dust exposure is eliminated, whereas PMF can progress after exposure has stopped.

There is no specific treatment for either form of disease.

Berylliosis

Beryllium is a metal used in high-technology industries. High-intensity exposure to beryllium can cause an acute chemical bronchitis and pneumonitis, which is very rare currently because of strict environmental controls. However, chronic berylliosis is still frequently seen. Chronic berylliosis is characterized by multisystemic granulomatous disease that has many similarities to sarcoidosis and that occurs months to years after exposure.[24] The number of chronic cases appears to be decreasing, probably because of increased awareness of the disease and the adoption of environmental controls. Beryllium is thought to bind to host proteins that are carried throughout the body. These beryllium-protein complexes stimulate a delayed hypersensitivity response, which produces granulomatous inflammation at the sites of disease activity.[24]

The symptoms of berylliosis are dyspnea, cough, chest pain, fatigue, weight loss, and arthralgia. Rales are not an early feature. The radiographic findings, which may precede clinical symptoms, include ill-defined nodular and irregular opacities that are sometimes associated with hilar adenopathy. As the disease progresses, the lungs become smaller and areas of honeycombing develop. Pulmonary function tests may be normal; more often, however, they are characterized by a low $D_{L_{CO}}$ with or without restriction, or they demonstrate mild obstruction. Other abnormalities include hyperuricemia, hypercalcemia, hypercalciuria, and elevated serum levels of ACE.

The criteria for diagnosis include a well-documented history of exposure or a demonstration of excess beryllium in patient specimens; objective evidence, on radiography and pulmonary function testing, of lower respiratory tract disease consistent with berylliosis; and demonstration of granulomatous inflammation in the lung, lymph nodes, or other sites of disease activity.

Differentiating berylliosis from sarcoidosis may be difficult. Sarcoidosis is suggested by the presence of uveitis and erythema nodosum, the presence of hilar adenopathy without parenchymal infiltrates, or improvement after short-term steroid treatment. Berylliosis is suggested by lymphocyte transformation in response to beryllium compounds; this testing is performed on lymphocytes obtained from blood or BAL.

The most important step in the management of berylliosis is prevention of further exposure. Glucocorticoids may improve the course of the disease, but these agents may have to be given for the rest of the patient's life.[24]

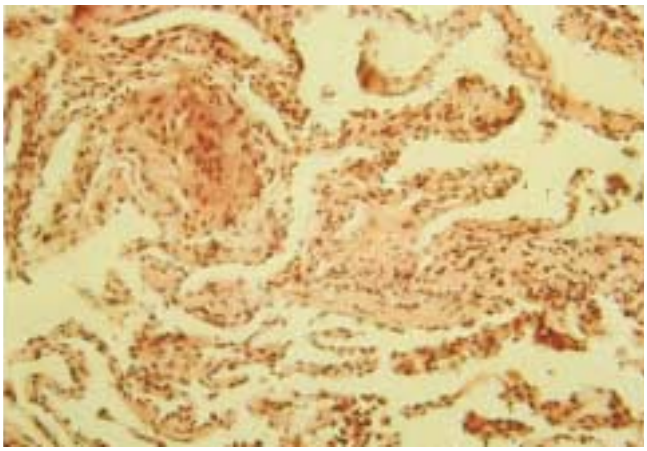
hypersensitivity pneumonitis

The term hypersensitivity pneumonitis (allergic alveolitis) refers to interstitial lung disease that results from inhalation of organic antigens.[25] Several organic antigens cause this syndrome [*see Table 1*], but the most common form of hypersensitivity pneumonitis, called farmer's lung, is caused by inhalation of proteins from thermophilic *Actinomyces* organisms present in moldy hay and grain. Other relatively common forms of hypersensitivity pneumonitis include pigeon breeder's disease and bird fancier's disease, in which inhaled proteins from pigeons or pet birds induce the syndrome. Humidifier lung disease is a type of hypersensitivity pneumonitis that results from exposure to contaminated forced-air systems with humidifiers or dehumidifiers. The responsible antigens in such cases are from *Actinomyces* organisms, as in farmer's lung, but also can include *Aureobasidium* organisms and various amebas. Forms of hypersensitivity pneumonitis other than farmer's lung, pigeon breeder's disease, bird fancier's disease, and humidifier lung disease are rare and generally result from exposure to antigens in rather arcane occupations (e.g., paprika slicing and mummy wrapping).

Pathogenesis and Pathology

The pathogenesis of hypersensitivity pneumonitis is not fully understood. The current hypothesis is that inhaled material causes direct activation of the alternative complement pathway, leading to the formation of chemotactic factors for neutrophils

a



b

Figure 3 **Open lung biopsy specimen from a patient with hypersensitivity pneumonitis (farmer's lung disease) shows characteristic features of (*a*) scattered granulomas and (*b*) bronchiolitis obliterans.**

and in turn to acute neutrophilic alveolitis. The products of complement activation also stimulate the alveolar macrophages to produce monokines, causing a sequence of events that results in granuloma formation.[25]

The pathologic changes in hypersensitivity pneumonitis have been well defined by examination of open lung biopsy specimens of a large number of patients with farmer's lung disease. All patients have an interstitial pneumonitis, and two thirds have scattered granulomas. Fibrosis may occur in more chronic forms of the disease, and as many as 50% of patients may have bronchiolitis obliterans. The pathologic picture of lymphocytic interstitial pneumonitis with granuloma formation and bronchiolitis obliterans is characteristic of hypersensitivity pneumonitis [*see Figure 3*]. BAL studies have examined the nature of the lymphocyte population in the lung and have demonstrated that the lymphocytes are predominantly of the suppressor-cytotoxic T cell subclass. This inversion of the ratio of helper T cells to suppressor-cytotoxic T cells in hypersensitivity pneumonitis contrasts with the predominance of helper T cells in patients with sarcoidosis. The finding of an intense lymphocytic alveolitis with inversion of the ratio of helper T cells to suppressor-cytotoxic T cells suggests hypersensitivity pneumonitis, but this pattern cannot be considered specific, because a similar lavage profile may be seen in other disorders (e.g., IPF associated with a lymphocytic alveolitis).

Clinical Manifestations

Hypersensitivity pneumonitis has two basic clinical forms: acute and chronic.

Acute hypersensitivity pneumonitis Acute hypersensitivity pneumonitis is characterized by fever, chills, cough, dyspnea, and malaise that typically occur 4 to 8 hours after antigenic exposure. Most patients with acute hypersensitivity pneumonitis improve spontaneously after exposure to the antigen ceases. Occasionally, patients experience a more severe episode characterized by hypoxemia and by considerable respiratory distress and require hospitalization. Because of the prominence of systemic symptoms during the acute episode, the patient may be erroneously diagnosed as having a respiratory infection. With continuing exposure to the inhaled antigen—as may occur in people living on a farm, for example—the patient may have daily episodes of acute hypersensitivity pneumonitis that blend into each other. If this pattern occurs, the patient may complain of having a flulike illness for many weeks. Respiratory symptoms, such as cough and wheezing, that occur immediately after exposure to an organic material should not be attributed to hypersensitivity pneumonitis but rather to an irritant response within the airways.

Chronic hypersensitivity pneumonitis In chronic hypersensitivity pneumonitis, there are usually no systemic symptoms; rather, the symptom complex is marked by chronic dyspnea and cough on exertion. The clinical presentation is that of interstitial lung disease of uncertain etiology.

Diagnosis

There is no single diagnostic test that can be used to establish an unequivocal diagnosis of hypersensitivity pneumonitis. Therefore, one must rely on a combination of history, radiography, serologic study, and exclusion of other possible causes.[25] A history of previous episodes of acute hypersensitivity pneumonitis is of great diagnostic value. In taking the history, the clinician should focus on establishing whether a relevant antigenic exposure has occurred and, if so, try to determine whether typical acute symptoms occurred several hours after the exposure. Such a history is more likely to be obtained in cases of heavy exposure (e.g., to moldy hay or a pigeon coop) than in cases of low-level exposure (e.g., to a humidifier or a single bird). In the latter circumstance, the exposure is more or less continuous, and it is much more difficult to establish a causal relation between antigenic exposure and symptoms. Patients should be questioned carefully as to their occupations and hobbies and whether symptoms resolve when they are on vacation or at other times when they are away from the putative source of illness. At least 50% of patients who present with the chronic form of the disease deny having a history of an acute episode. Such acute episodes may well have occurred, but the patient may have attributed the symptoms to respiratory tract infections. The patient may spontaneously improve on hospitalization for evaluation of a respiratory illness, only to experience a recurrence of symptoms soon after returning home. Such a history should always raise suspicion about hypersensitivity pneumonitis.

Chest radiography Chest radiographs of patients with acute hypersensitivity pneumonitis may range from normal to demonstration of alveolar, nonlobar infiltrates. As chronic disease develops, a reticular, nodular, or combined infiltrate evolves, and fibrosis may become evident during continued antigenic exposure. HRCT can be very useful in suggesting the diagnosis and differentiating hypersensitivity pneumonitis from IPF and other infiltrative lung diseases.[6]

Serologic study Serologic study is useful primarily in establishing exposure to a specific antigen. Nearly all patients with farmer's lung and pigeon breeder's disease have antibodies to thermophilic *Actinomyces* organisms and pigeon serum, respectively. However, these antibodies may also be present in the serum of a significant percentage of asymptomatic persons. Hence, the presence of antibody in serum does not establish a diagnosis of hypersensitivity pneumonitis but demonstrates that there has been significant exposure to the antigen.

Bronchoscopy Patients who present with subacute to chronic hypersensitivity pneumonitis should undergo diagnostic bronchoscopy with BAL and transbronchial biopsy. The lavage liquid in hypersensitivity pneumonitis typically shows an intense lymphocytosis, often with more than 50% lymphocytes. As noted (see above), these lymphocytes are primarily suppressor-cytotoxic T cells. As time passes after the last exposure to antigen, BAL results tend to return to normal.[26]

Lung biopsy Transbronchial lung biopsy shows a nonspecific interstitial pneumonitis in most patients and may show evidence of granuloma or bronchiolitis obliterans. Even in the two thirds of cases in which granulomas are present, these lesions are more scattered than sarcoid granulomas and are therefore not as likely to be demonstrated by transbronchial biopsy. Open lung biopsy is usually reserved for especially difficult and confusing cases in which a diagnosis cannot be established by a combination of history, radiography, serologic study, and bronchoscopy. Few patients who have hypersensitivity pneumonitis require open lung biopsy for diagnosis.

Table 5 Chronic Diffuse Parenchymal Lung Diseases of Unknown Cause*

Entity	*Clinical and Laboratory Clues*	*Chest Radiographic Clues*	*High-Resolution CT (HRCT) Findings*	*Pulmonary Function*
Sarcoidosis	Young African-American females; minimal symptoms; skin lesions; increased serum ACE activity	BHA; upper lung field infiltrates	Nodules with a perilymphatic distribution along bronchovascular bundles, interlobular septa, and subpleurally; ground-glass attenuation; reticular shadowing, distortion most commonly in the upper zones; air trapping; associated hilar and mediastinal lymphadenopathy	Restriction with decreased Dl_{CO}; some have obstruction
Idiopathic pulmonary fibrosis (IPF)	Older men; slowly progressive dyspnea; dry end-inspiratory rales; clubbing of digits	Sometimes normal initially; bibasilar reticular infiltrates	Lower-zone and subpleural predominance, occurring posteriorly at the bases and becoming increasingly anterior as disease progresses superiorly; reticular pattern with associated honeycombing in up to 95% of cases	Diffusion decreased more than lung volumes
Desquamative interstitial pneumonia / respiratory bronchiolitis interstitial lung disease (DIP / RBILD)	Middle-aged men more than women; slowly progressive dyspnea; clubbing of digits	May be normal; bibasilar hazy opacities	Ground-glass attenuation, basally and peripherally centered but diffusely spread throughout all zones; approximately half also show features of fibrosis, such as anatomic distortion or traction bronchiectasis	Restrictive defects less severe than in IPF
Acute interstitial pneumonia (AIP)	Rapid onset of dyspnea, cough, fever evolving to respiratory failure	Diffuse bilateral air-space opacities	Widespread disease, which less frequently demonstrates lower-zone predominance; ground-glass attenuation admixed with features of fibrosis, usually with air-space consolidation, possibly emphysema	Rapidly progressive restrictive defect with hypoxemia
Lymphocytic interstitial pneumonia (LIP)	Older women more than men; associated disorder may dominate clinical picture	Reticulonodular infiltrates	Centrilobular nodules, ground-glass attenuation, septal and bronchovascular thickening, thin-walled cysts	Restrictive defect with decreased Dl_{CO}
Nonspecific interstitial pneumonia and fibrosis (NSIP / F)	Middle-aged; women slightly greater than men; dyspnea and cough; often with fever	Bilateral hazy opacities	Bilateral patchy and subpleural areas of ground-glass opacity with lower-zone distribution, variably accompanied by areas of consolidation and irregular linear opacity; features suggestive of fibrosis, such as fissural distortion and bronchial dilatation in the absence of gross honeycombing	Restrictive defect with decreased Dl_{CO}
Bronchiolitis obliterans organizing pneumonia (BOOP)	Idiopathic BOOP seen in older patients; abrupt onset of cough, dyspnea, fever; rales and wheezes	Some have solitary focal infiltrates; bilateral patchy alveolar or ground-glass infiltrates	Bilateral areas of consolidation with air on bronchograms of the lower lung zones in a predominantly subpleural or peribronchial distribution, with associated nodules up to 4 cm in diameter; ground-glass attenuation in some cases	Mixed restriction and obstruction
Collagen vascular disease	Often asymptomatic; progressive dyspnea, cough, sometimes with chest pain, hemoptysis; positive serologies	Usually, bilateral diffuse or patchy infiltrates	Ground-glass, fibrotic, or combination	Restrictive defect with decreased Dl_{CO}

*After ruling out infections, drugs, and inhalants (organic and inorganic).
ACE—angiotensin-converting enzyme ARDS—acute respiratory distress syndrome BHA—bilateral hilar adenopathy DAD—diffuse alveolar damage Dl_{CO}—diffusing capacity of the lung for carbon monoxide ILD—interstitial lung disease LDH—lactate dehydrogenase MCTD—mixed connective tissue disease PM / DM—polymyositis / dermatomyositis PSS—progressive systemic sclerosis SLE—systemic lupus erythematosus UIP—usual interstitial pneumonia

Treatment

Treatment of hypersensitivity pneumonitis primarily involves stopping the exposure to the causative antigen. This step may be accomplished rather early in the case of humidifier lung disease or bird fancier's disease but is somewhat more difficult to accomplish in patients with farmer's lung. Sometimes, a dairy farmer is able to have another person do the work that involves exposure to the moldy hay. High-efficiency masks may help reduce the number of spores the patient inhales. Improvement in farming practices, including better ventilation and other steps to reduce the moisture content of hay, may significantly lessen the antigenic load. Referral of the patient to a center that deals with agricultural lung disease is appropriate.

Glucocorticoids are used primarily for acute hypersensitivity pneumonitis characterized by severe systemic symptoms and gas exchange abnormalities. Patients with subacute to chronic hypersensitivity pneumonitis may also improve more rapidly if they are given a course of glucocorticoids for several weeks. Elimination of further antigen exposure is essential when glucocorticoids are administered. Otherwise, the symptoms may be masked by use of the glucocorticoids, and continued exposure to the antigen could result in further lung damage. When antigenic exposure ceases, most patients undergo spontaneous improvement. Patients who have entered a fibrotic phase of the disease may not show substantial improvement, and there is a small subset of patients who seem to deteriorate even though antigenic exposure has apparently been eliminated. In the latter group, it may be beneficial to follow the serum antibody level; with lack of further exposure, the titer will gradually fall. An unchanging or rising titer would suggest continuing antigenic exposure.

malignant diffuse infiltrative lung disease

Diffuse involvement of the lung by malignancy occurs with

Table 5 (*continued*)

Associated Diseases, Exposures, Risk Factors	*Extrathoracic Manifestations*	*Histopathology*	*Therapy*	*Prognosis*
Familial incidence sometimes	Neurologic, eye, skin, heart, liver, hypercalcemia, joints	Noncaseous granulomas; must exclude granulomatous infection, berylliosis	For many—none; when indicated, steroids, antimalarials, methotrexate	Excellent
Familial IPF, cigarette smoking, chronic aspiration, ? viral infections or exposures	Arthralgias; cor pulmonale late in disease	UIP; fibrosis with widening of the alveolar septa; fibroblastic foci of varying age; minimal inflammation	Steroids, colchicine, and cytotoxic agents probably of no benefit; ? interferon gamma	Complete recovery not possible; mortality 68%; median survival 2–3 yr
Highly associated with cigarette smoking	None	Homogeneous filling of air spaces, especially in the peribronchiolar areas	Good response to discontinuance of smoking; good response to steroids	Complete recovery possible; mortality 27%; mean survival 12 yr
Viral prodrome	None	Diffuse alveolar damage; cannot be differentiated from ARDS pathologically	Supportive care with oxygen, mechanical ventilation; not clear whether steroids of any benefit	Mortality 33%–78%; survival often less than 6 mo; recurrences and progressive ILD seen
Autoimmune disorders (Sjögren syndrome), dysproteinemias, viral infections (HIV), drugs, bone marrow transplantation	Depends on associated disorder	Lymphocytic infiltrate of alveolar walls and alveoli that must be distinguished from lymphoma	Treatment of underlying disorder; some respond to steroids, others require immunosuppressive agents	Depends on underlying disorder; can be progressive
Collagen vascular disorders, exposures to agents known to cause hypersensitivity pneumonitis, other environmental exposures, drugs, HIV infection	None	Often confused with UIP; temporally uniform mixture of alveolar wall inflammation (mostly lymphocytes and plasma cells and fibrosis)	Good response to steroids	Complete recovery possible; median survival 13.5 yr; survival worse with increased fibrosis
Many idiopathic but some associated with infections, collagen vascular disorders, aspiration, transplantation, inhaled toxins, drugs, inflammatory bowel disease	Depends on associated disorder	Intraluminal plugs of connective tissue in the bronchioles, alveolar ducts, and alveolar spaces	Focal infiltrates do not require therapy; for others, steroids are successful but with high incidence of relapse	Patients with focal BOOP have no increased mortality; those with diffuse disease have a good prognosis with steroids
Rheumatoid arthritis, SLE, PSS, Sjögren syndrome, MCTD, PM / DM	Arthritis, skin rash or thickening, dysphagia, serositis, dry eyes / mouth, myositis, pulmonary hypertension	Some have UIP pattern, but NSIP / F, LIP, BOOP, DAD also seen	In some, steroids useful (PM / DM, Sjögren syndrome); in others, cytotoxic therapy indicated	Depends on the associated process, response to therapy

lymphangitic carcinomatosis, alveolar cell carcinoma, lymphoma, and leukemia.

Disease Caused by Pulmonary Lymphangitic Carcinomatosis

Pulmonary lymphangitic carcinomatosis most often results from adenocarcinomas. The adenocarcinomas usually originate in the breast, gastrointestinal tract, or lung. The symptoms referable to lymphangitic tumor—that is, cough and dyspnea—are the same as those of nonmalignant diffuse infiltrative lung disease. However, lymphangitic carcinomatosis generally progresses much faster than other interstitial lung diseases; survival beyond 3 to 6 months is unusual. The chest radiograph shows bilateral reticular or reticulonodular infiltrates and, often, Kerley B lines. The latter finding should, in the absence of heart failure, raise suspicion that malignancy is responsible for the pulmonary disorder. Pleural effusions and hilar adenopathy may also be observed. Less often, lymphangitic carcinomatosis presents as unilateral involvement, or the patient has an entirely normal chest radiograph despite severe dyspnea and hypoxemia. In patients with lymphangitic carcinomatosis and a normal chest radiograph, tumor cells are often found in abundance in small pulmonary vessels, occasionally resulting in severe pulmonary hypertension (tumor embolism syndrome). Diagnosis is generally made by bronchoscopy, either by BAL alone or by transbronchial biopsy. An alternative means of establishing the diagnosis is by microvascular cytologic examination of blood aspirated through a wedged pulmonary arterial catheter. This technique may be considered in the very breathless patient, in whom right heart catheterization may be better tolerated than bronchoscopy. Open lung biopsy is only occasionally required to diagnose lymphangitic carcinomatosis.

Disease Caused by Alveolar Cell Carcinoma

Alveolar cell carcinoma may present as a simple nodule or mass; as multiple nodules; or with air-space disease that can be focal, multifocal, or quite diffuse.[27] When the tumor presents as diffuse disease, the differential diagnosis includes nonmalignant causes of diffuse alveolar filling, such as pulmonary edema,

Table 5 (*continued*)

Entity	*Clinical and Laboratory Clues*	*Chest Radiographic Clues*	*High-Resolution CT (HRCT) Findings*	*Pulmonary Function*
Eosinophilic granuloma	Age 20–50 years; sometimes asymptomatic; cough and dyspnea	Pneumothorax common, sometimes at presentation; nodules and cysts	Bizarre cyst shapes and associated nodules spread throughout the lung fields but sparing the costophrenic angles and tips of the lingual and middle lobes	Mixed restriction and obstruction with decreased Dl_{CO}
Alveolar proteinosis	Abnormal radiograph, acute complicating infection, or progressive cough and dyspnea; increased LDH	Bilateral alveolar filling that looks like pulmonary edema without signs of congestion	Perihilar areas of patchy or geographic ground-glass opacities with some thickening of the interlobular septa, resulting in so-called crazy-paving pattern	Restrictive defect with decreased Dl_{CO}; increased shunt fraction
Chronic eosinophilic pneumonia (CEP)	Middle-aged women; productive cough, dyspnea, fever, wheezing; eosinophilia	Bilateral peripheral; often upper lung field infiltrates	Patchy unilateral or bilateral peripheral middle- and upper-lobe consolidation, with other areas of ground-glass attenuation	Restrictive and obstructive defects
Anti–glomerular basement membrane (anti-GBM) antibody disease	Young male cigarette smokers; most have hemoptysis; drop in hemoglobin, hematuria, iron deficiency; positive anti-GBM antibody	Fluffy perihilar acinar shadows	Perihilar alveolar filling	Restrictive pattern that improves with clinical resolution; Dl_{CO} increased with bleeding
Lymphangiomyomatosis	Women in childbearing years; dyspnea, hemoptysis, pneumothorax, chylothorax	—	Homogeneously distributed thin-walled parenchymal cysts, varying from a few millimeters to several centimeters in diameter; associated with retrocrural adenopathy, pleural effusion, thoracic duct dilatation, pericardial effusion, and pneumothorax	Obstruction with increased lung volumes; Dl_{CO} decreased

*After ruling out infections, drugs, and inhalants (organic and inorganic).
ACE—angiotensin-converting enzyme ARDS—acute respiratory distress syndrome BHA—bilateral hilar adenopathy DAD—diffuse alveolar damage Dl_{CO}—diffusing capacity of the lung for carbon monoxide ILD—interstitial lung disease LDH—lactate dehydrogenase MCTD—mixed connective tissue disease PM/DM—polymyositis/dermatomyositis PSS—progressive systemic sclerosis SLE—systemic lupus erythematosus UIP—usual interstitial pneumonia

alveolar proteinosis, alveolar sarcoidosis, and alveolar hemorrhage. Diagnosis of alveolar cell carcinoma is usually established fairly easily by bronchoscopy with BAL and transbronchial biopsy.

Disease Caused by Lymphoma or Leukemia

Lymphoma and leukemia may cause diffuse infiltrative lung disease. Lymphomatous involvement of the lung parenchyma is usually seen in association with mediastinal lymphadenopathy and evidence of extrathoracic lymphoma.[28] On occasion, isolated pulmonary disease is the presenting manifestation of lymphoma. When the underlying leukemia is poorly controlled, leukemic infiltration of the lung is usually seen and may contribute to death by causing respiratory failure. Diagnosis of leukemic or lymphomatous infiltration of the lung may require open lung biopsy to adequately characterize the nature of the infiltrating process and to completely exclude infection. However, in some cases, bronchoscopy may suffice for making the diagnosis.

Chronic Diffuse Infiltrative Lung Disease of Unknown Etiology

An overview of diagnosis and treatment for chronic diffuse infiltrative lung disease of unknown etiology is presented [*see Table 5*].

sarcoidosis

Sarcoidosis is a multisystem disease of unknown etiology that is characterized pathologically by the presence of noncaseating granulomas in various tissues.[29] Any organ system may be affected. Most patients are asymptomatic and seek medical attention because of unrelated respiratory symptoms; most of those patients who are asymptomatic are first recognized through a chest radiograph abnormality. Fewer than 5% of patients with sarcoidosis have a normal chest radiograph. Further, the morbidity and mortality that are associated with sarcoidosis result most often from pulmonary involvement. Thus, it is appropriate to think of sarcoidosis as primarily a respiratory tract disorder that may also have features of extrapulmonary disease.

Many infectious and noninfectious conditions are associated with granuloma formation and a histopathologic picture indistinguishable from that of sarcoidosis.[30] Thus, diagnosis of sarcoidosis requires the exclusion of other causes of granuloma formation. Berylliosis and histoplasmosis, for example, can have clinicopathologic features identical to those of sarcoidosis [*see* Approach to the Patient with Suspected Chronic Diffuse Infiltrative Lung Disease, *above*].

Epidemiology

Sarcoidosis occurs worldwide, in all ethnic groups, but there are striking regional and ethnic differences in its incidence and prevalence.[1] For example, in the United States, sarcoidosis is 10 times more common in blacks than in whites and tends to be more severe in black patients. However, this increased prevalence is not observed in blacks in Europe. It has been estimated that the prevalence of sarcoidosis in the United States is between one in 10,000 and one in 2,500 population. Persons 20 to 40 years of age are most often affected, but the disease can present in children and the elderly. Males and females are affected almost equally, with the prevalence of sarcoidosis being only slightly higher in females. Familial sarcoidosis has been reported in a number of kindreds[31]; less commonly, sarcoidosis has

Table 5 (*continued*)

Associated Diseases, Exposures, Risk Factors	*Extrathoracic Manifestations*	*Histopathology*	*Therapy*	*Prognosis*
Cigarette smoking	Bone lesions, diabetes insipidus	Nodular lesions containing Langerhans cells with Birbeck granules	Smoking cessation; steroids not clearly of benefit	Median survival 6 yr; poor prognosis with older age, airflow obstruction, hyperinflation
Most cases idiopathic; associated with acute silica exposure, several hematologic malignancies, busulfan	None	Granular, eosinophilic material within alveolar spaces that stains positively with the periodic acid–Schiff (PAS) staining	Some patients require no therapy; whole lung lavage is treatment of choice; ? GM-CSF	Some patients undergo spontaneous remission; excellent response to whole lung lavage
None	None	Massive, mixed interstitial and alveolar inflammatory infiltrates that have a high eosinophil content	Steroids are effective, producing rapid response; relapse common	Spontaneous remissions in 10%; many require long-term steroids; with steroids, death uncommon from CEP
Cigarette smoking, hydrocarbon exposure	Glomerulonephritis	Alveolar hemorrhage, sometimes with linear immunofluorescent staining; kidney biopsy shows crescentic glomerulonephritis and linear immunofluorescent staining	Immunosuppressive agents, glucocorticoids, plasmapheresis	50% mortality; dialysis needed after 2 yr
Tuberous sclerosis produces identical radiographic picture	Renal angiomyolipomas	Diffuse proliferation of smooth muscle cells in the lung and visceral pleura, with cyst formation	Oophorectomy, progesterone treatment, or a combination of the two; lung transplantation for end-stage disease	25% mortality at 8 yr

been diagnosed in both a husband and his wife, which would suggest a common environmental factor.

Pathogenesis

A specific sequence of events leads to granuloma formation in sarcoidosis[32] [*see Figure 4*]. Expansion of the helper T cell population in the lungs likely occurs through the activation of T cells by macrophages via interleuken-1 (IL-1) and the subsequent release of IL-2 (also termed T cell growth factor) by the helper T cell. IL-2 causes self-replication of the existing T cell population. This population of helper T cells (dominantly of the Th1-type), which are greatly increased in number and in degree of activity, recruits monocytes from peripheral blood into the lung by releasing monocyte chemotactic factor and colony-stimulating factors and thereby participates in the formation of granulomas. The monocytes become tissue macrophages and, ultimately, the epithelioid cells and multinucleated giant cells that form the core of the granuloma. Monocyte- and macrophage-derived fibroblast growth factors may, in some patients, lead to the development of fibrosis. Another effect of the expanded and activated helper T cell population at sites of disease activity is local stimulation of B cells to produce immunoglobulin, which accounts for the hypergammaglobulinemia that is often seen in this disorder.

Clinical Manifestations of Intrathoracic Sarcoidosis

The most common manifestations of intrathoracic sarcoidosis are bilateral hilar lymphadenopathy and diffuse infiltrative lung disease.[33] These cases are categorized according to a five-part staging system, as follows: stage 0, normal chest radiograph (8% of cases at presentation); stage I, bilateral hilar lymphadenopathy alone (40% of cases); stage II, bilateral hilar lymphadenopathy and diffuse infiltrative lung disease (37% of cases); stage III, diffuse infiltrative lung disease alone (10% of cases); and stage IV, lung fibrosis, often with upper lobe cystic disease (5% of cases) [*see Figure 5*].[33]

Symptoms resulting from parenchymal lung involvement include dyspnea and cough. Pulmonary function abnormalities are found in nearly all symptomatic patients and in some patients who are asymptomatic. Physiologic abnormalities in patients with symptomatic sarcoidosis typically consist of a reduction in $D_{L_{CO}}$ and vital capacity without airflow obstruction. The $D_{L_{CO}}$ typically becomes abnormal before the vital capacity becomes abnormal, but both are usually affected in persons with moderate to severe symptoms. Airflow obstruction is relatively uncommon except in patients with advanced disease or with endobronchial involvement of larger airways. In rare instances, diffuse endobronchial granulomas in small airways lead to a predominantly obstructive abnormality in patients who present with stage I disease.

Most patients with stage I sarcoidosis are asymptomatic, and the abnormality is detected on a routine chest radiograph. When stage I disease is symptomatic, the symptoms are nonpulmonary in nature and consist of systemic complaints of fever, malaise, arthralgia, or erythema nodosum. The combination of fever, bilateral hilar lymphadenopathy, arthralgia or arthritis, and erythema nodosum is known as Löfgren syndrome.[34] Approximately 10% of patients who have stage I disease display evidence of extrapulmonary organ involvement (e.g., involvement of the eyes, nervous system, or lacrimal glands).

The frequency of symptoms is higher in patients with stage II sarcoidosis, but asymptomatic cases are not unusual. Symptoms may be primarily systemic, as in stage I disease, or may arise from pulmonary involvement. A presentation of extensive radiographic abnormalities associated with only minimal respiratory symptoms is not uncommon.

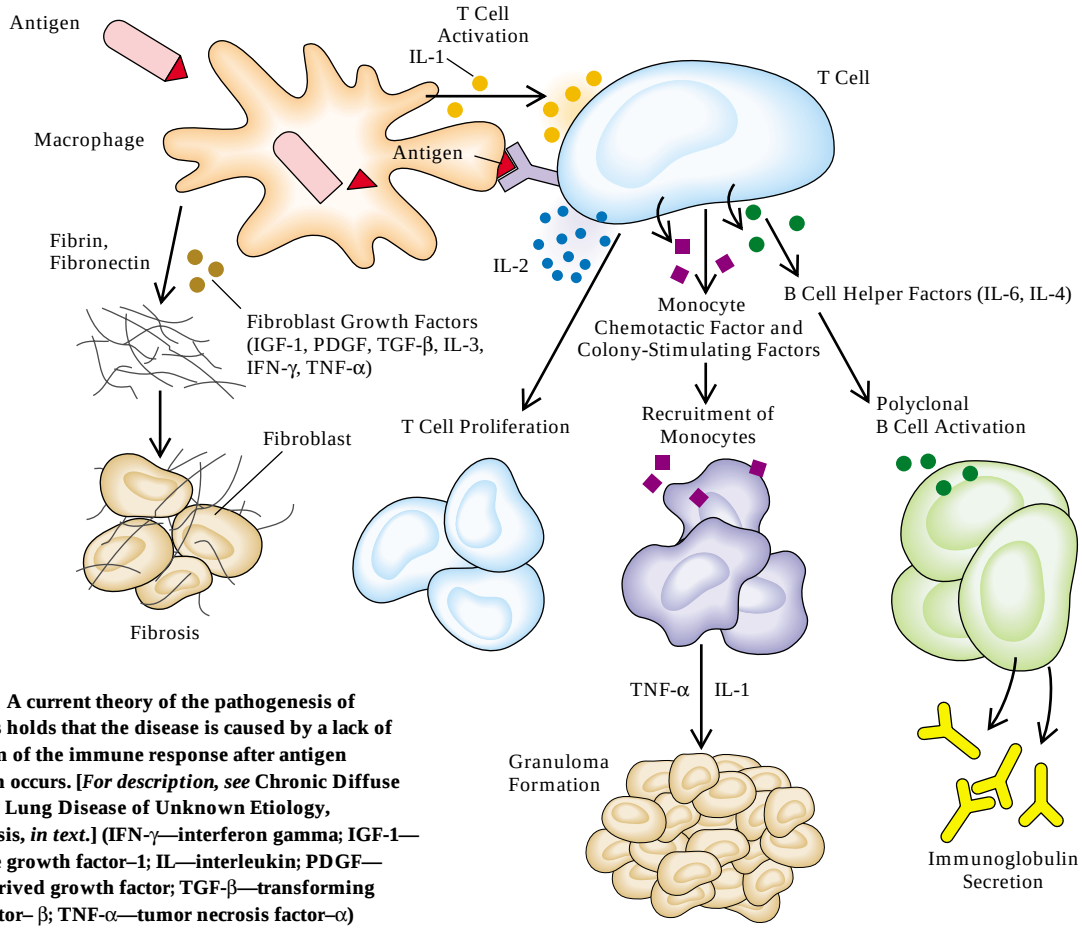

Figure 4 **A current theory of the pathogenesis of sarcoidosis holds that the disease is caused by a lack of modulation of the immune response after antigen recognition occurs. [*For description, see* Chronic Diffuse Infiltrative Lung Disease of Unknown Etiology, Pathogenesis, *in text.*] (IFN-γ—interferon gamma; IGF-1—insulinlike growth factor–1; IL—interleukin; PDGF—platelet-derived growth factor; TGF-β—transforming growth factor– β; TNF-α—tumor necrosis factor–α)**

Stage III disease is found at presentation in 5% to 15% of patients. Respiratory symptoms are common, but as in stage II disease, the chest radiograph may make the patient appear much worse than is actually the case. Certain extrapulmonary manifestations of chronic sarcoidosis, such as infiltrative skin disease, occur much more often in patients with stage III disease than in patients with stage I or stage II disease. This chronic course of stage III disease is not surprising, because patients who are diagnosed at this point in the disease process may represent those persons who earlier had bilateral hilar lymphadenopathy (stages I and II) and failed to undergo spontaneous remission.

Patients with stage IV disease have shrinking of the upper lobes, with upward retraction of the hili, as well as formation of bullae, cysts, and bronchiectasis. Many of these patients will have problems with recurrent bacterial infections and hemoptysis, which is often associated with the development of one or more aspergillomas in the upper lobe cysts.

Unusual manifestations of intrathoracic sarcoidosis include pleural effusion, alveolar infiltrates, large nodular opacities, cavitation, atelectasis, and calcification. Pleural involvement occurs in 1% to 4% of patients and consists of pleural effusion or thickening of the visceral and parietal pleurae. Rarely, chylothorax, hemothorax, or pneumothorax occurs.[35] Effusions are rarely large, and they typically contain a high percentage of lymphocytes. Pleural biopsy reveals granulomas, and the major alternative diagnosis to consider in patients with pleural sarcoidosis is tuberculosis. Alveolar sarcoidosis has variable presentations, ranging from patchy infiltrates in asymptomatic patients to rather extensive air-space consolidation in patients with respiratory failure. Nodules 2 to 10 cm in diameter occur and rarely cavitate. The differential diagnosis of nodular sarcoidosis includes fungal infection, tuberculous infection, and, especially, metastatic tumor. Atelectasis can be caused by endobronchial sarcoidosis. Calcification in lymph nodes is a late manifestation of disease and is seen in 5% of patients.

Necrotizing sarcoid granulomatosis, characterized by masses of confluent granulomas with some degree of vasculitis, is probably a variant of sarcoidosis. The two disorders have many features in common, including hilar lymphadenopathy and extrapulmonary granulomatous inflammation.

Clinical Manifestations of Extrathoracic Sarcoidosis

Although extrathoracic sarcoidosis is a much less common cause of morbidity than intrathoracic disease, it can dominate the clinical picture in some patients.

Erythema nodosum, a nongranulomatous panniculitis, is the most common cutaneous manifestation of sarcoidosis. More than 90% of patients with sarcoidosis who develop erythema nodosum have a stage I radiograph; the other 10% have stage II radiographs. Granulomatous skin lesions occur in 10% to 30% of patients and are especially common in African Americans. Lupus pernio is a potentially disfiguring bluish-purple swollen lesion on the nose, cheeks, earlobes, fingers and toes, lips, or knees. Skin plaques tend to be violaceous, angular, and flat with a raised edge. Psoriasislike plaques may also be seen.

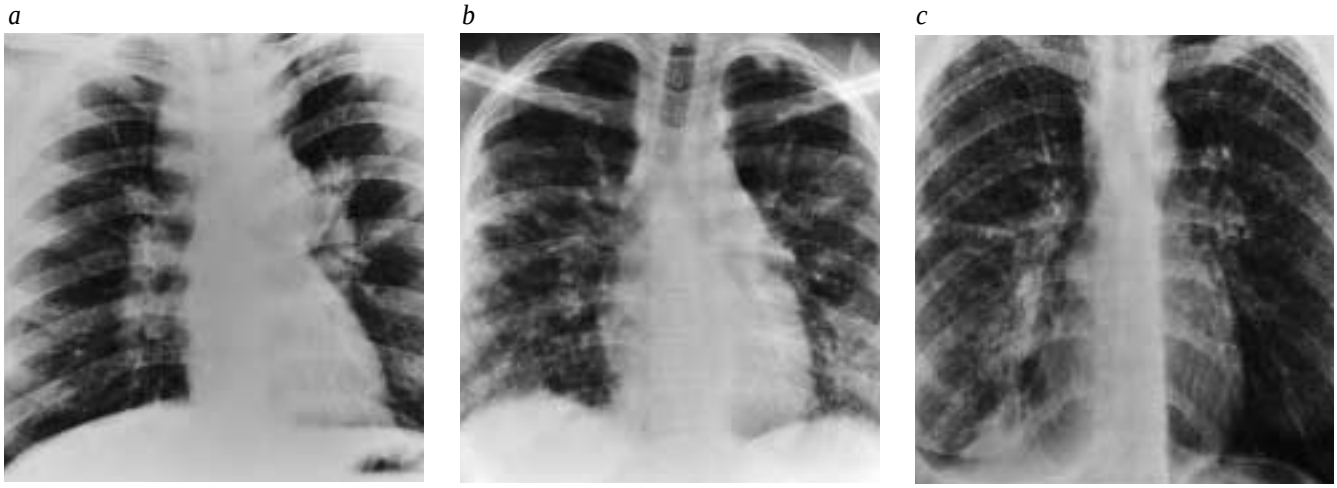

Figure 5 **(*a*) In stage I sarcoidosis, the chest radiograph reveals bilateral hilar and right paratracheal adenopathy with normal lung parenchyma. (*b*) In stage II sarcoidosis, adenopathy and parenchymal infiltration are apparent on the radiograph. (*c*) Stage III sarcoidosis is characterized by parenchymal infiltration, without definite adenopathy.**

Nodules may be elevated or may arise in the subcutaneous tissue. As a rule, these granulomatous skin manifestations of sarcoidosis are seen with chronic and persistent stage III pulmonary disease.

Ocular involvement occurs in about 25% of patients with sarcoidosis. The uveal tract is most often affected; sarcoidosis is responsible for 2% to 4% of all cases of uveitis. In some instances of chronic uveitis, sarcoidosis is suspected but cannot be confirmed.[36] Anterior uveal tract disease with iridocyclitis usually presents as tearing and photophobia with little or no pain. Heerfordt syndrome, or uveoparotid fever, is an uncommon manifestation of sarcoidosis that consists of uveitis, parotid enlargement, cranial nerve palsies, subacute meningitis, and systemic symptoms. Posterior uveitis (chorioretinitis) causes blurring of vision, or patients may be asymptomatic. Chorioretinitis may be difficult to detect when anterior uveitis is present.

The nervous system is affected in fewer than 5% of patients with sarcoidosis. Central nervous system manifestations include chronic meningitis, encephalopathy, hypothalamic lesions, cranial nerve involvement, and seizures. Peripheral sensory and motor neuropathy may be seen. Chronic meningitis in sarcoidosis may be difficult to distinguish from tuberculous or fungal meningitis and is typically associated with cerebrospinal fluid lymphocytosis, increased CSF protein levels, and, sometimes, low CSF glucose levels. Sarcoidosis can give rise to space-occupying lesions in various locations, resulting in diverse neurologic abnormalities. Magnetic resonance imaging is particularly useful in the diagnosis and management of patients with brain parenchymal lesions.[37]

Evidence of cardiac sarcoidosis is seen much more often at autopsy than would be suspected on the basis of clinical manifestations. Rhythm disturbances are the most common manifestations of cardiac sarcoidosis. Both ventricular tachyarrhythmias and complete heart block can occur and can lead to sudden death. Other, less common features of cardiac sarcoidosis include heart failure, pericardial disease, papillary muscle dysfunction, and ventricular aneurysm in the absence of coronary artery disease. Echocardiography, Holter monitoring, and thallium-201 scanning may show abnormalities but do not necessarily indicate that granulomas are in the myocardium. Age, comorbidities, and the types of abnormalities must be taken into account to assess the probability of myocardial sarcoidosis.

Bone or joint involvement is observed in 1% to 10% of patients.[38] Bone disease is characterized by cystic lesions and tends to be restricted to the fingers and toes. Swollen digits may be seen. Synovial sarcoidosis can present as monoarticular or polyarticular chronic arthritis.

Patients with sarcoidosis often have liver and spleen granulomas, but liver dysfunction or massive splenomegaly is unusual. In rare cases, sarcoidosis leads to cirrhosis and portal hypertension. Upper respiratory tract involvement is usually manifested by nasal or laryngeal symptoms. Epistaxis and nasal congestion, which may be mistaken for allergic or vasomotor rhinitis, are common symptoms. Sarcoidosis should be considered when nasal obstruction is refractory to conventional therapy. Laryngeal sarcoidosis involves the supraglottic structures and, on occasion, the vocal cords. Hoarseness is the most common symptom, but upper airway obstruction can occur.

Endocrine abnormalities in sarcoidosis include hypercalcemia[39] and pituitary dysfunction, which may present as diabetes insipidus. Hypercalcemia is seen much less often than hypercalciuria. Hypercalcemia and hypercalciuria in sarcoidosis are caused by the unregulated, increased synthesis of 1,25-dihydroxyvitamin D by activated macrophages in the granulomas, resulting in an increase in calcium absorption in the gut.

Diagnosis

The diagnosis of sarcoidosis is established by demonstration of noncaseating granulomas in tissue [*see Figure 6*] and exclusion of other causes of granulomas. Intrathoracic sarcoidosis is diagnosed most easily by bronchoscopy with transbronchial lung biopsy. The yield of transbronchial lung biopsy depends on the radiographic stage. In patients with pulmonary infiltrates (stages II and III), transbronchial lung biopsy demonstrates noncaseating granulomas in approximately 90% of cases. In stage I disease, the yield is 60% to 70%. If a diagnosis is not established by transbronchial lung biopsy, mediastinoscopy is indicated and will provide a diagnosis in over 95% of cases in which mediastinal adenopathy is present. Biopsy of extrapulmonary tissues can be used for diagnosis when clinically indicated (e.g., in patients with peripheral lymph node enlargement or skin lesions).

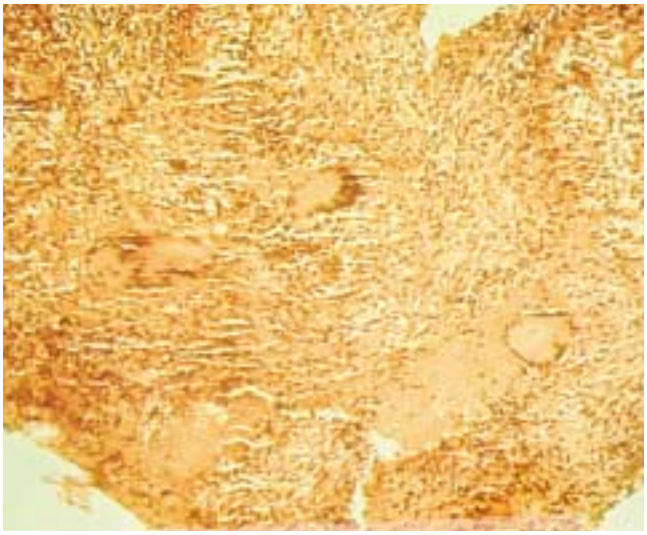

Figure 6 **Noncaseating granulomas can be seen in this tissue biopsy specimen from a patient with sarcoidosis.**

When noncaseating granulomas are found in tissue, possible causes of granuloma formation other than sarcoidosis must always be excluded. Occasionally, lymphoma or carcinoma is associated with granulomatous inflammation in local lymph nodes. Infectious causes of granulomas in the lungs and mediastinal lymph nodes, particularly tuberculosis and histoplasmosis, should be ruled out. A tuberculin skin test, fungal serologic studies, and the use of special stains on tissue biopsy specimens are necessary. For example, such findings as hilar lymphadenopathy, pulmonary infiltrates, and noncaseating granulomas in tissue may prompt the physician to make a presumptive diagnosis of sarcoidosis while these special studies are pending. If a high complement fixation titer for histoplasmosis were detected, the diagnosis would be changed to histoplasmosis.

At the time of bronchoscopy, BAL is usually performed in addition to biopsy. In active sarcoidosis, the lavage liquid usually shows increased numbers of lymphocytes, and the ratio of helper T cells to suppressor-cytotoxic T cells is elevated. Because other pulmonary disorders, both infectious and noninfectious, may be associated with lymphocytosis, this finding lacks diagnostic specificity. Hypersensitivity pneumonitis may be confused with sarcoidosis because both disorders are associated with lavage-liquid lymphocytosis and noncaseating granulomas in tissue. However, an inverted ratio of helper T cells to suppressor-cytotoxic T cells is typically seen in hypersensitivity pneumonitis. Levels of ACE are usually elevated in active sarcoidosis. Therefore, the measurement of ACE levels may aid in the diagnosis of sarcoidosis. Diagnosis of sarcoidosis on the basis of an elevated ACE level alone, without confirmation of the diagnosis by demonstration of noncaseating granulomas in tissue, is not recommended. Elevated ACE levels have also been detected in miliary tuberculosis, leprosy, biliary cirrhosis, silicosis, and asbestosis. With the exception of miliary tuberculosis, it is not likely that these diseases would be clinically confused with sarcoidosis. When the ACE level is elevated, repeated ACE measurements during treatment of sarcoidosis may be helpful because the ACE level often correlates with disease activity.

Differential Diagnosis

The differential diagnosis of stage I sarcoidosis primarily includes lymphoma and granulomatous infections such as tuberculosis and histoplasmosis. More infrequent causes of bilateral hilar lymphadenopathy include metastatic carcinoma (especially renal cell carcinoma) and amyloidosis. Most patients who have lymphoma that presents as bilateral hilar lymphadenopathy have peripheral lymphadenopathy, splenomegaly, or systemic symptoms such as fever, weight loss, and night sweats. Young adults who present with asymptomatic bilateral hilar adenopathy but neither peripheral lymphadenopathy nor splenomegaly are very unlikely to have lymphoma. It is therefore reasonable to make a presumptive diagnosis of stage I sarcoidosis in such patients without confirming the diagnosis by examination of a tissue specimen. However, a tuberculin skin test and fungal serologic studies should be performed. Clinical and radiographic follow-up is required to ensure that there is no progression of the disease. If disease progression is observed, it is imperative to perform a tissue biopsy to establish the diagnosis.

Treatment

Glucocorticoids are standard therapy for symptomatic sarcoidosis, though there is no definitive proof that they influence long-term outcome. Most patients respond very well to therapy, and often, low dosages of prednisone (e.g., 15 mg every other day) are effective in suppressing disease activity. A higher dosage (e.g., 40 to 60 mg / day) is usually given for a few weeks to induce regression of disease activity. The primary indication for glucocorticoids is symptomatic pulmonary involvement. Other indications include significant systemic symptoms (e.g., fever or weight loss), hypercalcemia, and involvement of extrapulmonary tissues that leads to established functional impairment or a risk of organ dysfunction. The required duration of therapy is uncertain. It is common practice to treat pulmonary sarcoidosis with prednisone for 1 year, then to withdraw the drug to see whether the disease is in remission. Relapses of the disease are treated in a similar fashion, with higher initial dosages of prednisone that are tapered to a low dosage for maintenance. Some patients experience relapses repeatedly as prednisone is withdrawn and, as a result, require low-dose suppressive therapy indefinitely.

If the use of steroids is strictly contraindicated or if the patient does not respond to steroid therapy, methotrexate[40] or chlorambucil may be tried. Chloroquine is often useful in patients with skin disease.

Lung transplantation in sarcoidosis has been associated with histologic evidence of recurrence in the transplanted lung, but the survival of these patients has been comparable to the survival of patients undergoing lung transplantation for other indications.[41]

Prognosis

The natural history of sarcoidosis is highly variable.[20] In 60% to 70% of all cases, spontaneous remission will occur; in 10% to 30%, the disease will have a progressive course. The mortality is 1% to 5%; death usually results from progressive lung disease, neurosarcoidosis, or cardiac disease. Other adverse prognostic features include lupus pernio, chronic uveitis, onset after 40 years of age, hypercalcemia or nephrocalcinosis, black race, nasal mucosal involvement, and cystic bone disease.

Despite many investigative efforts over the past 30 years, no test has been shown to be better than the chest radiographic staging system in predicting the clinical course of sarcoidosis. Approximately 75% of patients who have stage I sarcoidosis will undergo spontaneous remission within 2 years after presentation. Erythema nodosum at initial presentation increases the likelihood of spontaneous remission. Patients in whom bilateral hilar lymphadenopathy fails to remit within 2 years may remain stable, may undergo spontaneous remission at a later time, or may develop progressive pulmonary disease. No more than 10% to 15% of patients develop progressive pulmonary disease. Roughly 50% of patients with stage II sarcoidosis will be in remission 2 years after presentation. Stage II disease is more likely than stage I disease to be progressive and to follow a chronic symptomatic course than stage I disease. Only one third of patients with stage III sarcoidosis will be in remission 2 years after presentation. The disease commonly takes a chronic course that eventually leads to lung fibrosis (stage IV). Patients with stage IV disease have irreversible disease, though many such patients have clinically inactive disease and therefore do not require immunosuppressive treatment.

idiopathic pulmonary fibrosis

IPF, also known as cryptogenic fibrosing alveolitis, is one of the most common and most serious causes of chronic diffuse infiltrative lung disease.[1,42] Although this disorder has characteristic clinical, radiographic, physiologic, and histopathologic features, none of these features is pathognomonic. Therefore, a diagnosis of IPF requires not only a compatible clinicopathologic picture but also the exclusion of all other causes of diffuse disease. For example, the pulmonary manifestations of IPF may be indistinguishable from diffuse disease associated with collagen vascular disorders; asbestosis; chemotherapy-induced lung fibrosis and several closely associated disorders; bronchiolitis obliterans organizing pneumonia (BOOP); lymphocytic interstitial pneumonia (LIP); desquamative interstitial pneumonia / respiratory bronchiolitis interstitial lung disease (DIP / RBILD); acute interstitial pneumonia (AIP); and nonspecific interstitial pneumonia / fibrosis (NSIP / F).[43]

Pathogenesis

The pathogenesis of IPF is not well understood and is the topic of continued debate.[44,45] A viral trigger has been suspected of playing a role in certain instances because a substantial minority of patients date the onset of their respiratory symptoms to a flulike illness. Cigarette smoking; chronic aspiration; exposure to various environmental factors (metal and wood dusts); latent viral infections, especially from the herpesvirus family; and use of antidepressant drugs have been suggested as risk factors.[42] A genetic susceptibility may also be important, as evidenced by familial clustering,[46] the recent identification of a candidate gene,[47] and the occurrence of pulmonary fibrosis in the inherited disorder Hermansky-Pudlak syndrome.[48] It may be that IPF results when a genetically susceptible person is exposed to a viral or environmental agent that triggers a set of events leading to a cascade of inflammatory, possibly immune, events that result in fibrosis.

Whatever the stimulus, the pathology of IPF suggests that the lung is subjected to repeated episodes of injury that lead to activation of pathways resulting in pulmonary fibrosis [*see Figure 7*]. Neutrophilic inflammation, previously thought to play an important role in initiating the process, is probably an epiphenomenon.[49] There may be a role for T helper type 2 (Th2) lymphocytes and their cytokine products in the process. The current hypothesis[42,49] is that repeated episodes of injury to the epithelium results in formation of a microscopic lesion—in essence, a wound—in the wall of the alveolus, with the development of a fibrin clot in the alveolar space and disruption of the basement membrane. The alveolar cells secrete growth factors (platelet-derived growth factor [PDGF], transforming growth factor–β [TGF-β], and tumor necrosis factor–α [TNF-α]) that induce migration and differentiation of fibroblasts. These cells produce gelatinases that further disrupt the normal extracellular matrix and the basement membrane. Angiogenic factors (vascular endothelial growth factor [VEGF] and fibroblast growth factor–2 [FGF-2]) induce new-vessel formation. An imbalance of increased synthesis of extracellular matrix proteins, mainly collagen, and decreased collagenolytic activity results in the progressive deposition of matrix. Deficient apoptosis of fibroblasts and increased epithelial cell death impair reepithelialization. This aberrant wound healing, as it may be termed, leads to the development of pulmonary fibrosis.

Clinical Manifestations

As with other types of diffuse infiltrative lung disease, dyspnea on exertion and cough are the most prominent symptoms. Physical examination typically reveals fine, dry inspiratory rales. Cyanosis may be noted when hypoxemia is severe, and features of cor pulmonale (e.g., elevated jugular venous pressure, edema, and a prominent pulmonic second heart sound) indicate advanced disease. Clubbing of the digits is noted in 25% to 50% of cases but is often absent early in the course of the disease. There are no other extrathoracic manifestations of disease. Clinical evidence of extrapulmonary disease (e.g., arthritis, skin disease, or serositis) suggests a systemic disorder, such as sarcoidosis or one of the collagen vascular diseases, rather than IPF.

Diagnosis

A diagnosis of IPF is established by correlating histopathologic and clinical findings. Clinically, IPF is suspected when a diffuse infiltrative lung disease occurs with no involvement of other organ systems and there is no apparent relation to infection, environmental exposure, or drugs. The chest radiograph shows no evidence of hilar adenopathy or pleural effusion. Laboratory tests in IPF are generally unrevealing, except for the presence of a positive antinuclear antibody or positive rheumatoid factor in up to 50% of cases. Thus, serum antinuclear antibody and rheumatoid factor cannot be relied on to differentiate IPF from diffuse infiltrative lung disease associated with collagen vascular disorders if the titers are low.

The initial approach to diagnosing IPF is to exclude as many causes of diffuse infiltrative lung disease as possible by a combination of history and clinical examination. However, a number of causes remain that cannot be reliably identified without a lung biopsy. Such causes include stage III sarcoidosis, lymphangitic carcinomatosis, lymphangioleiomyomatosis, eosinophilic granuloma, DIP / RBILD, NSIP / F, LIP, AIP, and the more diffuse forms of BOOP.

Imaging studies The radiographic features are nonspecific and most often consist of a bilateral reticular or reticulonodular pattern that typically appears in the lower lung fields; if cor pulmonale develops, enlargement of the pulmonary arteries and hypertrophy of the right ventricle occurs. In as many as

10% of patients with symptomatic IPF, the chest radiograph may be entirely normal. Radiographic findings in patients with IPF are limited to the lung fields. Hilar lymphadenopathy or pleural effusion suggests a different cause of diffuse infiltrative lung disease.

HRCT may be helpful at this stage of the evaluation because the pattern of abnormalities seen in IPF is specific, and many of these other causes have characteristic and very different patterns.[6] Also, HRCT is likely to reveal abnormalities in cases in which the chest radiograph is normal.

The HRCT pattern in IPF includes patchy, peripheral, subpleural, bibasal reticular abnormalities with minimal ground-glass opacity. With advanced disease, honeycomb lung and traction bronchiectasis / bronchiolectasis, indicating end-stage lung fibrosis, are seen. Extensive areas of ground-glass haziness, indicating an acinar filling process, are not characteristic of IPF but may be seen in AIP, LIP, DIP / RBILD, and NSIP / F.

Pulmonary function testing The physiologic abnormalities of IPF are basically the same as those described for diffuse infiltrative lung disease. The classic composite physiologic picture of IPF is reduced $D_{L_{CO}}$, restriction of lung volume, exercise-induced oxygen desaturation, and absence of airflow obstruction. Some of the alterations correlate with the pathologic findings.[50]

Histopathologic features The histopathologic features of IPF are nonspecific. Similar histopathologic findings are observed in diffuse infiltrative lung disease associated with collagen vascular disease, various types of drug-induced diffuse disease, chronic hypersensitivity pneumonitis, asbestosis, and other disorders. Chronic fibrosis and a scant inflammatory cell infiltrate, the essential pathologic features of IPF, are common reactions to a variety of agents.

The histopathologic picture in IPF is termed usual interstitial pneumonitis (UIP) and is characterized by minimal interstitial inflammatory round cell infiltrate, widening of alveolar septa, and fibrosis with fibroblastic foci[43] [*see Figure 8*]. The distribution of the lesion is irregular: areas of intense fibrosis can coexist with areas of near-normal lung in the same open lung biopsy specimen. In some cases, more than one histologic pattern is seen; in such cases, if any areas of UIP are seen, the clinical diagnosis should be IPF.[51]

UIP must be differentiated from DIP / RBILD, AIP, LIP, NSIP / F, and BOOP, because of different prognoses [43] and treatment approaches (see below).
