Rodents	*Staphylococcus, Streptococcus, S. moniliformis*	Penicillin G (for *S. moniliformis*), amoxicillin–clavulanic acid, doxycycline*
Nonhuman primates	*Staphylococcus, Streptococcus,* monkey B virus	Amoxicillin–clavulanic acid; third-generation fluoroquinolones; acyclovir, valacyclovir, or famciclovir (for monkey B virus)

*Consider doxycycline in penicillin-allergic patients but do not use in pregnant patients or young children.

After the examination and provision of adequate anesthesia, the wound should be meticulously cleaned and irrigated. Wound soaking or scrubbing is to be avoided. Irrigation with 200 to 250 ml of normal saline or dilute povidone-iodine solution using moderate pressure (20 psi, the pressure generated using a syringe and a 19-gauge needle) has been shown to decrease wound infection fivefold.[16,43] Careful debridement of nonviable or grossly contaminated tissue may be necessary. If the risk of rabies is high, a benzalkonium chloride scrub should be used, because povidone-iodine irrigation has not been shown to be effective in reducing viral load.[16] Benzalkonium chloride should be rinsed out to avoid tissue irritation.

Whether lacerations associated with bite wounds should be treated with primary closure is an area of debate. A number of studies suggest that it is safe to suture bite-wound lacerations that are greater than 1 to 2 cm in length and less than 12 hours old—especially those about the head and face, where there is good circulation and greater concern for a good cosmetic result.[44,45] Bite wounds to the hand and to the lower extremities often result in complications and probably have increased rates of infection with primary closure.[44,46]

The use of prophylactic antibiotics for any bite wound is debatable,[47] but there is general consensus that certain wounds in all patients and most wounds in certain patients deserve prophylactic antibiotics [*see Table 1*]. The antibiotic of choice for prophylaxis of most mammalian-bite wounds is amoxicillin–clavulanic acid. For the penicillin-allergic patient, a third-generation fluoroquinolone (e.g., moxifloxacin)[48] or a cephalosporin (e.g., cefotaxime)[49] serves as a good alternative [*see Table 2*]. The timing of prophylactic antibiotics is important. Prophylactic antibiotics should be given as soon after the bite injury as possible. A systematic review suggests that prophylactic antibiotics may reduce the incidence of infection in all hand-bite wounds and human bites, regardless of location.[49]

Table 3 Recommendations for Tetanus Prophylaxis after Animal Bites

Primary Tetanus Immunization Series Received?	*Wound*	*Time since Last Tetanus Toxoid Dose*	*Recommended Prophylaxis*
Yes	Clean, minor	> 10 yr	Td*
	All other	> 5 yr	Td*
Uncertain	Clean, minor	—	Td*
	All other	—	Td*, TIG†

*Adult (> 7 yr) Td dose is 0.5 ml I.M.; DTaP (diphtheria, tetanus, acellular pertussis) vaccine may be used in patients younger than 7 yr.
†Dose of TIG is 250 units I.M.; give in opposite arm from Td.
Td—diphtheria and tetanus toxoids adsorbed TIG—tetanus immune globulin

Tetanus prophylaxis should be given to those patients who have not been immunized in the previous 10 years [*see Table 3*]. The standard adult dose is 0.5 ml of tetanus and diphtheria toxoids adsorbed, given intramuscularly. If tetanus immune globulin is required, it is usually given in a single dose of 250 units intramuscularly, but not in the same arm as the tetanus toxoid.

Postexposure rabies prophylaxis consists first and foremost of appropriate wound care. The use of rabies immune globulin and vaccine administration depend on local epidemiology, the animal involved (species and behavior), and the type of exposure[16] [*see 7:XXXI Viral Zoonoses*]. Postexposure rabies prophylaxis for domestic animal bites is warranted in any of the following circumstances: (1) the animal is observed to be abnormal, (2) the animal is not available for observation and the rate of endemic rabies in domestic animals for the region is not exceedingly low, or (3) the animal exhibited abnormal behavior, including an unprovoked attack [*see Table 4*].[26]

Snakebites

EPIDEMIOLOGY

Over 3,000 species of snakes exist worldwide. Snakes are found everywhere on Earth except for the Arctic and Antarctic, New Zealand, Madagascar, and a few small islands. Snakes live in almost all land environments and in both saltwater and freshwater.

Approximately 10% of snakes are venomous. Of the 14 families of snakes, only five include venomous species: the Colubridae, Hydrophidae (sea snakes), Elapidae (cobras, kraits, mambas, and coral snakes), Viperidae (Russell viper, puff adder, Gaboon viper, saw-scaled viper, and European viper), and Crotalidae (rattlesnake, water moccasin, copperhead, bushmaster, and fer-de-lance). Snakes are carnivores; venomous snakes use their venom to immobilize prey for digestive purposes.

The number of snakebites in the United States is estimated to be approximately 8,000 a year. Many bites occur when patients are hiking, walking, or handling a snake. Frequently, the patient is intoxicated at the time of the bite.[50] Most snakebites do not result in envenomation, but nine to 15 deaths occur annually from

Table 4 Recommendations for Rabies Postexposure Prophylaxis[27]

Animal Type	*Evaluation and Disposition of Animal*	*Postexposure Prophylaxis Recommendations*
Dogs, cats, ferrets	Healthy and available for 10 days of observation	Do not begin prophylaxis unless animal develops clinical signs of rabies*
	Rabid or suspected rabid	Immediately vaccinate
	Unknown (e.g., escaped)	Consult public health officials
Skunks, raccoons, foxes, most other carnivores; bats	Regarded as rabid unless animal proved negative by laboratory tests†	Consider immediate vaccination
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), other mammals	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies postexposure prophylaxis

*During the 10-day observation period, begin postexposure prophylaxis at first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.
†The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

bites that do result in envenomation.[51] In the United States, rattlesnake bites most frequently result in significant envenomation and death.

Snakes are most active in the spring, when they begin to mate and are no longer hibernating[52]; however, the incidence of snakebite is highest in the summer months. Snakes remain active throughout the day and night, but because they are poikilothermic, they must contain their activity within a narrow temperature range of approximately 25° to 35° C.

CORAL SNAKES

The range of the eastern coral snake extends from North Carolina south and west to Texas. The western coral snake is found mainly in Arizona and New Mexico. Coral snakes are nocturnal and shy away from human contact.

Coral snakes are identified by their color, pattern, and permanently erect fangs. The nose of the coral snake is black, and the body has black, red, and yellow bands. The black bands do not separate the red and yellow bands, as they do on the nonvenomous but similarly banded kingsnake. This pattern is commonly remembered through the rhyme "red on black, venom lack; red on yellow, kills a fellow" [*see Figure 1*]. Coral snakes release their venom slowly, so they attach themselves to their prey and envenomate through a chewing motion. Instead of the puncture wounds typical of most snakebites, the chewing leaves what appear to be scratches on the skin.[52,53]

The bite of the eastern coral snake can be fatal. There are no confirmed fatalities from western coral snake envenomations.

PIT VIPERS

In the United States, pit vipers (Crotalidae) are found in all states except Maine, Alaska, and Hawaii. South America has nine subspecies of rattlesnakes; Mexico and Central America have four subspecies of rattlesnakes. These snakes can be found in a variety of habitats and at elevations up to 14,000 ft. The eastern and western diamondback rattlesnakes (*Crotalus adamanteus* and *C. strox*) [*see Figure 2*] are the largest and most dangerous in the United States and are found in the southwestern states and in Nevada, California, and Oklahoma.[54,55] The timber rattlesnake (*C. horridus*) is the second most dangerous rattlesnake common to the eastern United States, but it is rarely found in Delaware, Maine, Michigan, or Washington, D.C. Pigmy rattlesnakes (*Sistrurus catenatus* and *S. miliarius*) are found in areas ranging from New York to Michigan and from Texas to Arizona; they have the least toxic venom of all of the rattlesnakes.[51] Overall, rattlesnakes are responsible for 65% of envenomations in the United States. Their venom is 2.5 to 5 times more toxic than other North American species of venomous snakes.[50] Cottonmouths (*Agkistrodon piscivorus*), also known as water moccasins, live in the southern and southeastern states along streams and in low-lying trees. Copperheads (*A. contortix*) [*see Figure 3*] are found in mountains, rock piles, and sawdust piles. Their range extends from Massachusetts southwest to Texas. Cottonmouths and copperheads have only moderately toxic venom; their bite is painful but rarely fatal. In a study of 400 copperhead bites, 32 of which were treated with antivenin, 88% of bites responded to the antivenin, as evidenced by a cessation of local tissue injury progression.[56]

Pit vipers are identified by a small depression (pit) between the eyes and the nostrils bilaterally. They have a triangular-shaped head, an elliptical pupil, and fangs that fold back when the mouth is closed and unfold via a hingelike mechanism when the mouth is opened. The pit is a heat-sensitive organ that enables the snake to locate live, warm-blooded prey. Snakes can detect movement at a distance of about 40 ft. They can strike at a distance of approximately half their body length. Rattlesnakes use their rattle when threatened or endangered, not necessarily just when they are about to attack. The pit viper is aggressive and will stand its ground when provoked or cornered.[54,55] The venom is stored in glands that are located on each side of the head above the maxillae and behind the eyes. The glands are similar in function to the human submaxillary glands. The snake may discharge anywhere from 25% to 75% of its venom when biting a human. The fangs are either hollow or grooved. Even young snakes are venomous, and the venom of young snakes may be 12 times as strong as the venom of adult snakes.

ENVENOMATION

Toxicology

Snake venom has both neurotoxic and hematotoxic properties. The venom is a complex mixture of hydrolases, polypeptides, glycoproteins, and low-molecular-weight compounds. Snake venom, especially that of the Elapidae and Hydrophidae families, contains polypeptides that produce neuromuscular blockade at the presynaptic or postsynaptic terminals, or both, causing a flaccid paralysis. Composition of the venom varies greatly between species and between individual snakes. Viper venom is mainly cytotoxic, Elapidae (cobra, coral) venom is usu-

Figure 1 **The nose of the coral snake is black, and the body has black, red, and yellow bands. The black bands do not separate the red and yellow bands, as they do on the nonvenomous but similarly banded kingsnake. Snake shown is an eastern coral snake, *Micrurus fulvius*.**

Figure 2 **Diamondback rattlesnakes are the largest and most dangerous rattlesnakes in the United States. Shown is an eastern diamondback rattlesnake, *Crotalus adamanteus*.**

Figure 3 **The copperhead (*Agkistrodon contortix*) has a geographic range that extends from Massachusetts southwest to Texas. Bites from these snakes are painful but rarely fatal.**

ally neurotoxic, and Hydrophidae (sea snake) venom is mainly myotoxic.[57]

Snake venom has profound effects on coagulation pathways, causing a hypercoagulable state. Over the first few hours after a person is bitten, thrombocytopenia occurs, with a platelet count of less than 10,000/mm^3, a decrease in fibrinogen, and an increase in fibrin degradation products. The venom proteins may induce distention of the vascular basement membrane and capillary matrix.[58] Prothrombin time and partial thromboplastin time increase with severe envenomation. Usually, these increases occur because consumption of coagulation factors results in clinical anticoagulation. In dog experiments, activation of fibrinolysis may be preceded by thrombus formation, with clotting of critical vessels in the coronary vasculature, which can lead to cardiac arrest and death. This may also explain pulmonary emboli, as the thrombus formation may occur in the legs and cause deep vein thrombosis.[59] Drops in hematocrit may also occur, along with so-called burring of erythrocytes.[54] Approximately 53% of patients experience coagulopathy 2 to 14 days after envenomation. In one study, 76% of patients with pit viper envenomations developed coagulopathy during their hospital course.[60] The coagulopathy may last up to 26 days.[59]

Clinical Features

From 30% to 50% of snakebites do not result in envenomation. The snake can control the amount of venom injected and may inject up to 90% of its venom to immobilize its prey. Other factors involved in the injection of venom include the health of the snake; its satiety; the condition of the fangs; the toxicity of the venom; whether the snake is injured; and the size, age, and health of the victim.

Minor pit viper envenomation causes local pain and swelling (edema with a diameter of approximately 1 to 5 in.), without systemic symptoms or signs. Moderate envenomation is characterized by greater edema (diameter of 6 to 12 in.), weakness, sweating, nausea, fainting, dizziness, ecchymoses, and tender adenopathy.[51] As the envenomation becomes more severe, the symptoms increase to include tachycardia, tachypnea, hypothermia, hypotension, ecchymoses, paresthesias, fasciculations, gingival bleeding, hematemesis, hematuria, melena, oliguria, epistaxis, intracerebral hemorrhage, or coma.[58] Fasciculations are a characteristic manifestation of bites from the eastern diamondback rattlesnake.[61] The skin around and over the snakebite will develop a tense, discolored bulla with serous or hemorrhagic fluid. Death usually results from hemorrhage, increased vascular permeability, and thromboembolic events secondary to disruption of the coagulation pathways.

Coral snake envenomation is painful and has the appearance of scratch marks with no surrounding edema. Systemic symptoms are delayed by about 1 to 6 hours. They begin with paresthesias around the wound margins, followed by weakness, apprehension, giddiness, nausea, vomiting, and a sense of euphoria. Excess salivation is nearly always present.[61] Bulbar and cranial nerve paralysis and ptosis may develop. Ptosis is very common and is often the first sign of coral snake envenomation. Diplopia, papillary dilatation, salivation, dysphagia, and respiratory failure may occur. The paralysis may last up to 14 hours, and full strength may not return for 6 to 8 weeks. In fatal cases, the usual cause of death is respiratory failure.

Viperid venom may increase vascular permeability, leading to bleeding into the gastrointestinal or genitourinary tract. In addition to the obvious signs and symptoms, renal failure may oc-

cur secondary to hemorrhage, coagulopathy, or secondary shock. Intracranial hemorrhage, especially into the anterior pituitary gland (leading to Sheehan syndrome) has been seen in envenomation by the Russell viper. Nephrotic syndrome, glomerulonephritis, hemolytic-uremic syndrome, and DIC have an incidence of 1.4% to 28%, especially in envenomations by the Russell viper, puff adder, and sea snake.[59,62]

TREATMENT

First Aid

Treatment in the field should focus on preventing systemic absorption of the toxin. This may be done with compressive dressings and immobilization of the bitten extremity. Stabilization may be accomplished via an inflatable splint. Nothing should be given by mouth.

If signs of envenomation begin to occur, a constriction band to impede lymphatic flow should be placed on the extremity, proximal to the bite.[63] The Commonwealth Serum Laboratory technique (Australia) uses an elastic band or air splint for wrapping the extremity. The Monash method uses a thick pad and tight bandage over the wound site to impede flow of the venom. Both of these methods have proven efficacy only with Elapidae bites. Transport to a hospital should take place immediately, because the absorption of neurotoxic venoms may result in respiratory compromise or arrest. In patients with a facial envenomation, edema may cause airway obstruction, so emergency response personnel may have to establish immediate airway control.[64]

The site should be wiped off and cleaned. However, the old practice of incising the bite site and applying suction to remove the snake venom should not be used. This practice, which dates from the 1920s, was tested in animal models and found not to increase survival. In fact, incision and suction at the wound site poses more hazard than benefit. The incision may aggravate bleeding, damage nerves and tendons, introduce infection, and delay healing. Cryotherapy (e.g., placing ice on the bite site), which was once thought to lower venom enzyme activity and absorption into the systemic circulation, has also been shown to provide no significant benefit; rather, it causes tissue loss, cold injury, and possible permanent disability.

Extraction therapy has also fallen out of favor. In this procedure, a suction device is placed over the fang wounds, and suction is applied to remove the venom from the bite site and the surrounding tissue without an incision. Prehospital personnel who find a suction device already in place when they arrive at the scene should remove the device, provided there is no fluid accumulating in the cup.[64] The use of field first-aid methods such as incision and suction, tourniquets, and cryotherapy has been associated with a threefold increase in the likelihood of the need for surgical intervention.[50]

Although popular belief has it that snakebites kill within minutes, in fact, the toxicity from snake venom usually does not even begin to affect the body for several hours. In one review, 64% of deaths from snakebite occurred between 6 and 48 hours after the patient was bitten.[65]

Emergency Department Management

History When a snakebite victim arrives at the hospital, the history of the bite should be obtained. This should include (1) a description of the snake, (2) the time elapsed since the bite, (3) the circumstances surrounding the bite, (4) the number of bites, (5) the location of the bite, (6) the type of first aid administered, and (7) any symptoms that have occurred since the bite. The patient's past medical history and allergy history should be reviewed briefly. In particular, the clinician should ask whether the patient has ever experienced allergic symptoms around horses or on exposure to horse serum and whether the patient has asthma, hay fever, or urticaria.

Physical examination Special attention should be paid to the area around the snakebite. The wound should be examined for fang marks, edema, petechiae, ecchymoses, and bullae. Thorough neurologic and cardiovascular examinations are indicated. If the patient was bitten on an extremity, circumferential measurements of the extremity should be taken at the site of injury and 5 in. proximal to the site. Distal pulses and neurologic status should be assessed and recorded, because edema from snakebites may result in elevated compartment pressures, leading to compartment syndrome.[50,64] The patient should be monitored in an intensive care setting.

Laboratory tests All patients should have baseline laboratory studies performed, including a complete blood count, urinalysis, electrocardiogram, prothrombin time, partial thromboplastin time, fibrinogen levels, fibrin split products, serum electrolytes, blood urea nitrogen, and serum creatinine. Blood should be typed and screened. In severe envenomations, arterial blood gas determinations also are indicated. In patients with extremity edema, arterial Doppler evaluation and, in some cases, compartmental pressure determinations may be necessary.

Antivenin Therapy

Antivenins are available for bites of North American pit vipers and eastern coral snakes. Water moccasin and copperhead bites are typically managed without the use of antivenin. The choice whether to use antivenin is based on many factors, including clinical signs and symptoms of envenomation and the physiologic status of the victim. Antivenin is indicated only for severe envenomations.[66]

Antivenin can be obtained through hospital pharmacies, veterinarians, local zoos, and poison control centers. Antivenin is most therapeutic when given within 4 hours after the bite. It is of limited value when given after 12 hours.[52]

Classification of envenomation Envenomations are classified according to a five-level system. The amount of antivenin given correlates with the grade of envenomation.

In grade 0 envenomations, the patient may have fang marks or superficial abrasions of the skin at the bite site but has minimal local edema or pain and no associated systemic manifestations.

Grade 1 envenomations involve some pain or throbbing at the bite site, with 1 to 5 in. of edema and erythema surrounding it. There are no systemic manifestations.

Grade 2 envenomations produce more severe pain over a larger area. The edema spreads toward the trunk, and petechiae and ecchymosis are present in the edematous area. There may be systemic involvement consisting of nausea, vomiting, and temperature elevation.

Grade 3 envenomation is considered severe. Edema spreads up the extremity and may move to the trunk. There may be generalized ecchymosis and petechiae. The patient may have a rapid pulse, hypotension, and hypothermia and may go into shock.

Grade 4 envenomation is very severe and usually results from the bite of a large snake or from a very large venom load. Edema,

petechiae, ecchymosis, and necrosis rapidly overtake the extremity and a large portion of the trunk. Muscle fasciculations, sweating, nausea, vomiting, cramping, pallor, weak pulse, incontinence, convulsions, and coma may all occur.

Antivenins Multiple types of antivenin are on the market. The first marketed antivenin (Antivenin [Crotalidae] polyvalent [ACP]) was a horse-serum–based, whole antibody preparation. The dosage for that preparation was three to five ampules of antivenin diluted in 500 ml of intravenous fluid. Up to 54% of patients treated in studies were allergic to the ACP antivenin. Rash, hypotension, wheezing, and phlebitis occurred in 20% of patients.[67] Nevertheless, clinicians would frequently forgo skin testing for allergy to ACP because it delayed administration of the antivenin.

Although the ACP antivenin is still produced and is used in some areas, a polyvalent crotalid (ovine) Fab antivenin (CroFab) has been introduced. This antivenin minimizes the risk of immediate hypersensitivity and prevents delayed serum sickness. It is based on sheep serum and is four to five times more potent than ACP.[60] CroFab is made by immunizing sheep with crotaline snake venom and digesting the immune serum with papain to produce antibody fragments (Fab and Fc); the antigenic Fc segment is removed during purification.[66] In a study of 1,000 treated patients, none showed evidence of true anaphylaxis.[68] Each vial of CroFab contains 750 mg of Fab and is reconstituted in 10 ml of normal saline; four vials are diluted in 250 ml of normal saline. Studies have shown improvement at the 4-hour mark in all patients given this regimen, although some patients subsequently worsened.[68] The half-life of Fab antivenin is less than 12 hours, compared with 61 to 194 hours for ACP,[69,70] so repeat dosing of Fab may be needed to maintain therapeutic serum levels.[71] In studies, only 16% of patients experienced serum sickness after administration of Fab antivenin, and the severity of the serum sickness was classified as only mild to moderate; in one study, the only reaction in 64 of 65 patients receiving antivenin was simple urticaria.[72] The Fab antivenin is given in interval doses, with the first dose given to achieve initial control (defined as cessation of all symptoms—local, systemic, and coagulopathy) and subsequent doses given 6, 12, and 18 hours after the first dose. It is presumed that in some cases, coagulopathy may recur after initial neutralization of the venom. Recurrence may result from a depot of unneutralized venom at the bite site that is released into the circulation after the venom-antivenin complexes are cleared. A combination of edema, circulatory injury, and a lesser amount of subcutaneous tissue at the site of the bite may inhibit the antivenin from reaching the venom depot.[60,73] Alternatively, uncleared complexes may dissociate, leaving free venom to recirculate.[60,68]

Adjunctive Therapy

A number of adjunctive therapies have been proposed for snakebite envenomations. Excision of tissue around the snakebite to remove the depot of venom was proposed at one time, but this approach is no longer used. The strategy of excising only necrotic-appearing tissue has likewise proved inadvisable, because histologic examination of the excised tissue revealed live muscle fibers interwoven with the macroscopically necrotic tissue. Aggressive debridement and antibiotic therapy may be indicated in the event of complications from infection. This may be seen with necrotizing fasciitis from either *Vibrio vulnificans* or *Aeromonas hydrophila*.[74]

Extremity edema from a snakebite may mimic compartment syndrome, but true compartment syndrome is rare in such cases. Most often, the subcutaneous tissue rather than the deep compartmental space is involved. When a deep envenomation occurs and a true compartment syndrome does develop, first-line treatment is antivenin administration, which diminishes the compartmental pressure and swelling. Compartmental pressures greater than 30 mm Hg may indicate a need for fasciotomy, but fasciotomy and debridement should be avoided if possible because this procedure is associated with worse functional results. Fasciotomy is recommended only if a patient's fingertip was bitten and has swelled, with loss of neurovascular or functional activity. Such patients are candidates for so-called digit dermotomy. The incision should be made on the lateral or medial aspect of the finger, through the skin only, and should extend from the web to the middle of the distal phalanx.[61,75]

General Management

A regional poison control center or the local zoo should be used as a resource when dealing with a venomous snakebite. This is especially true if the snake is not believed to be native to the area, as might occur with hobbyists who keep exotic snakes as pets. For cases in which an expert is not available, the Department of Surgery at the University of California, San Diego, School of Medicine has established a Web site that lists protocols (including antivenin availability) for management of snakebites from venomous species around the world. This information is available online at http://www.surgery.ucsd.edu/ENT/DAVIDSON/snake/index.htm.

Other therapeutic measures are keyed to specific symptoms. Isotonic fluid replacement should be given if the patient is hypotensive. Abnormalities of the clotting mechanism should be corrected with blood product replacement as necessary, but this should be done only after antivenin therapy has been started. In fact, common treatments for standard coagulopathies are ineffective or dangerous for snakebite-induced coagulopathies. Instead, the effects of the venom should be treated (with antivenin) before usual coagulopathy treatment is initiated.[59] Corticosteroids are contraindicated during the acute stages of envenomation, but they may be used if the patient experiences serum sickness from antivenin use. Studies in Costa Rica have shown that in viper bites, the release of inflammatory cytokines leads to clinical and pathologic alterations similar to those found in trauma patients.[76] Further research on this reaction and on the potential use of steroids is indicated. Patients should be placed on oxygen and should be given mechanical support if necessary for signs of trismus, laryngeal spasm, or excessive salivation. Tetanus therapy should be given if indicated [*see Table 3*]. Antibiotics are recommended only if signs of infection are present. In one study, there were no wound infections in patients with nonenvenomated snakebite.[77]

The wounds should be examined daily. Superficial necrosis and hemorrhagic blebs should be debrided at days 3 through 10. Debridement may need to be done in stages.

SPECIAL CONSIDERATIONS

Snakebite in Pregnancy

In pregnant women who have been bitten by snakes, what is best for the mother will usually be best for the fetus. Fetal outcome may depend on the gestational age of the fetus, with younger age associated with a negative outcome. The miscarriage rate after snake envenomation may be as high as 43%.[78] Miscarriage may result from shock, uterine contractions, pyrex-

ia, or placental or uterine bleeding. Venom may cross the placental barrier and cause some systemic poisoning of the fetus, even if the mother remains symptom free.[78]

In pregnant snakebite victims, airway compromise and shock states should be corrected to ensure perfusion of the placenta and uterus and thereby prevent fetal hypoxia. Circulatory support with vasopressors should be avoided because they reduce uterine blood flow and are detrimental to the fetus. Pregnant women are already in a hypercoagulable state and therefore are even more susceptible to DIC.[78] Abruptio placentae from hypercoagulability has occurred after snakebites.

Antivenin is the therapy of choice in pregnant patients, but there is no reliable information regarding the risks of administration of antivenin during pregnancy. Serum sickness and anaphylactic reactions remain the highest risks associated with antivenin administration.[79]

Snakebite in Children

Snakebites in children are often on the lower extremities or—if the child was handling the snake—on the hands. Signs and symptoms are typically similar to those in adults.[80] Because of their smaller blood volume, however, children may experience a more severe envenomation syndrome.[81] In a study of 67 children with severe envenomation, 72% had systemic involvement and 50% developed coagulopathy; 61% received antivenin, and 36% of those treated experienced adverse reactions.[82] In another case study of 12 children with rattlesnake envenomation who were treated with with CroFab, no evidence of acute or delayed hypersensitivity was noted.[83] Recurrence of local swelling was seen in one patient despite repeated treatment with antivenin. In children, dosing of antivenin should be based on venom load and severity of signs and symptoms rather than on patient age or weight.[82] Although envenomation can lead to multiorgan failure in children, most of the symptoms are localized and limited to erythema, edema, and blisters at the snakebite site.[83] Although most patients are admitted to an intensive care unit, only hemodynamically unstable patients must be admitted to such a setting. Mild and moderate symptoms can be treated in the emergency department or the floor setting.[83]

Disposition

All victims of suspected snakebites should be observed for a minimum of 4 to 6 hours. If there is no sign of envenomation after 6 hours and it is believed that the snake was either nonvenomous or a pit viper, the patient can be discharged. The patient should be given instructions to return to the emergency department immediately if any symptoms of envenomation occur. A patient who has minimal edema and pain should be observed for at least 12 hours. If the swelling has begun to diminish and the pain has resolved, the patient may be discharged with the same discharge instructions.

Pit viper envenomation may result in significant hypofibrinogenemia and thrombocytopenia lasting up to 2 weeks, which may lead to complications from surgery or trauma.[84] If coagulation abnormalities have resolved, however, no further workup of the coagulation system is needed. The best predictor of late hypofibrinogenemia is early hypofibrinogenemia.[60]

Any patient who has been bitten by a Mojave rattlesnake, coral snake, or other exotic snake should be admitted to the intensive care unit, with cardiorespiratory and dialysis equipment readily available. Antivenin should be administered to such patients.[52]

SNAKEBITE PREVENTION

Snakes should not be handled except by a professional herpetologist. Even a dead snake can envenomate its handler. Persons spending time outdoors in areas known to be heavily populated with snakes should wear long pants and closed shoes. Because of the varying size of snake fangs, loose pants are preferred to tight-fitting trousers. Heavy leather boots are recommended rather than sandals, open-toed shoes, or sneakers. Persons who are going to handle snakes, even dead ones, should also wear protective gloves.

Spider Bites

The class Arachnida contains the largest number of known venomous species, including 20,000 venomous spiders. In the United States, only 50 species can envenomate humans, partly because most spiders' fangs are not long enough to penetrate human skin. All spiders are carnivorous; they capture their prey either by hunting or trapping it. Trappers spin webs and wait for prey to become ensnared. They have limited vision and sense prey on their web with their jaw, which can detect movement. Hunters have better eyesight than trappers, and most hunters eat their prey on the spot. For a true diagnosis of a spider bite with possible envenomation, there should be evidence of a bite with pain or discomfort (except with bites from *Loxosceles* species, which are considered painless), collection of the spider at the time of the bite, and identification of the spider by an expert arachnologist. Other signs should be the appearance of fang marks, redness at the site of injury, immediate or delayed itching, and the presence of spines and swelling (which may not be seen in all cases).[85]

BLACK WIDOW SPIDERS

The black widow spider, *Latrodectus mactans* [*see Figure 4*], is found throughout the United States and southern Canada, with other closely related species found mainly in the western United States. There have been no recorded findings of the spider in Alaska. The female is twice the size of the male and is the only sex that is able to envenomate. The male does have venom, but because of its smaller size and less powerful fangs, it is unable to bite and envenomate a human. The female is glossy black, with a bright-red marking on the abdomen that may appear to be two spots or have an hourglass shape. Occasionally, it has red stripes. Immature females are red, brown, and cream colored. The spider's body is about $^1/_2$ in. long; with the legs, it measures approximately $1^1/_2$ in. in length. It is usually found under rocks and in woodpiles, outhouses, and stables, and it is not aggressive unless guarding its eggs. The black widow is a trapper. The webs are close to the ground to have access to crawling insects and are usually in secluded, dim areas.

Envenomation

Toxicology Black widow venom contains various proteinaceous compounds. The venom paralyzes the prey and begins the digestive process by liquefying the victim's tissues. The toxin depletes acetylcholine from the presynaptic nerve terminals, thereby destabilizing nerve cell membranes and opening ionic channels. The toxin of the black widow is thought to cause a massive release of acetylcholine and then block its reuptake, which leads to both sympathetic and parasympathetic stimulation.[86] There is a patchy paralysis of skeletal muscles with various changes in the autonomic nervous system. This paralytic syndrome has been likened to polio.[87]

Figure 4 **The mature female black widow spider is glossy black, with a bright-red marking on the abdomen that may appear to be two spots or have an hourglass shape.**

Clinical features On being bitten by a black widow spider, a person may feel a pinprick sensation, with minimal local swelling and erythema. Two small fang marks may be visible. The middle of the bite site may be white, with surrounding erythema and a reddish-blue border. Within an hour, the patient may feel a dull ache or crampy pain in the area of envenomation. This feeling may spread throughout the body shortly thereafter. The pain will increase over the first hour in approximately one half of the cases.[85] The pain spreads to the chest from upper extremity bites and to the abdomen from lower extremity bites. This pain may mimic pancreatitis, appendicitis, or a peptic ulcer. The abdomen may have boardlike rigidity but will not necessarily be painful to palpation. In addition, there may be other myopathic signs such as facial trismus, muscle fibrillation, tonic contractions, or so-called facies latrodectismica, a constellation of symptoms that includes blepharoconjunctivitis, flushing, and contortions.[88] Other systemic symptoms may include dizziness, nausea, vomiting, headache, itching, conjunctivitis, diaphoresis, piloerection, priapism, anxiety, and dyspnea. There is wide variability in the percentage of each symptom experienced by people bitten by the spider.[85] The symptoms may last for 2 to 3 days, abating slightly after a few hours. Patients with preexisting hypertension, cerebrovascular disease, or cardiovascular disease are at risk for a worsening of those conditions. Rare complications of the bites also include compartment syndrome, rhabdomyolysis, and obstruction of the venous outflow in the affected extremity.[89]

Treatment

First aid Patients bitten by a black widow spider should have cool compresses applied to the bite and be transported to a hospital. Laboratory experiments have shown that a Sawyer extraction device may be helpful in removing venom if applied to the skin within 3 minutes after the bite.[88] Basic or advanced life support should be given on the way to the hospital. If possible, the spider should be brought along with the patient, because many nonvenomous species may resemble the black widow.

Emergency department management A complete history and physical examination should be done, with attention paid to the circumstances surrounding the bite, a description of the spider, and allergies to other bites or to horse serum. The site should be inspected and cleansed. Tetanus immunization should be updated, if necessary. Laboratory studies should be obtained, including a complete blood count, serum electrolytes, clotting studies, urinalysis, electrocardiogram, blood urea nitrogen, and serum creatinine.

Patients with envenomations should be treated symptomatically. Nitroprusside may be used for hypertensive episodes related to the envenomation. Abdominal cramps may be alleviated with calcium gluconate (10 ml of a 10% solution given intravenously over 20 minutes). Serum calcium levels should be followed. Diazepam may be given to alleviate muscle spasms.[90] Dantrolene has also been shown to provide muscle relaxation in these patients.[91]

Antivenin therapy *Latrodectus* antivenin exists and is indicated for patients who have hypertensive heart disease, underlying respiratory disease, or severe envenomation. Patients between 16 and 65 years of age may receive the antivenin. The antivenin is derived from horse serum and may cause allergic reactions. The intravenous route is preferred. The contents of the vial are diluted in 50 ml of normal saline and given over 15 minutes. The typical dose is one to two vials. Widow antivenin is available in Australia, South Africa, and the United States, which are the primary locations of the widow spiders. Intramuscular administration in Australian studies has shown few adverse reactions. However, American black widow antivenin has a higher incidence of early allergic reactions.[92]

Special Considerations

Spider bites in children Children who are bitten by a black widow spider may have severe symptoms that may lead to death. Possibly because of the smaller volume in which the venom is circulated, a dose that would be tolerable in an adult may cause fatal cardiovascular or respiratory decompensation in a child. A retrospective Australian study of red-back spider bites showed systemic symptoms of diaphoresis, irritability, and hypertension in 85% of pediatric patients admitted to the hospital.[93]

Spider bites in pregnancy A pregnant woman who is bitten by a black widow spider will have signs and symptoms that are otherwise typical, but she may not have a rigid abdomen because of the stretching and laxity of the gravid abdominal wall. However, the cramping may be severe enough to induce miscarriage. The toxin does not seem to have a direct effect on the fetus, possibly because it is not able to cross the placental barrier, nor is it able to cross the blood-brain barrier. Antivenin is indicated for the symptomatic pregnant patient.[78]

Disposition

Patients with signs or symptoms of black widow spider envenomation should be admitted to the hospital. The patient should be observed for a minimum of 2 hours and, if totally asymptomatic, may be discharged with instructions to return if any symptoms develop.

BROWN RECLUSE SPIDERS

The brown recluse spider, *Loxosceles reclusa* [*see Figure 5*], is approximately 1 in. long and ranges in color from tan to dark brown. The female has a violin-shaped dark-brown spot on its abdomen. Males and young spiders may also have a darkened violin pattern on the thorax.[94] The brown recluse has three sets of eyes arranged in pairs called dyads.

The brown recluse is frequently found in clothing, bedsheets, and blankets in a closet; in woodpiles in a shed; or under rocks. The brown recluse hunts for its food but can live for 6 months without food or water.[95] It forages at night but is not aggressive unless threatened, hence the "recluse" name.[95]

The brown recluse is found in the south central United States, especially in Missouri, Kansas, Arkansas, Louisiana, east Texas, and Oklahoma. It is occasionally found in other states, but these cases likely represent spiders uprooted and transported from the endemic areas.[94] The diagnosis of true *Loxosceles* spider bites in the United States is considered to be far less than the number of patients who are treated for recluse spider envenomations.[95] Strict inclusion criteria for recluse envenomation include sighting of the biting spider and identification of that specific spider. In studies from areas endemic for *Loxosceles,* patients present with almost no true *Loxosceles* bites or envenomations despite exposure to dozens to hundreds of spiders; these results suggest that nonendemic areas should have minimal to no true *Loxosceles* bites.[85,96]

Loxosceles spiders are also found outside of North America, most notably in Brazil and elsewhere in South America. *L. laeta* is the most toxic of these species.[97]

Envenomation

Toxicology Brown recluse venom is protein based, and it has antigenic and locally destructive properties. Esterases, hyaluronidases, and proteases have been isolated from recluse spider venom.[95] The components of the venom are cytotoxic to endothelial cells and red blood cells. Sphingomyelinase-D acts directly on red blood cells to cause lysis.[98] Unlike black widow venom, brown recluse venom has no known neurotoxic effects.

Clinical features Brown recluse spider venom produces both localized and systemic symptoms. These are referred to as cutaneous and viscerocutaneous symptoms.[85] Cutaneous loxoscelism presents initially as pain in the area of the bite, or pain may be absent at first and then develop over the next 3 to 4 hours. Soon thereafter, a ring of pallor from vasoconstriction appears around the bite, with a surrounding area of erythema. A bleb develops in the center and, after a few days, becomes necrotic. The bleb may spread with gravity-dependent flow. This necrotic area spreads over the next few days, involving both superficial and deep tissues. An eschar usually forms days later, and the wound may not heal for months after the eschar separates.[99,100] Subcutaneous fat may liquefy below the eschar, leaving a depressed scar. This occurs in areas with more subcutaneous tissue, such as the thigh. Healing of the eschar takes from 5 days to 17 weeks.[101] Viscerocutaneous loxoscelism may present as systemic effects that include fever, chills, rash, nausea, vomiting, shock, renal failure, hemorrhage, DIC, or pulmonary edema. There have been case reports of transverse myelitis and paralysis from the brown recluse spider bite; these are believed to result from microthrombosis at the anterior vertebral artery.[102] Also, loss of cutaneous sensation may be caused by damage to or destruction of a nerve or its branch by the venom itself or ischemia from the edema.[98]

The differential diagnosis of the skin changes caused by brown recluse spider envenomation includes Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema nodosum, purpura fulminans, diabetic ulcer, allergic dermatitis, Lyme disease, and pyoderma gangrenosum.[88] Patients who have had numerous brown recluse spider bites have demonstrated an antibody response and may have a decreased response to subsequent bites.[95]

Figure 5 **The brown recluse spider (7 to 12 mm body length) is a timid arachnid that may be encountered in basements, closets, and woodpiles.**

In the few cases of fatal bites, death usually results from DIC and renal failure. In the United States, however, brown recluse spider envenomations frequently result in little more than an inflammatory reaction.[94]

Spider bites in children Brown recluse spider bites in children may result in severe systemic reactions, among which are hemolytic anemia, hypotension, and anemia.[103] It is thought that sphingomyelinase-D in the venom leads to hemolysis, platelet aggregation, thrombosis, and vasoconstriction in children. The severity of any reaction is a function of the amount of venom injected and the location of the bite. Swelling of the neck and subsequent airway obstruction has been reported in a child.[104] Death is a rare but known complication.

Treatment

Prehospital care should include basic or advanced life support, cool compresses, and immobilization of the extremity. On the patient's arrival at the emergency department, a complete history and physical examination should be done, with attention paid to the circumstances surrounding the bite, the description of the spider, and allergies to other bites or to horse serum. Early diagnosis is most easily accomplished if the patient brings the spider to the emergency department. The site should be inspected and cleansed. Tetanus toxoid should be administered, if appropriate.

Brown recluse antivenin is available and has been shown in some studies to be successful in limiting necrosis, but it must be given within the first 24 hours of the bite. During this time, however, it is difficult to assess the future severity of the cutaneous lesion.[105] A 1983 study found some evidence that systemic steroids should be used with brown recluse bites if the patient is seen within 24 hours.[106] Other studies have shown that the intralesional injection of steroids may help control inflammation or thrombosis but does not alter eschar size or outcome[107,108] Dapsone has also been shown to be helpful in treating the local effects of the venom. However, it should be used only in adults who have been screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency. Dapsone is most effective in the first few hours after a

bite, but its side effects usually outweigh its benefits for prophylactic use.[105] The complications of dapsone use include hemolysis, agranulocytosis, aplastic anemia, methemoglobinemia, rashes, toxic epidermal necrolysis, and fatal reactions.[106] Phentolamine has not been shown to have any appreciable effect on the necrotic activity.[95] In animal models, hyperbaric oxygen therapy has not been conclusively proved to be effective, but studies have shown some positive outcomes.[109] In one study, electric-shock treatment of the envenomation site in a human showed a potentially positive outcome to the lesion; however, no benefit was shown in animal models, and delayed healing was actually found to occur in some cases. Therefore, electric-shock therapy has not been supported by the literature.[94,110] Excision has not been shown to improve outcome and, in fact, may be detrimental. Antibiotics may be prescribed if signs of infection are present. Analgesia should also be offered to the patient.[98] Patients who have signs or symptoms of envenomation should be admitted to the hospital. If acute renal failure develops, dialysis may be necessary. Tissue necrosis at the wound site may necessitate surgical intervention, but only if the lesion is large, has persisted for 6 to 8 weeks, and has stopped progressing in size.

Disposition

A patient who has been bitten by a brown recluse spider should be observed in the emergency department for a minimum of 6 hours. If no local or systemic symptoms develop, the patient may be discharged with instructions to return if any symptoms appear.

TARANTULAS

At least 30 species of tarantula (*Theraphosidae*) live in the deserts of the western United States. Tarantulas are hunters that eat nocturnal insects. Because of the location of its fangs, a tarantula must raise itself on its hind legs to inflict a bite. In addition, when it is handled, a tarantula releases the hairs of its abdomen, which cause a local urticarial reaction in humans.

Bites from the tarantula are relatively innocuous and result in a low-grade histamine reaction. However, they should be cleansed, and tetanus immunization should be updated if necessary.

Bites from tarantulas from the Panama Canal Zone may cause paresthesias and local discomfort. The South American tarantula has a more toxic bite, for which antivenin is available.

Treatment of all tarantula bites should be supportive, with the administration of antihistamines and oral analgesics. The tarantula hairs, which may be barbed, can be removed with adhesive tape.

Scorpion Stings

EPIDEMIOLOGY

Scorpion stings are common in tropical and subtropical regions of the world. For example, Tunisia reports almost 40,000 stings a year, which result in approximately 1,000 hospitalizations and 100 deaths.[111] Deaths from severe envenomation are the result of cardiogenic shock and pulmonary edema.[112]

Scorpion envenomation is not rare in the United States, with 14,569 consultations for scorpion stings reported in 2001 by the American Association of Poison Control Centers.[113] Most scorpion stings occur in the southwestern states. The scorpion responsible for severe envenomations in the United States is *Centruroides exilicauda*.[114]

Table 5 Grading System for Severity of *Centruroides exilicauda* Envenomation[117]

Grade	*Features*
I	Pain or paresthesia at the site of envenomation
II	Local findings plus pain or paresthesia remote from the sting site
III	Cranial nerve dysfunction* or somatic-skeletal neuromuscular dysfunction†
IV	Cranial nerve dysfunction* and somatic-skeletal neuromuscular dysfunction†

*Blurred vision, wandering eye movements, hypersalivation, trouble swallowing, tongue fasciculation, problems with upper airway, slurred speech.
†Restlessness, severe involuntary shaking, and jerking of extremities (may be mistaken for seizures).

ENVENOMATION

Toxicology

The toxin of *C. exilicauda* is a heat-stable neurotoxin that increases permeability of neuronal sodium channels, causing depolarization of the nerve and myocyte.[115] Severe envenomation results in stimulation of both cholinergic and adrenergic neurons by its action on presynaptic cell membranes.[116] Increased permeability of neuronal sodium channels in the autonomic nervous system results in tachycardia, agitation, hypertension, hypersalivation, dysphagia, and gastrointestinal symptoms.[117,118]

Clinical Features

Scorpion envenomation can produce effects ranging from local to life threatening. Envenomations are categorized by severity from grade I (pain or paresthesia at the sting site) to grade IV (combined cranial nerve and somatic-skeletal neuromuscular dysfunction) [*see Table 5*].[116]

Treatment

Most adults stung by *C. exilicauda* experience only local pain and paresthesia and can be managed as outpatients.[119] Young children, however, often present with severe involuntary motor activity, agitation, and respiratory symptoms requiring intensive supportive care.[119,120]

Initial hypertension and tachycardia may occur in close to half the patients with milder envenomation.[121] These patients normally respond well to treatment with an antihypertensive agent such as prazosin[121] or captopril.[122]

Patients with severe envenomation may have hypotension, left ventricular failure, and pulmonary edema.[122] Supportive care and afterload reduction with vasodilators appear to reduce mortality.[121,122]

The use of specific antivenin in scorpion stings is controversial.[123-127] Antivenin specific to *C. exilicauda* is not available except in Arizona,[115] where it is commonly used for severe grade III and almost all grade IV envenomations.[128] It is rarely associated with anaphylaxis but commonly results in mild serum sickness.[115,128] A majority of opinions recommend the treatment of scorpion stings with antivenin, but this recommendation depends on the dose of the antivenin and its route of administration. Intravenous administration is recommended because of the slow absorption of the intramuscular route compared with the rapid distribution and absorption of scorpion venom. In studies using the intravenous administration of antivenin, overall mortality

was reduced to less than 0.05%.[129] However, some of the symptoms, such as pulmonary edema, labile vital signs, and dysrhythmias, were still seen in envenomated patients.

The use of sedative-hypnotics has been advocated for the severe agitation and motor restlessness associated with *C. exilicauda* envenomation. Careful assessment (to ensure adequate airway, breathing, and circulation) and monitoring of patients treated with sedative-hypnotics is essential because respiratory depression and even respiratory arrest have been reported with this therapy.[115,120]

Insect Bites and Stings

Insect bites are medically important primarily because insects can act as vectors for pathogenic microorganisms by directly inoculating their human hosts while feeding on blood or tissue fluids. In addition, stinging insects have venom, and the exoskeleton, hair, and secretions may act as irritants or allergens. Allergic reactions to Hymenoptera venom are discussed elsewhere [*see 6:XV Allergic Reactions to Hymenoptera*].

Although insect bites and stings are an essentially universal human experience, the exact incidence of serious morbidity and mortality is difficult to determine because of different reporting practices, regional differences of endemic species, and the wide spectrum of clinical effects, particularly severity. In 2003, the American Association of Poison Centers reported 94,247 bites and envenomations (representing 3.5% of all toxic exposures), with six deaths (0.25% fatal exposure cases).[130] These statistics include bites and stings not only from insects but also from marine species and mammals.

FIRE ANTS

Two species of fire ants were imported into Alabama in the early part of the 1900s. Since that time, they have spread throughout the southeastern United States and Texas.[131] Fire ants both bite and sting, anchoring themselves with their mandibles to leverage the thrust of their stinger. Their venom is primarily composed of an insoluble alkaloid that has local hemolytic and necrotic effects.[132] Fire ants have a propensity to swarm, resulting in multiple bites. Initially, stings cause an erythematous papule or wheal that develops into a pruritic sterile pustule over the course of 6 to 24 hours and may persist for weeks [*see 6:XV Allergic Reactions to Hymenoptera*]. Because of the alkaloid nature of the venom, reactions typically remain local; systemic or anaphylactic reactions are rare. Occasionally, secondary infection occurs.[133]

Treatment consists of local wound care, cold packs, antihistamines, and topical steroids. Extensive involvement may necessitate oral steroids. Anaphylactic reactions are managed in the same manner as those from other causes. Secondary infection requires treatment with antibiotics. Desensitization therapy should be considered for patients who experience life-threatening reactions.[134]

KISSING BUGS AND BEDBUGS

The kissing bug (*Triatoma* species), also known as the assassin, cone-nosed, or reduviid bug, is found mostly in the southern and western regions of the United States. It feeds on the blood of vertebrates, including humans, mostly at night. Kissing bugs possess a long proboscis from which they suck blood from the victims without pain. Bites commonly occur on the face because that area is usually exposed during the night.[132] In Central and South America, kissing bugs are the vector for *Trypanosoma cruzi,* the causative agent of Chagas disease.[135]

Bedbugs (*Cimex* species) are also nocturnal bloodsucking insects that have adapted to human environments. They are found throughout the United States and live in baseboards, furniture, clothing, and bedding. Bedbugs are not known to be vectors for human disease, but allergic reactions to their bites can present as multiple clustered, erythematous, pruritic papules that can last over a week.[136] Systemic effects are rarely encountered. Treatment consists of symptomatic care with antihistamines and topical steroids.

CATERPILLARS AND MOTHS

The order *Lepidoptera* includes venomous caterpillars and moths. Some of these caterpillars have hollow spines among their body hairs; injection of venom through these spines can cause symptoms ranging from local dermatitis to generalized systemic reactions.[137] The puss caterpillar, or woolly slug, is found in the southeastern United Sates and Texas and accounts for most of the envenomations from this insect family for which patients seek medical care. Stings produce small, erythematous, painful papules at the site of contact. Fever and muscle cramps may occur, but serious systemic effects are rare.[137]

Gypsy moths infest much of the eastern United States but also are present elsewhere in the country. Skin contact with gypsy moth caterpillars can cause dermatitis from delayed hypersensitivity. Treatment is symptomatic, with topical steroids and oral antihistamines. Analgesics occasionally are needed for pain control.[135]

BLISTER BEETLES

The blister beetle is found throughout the United States.[132] Blister beetles do not have a toxic bite or sting, but they secrete cantharidin, which acts as a vesicating agent, causing skin irritation and blisters several hours after contact.[132] The blisters can range from a few millimeters to several centimeters in diameter. Pulverized blister beetles were used as an aphrodisiac known as Spanish fly, which causes urethral irritation when ingested orally. Local blisters from blister beetle contact are treated as a chemical burn, with diligent wound care and prevention of secondary infection.[135]

TICKS

Ticks are found throughout the world and are members of the class Arachnida. They painlessly attach to their host (mostly mammals) to feed on blood. The primary medical importance of ticks is as vectors for infection. Infectious diseases carried by ticks include Lyme disease, Rocky Mountain spotted fever, babesiosis, ehrlichiosis, tularemia, Colorado tick fever, and relapsing fever.[138]

Some *Ixodid* species of ticks produce a neurotoxin in their salivary gland that can induce a syndrome known as tick paralysis.[139] The toxin is usually transmitted by an engorged, gravid female and causes an ascending flaccid paralysis approximately 2 to 7 days after the tick begins feeding. Children are the ones who are most often affected. Respiratory failure may occur, and ventilatory support is required in some cases. The diagnosis is confirmed by finding an embedded tick on the victim. Removal of the tick is essential to recovery. Symptoms improve several hours to days after the tick is removed.[140]

Ticks generally attach themselves to their hosts after approximately 1 to 2 hours, so persons in tick-infested areas should perform frequent checks of their clothing and body. If a tick does attach, it should be removed promptly to minimize the risk of dis-

ease transmission. The tick should be grasped as close to the skin as possible, using blunt forceps, tweezers, or protected fingers. Steady pressure should be applied while pulling out the tick. After removal, standard wound care should be employed. If the mouth parts are only partially removed, foreign-body reactions, secondary infections, and granuloma formation can occur.

Marine Envenomations

Almost 75% of the earth's surface is covered with water, and approximately 80% of our planet's organisms live in this environment. Only a few of these marine creatures pose a threat to humans, but the dangers have been recognized since ancient times. Significant human morbidity and mortality, ranging from minor dermatitis to life-threatening infections, envenomations, and trauma, may result from exposure to marine life.

Over recent decades, human exposure to the aquatic environment has greatly increased, thanks to scientific and technological advancement and exploration, increased sport diving and recreational activities, increased harvesting of marine resources for food, private and commercial saltwater aquariums, and more travel to and greater accessibility of exotic locations. These factors have increased the risk of exposure to marine organisms. Consequently, it is imperative for clinicians, not only in coastal areas but also inland, to be familiar with the hazards.

Marine organisms that are harmful to humans range from one-celled diatoms and dinoflagellates that cause poisoning by being bioamplified up the food chain (e.g., ciguatera and amnestic shellfish poisoning) to invertebrates with lethal toxins (e.g., jellyfish poisoning) to large vertebrates, such as sharks, that can inflict massive trauma. This discussion reviews some of the more common and clinically relevant envenomations (and their associated injuries and infections) that humans may incur in freshwater and saltwater around the United States.

TOXIC INVERTEBRATES

Coelenterates

The phylum Cnidaria (which includes the former phylum Coelenterata) is divided into three classes: (1) *Hydrozoa* (which includes Portuguese man-of-war, feather hydroids, and fire coral); (2) *Schyphozoa* (true jellyfish, sea nettles, and box jellyfish); and (3) *Anthozoa* (sea anemones, stony corals, and soft corals).[141]

Coelenterates are characterized by venomous stinging organoids called nematocysts. The nematocyst is a fluid-filled capsular structure that encloses a tightly coiled, hollow, sharply pointed tubule that bursts forth into the victim when it is discharged after contact. The venom is a complex mixture of proteins, carbohydrates, and other nonproteinaceous substances.[142]

Clinical effects The clinical features of coelenterate envenomation are fairly constant but have a range of severity from mild dermatitis to rapid cardiovascular collapse resulting in death. Factors that determine severity include the following: species (the Australian box jellyfish is the most deadly of all stinging marine life[143]); season; number of nematocysts triggered; size and age of the victim; location and surface area of the sting; and the sensitivity of the victim to the venom.[141,144] Knowledge of the species of coelenterates indigenous to the geographic location is important in predicting the potential severity of the envenomation. Most hydroids and hydroid corals (which inhabit both temperate and tropical waters off the Atlantic and Pacific coasts of the United States) initially produce a stinging sensation, paresthesias, and pruritus, with local edema, blistering, and wheal formation. Occasionally, the injury can progress over several days to local necrosis, ulceration, and secondary infection.

Physalia physalis (Portuguese man-of-war) consists of a violet-blue floating sail with several nematocyst-bearing tentacles that can be up to 30 m in length.[145] They are widely distributed but are prevalent in the tropical and semitropical waters off the southeastern coast of the United States and in the Gulf of Mexico.

The man-of-war's sting produces an intense pain radiating up the involved extremity, with the development of linear, edematous, erythematous, cutaneous eruptions. Systemic involvement can occur, involving multiple organ systems, with nausea, vomiting, headache, myalgias, respiratory distress, hypotension, anaphylaxis, and cardiovascular collapse.[145,146]

Jellyfish from the class Scyphozoa display a wide variety of colors, shapes, and sizes and vary in toxic potential. They are the most common coelenterates that produce clinical injuries and that cause people to seek medical attention. They have a worldwide distribution and can range in size from a few millimeters to greater than 2 m at the bell with tentacles up to 36 m in length.[147] Because the tentacles are so long in some species, it is possible to undergo a significant envenomation without ever seeing the bell. Organisms that have washed ashore also pose a risk, because undischarged nematocysts can fire if an unwary person steps on or picks up a tentacle or part of it. Envenomations from most jellyfish are of mild to moderate severity, with clinical symptoms similar to those of the hydroids and *Physalia* species.[148]

Treatment Treatment of coelenterate stings includes advanced-life-support measures, symptomatic care, pain control, and prevention of further envenomation by nematocyst inactivation. In the case of box jellyfish envenomations, an antivenin is available (Commonwealth Serum Laboratories, Melbourne, Australia) and should be administered as soon as possible.[149] Anaphylaxis and bronchospasm should be treated with epinephrine, oxygen, intravenous fluids, glucocorticoids, antihistamines, bronchodilators, and vasopressors if needed. The area of the sting should immediately be rinsed with saltwater (not freshwater) or 5% acetic acid (vinegar) for nematocyst inhibition. In the case of a Portuguese man-of-war sting, vinegar should be avoided and only saltwater used. Tentacles should then be removed with a gloved hand, hemostats, or a towel to prevent envenomation of the treating individual.[141] Alternatively, isopropyl alcohol (40% to 70%) may be effective. For *Chrysaora* (sea nettle) or *Cyanea* (lion's mane) stings, a baking-powder slurry applied to the affected area is an effective treatment.[144] In patients with seabather's eruption, a vesicular or morbilliform, pruritic dermatitis caused by larval forms of certain coelenterates [*see 2:VIII Parasitic Infestations*], a papain (meat tenderizer) solution is effective.[150] Topical anesthetics, antihistamines, and corticosteroids may be of benefit. Prophylactic antibiotics are generally not indicated, but appropriate tetanus prophylaxis and proper wound care should be provided.

Echinodermata

The phylum Echinodermata consists of poisonous species of starfish, sea urchins, and sea cucumbers. Toxic sea urchins (mostly found in the Pacific and Indian oceans and the Red Sea) have sharp, brittle, venom-filled spines and may also possess pincerlike seizing organs termed pedicellariae.[147] Spines can eas-

ily penetrate wet suits and skin to lodge in the victim.[151] The immediate reaction consists of intense local pain, erythema, edema, and bleeding. Subcutaneous staining from pigments in the spine can also occur. If multiple spines have penetrated the skin, the patient may develop systemic envenomation symptoms, such as nausea, vomiting, paresthesias, muscular paralysis, hypotension, and respiratory distress. Nontoxic sea urchins can also cause significant morbidity by foreign-body reactions and soft tissue infections or septic arthritis if a spine enters a joint.[145]

Most starfish are nontoxic, but the crown-of-thorns sea star (*Ancanthaster planci*) is covered with thorny spines that deliver a secreted venom produced in specialized glandular tissue.[152] Sea cucumbers are free-living bottom dwellers that produce a mild toxin that is concentrated in the tentacular organs. Direct contact can cause dermatitis. The venom is usually diluted in the seawater, and the greatest risk is exposure of the corneas and conjunctiva, resulting in an intense inflammation.[148] Treatment consists of immersion in hot water (110° to 115° F) for 30 to 90 minutes or until the patient has significant relief of pain. Spines should be localized under direct visualization or by appropriate radiographic technique and carefully removed; retained spines may produce a granulomatous reaction requiring surgical excision. Routine antibiotics are not necessary, but diligent wound care and tetanus prophylaxis should be employed.[147]

Mollusca

Two classes in the phylum Mollusca that have potential toxicities include gastropods (coneshells) and cephalopods (octopuses). Coneshells are univalve animals found in shallow Indo-Pacific waters.[147] They inject potent neurotoxins (conotoxins) into their victims via a detachable, dartlike, radular tooth.[153] Local symptoms resemble a bee or wasp sting, followed by ischemia, cyanosis, and numbness in the area surrounding the wound. In severe envenomations, local paralysis can progress to generalized weakness, paralysis, and respiratory failure.[145] Octopus bites are rare, but deaths have been reported from the Australian blue-ringed octopus. This creature possesses a potent neurotoxin with at least one fraction identical to tetrodotoxin (also found in tissues from the pufferfish), which blocks neuronal sodium conduction.[153] Local symptoms are usually minimal, but significant envenomations can lead to generalized paresthesias, followed by paralysis and respiratory failure.[145] Treatment of octopus envenomation is mostly supportive, with close attention to the need for respiratory support.

Porifera

The phylum Porifera consists of over 5,000 species of sponges. Sponges are stationary acellular animals that attach to the ocean floor or coral beds and may be colonized by other animals.[147] Sponges inhabit waters off both the Atlantic and Pacific coasts of the United States, as well as Hawaii. Sponge diver's disease is usually caused by colonization of the sponges by coelenterates and manifests as a dermatitis or a local necrotic skin reaction.[152] Two primary syndromes can also occur from contact with sponges.[145] The first is a contact dermatitis similar to that caused by plants. The second is an irritant dermatitis caused by the penetration of small spicules of silica or calcium carbonate into the skin. Because it is difficult to distinguish between the two different reactions, treatment of both should be initiated. The skin should be dried, and the spicules should be removed with adhesive tape or a facial peel. Acetic acid 5% soaks should be applied for 10 to 30 minutes three or four times a day (isopropyl alcohol, 40% to 70%, may be substituted). Topical steroids may help with secondary inflammation but should not be used initially.[145]

Annelida

The phylum Annelida includes bristleworms, or fireworms, which are covered by cactuslike bristles and spines. On contact, these bristles easily enter the skin and break off, causing an intense inflammation with a burning sensation and erythema. Bristles should be removed with adhesive tape or a facial peel, with subsequent treatment similar to that used for sponge envenomations (see above).[145,147]

TOXIC VERTEBRATES

Stingrays

Stingrays are found in temperate to tropical waters worldwide and represent the most common source of human envenomations from vertebrates.[145] The stingray is armed with one to four venomous spines on a whiplike tail. Envenomations usually occur when an unwary swimmer steps on a buried stingray. The fish reflexively whips its tail upward, thrusting its spine into the victim. The venomous spine has a sharp tip with serrated edges that often cause a jagged laceration in addition to a puncture wound. Occasionally, a spine breaks off and remains in the wound.[154] Most envenomations occur on the ankle or foot. Initial symptoms include an intense, localized pain that may radiate centrally. Local edema and variable bleeding may occur. The pain intensifies, peaking after approximately 30 to 60 minutes.[155] The wound often appears dusky or cyanotic and progresses to an erythematous, hemorrhagic stage, occasionally with deep tissue involvement and frank necrosis.[154] Systemic effects can occur and include muscle cramps, nausea, vomiting, weakness, headache, diaphoresis, dizziness, and, in rare cases, seizures, paralysis, cardiovascular collapse, and death.[145] Initial treatment consists of hot-water immersion for 60 minutes to deactivate the venom, which is heat labile, and to provide pain relief. The wound should then be thoroughly irrigated and debrided, if needed. Hot-water immersion often provides adequate pain relief, but if pain continues, analgesics should be given, as well as tetanus prophylaxis. These wounds are at risk for infection, and antibiotics are often necessary, along with diligent wound care and close follow-up.[155]

Scorpionfish and Lionfish

The Scorpaenidae family consists of over 80 species and includes stonefish, lionfish, and zebrafish. Most Scorpaenidae species are reef-dwelling fish found in tropical waters of the Pacific and Indian oceans and the Red Sea.[156] They are exquisitely camouflaged, and envenomations occur when a victim inadvertently grasps or steps on one of these fish. Lionfish are often kept in home saltwater aquariums because of their beauty and, therefore, may be involved in accidental envenomations. These fish possess venomous spines covered by an integumentary sheath. The venom consists of a complex mixture of inflammatory mediators and heat-labile proteins and is injected after the spine punctures the skin.[154] The spine may also fracture and remain in the puncture site, causing a foreign-body reaction or acting as a nidus for secondary infection.

Clinical manifestations of envenomation vary from mild toxicity with the lionfish to severe life-threatening toxicity with the stonefish.[156] Initial symptoms include an intense pain at the sting site, with central radiation, that can continue to intensify for sev-

eral hours. The wound appears ecchymotic and cyanotic initially; subsequently, it often becomes erythematous and swollen. Localized tissue necrosis and skin sloughing can occur after several days.[155] Systemic symptoms can include nausea, vomiting, abdominal pain, headache, myalgias, weakness, tremor, syncope, hypotension, paralysis, seizures, cardiac arrhythmias, hypotension, cardiopulmonary arrest, and death.[154] Initial treatment is immediate immersion of the affected area in hot water (110° to 115° F) for 60 to 90 minutes in an attempt to denature the venom proteins and provide pain relief.[155] Supportive care for systemic symptoms, diligent local wound care (including evaluation for retained spines), tetanus prophylaxis, and analgesics are also the mainstay of treatment. An antivenin is available but is usually reserved for the more serious stonefish envenomations.[156]

Catfish

There are over 1,000 species of catfish worldwide that inhabit both freshwater and saltwater environments.[156] Freshwater catfish are typically sedentary bottom dwellers of slow-moving and often dirty waters. Saltwater catfish, on the other hand, travel in schools and typically stay on the move. Catfish have a smooth, scaleless skin and derive their name from the perioral barbels (which, contrary to popular belief, are incapable of inflicting any stings or envenomation). However, catfish do possess serrated dorsal and pectoral spines that have venom glands enclosed in an integumentary sheath. The spines can produce a deep puncture wound, and the glands release their venom after being traumatized.[157] Most stings occur when the fish is handled after capture, although occasionally, a wader will be stung on the foot. The initial symptom is intense pain, which radiates up the affected limb and is out of proportion to the mechanical trauma. The pain is followed by an intense inflammatory reaction that can include erythema, swelling, local hemorrhage, and tissue necrosis.[158] Systemic reactions are rare but can include nausea, vomiting, weakness, hypotension, syncope, and respiratory distress.[155]

The main concern with catfish stings, as with all aquatic trauma, is the risk of secondary infection. Catfish spines can be retained in the puncture site. Because spines are often radiopaque, x-rays should be obtained to locate them.[157] If there is evidence of a retained spine, the wound should be surgically explored and the foreign matter removed. Initial treatment includes immersion of the affected site in hot water (100° to 115° F) for 60 to 90 minutes, meticulous wound care and debridement, tetanus prophylaxis, and analgesics.[155]

Weeverfish

The weeverfish is the most venomous fish of the temperate zone and is found in the Mediterranean Sea, the Black Sea, and the eastern Atlantic coastal waters from North Africa to the North Sea.[156] It has four to eight sharp dorsal spines and two opercular spines, with which it can cause one of the most painful envenomations known. Weeverfish inhabit flat sandy or muddy bays and hide on the bottom with only their head exposed. Injuries usually occur to the hands or feet of fishermen or unwary swimmers. Weeverfish are typically sedentary but can be aggressive when provoked and can remain alive for many hours after removal from the water.[155]

Initially, weeverfish envenomations cause an intense pain that spreads to involve the entire limb; the pain is often so severe that the victim acts irrationally or loses consciousness. The wound becomes swollen, ecchymotic, and warm and may take months to heal. Systemic symptoms may occur, and secondary infection is common.[145] The affected area should be immediately placed in hot water, as for other marine invertebrate envenomations (see above), although this may not be as effective for weeverfish envenomations. The wound should be cleaned and gently explored, although retention of spines is uncommon. Tetanus prophylaxis should be administered. Systemic analgesics and possibly infiltration of local anesthetics or regional nerve blocks may be needed for pain relief.[155]

Table 6 Pathogens Associated with Aquatic Sources of Infections

Freshwater Organisms	*Saltwater Organisms*
Aeromonas hydrophila	*Aeromonas hydrophila*
Agrobacterium sanguineum	*Bacteroides fragilis*
Chromobacterium violaceum	*Clostridium perfringens*
Escherichia coli	*Erysipelothrix rhusiopathiae*
Pseudomonas aeruginosa	*Mycobacterium marinum*
Staphylococcus aureus	*Salmonella enteritidis*
Streptococcus species	*Staphylococcus aureus*
Vibrio parahaemolyticus	*Streptococcus* species
	Vibrio species

WATER-BORNE INFECTIONS

Freshwater and saltwater environments provide a medium for a host of microbes not typically encountered in traumatic wounds of nonaquatic origin. The concentration and diversity of these organisms vary, depending on temperature, sunlight, depth, salinity, nutrients, coexisting lifeforms, and pollutants. However, most aquatic microbes are heterotrophic, motile, gram-negative rods that are facultative anaerobes [*see Table 6*].[159,160] Antibiotic coverage should include gram-negative organisms, as well as *S. aureus* and *Streptococcus* species, which are the pathogens in most secondary aquatic wound infections.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III CARDIAC RESUSCITATION

TERRY J. MENGERT, M.D.

Out-of-hospital sudden cardiac arrest claims the lives of more than 300,000 persons in the United States each year, making it the leading cause of death.[1-4] In fact, approximately 50% of all cardiac deaths are sudden deaths.[5] In hospitals, a minimum of 370,000 patients also suffer a cardiac arrest, followed by an attempted, but only sometimes successful, resuscitation.[6] Although most victims of sudden death have underlying coronary artery disease (70% to 80%), sudden death is the first manifestation of the disease in half of these persons.[2] Other causes and contributing factors include abnormalities of the myocardium (i.e., chronic heart failure or hypertrophy from any cause), electrophysiologic abnormalities, valvular heart disease, congenital heart disease, and miscellaneous inflammatory and infiltrative disease processes (e.g., myocarditis, sarcoidosis, and hemochromatosis).[7-9]

The pathophysiology that culminates in a sudden cardiac death is complex and poorly understood. It likely represents a mix of electrical abnormalities combined with acute functional triggers, such as myocardial ischemia, central and autonomic nervous system effects, electrolyte abnormalities, and even pharmacologic influences.[1] Classically, most sudden deaths that occur in adults in the community are thought to be secondary to ventricular tachycardia (VT) that quickly degenerates into ventricular fibrillation (VF). In a 10-year study in the Seattle area, the different arrhythmias found in prehospital cardiac arrest patients presumed to have underlying cardiovascular disease were VF (45%), asystole (31%), pulseless electrical activity (PEA; 10%), VT (1%), and other arrhythmias (14%).[3] Studies indicate that the out-of-hospital incidence of VF has decreased in recent years, probably because of the decrease in mortality from coronary artery disease.[10]

The Chain of Survival

The resuscitation of an adult victim of sudden cardiac arrest should follow an orderly sequence, no matter where the patient's collapse occurs. This sequence is called the chain of survival.[11] It comprises four elements, all of which must be instituted as rapidly as possible: activation of the emergency medical service network, cardiopulmonary resuscitation (CPR), early defibrillation, and provision of advanced care.

ACTIVATION OF EMERGENCY MEDICAL SERVICES

A person in cardiac arrest is unresponsive and pulseless, although agonal respirations may last for minutes. Confirm unresponsiveness by speaking loudly and gently shaking the patient. If the patient is truly unresponsive, immediately call for help by activating the emergency medical service in the community (in most locales, this means calling 911); or if the patient is already in the hospital, call a code (e.g., code blue, code 199). If an automated external defibrillator (AED) is available, have it brought to the resuscitation scene. AEDs are both easily used and lifesaving.[12-16]

INITIATION OF CPR

While awaiting the arrival of a defibrillator and advanced help, the rescuer assesses the patient's airway, breathing, and circulation [*see* The Primary Survey, *below*], and initiates CPR [*see Table 1*]. When CPR is started within 4 minutes of collapse, the likelihood of patient survival at least doubles.[17,18]

INITIATION OF DEFIBRILLATION

When the AED or monitor-defibrillator arrives, attach it appropriately to the patient and analyze the patient's rhythm; if the patient is in VF or pulseless VT, a defibrillatory shock should be rapidly applied [*see Tables 2 and 3*]. If required, two additional shocks may be administered sequentially. The importance of rapid access to defibrillation cannot be overemphasized. In a patient who is dying from a shockable rhythm, the chance of survival declines by 7% to 10% for every minute that defibrillation is delayed.[19]

INITIATION OF ADVANCED CARE

If the patient remains pulseless despite the steps described above, resume CPR; establish a definitive airway, confirm its correct placement, and then secure it; establish intravenous access; then administer appropriate medications as determined by the rhythm and the arrest circumstances. If the patient is in VF or pulseless VT, repeated attempts at defibrillation are interspersed with delivery of vasoactive and antiarrhythmic drugs [*see Table 4*].

RESUSCITATION OUTCOME

When every link in the chain of survival is quickly and sequentially available, the patient is provided an optimal opportunity for return of spontaneous circulation.[19-22] In the United States, individual communities report survival rates of 4% to 40% or more in cases of sudden cardiac death.[23-27] Prehospital victims of VF have had survival rates to hospital discharge of

Table 1 Initial Resuscitation Steps in the Unresponsive Patient

- Confirm unresponsiveness
- Activate the emergency medical system
  - In most community locales, call 911
  - In the hospital, activate the appropriate code response
- Call for an automatic external defibrillator (AED)
- Begin basic life support (CPR)
  - Open airway
  - Check breathing; if not breathing, deliver two initial breaths
  - Check for a carotid pulse; if pulseless, do the following:
    - Begin chest compressions at the rate of 100 compressions/min, depressing the sternum 1.5–2 in. per compression in patients older than 8 yr
    - Intersperse ventilations with chest compressions: in nonintubated patients, deliver 15 compressions, pause for two breaths, then repeat; in intubated patients, deliver one breath every 5 sec, with no pause in compressions
- Reassess for return of spontaneous circulation every 1–3 min
- When defibrillator arrives, immediately analyze and treat arrhythmia
  - Attach patient to AED [*see Table 2*] or the monitor-defibrillator [*see Table 3*]
  - Analyze arrhythmia and treat as appropriate [*see Figure 2*]

Table 2 Using an Automatic External Defibrillator in Patients Older than 8 Years

Automatic external defibrillator (AED) arrives (CPR is in progress)
- Place AED beside patient.
- Turn on the AED.
- Attach the electrodes to the AED (they may be preattached).
- Attach the electrode pads to the patient (as diagrammed on the pads).

AED analyzes patient's rhythm
- Stop CPR (and ensure no one is touching the patient).
- Press the Analyze button on the AED (some devices analyze the rhythm automatically as soon as the pads are placed on the patient).

AED instructs rescuers (via an audible voice prompt and/or on-screen instructions)
- Shock is indicated: clear the patient (ensure no one is touching the patient) and push the Shock button.
- After delivering shock, press the Analyze button again; the sequence of analysis followed by shock (if so indicated) may be performed a total of three times.

or

- Shock not indicated: reassess the patient for signs of circulation; if present, assess the adequacy of breathing; if there are no signs of circulation, resume CPR for 1–2 min. After 1 min of CPR, assess the patient again for signs of circulation; if present, assess the adequacy of breathing. If the patient is still pulseless, repeat rhythm analysis, followed (if indicated) by shock steps.

greater than 50% when an AED was expeditiously used.[28] Many other factors also influence patient survival, however; these include whether the patient's collapse was witnessed, the rapidity and effectiveness of bystander CPR, the rhythm associated with the cardiac arrest, and underlying comorbidities.[29,30] With inpatient cardiac arrest, for example, overall survival rates vary from 9% to 32%,[31-37] but in one study, survival to hospital discharge was 30% for patients with primary heart disease, 15% for patients with infectious diseases, and only 8% for patients with other end-stage diseases (e.g., cancer, lung disease, liver failure, or renal failure).[38]

Such statistics underline the importance of using cardiac resuscitation appropriately and with discrimination. Cardiac resuscitation provides rescuers with powerful tools that save the lives of thousands of people every year. These techniques are capable of returning patients who would otherwise die to productive and meaningful lives. However, cardiac resuscitation should not be employed to reverse timely and natural death. Under those circumstances, it has the potential to lengthen the dying process and to increase human suffering. All practitioners are well advised to remember that "death is not the opposite of life, death is the opposite of birth. Both are aspects of life."[39] It is untimely death that requires immediate intervention with cardiac resuscitation.

The Primary and Secondary Surveys of Cardiac Resuscitation

A cardiac resuscitation is a stressful event for everyone involved. Too often, clinic and inpatient cardiac arrests and their management are episodes of chaos in the busy lives of resident and attending physicians. Yet, it has been eloquently stated that a good resuscitation team should function like a fine symphony orchestra.[40] Such skill levels require dedicated individual and team practice and careful code-team organization. Mastery in cardiac resuscitation is in fact a lifelong pursuit that requires training and retraining in advanced cardiac life support (ACLS); regular practice and review; and leadership and team skill development. Its key elements include not only the resuscitation itself but the response to the announcement of a code, postresuscitation stabilization of the patient, notification of the family and primary care provider, and code critique and debriefing. To help practitioners learn and apply some of the most essential techniques used in cardiac resuscitation more easily and effectively, the American Heart Association (AHA) has developed the concepts of primary and secondary surveys of a patient in atraumatic cardiac arrest.[41]

Table 3 Using a Manual Defibrillator[52,89]

Defibrillator arrives (CPR is in progress)
- Place defibrillator beside patient.
- Turn defibrillator on (initial energy level setting is typically 200 J).*
- Set Lead Select switch to Paddles. Alternatively, if patient is already attached to monitor leads, set Lead Select switch to lead I, II, or III; ensure all three leads are correctly attached to the patient and the defibrillator: white to right shoulder, black to left shoulder, red to ribs on left side.
- Apply gel to paddles or place conductor pads on patient's chest. Some devices use disposable electrode patches that are prepasted with a conducting gel. In either case, the appropriate positions of the paddles with applied gel, conductor pads, or disposable paddles are as follows: sternal paddle is placed to the right of the sternum, just below the right clavicle; apex paddle is placed to the left of the left breast, centered in the left midaxillary line at the fifth intercostal space.

Analyze rhythm

Briefly withhold CPR
- If using paddles to assess rhythm, apply paddles as described with firm pressure (25 lb of pressure to each paddle) and visually assess rhythm on monitor (if using leads, briefly withhold CPR and assess rhythm in leads I, II, or III). If rhythm is either pulseless VT or VF, proceed as follows:

Defibrillate, then reassess
- Announce to resuscitation team, "Charging defibrillator, stand clear!" and press Charge button on either paddles or defibrillator (initial energy, 200 J, not synchronized).*
- Warn resuscitation team that a defibrillatory shock is coming: "I am going to shock on three! ONE, I'm clear; TWO, you're clear, THREE, everybody's CLEAR!" Simultaneously with these statements, visually ensure that no resuscitation team member is in contact with patient.
- Press the Discharge buttons on both paddles simultaneously to deliver a defibrillatory shock.
- Reassess rhythm on monitor; if patient is still in VT or VF, recharge defibrillator (now 300 J)* and repeat process of loudly informing team members by giving the warning statements as above, and then apply defibrillatory shock.
- Reassess rhythm on monitor; if patient is still in VT or VF, recharge defibrillator (now 360 J)* and repeat process of loudly informing team members by giving the warning statements as above, and then apply defibrillatory shock.
- Reassess rhythm on monitor; if patient is still in VT or VF, resume CPR and continue with resuscitation sequence [*see Figure 2*].

*Note: if using a biphasic defibrillator, a lower initial defibrillatory energy level (< 200 J) without energy escalation on subsequent shocks is acceptable.

VF—ventricular fibrillation VT—ventricular tachycardia

Table 4 Drugs Useful in Cardiac Arrest[3,90]

Category	*Drug and Doses Supplied*	*Indications in Cardiac Arrest*	*Adult Dosage*	*Comments*
Vasopressors	Epinephrine, 1 mg in 10 ml emergency syringe; 1 mg/ml (1 ml and 30 ml vials)	Pulseless VT or VF unresponsive to initial defibrillatory shocks; PEA; asystole	1 mg I.V. push; may repeat every 3–5 min for as long as patient is pulseless; can also be given via the endotracheal route: 2–2.5 mg diluted with normal saline (NS) to 10 ml total volume	I.V. boluses of epinephrine (1 mg) are appropriate only in pulseless cardiac arrest patients; if continued epinephrine is required postresuscitation, a continuous infusion should be started (1–10 μg/min). High-dose epinephrine (up to 0.2 mg/kg I.V. per dose) does not improve survival to hospital discharge in cardiac arrest patients and is no longer recommended in adults.
	Vasopressin, 20 IU/ml (1 ml vial)	Pulseless VT or VF unresponsive to initial defibrillatory shocks	40 IU I.V. push, single dose only; can also be given via endotracheal tube: same dose, diluted with NS to 10 ml total volume	If no response after 10 min of continued resuscitation, administer epinephrine, as above.
Antiarrhythmics	Amiodarone, 50 mg/ml (3 ml vial)	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s)	VT/VF: 300 mg diluted in 20–30 ml; NS or D5W rapid I.V. push; a repeat dose of 150 mg may be given if required in 5 min; maximum dose in 24 hr should not exceed 2,200 mg	Side effects may include hypotension and bradycardia in the postresuscitation phase.
	Lidocaine, 50 mg or 100 mg in 5 ml emergency syringes; premixed bag, 1 g/250 ml or 2 g/250 ml	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s)	Initial dose: 1–1.5 mg/kg I.V.; for refractory VF or unstable VT, may repeat 1–1.5 mg/kg I.V. in 3–5 min; maximum dose, 3 mg/kg May also be given endotracheally: 2–4 mg/kg diluted with normal saline to 10 ml total volume	If lidocaine is effective, initiate continuous I.V. infusion at 2–4 mg/min when patient has return of a perfusing rhythm (but do not use if this rhythm is an idioventricular rhythm or third-degree heart block with an idioventricular escape rhythm). Continuous infusion should begin at 1 mg/min in congestive heart failure or chronic liver disease or in elderly patients.
	Magnesium sulfate, 500 mg/ml (2 ml and 10 ml vials), or 10 ml emergency syringe	Pulseless VT or VF unresponsive to initial defibrillatory shocks and epinephrine plus shock(s) if suspected hypomagnesemic state	Administer 1–2 g diluted in 100 ml D5W I.V. over 1–2 min Total body magnesium deficits should be replaced gradually after initial therapy has stabilized the emergency: administer 0.5–1 g/hr for 3–6 hr, then reassess continued need	Measured magnesium levels correlate only approximately with the actual level of deficiency. Patients with renal insufficiency are at risk for dangerous hypermagnesemia; use appropriate caution. Side effects may include bradycardia, hypotension, generalized weakness, and temporary loss of reflexes.
	Procainamide, 100 mg/ml (10 ml injection); 500 mg/ml (2 ml vial)	Recurrent or intermittent pulseless VT or VF	20–30 mg/min I.V. (up to 50 mg/min if situation is critical); maximum dose is 17 mg/kg over time (but maximum dose is reduced to 12 mg/kg in setting of cardiac or renal dysfunction) Maintenance infusion is 1–4 mg/min	Administer procainamide during a perfusing rhythm. Stop procainamide administration when arrhythmia is adequately suppressed, hypotension occurs, QRS widens to > 50% of original duration, or maximum dose is administered.
Anticholinergic	Atropine, 1 mg in 10 ml emergency syringe	Asystole or PEA (if rate of rhythm is slow)	For asystole or PEA: 1 mg I.V. every 3–5 min up to 3 mg May be given via ET tube: 2–3 mg diluted with normal saline to 10 ml	Minimal adult dose is 0.5 mg. Avoid use in type II second-degree heart block or third-degree heart block.
Miscellaneous	Bicarbonate, 50 mEq in 50 ml emergency syringe	Significant hyperkalemia Significant metabolic acidosis unresponsive to optimal CPR, oxygenation, and ventilation Certain drug overdoses, including tricyclic antidepressants and aspirin	Hyperkalemia therapy: 50 mEq I.V. Metabolic acidosis: 1 mEq/kg slow I.V. push; may repeat half initial dose in 10 min; ideally, ABGs should help guide further therapy Use in overdose: discuss with toxicologist	In non–dialysis-dependent hyperkalemic patients, bicarbonate is most useful if metabolic acidosis is also present; bicarbonate is less effective in dialysis-dependent renal failure patients. The use of bicarbonate in metabolic acidosis management in cardiac arrest patients is controversial. Side effects may include sodium overload, hypokalemia, and metabolic alkalosis.
	Calcium chloride, 100 mg/ml in 10 ml prefilled syringe	Significant hyperkalemia Calcium channel blocker drug overdose Profound hypocalcemia of other causes	In hyperkalemia: 5–10 ml slow I.V. push; may repeat if required In calcium channel blocker overdose: discuss with toxicologist	Do not use if hyperkalemia is suspected to be caused by acute digoxin poisoning. Do not combine in same I.V. with sodium bicarbonate. Calcium chloride is not a routine medication in cardiac arrest.

Note: All medications used during cardiac arrest, when given via a peripheral venous site in an extremity, should be followed by a 20 ml I.V. saline bolus and elevation of the extremity for 10 to 20 sec.

ABG—arterial blood gases D5W—5% dextrose in water ET—endotracheal PEA—pulseless electrical activity VF—ventricular fibrillation VT—ventricular tachycardia

THE PRIMARY SURVEY

The primary survey for the victim of sudden cardiac arrest consists of the appropriate assessment of the patient's airway (A), breathing (B), and circulation (C) and the simultaneous application of expert CPR until defibrillation (D) becomes possible (assuming the patient is in VF or pulseless VT). Thus, the primary survey includes the second and third links in the chain of survival (see above).

In 1958, Kouwenhoven noted that when his research fellow forcefully applied external defibrillating electrodes on a dog's chest in the laboratory, an arterial pressure wave occurred.[42] Further study and refinements led to the technique of closed-chest CPR, the careful description of which was published in 1960.[43] The first report of the use of this technique in patients was in 1961.[44] Since those early days, the fundamentals of closed-chest CPR have remained relatively unchanged. Mouth-to-mouth, mouth-to-mask, or bag-valve-mask ventilation oxygenates the blood. Chest compressions produce forward blood flow. This flow appears to result from a combination of direct compression of the heart and intrathoracic pressure changes.[45,46]

CPR in isolation does not defibrillate the heart. Its main benefit is to extend patient viability until a defibrillator and advanced interventions become available and, one hopes, succeed in restoring spontaneous circulation in the patient. CPR is not nearly as effective as a contracting heart; systolic arterial pressure peaks of 60 to 80 mm Hg may be generated, but diastolic blood pressure remains low, and a cardiac output of only 25% to 30% of normal can be achieved even under optimal conditions.[47] Still, effective CPR is critical to keeping the patient alive. It is worth remembering that the most important rescuers at a cardiac resuscitation are those who are performing expert CPR, because it is only through their efforts that the patient's heart and brain are kept viable until defibrillation and other advanced interventions can restore spontaneous circulation.

After unresponsiveness is confirmed, the emergency medical system is activated and an AED is called for; the primary survey (A, B, C, and D) proceeds as described (see below) until the AED arrives.

Airway Optimization

Open the patient's mouth and optimize the airway in the nontrauma patient by use of the head-tilt and chin-lift maneuver. A jaw-thrust maneuver should be used instead of the head-tilt technique if cervical spine injury is suspected. In patients with suspected spine injury, proper spine alignment must be maintained throughout all phases of the resuscitation. In such circumstances, as equipment becomes available, the patient's spine requires immobilization with a padded backboard, hard cervical collar, appropriate bolstering around the patient's head to prevent movement, and strapping of the patient to the backboard.[48]

Breathing Assessment

To assess breathing, the rescuer places his or her cheek close to the patient's mouth and looks, listens, and feels for patient respirations. If the respirations are agonal or the patient is apneic, the rescuer then delivers two initial breaths. Each breath is delivered over 1.5 to 2.0 seconds. The patient's chest should rise with each delivered breath, and exhalation is allowed for between breaths. Breaths may be delivered using the mouth-to-mouth technique with appropriate barrier precautions (the patient's nose should be pinched if the mouth-to-mouth technique is used) or mouth-to-mask technique. The ideal device, if available, is a bag-valve-mask device attached to high-flow oxygen; this allows the delivery of a substantially higher oxygen concentration to the patient. If the patient cannot be ventilated, the rescuer repositions the airway and attempts the technique again. If the airway is still obstructed, up to five abdominal thrusts are then applied, followed by a finger sweep of the oropharynx to relieve suspected obstruction, and then ventilation attempts are repeated. Definitive intervention for an obstructed airway in the hospital setting may involve laryngoscopic visualization of the cause of obstruction and foreign-body removal. If an adequate airway cannot be established by less invasive means, cricothyrotomy may be required.

CPR Initiation

The health care rescuer next checks for a carotid pulse in the unresponsive patient but should allow no more than 10 seconds to do so. (The AHA no longer recommends pulse checks for rescuers who are not health care providers.[49] Instead, lay rescuers should initiate chest compressions if the patient is not breathing, coughing, or moving after the initial two breaths). If the patient has no carotid pulse, begin chest compressions. The patient should be on a firm surface, and the heel of the rescuer's hand should be in the center of the inferior half of the patient's sternum (but cephalad to the xiphoid process). The rescuer's other hand is placed on top of the lower hand, with the fingers interlocked.

The rescuer's arms are held straight, with the force of each compression coming from the rescuer's trunk. In patients older than 8 years, the sternum is smoothly compressed by 1.5 to 2.0 inches, then released. The duration of the compression-release cycle is divided equally between compression and release. The rate of chest compression is 100 compressions/min in patients older than 8 years. The chest should be allowed to rebound to its precompression dimensions between compressions, but the resuscitator's palm closest to the patient should remain in contact with the sternum.

In nonintubated patients, chest compressions are regularly interrupted for the delivery of ventilations. The sequence is the same, regardless of whether one-rescuer or two-rescuer CPR is being performed: the rescuer delivers 15 compressions, pauses for two breaths (each given over 2 seconds), then resumes compressions. In endotracheally intubated patients, no pause for ventilation is necessary; every 5 seconds, one ventilation is delivered over a period of 1 to 2 seconds, while compressions continue.[18]

The optimal timing and ratio of ventilations to compressions in CPR is an ongoing area of research, which may lead to changes in the current recommendations. In the porcine model, for example, optimal neurologic outcome was achieved with the use of only compressions for the first 4 minutes, followed by a compression-ventilation ratio of 100:2.[50] In the prehospital setting, when rapid advanced care is available within minutes, bystander-initiated mouth-to-mouth ventilation combined with chest compressions offers no advantage over chest compressions alone.[51]

Good technique is critical throughout CPR delivery. The patient should have carotid pulses with chest compressions and should have appropriate breath sounds and chest movement with ventilations. Interestingly, femoral pulsations with CPR do not necessarily indicate effective CPR; these pulsations often are venous rather than arterial. Quantitative end-tidal carbon dioxide levels can be monitored, if practical. Higher levels correlate with more effective CPR and increased survival.[52] The patient should be reassessed for return of spontaneous circulation every 1 to 3 minutes [*see Table 1*].

Defibrillation

When the monitor-defibrillator or AED arrives, it is attached to the patient; the rhythm is analyzed, and if the patient is in VF or pulseless VT, defibrillation is provided [*see Tables 2 and 3*].

Defibrillation is thought to work by simultaneously depolarizing a sufficient mass of cardiac myocytes to make the cardiac tissue ahead of the VT or VF wavefronts refractory to electrical conduction. Subsequently, the sinus node or another appropriate pacemaker region of the heart with inherent automaticity can resume orderly depolarization-repolarization, with return of a perfusing rhythm.[15,53] The sooner defibrillation occurs, the higher the likelihood of resuscitation. When defibrillation is provided immediately after the onset of VF, its success rate is extremely high.[54] In a study of sudden cardiac arrest patients in Nevada gambling casinos, the survival rate to hospital discharge was 74% for patients who received their first defibrillation no later than 3 minutes after a witnessed collapse.[28] In this study, defibrillation was delivered via an AED operated by casino security officers.

Early defibrillation is so critical that if a defibrillator is immediately available, its use traditionally takes precedence over CPR for patients in VF or pulseless VT of recent onset. If CPR is already in progress, it should of course be halted while defibrillation takes place. Newer defibrillators can compensate for thoracic impedance, ensuring that the selected energy level is in fact the energy that is delivered to the myocardial tissue. In addition, defibrillators that deliver biphasic defibrillation waveforms instead of the standard monophasic damped sinusoidal waveforms allow effective defibrillation at lower energy levels (< 200 joules) and without the need for energy-level escalation during subsequent shocks.[15,55-58] In the Optimized Response to Cardiac Arrest (ORCA) study, which involved 115 patients with prehospital VF, the 150-joule biphasic-shock AED was more effective than the traditional high-energy monophasic-shock AED in four respects: it was more successful in producing defibrillation with the first shock (96% versus 59%); it led to a higher rate of ultimate success with defibrillation (100% versus 84%); it had a better rate of return of spontaneous circulation (76% versus 54%); and its use was associated with a higher rate of good cerebral performance in the survivors (87% versus 53%).[59] There were no differences, however, in terms of survival to hospital admission or discharge, and replication of the ORCA findings is lacking at this time. Current AHA guidelines state that lower-energy biphasic waveform defibrillators are safe and have equivalent or higher efficacy for termination of VF, as compared with the standard monophasic waveform defibrillator.[15,49]

Ongoing research suggests that the duration of VF is a consideration in deciding whether to defibrillate immediately and as soon as a defibrillator is available or to perform CPR for a brief period first to "prime the pump" before proceeding to defibrillation. In the porcine model in the setting of prolonged VF (> 10 minutes), CPR before countershock provides several physiologic benefits.[60] Studies have found that patients with VF of longer than 5 minutes' duration had better return of spontaneous circulation, survival to hospital discharge, and 1-year survival if ambulance personnel provided 3 minutes of CPR before performing defibrillation than if ambulance personnel performed defibrillation immediately after arriving at the scene; however, some experts question the validity of these results, on the basis of study design.[61,62]

THE SECONDARY SURVEY

The secondary survey for a victim of persistent cardiac arrest takes place after completion of the primary survey. Like the primary survey, the secondary survey follows an ABCD format, which in this case consists of advanced airway interventions (A); optimized oxygenation and ventilation by confirmation of endotracheal (ET) tube placement and repeated reassessment of the adequacy of delivered breaths (B); intravenous access and appropriate medication delivery to the patient's circulation (C); and definitive therapy (D), based on a differential diagnosis that considers the specific disease processes thought to be responsible for, or contributing to, the cardiac arrest. The secondary survey includes the fourth link in the chain of survival, rapid advanced care (see above).

Placement of an Advanced Airway

Patients who remain in cardiac arrest after completion of the primary survey require placement of an advanced airway. Depending on the setting and the experience of the rescuers, this advanced airway may be a laryngeal mask airway, an esophageal-tracheal Combitube (a tracheal tube bonded side by side with an esophageal obturator), or an ET tube.[36,63,64] The laryngeal mask airway and the Combitube can be placed by personnel with less training than that required for endotracheal intubation, and they do not require additional special equipment or visualization of the vocal cords. Nevertheless, oral endotracheal intubation is generally the preferred advanced airway technique for cardiac resuscitation, especially in the hospital setting, where experienced intubators are generally present; in the prehospital setting, the evidence supporting endotracheal intubation remains inconsistent. Endotracheal intubation isolates the airway, maintains airway patency, helps protect the trachea from the ever-present risk of aspiration, helps permit optimal oxygenation and ventilation of the patient, allows for tracheal suctioning, and even provides a route for delivery of some medications to the systemic circulation (via the pulmonary circulation) if intravenous access is unobtainable or lost.[63]

Optimization of Breathing and Ventilation

When a cardiac arrest patient undergoes endotracheal intubation, correct positioning of the ET tube must be immediately confirmed and regularly reconfirmed during and after the resuscitation [*see Table 5*]. Routine use of an esophageal detector device or end-tidal CO_2 detector is recommended, along with careful patient examination. Caution is necessary with qualitative colorimetric end-tidal CO_2 detectors because both false positive and false negative results have been documented during cardiac arrests.[65] Breath sounds should be present during auscultation over the anterior and lateral chest walls, and the patient's chest should rise and fall with delivered ventilations. No gurgling should be heard when the epigastrium is auscultated. The ET tube should be inserted to the appropriate depth marking: for average-sized adults, this is 21 cm at the corner of the mouth in a woman and 23 cm in a man. The patient's skin color should be reasonable (i.e., not dusky or cyanotic), provided that the patient's pigmentation allows such assessment.

Once correct positioning is confirmed, the ET tube is then appropriately secured to prevent its dislodgment. When feasible, an arterial blood gas (ABG) measurement will help further confirm the adequacy of oxygenation and ventilation as the resuscitation proceeds.

Establishment of Circulation Access

Access to the patient's venous circulation is mandatory; such

Table 5 Confirmation of Oral Endotracheal Tube Placement

Intubation process
Vocal cords are visualized by intubator
Tip of ET tube is seen passing between the cords
Cuff of ET tube also passes cords by 1 cm
Postintubation checks
Esophageal detector device or end-tidal CO_2 detector confirms ET tube placement in trachea
Breath sounds are symmetrical (auscultate over lateral anterior chest and in midaxillary line bilaterally)
No gurgling heard with auscultation over epigastrium
Patient's chest rises and falls appropriately with ventilation
ET tube depth is appropriate: 21 cm at the corner of the mouth in women, 23 cm in men
Secure the ET tube to prevent dislodgment
Reassess the adequacy of oxygenation and ventilation throughout the resuscitation (bedside patient assessment; also obtain ABGs when feasible)
Postresuscitation, obtain a portable chest radiograph

ABG—arterial blood gas ET—endotracheal

access may be achieved by a code-team member or members simultaneously while other resuscitators pursue steps A and B of the secondary survey. Ideally, a large intravenous cannula is placed in a prominent upper-extremity vein or the external jugular vein to optimize delivery of needed medications. If a peripheral line is not achievable, additional access possibilities include central line placement via the internal jugular, subclavian (via the supraclavicular approach), or, less ideally, femoral vein; even intraosseous access is possible (intraosseous access is a common emergency vascular access site in pediatric patients, but it is an unusual route of access in adults). It is useful to remember, as already noted, that some important resuscitation medications can be delivered via the ET tube in cases of failed intravenous access; such medications include naloxone, atropine, vasopressin, epinephrine, and lidocaine (mnemonic: NAVEL).

The commonly used medications in cardiac resuscitation may be grouped into the following general categories: vasopressors (epinephrine or vasopressin), antiarrhythmics (amiodarone, lidocaine, magnesium, and procainamide), anticholinergic agents (atropine, if the arrest arrhythmia is asystole or PEA is slow), and miscellaneous drugs used to treat specific problems contributing to the arrest state, such as sodium bicarbonate (for severe metabolic acidosis, hyperkalemia, and certain drug overdoses), and calcium chloride (for hyperkalemia, calcium channel blocker drug overdose, or severe hypocalcemia) [*see Table 4*].

Persons in cardiac arrest (which can result from pulseless VT, VF, PEA, or asystole) require a vasopressor for as long as they remain pulseless. Typically, this consists of 1 mg of epinephrine intravenously every 3 to 5 minutes. Epinephrine stimulates adrenergic receptors, which leads to vasoconstriction and optimization of CPR-generated blood flow to the heart and brain. Vasopressin (40 units I.V. once only) is a reasonable alternative to epinephrine, at least initially. Vasopressin in the recommended dose is a potent vasoconstrictor. It also has the theoretical advantage over epinephrine of not increasing myocardial oxygen consumption or lactate production in the arrested heart.[66] Despite its potential advantages, however, in a study of 200 inpatient cardiac arrest patients, vasopressin did not provide a better survival rate than epinephrine.[67] Vasopressin was also found to be comparable to epinephrine in out-of-hospital cardiac arrests when the rhythm was VF or PEA but superior to epinephrine for patients in asystole.[68,69]

During resuscitation with ongoing CPR, medication delivery through an intravenous cannula needs to be followed by a 20 ml saline bolus; if the cannula is in a peripheral vein, the extremity containing the cannula should then be elevated for 10 to 15 seconds to augment delivery of the medication to the central circulation. This is especially important because of the low-flow circulatory state with closed-chest CPR.

Differential Diagnosis and Definitive Care

The most challenging part of the secondary survey, as well as cardiac resuscitation management in general, is the problem-solving required when spontaneous circulation does not return despite appropriate initial interventions. This situation poses a critical question to the resuscitators: Why is this patient dying right now? The intellectual challenge of that question, which the resuscitators must try to answer expeditiously and at the bedside, is compounded by the emotional intensity that pervades most cardiac resuscitations.

The solvable problems that may interfere with resuscitation can be grouped into three broad categories: technical [*see Table 6*], physiologic, and anatomic [*see Table 7*]. Technical problems consist of difficulties with the resuscitators' equipment or skills; such difficulties include ineffective CPR, inadequate oxygenation and ventilation, ET tube complications, intravenous access difficulties, and monitor-defibrillator malfunction or misuse. The physiologic and anatomic problems consist of life-threatening but potentially treatable conditions that may have led to the cardiac arrest in the first place. This differentiation between physiology and anatomy is admittedly artificial, given that physiology is always involved in a cardiac arrest, but it has some usefulness as a teaching and problem-solving tool. Physiologic problems classically include hypoxia, acidosis, hyperkalemia, severe hypokalemia, hypothermia, hypoglycemia, and drug overdose. Anatomic problems are hypovolemia/hemorrhage, tension pneumothorax, cardiac tamponade, myocardial infarction, and pulmonary embolism.[41]

Whenever possible, the patient's medical and surgical history and the circumstances and symptoms immediately before the cardiac arrest should be sought from family members, bystanders, or hospital staff as the resuscitation proceeds. This information may contain important clues to the principal arrest problem and how it may be expeditiously treated. For example, a patient who presents to an emergency department with chest pain and then suffers a VF cardiac arrest is probably dying of a massive myocardial infarction, pulmonary embolism, or aortic dissection, with tension pneumothorax or cardiac tamponade also being possibilities.

Specific questions to consider include the following: Does the patient have risk factors for heart disease, pulmonary embolism, or aortic disease? What was the quality of the patient's pain and its radiation before the cardiac arrest? What were the prearrest vital signs and physical examination findings? What did the prearrest ECG show (if available)? Can any of this information be used now, at the bedside, to dictate the needed resuscitation interventions during the D phase of the secondary survey? For example, if the prearrest ECG showed prominent ST segment elevation in leads V1 through V4 consistent with a large anterior myocardial infarction, if the patient's resuscitation is failing de-

Table 6 Technical Problems That May Prevent a Successful Resuscitation

Problem	*Patients at Risk*	*Recommendations*
Ineffective CPR	All cardiac arrest patients	Ensure technically perfect CPR. Confirm carotid pulses with CPR. If arterial line was in place before cardiac arrest, confirm adequate arterial waveform with CPR on arterial line monitor. Monitor end-tidal CO_2 if available (higher levels correlate with better CPR and improved patient survival). Confirm adequate oxygenation with an ABG when feasible.
Inadequate oxygenation and ventilation	All cardiac arrest patients	Ensure optimal airway positioning and control. Have suction immediately available to manage pharyngeal and airway secretions. Ensure use of properly fitting, tightly sealed face mask for bag-valve mask (BVM) ventilation until a definitive airway is established. Apply cricoid pressure to prevent gastric distention during BVM ventilation until a definitive airway is established. Ensure that supplemental oxygen is flowing to BVM at 15 L/min. Deliver an appropriate tidal volume per breath (6–7 ml/kg if oxygen is available) at the rate of 12–15 breaths/min. Confirm bilateral and equal breath sounds with ventilation. Confirm that patient's chest rises with each ventilation. Allow adequate time for exhalation between breaths. Confirm optimal oxygenation and ventilation with an ABG when feasible.
ET tube difficulties	All patients intubated with ET tube	Allow ≤ 20–30 sec/intubation attempt. Intubator should see tip of ET tube and cuff pass between vocal cords at time of intubation. After intubation, immediately confirm correct ET tube placement; regularly reconfirm ET tube placement throughout resuscitation. Confirm adequacy of oxygenation and ventilation with an ABG. After intubation, consider nasogastric tube placement to decompress stomach and optimize diaphragmatic excursions with ventilation.
Intravenous line difficulties	All cardiac arrest patients	Place one or more 18-gauge or larger I.V. cannulas in an antecubital or external jugular vein site. Check for I.V. infiltration regularly throughout the resuscitation. Follow all medications administered through a peripheral I.V. site with a 20 ml saline bolus and elevation of the extremity containing the I.V. for 10–15 sec (if possible). Consider central line placement if the resuscitation is prolonged. Be aware of all I.V. infusions the patient is receiving. Stop all nonessential medications that had been started before the cardiac arrest. During the resuscitation, the only infusions the patient should receive are normal saline, blood products (if clinically indicated), and pertinent medications necessary to assist with return of spontaneous circulation. Pulmonary artery catheters and central lines occasionally act as an arrhythmogenic focus within the right ventricle. If applicable, deflate all relevant balloons on the catheter and withdraw the catheter to a superior vena cava position.
Monitor-defibrillator difficulties	All cardiac arrest patients	Make sure Synchronization Mode button is in the off position when defibrillating patients in pulseless VT or VF. Make sure electricity is not arcing over the patient's chest because of perspiration or smeared conducting gel; dry patient's chest with a towel except for areas directly beneath pads or paddles. Do not administer shock through nitroglycerin paste or patches. If the patient has an internal cardioverter-defibrillator (ICD) or a pacemaker, the patient may still be manually defibrillated, but do not shock directly over the internal device. Under these circumstances, place the pads or paddles at least 1 in. away from the patient's internal device. If the ICD is intermittently firing but not defibrillating the patient and if the ICD is thought to be compromising the resuscitation, turn the device off with a magnet so that manual defibrillation may take place without interference. Maximize the gain or electrocardiography "size" and check the rhythm in several leads (or change the axes of the paddles if reading the rhythm in Paddles mode) to confirm asystole when the initial rhythm appears to be asystole.

ABG—arterial blood gas ET—endotracheal VF—ventricular fibrillation VT—ventricular tachycardia

spite appropriate interventions, and if there appear to be no technical problems hampering the resuscitation, a working diagnosis of massive myocardial infarction can be made; intravenous thrombolytic therapy may then be a reasonable and needed step in such a resuscitation.[70]

Thoughtful consideration of the possible reasons why a resuscitation is failing will regularly push the code-team captain's and resuscitation team's expertise and clinical skills to the limits. Nevertheless, the failure to consider these formidable issues will deprive the patient of an optimal opportunity to survive the cardiac arrest.

Cardiac Resuscitation Based on Rhythm Findings

When a monitor-defibrillator arrives at the scene of a cardiac arrest, the patient's rhythm is immediately analyzed.

Table 7 Potentially Treatable Conditions That May Cause or Contribute to Cardiac Arrest[3]

Condition	*Clinical Setting*	*Diagnostic and Corrective Actions*
Acidosis	Preexisting acidosis, diabetes, diarrhea, drugs, toxins, prolonged resuscitation, renal disease, shock	Obtain stat ABG. Reassess technical quality of CPR, oxygenation, and ventilation. Confirm correct endotracheal tube placement. Hyperventilate patient (P_aCO_2 of 30–35 mm Hg) to partially compensate for metabolic acidosis. If pH < 7.20 despite above interventions, consider I.V. sodium bicarbonate, 1 mEq/kg I.V. slow push.
Cardiac tamponade	Hemorrhagic diathesis, malignancy, pericarditis, postcardiac surgery, postmyocardial infarction, trauma	Initiate large-volume I.V. crystalloid resuscitation. Confirm diagnosis with emergent bedside echocardiogram, if available. Perform pericardiocentesis. Immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected clinically.
Hypoglycemia	Adrenal insufficiency, alcohol abuse, aspirin overdose, diabetes, drugs, toxins, liver disease, renal disease, sepsis, certain tumors	Consider clinical setting and obtain finger-stick glucose or stat blood glucose measurements (may be obtained on ABG specimen). If glucose < 60 mg/dl, treat: 50 ml = 25 g of D50W I.V. Follow glucose levels closely posttreatment.*
Hypomagnesemia	Alcohol abuse, burns, diabetic ketoacidosis, severe diarrhea, diuretics, drugs (e.g., cisplatin, cyclosporine, pentamidine), malabsorption, poor intake, thyrotoxicosis	Obtain stat serum magnesium level. Treat: 1–2 g magnesium sulfate I.V. over 2 min. Follow magnesium levels over time, because blood levels correlate poorly with total body deficit.
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated and elderly patients, drowning, drugs, toxins, endocrine disease, exposure history, homelessness, poverty, extensive skin disease, spinal cord disease, trauma	Obtain core body temperature. If severe hypothermia (< 30° C), limit initial shocks for pulseless VT/VF to three, initiate active internal rewarming and cardiopulmonary support, and hold further resuscitation medications or shocks until core temperature > 30° C.† If moderate hypothermia (30°–34° C), proceed with resuscitation (space medications at intervals greater than usual), passively rewarm, and actively rewarm truncal body areas.
Hypovolemia, hemorrhage, anemia	Major burns, diabetes, gastrointestinal losses, hemorrhage, hemorrhagic diathesis, malignancy, pregnancy, shock, trauma	Initiate large-volume I.V. crystalloid resuscitation. Obtain stat hemoglobin level on ABG specimen. Emergently transfuse packed red blood cells (O negative if type-specific blood not available) if hemorrhage or profound anemia is contributing to arrest. Emergently consult necessary specialty for definitive care. Emergent thoracotomy with open cardiac massage is a consideration if experienced providers are available for the patient with penetrating trauma and cardiac arrest.
Hypoxia	All cardiac arrest patients are at risk	Reassess technical quality of CPR, oxygenation, and ventilation. Confirm correct ET tube placement. Obtain stat ABG to confirm adequate oxygenation and ventilation.
Myocardial infarction	Consider in all cardiac arrest patients, especially those with risk factors for coronary artery disease, a history of ischemic heart disease, or prearrest picture consistent with an acute coronary syndrome	Review prearrest clinical presentation and ECG. Continue resuscitation algorithm; proceed with definitive care as appropriate for the immediate circumstances (e.g., thrombolytic therapy, cardiac catheterization/coronary artery reperfusion, circulatory assist device, emergent cardiopulmonary bypass).

This step constitutes the beginning part of the defibrillation stage, or step D, of the AHA's primary survey). There are four rhythm possibilities [*see Figure 1*]: (1) pulseless VT; (2) VF; (3) organized or semiorganized electrical activity despite the absence of a palpable carotid pulse, which defines PEA; and (4) asystole. The detailed management of these different cardiac resuscitation scenarios is based on the recommendations of the AHA[49] and the International Liaison Committee on Resuscitation.[71] In following these guidelines, the clinician should remember that, with the exception of early CPR and early defibrillation for VF and pulseless VT, many of the recommendations that form the foundation of modern resuscitation are evidence supported or consensus based (rather than evidence based, as would be ideal). Because of the nature of cardiac arrest and the multiple variables involved, it is exceptionally difficult to perform high-quality research in cardiac resuscitation.

PULSELESS VENTRICULAR TACHYCARDIA OR VENTRICULAR FIBRILLATION

The appearance of either VF or pulseless VT on the rhythm monitor in a patient with ongoing CPR is a relatively favorable finding, because there is reasonable hope for a successful outcome with these rhythms. In addition, the interventions and medications sequentially used in the resuscitation are plainly delineated, and the initial course of action is clear. VF and pulseless VT are managed identically.

Initiation of Defibrillation

Defibrillation with 200 joules should be attempted immediately. However, if the time from onset of arrest to CPR to the availability of defibrillation is estimated to be longer than 5 minutes, it may be reasonable to continue CPR for another 3 minutes before initiating defibrillation [*see* Defibrillation, *above*]. If the VF or VT persists after the initial shock, subsequent attempts

Table 7 (*continued*)

Condition	*Clinical Setting*	*Diagnostic and Corrective Actions*
Poisoning	Alcohol abuse, bizarre or puzzling behavioral or metabolic presentation, classic toxic syndrome, occupational or industrial exposures, history of ingestion, polysubstance abuse, psychiatric disease	Consider clinical setting and presentation; provide meticulous supportive care. Emergently consult toxicologist (through regional poison center) for resuscitative and definitive care advice, including appropriate antidote use. Prolonged resuscitation efforts are appropriate. If available, immediate cardiopulmonary bypass should be considered.
Hyperkalemia	Metabolic acidosis, excessive administration, drugs and toxins, vigorous exercise, hemolysis, renal disease, rhabdomyolysis, tumor lysis syndrome, significant tissue injury	Obtain stat serum potassium level on ABG specimen. Treatment: calcium chloride 10% (5–10 ml I.V. slow push [do not use if hyperkalemia is secondary to digitalis poisoning]), followed by glucose and insulin (50 ml of D50W and 10 U regular insulin I.V.); sodium bicarbonate (50 mEq I.V.); albuterol (15–20 mg nebulized or 0.5 mg I.V. infusion).‡
Hypokalemia	Alcohol abuse, diabetes, diuretic use, drugs and toxins, profound gastrointestinal losses, hypomagnesemia, excess mineralocorticoid states, metabolic alkalosis	Obtain stat serum potassium level on ABG specimen. If profound hypokalemia (K^+ < 2–2.5 mEq/L) is contributing to cardiac arrest, initiate urgent I.V. replacement (2 mEq/min I.V. for 10–15 mEq) then reassess.§
Pulmonary embolism	Hospitalized patients, recent surgical procedure, peripartum, known risk factors for venous thromboembolism (VTE), history of VTE, prearrest presentation consistent with acute pulmonary embolism	Review prearrest clinical presentation; initiate appropriate volume resuscitation with I.V. crystalloid and augment with vasopressors as necessary. Attempt emergent confirmation of diagnosis, depending on availability and clinical circumstances; consider emergent cardiopulmonary bypass to maintain patient viability. Continue resuscitation algorithm; proceed with definitive care (thrombolytic therapy, embolectomy via interventional radiology, or surgical thrombectomy) as appropriate for immediate circumstances and availability.
Tension pneumothorax	Post–central line placement, mechanical ventilation, pulmonary disease (including asthma, COPD, necrotizing pneumonia), postthoracentesis, trauma	Consider risks and clinical presentation (prearrest history, breath sounds, neck veins, tracheal deviation). Proceed with emergent needle decompression, followed by chest tube insertion.

*Unrecognized hypoglycemia can cause significant neurologic injury and can be life threatening, but caution with I.V. glucose is appropriate in the setting of cardiac arrest. Available evidence indicates that hyperglycemia may contribute to impaired neurologic recovery in cardiac arrest survivors.

†Active internal or core rewarming includes warm (42°–46° C) humidified oxygen delivered through the endotracheal tube; warm I.V. fluids; peritoneal lavage; esophageal rewarming tubes; bladder lavage; and extracorporeal rewarming if immediately available. Active external rewarming includes warming beds, hot-water bottles, heating pads, and radiant heat sources applied externally to the patient.

‡Glucose is not necessary initially if patient is already hyperglycemic, but glucose levels should be followed closely after administration of I.V. insulin because of the risk of hypoglycemia (especially in patients with renal failure, because of the long duration of action of I.V. insulin in such patients). Sodium bicarbonate is most helpful in patients with concomitant metabolic acidosis; it is less effective in lowering serum potassium in dialysis-dependent renal failure patients. High-dose nebulized albuterol should lower serum potassium by 0.5 to 1.5 mEq/L within 30 to 60 min, but administration during cardiac arrest may be difficult.

§In a non–cardiac arrest situation, usual I.V. potassium replacement guidelines for patients requiring parenteral therapy are generally 10 to 20 mEq/hr with continuous electrocardiographic monitoring. If profound hypokalemia is contributing to cardiac arrest, however, these usual replacement rates are not timely enough, given the critical nature of the situation. Under these circumstances, potassium chloride, 2 mEq/min I.V. for 10 to 15 mEq, is reasonable, but reassessment and careful attention to changing levels, redistribution, and ongoing clinical circumstances are essential to prevent life-threatening hyperkalemia from developing.

ABG—arterial blood gas COPD—chronic obstructive pulmonary disease D50W—50% dextrose in water ET—endotracheal VF—ventricular fibrillation VT—ventricular tachycardia

should be made with 200 to 300 joules and then 360 joules [*see Figure 2*].

A lower, nonescalating equivalent biphasic energy level is acceptable, if the defibrillator offers this option. Manually checking the patient's carotid pulse between shocks is no longer recommended, but the displayed rhythm on the monitor must be carefully assessed after each defibrillation attempt. If there are any doubts concerning the rhythm or if there is suspicion of a dysfunctional lead or paddle cable, then a manual pulse check would be appropriate. If VF or pulseless VT persists, CPR is resumed, the patient endotracheally intubated, correct ET tube placement confirmed, and the tube secured. Simultaneously, intravenous access should be established.

Initiation of Drug Therapy

In patients with ongoing VF, drug therapy begins with the administration of a vasoconstrictor (either epinephrine or vasopressin) [*see Table 4*]. If there is no intravenous access, the drug can be given endotracheally. After each intravenous dose, drug delivery is followed by a 20 ml saline bolus and the extremity containing the I.V. line is elevated. Rescuers continue CPR for 30 to 60 seconds to allow the drug to reach the heart, then attempt defibrillation again with one to three shocks at 360 joules each. As long as the patient remains pulseless, epinephrine is administered every 3 to 5 minutes, with each dose followed by one to three attempts at defibrillation. When vasopressin is the chosen initial drug, only a single dose is given; if the resuscitation continues 10 minutes or longer after vasopressin is administered, epinephrine should be substituted for vasopressin for the remainder of the code. If VF or pulseless VT persists despite the initial administration of a vasoconstrictor and repeated defibrillation attempts, parenteral antiarrhythmic drug therapy is added; amiodarone or lidocaine is an appropriate agent [*see* Choice of Antiarrhythmic Drugs, *below*]. Throughout all of these steps, the code-team leader is also actively looking for and correcting any technical and physiologic or anatomic problems that may be preventing a successful resuscitation [*see Tables 6 and 7*].

Emergency Laboratory Tests

If spontaneous circulation does not return after the first round of antiarrhythmic drug therapy, the resuscitation team must also endeavor to identify and treat the clinically relevant conditions

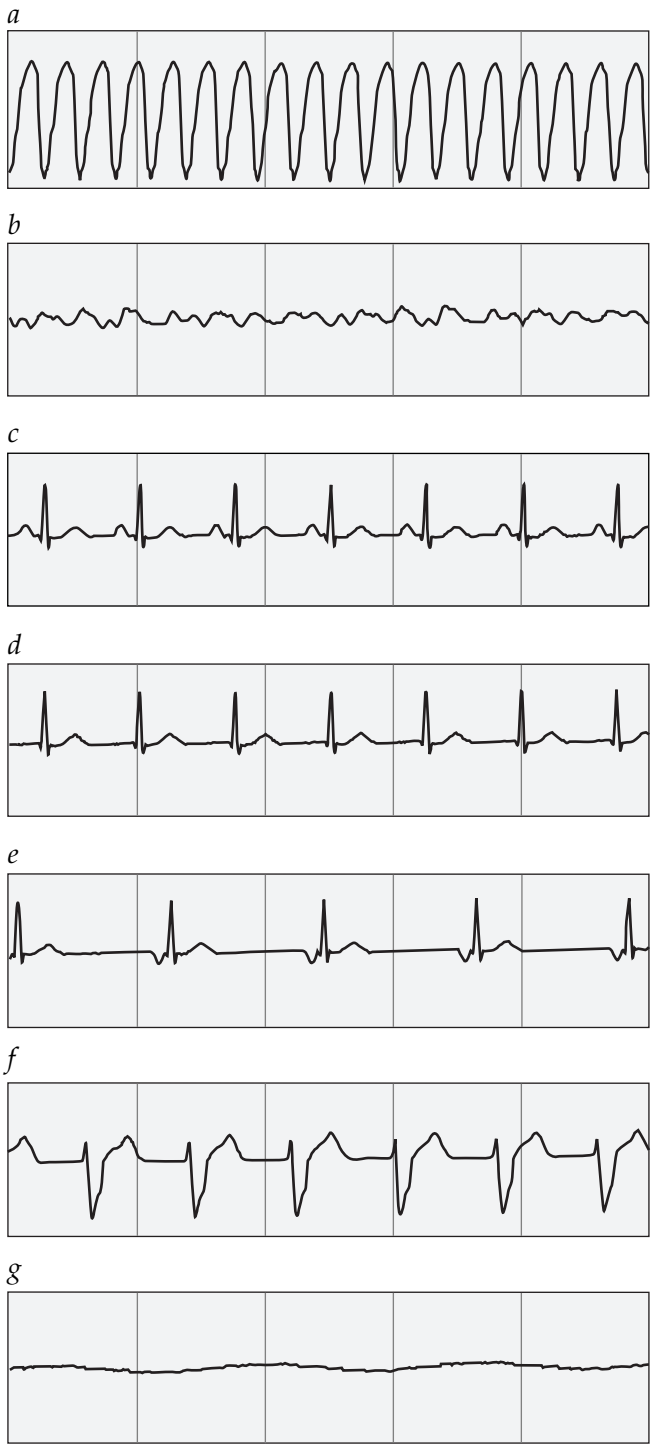

Figure 1 **The sudden cardiac arrest arrhythmias. (*a*) Ventricular tachycardia. (*b*) Ventricular fibrillation. Pulseless electrical activity encompasses any of several forms of organized electrical activity in the pulseless patient; these include (*c*) normal sinus rhythm, (*d*) junctional rhythm, (*e*) bradycardic junctional rhythm, and (*f*) idioventricular rhythm. (*g*) Asystole.**

causing or contributing to the cardiac arrest [*see Table 7*]. In theory, the interventions conducted to this point should have resulted in a perfusing rhythm. The code team must ask why this has not occurred and then attempt to answer this question as the resuscitation continues. Emergency laboratory studies that may prove helpful include a stat ABG measurement and measurements of hemoglobin, potassium, magnesium, and blood glucose levels (most of which can be obtained from the ABG specimen).

Choice of Antiarrhythmic Drugs

Four antiarrhythmic drugs are used in cardiac resuscitation: amiodarone, lidocaine, magnesium (if the patient is thought or proved to be hypomagnesemic), and procainamide (for intermittent or recurrent VT or VF that initially responds to defibrillation).[72] It is not known which one of these drugs or which combination of them will optimize the chances of patient survival to hospital discharge. Despite many years of routine use, there are no controlled studies demonstrating a survival benefit with lidocaine, versus placebo, in the management of VF or pulseless VT. Two studies in patients with shock-refractory prehospital VF showed that survival to hospital admission was better with amiodarone than with placebo (44% versus 34%; $P = 0.03$)[73] or with lidocaine (22.8% versus 12.0%; $P = 0.009$).[74] Neither of these studies demonstrated an improved survival to hospital discharge in the amiodarone groups, but neither study had the statistical power to demonstrate such a difference. Amiodarone is also considerably more expensive than lidocaine.

The optimal role and the exact benefit of antiarrhythmic medications in cardiac resuscitation are yet to be fully elucidated. According to AHA guidelines, either amiodarone or lidocaine is an acceptable initial antiarrhythmic drug for the treatment of patients with VF or pulseless VT that is unresponsive to initial shocks, CPR, airway management, and administration of epinephrine or vasopressin plus shocks. On the basis of available evidence, however, amiodarone may be the antiarrhythmic agent of first choice in the setting of prehospital refractory VF, allowing for optimal survival to hospital arrival.[72-74]

PULSELESS ELECTRICAL ACTIVITY

Community ACLS providers are encountering nonventricular arrhythmias (i.e., PEA and asystole) with increasing frequency. Classically, the prognosis for PEA has been poor, with outpatient survival rates generally reported as 0% to 7%.[75,76] The sequence of resuscitation steps in the management of PEA is as follows: activation of the emergency medical or code response, primary survey (CPR and rhythm evaluation), and secondary survey (intubation and confirmation of correct ET tube placement, optimal oxygenation and ventilation, establishment of I.V. access, epinephrine administration, and, finally, problem solving for technical difficulties and establishment of the cause of the cardiac arrest) [*see Figure 2*]. The two core drugs for PEA management are epinephrine (repeated every 3 to 5 minutes for as long as the patient is pulseless) and atropine (up to 3 mg over time if the PEA rhythm on the monitor is inappropriately slow). Although not currently on the AHA PEA algorithm, vasopressin is probably a reasonable alternative to epinephrine. The best hope for a successful resuscitation is to find and treat the cause of PEA; therein lies the exceptionally challenging aspect of PEA resuscitation management [*see Tables 6 and 7*]. Because coronary artery thrombosis and pulmonary thromboembolism are common causes of cardiac arrest, a trial evaluated the efficacy of tissue plasminogen activator (t-PA) in the setting of PEA of unknown or presumed cardiovascular cause in 233 patients in prehospital and emergency department settings.[77] No benefit was found with thrombolytic therapy for PEA in this study; the proportion of patients with return of spontaneous circulation was 21.4% in the t-PA group and 23.3% in the placebo group.

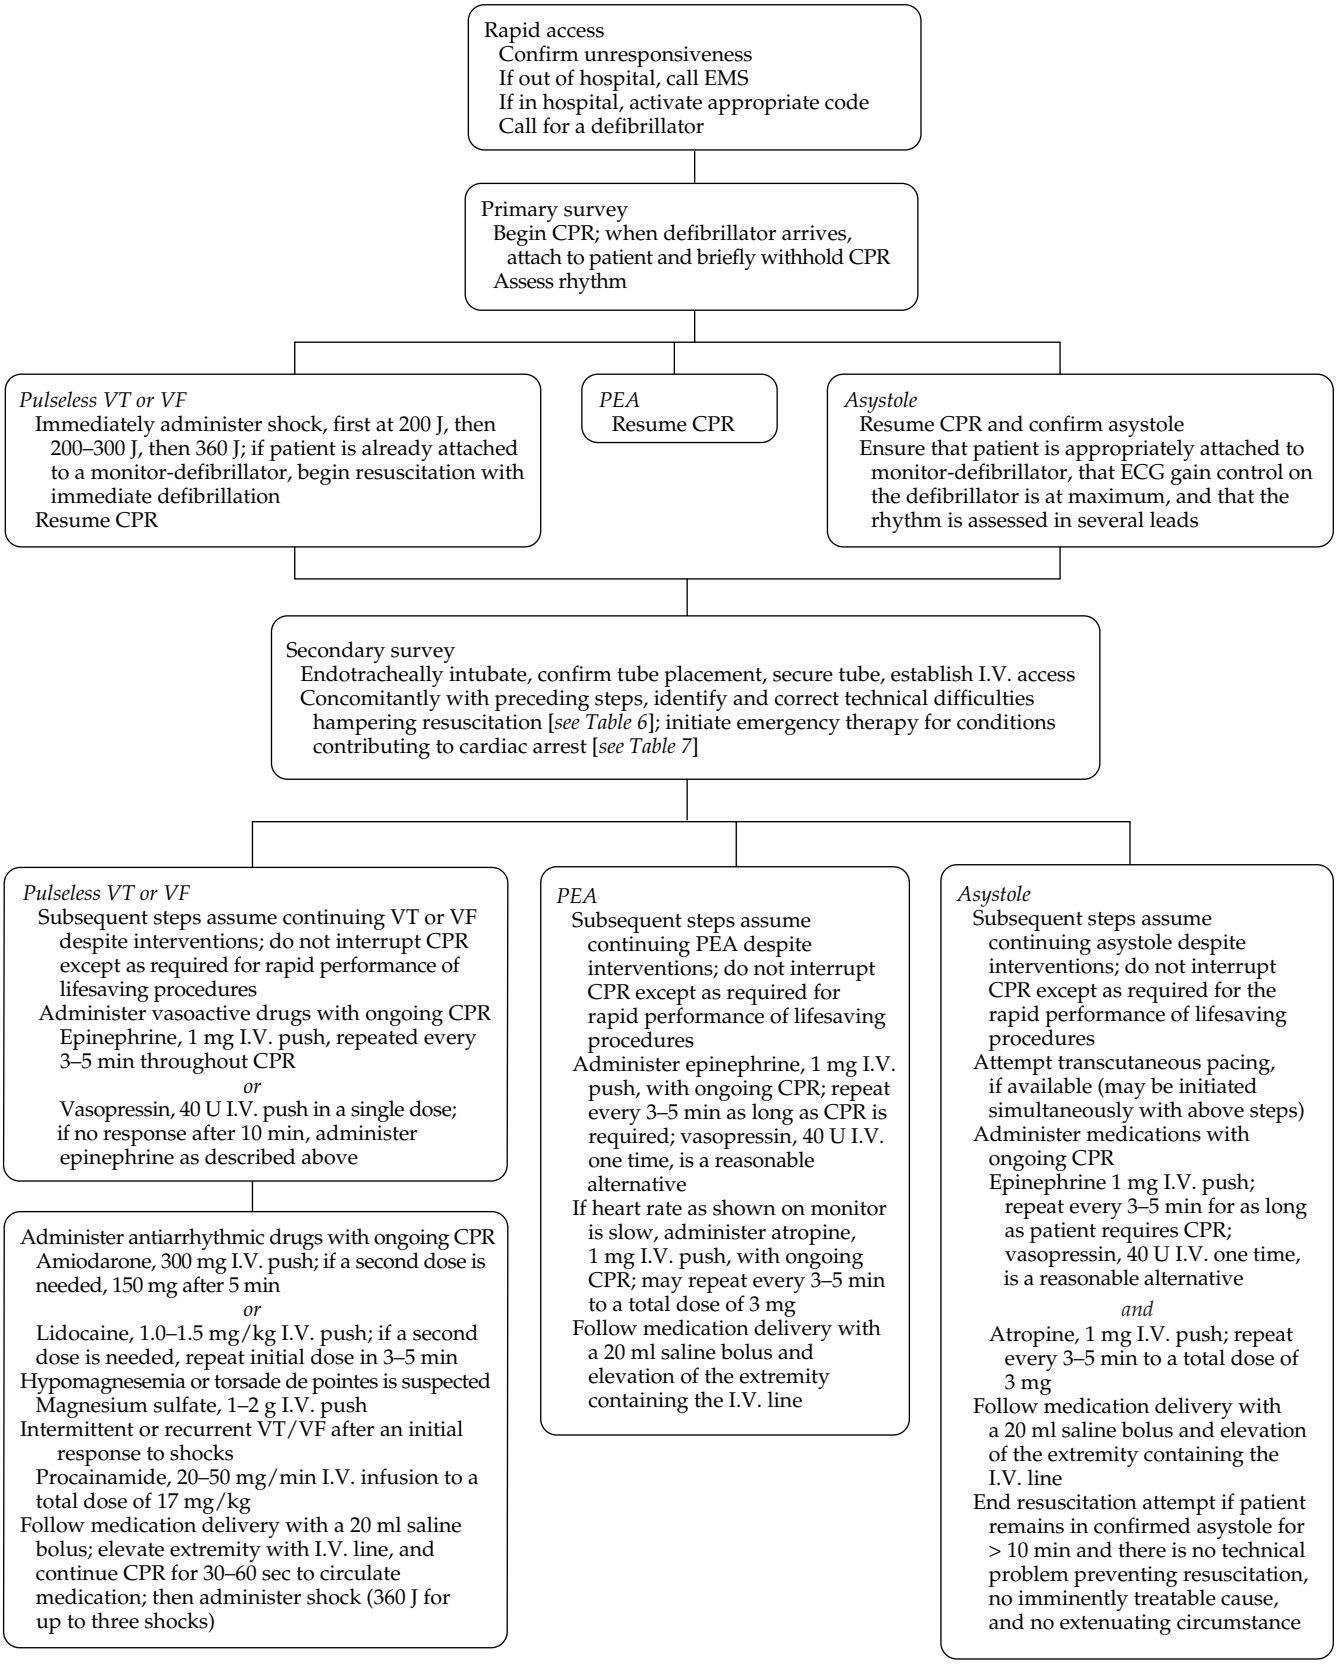

Figure 2 **Treatment algorithm for patients with VT, VF, PEA, or asystole. (PEA—pulseless electrical activity; VF—ventricular fibrillation; VT—ventricular tachycardia)**

ASYSTOLE

The prognosis for asystole is generally regarded as dismal unless the patient is hypothermic or there are other extenuating but treatable circumstances. The sequence of resuscitation steps in the management of asystole is as follows: activation of the emergency medical or code response, primary survey (CPR, rhythm evaluation, and asystole confirmation), and secondary survey (intubation and confirmation of correct ET tube placement, optimal oxygenation and ventilation, I.V. access with epinephrine and atropine administration, immediate transcutaneous pacing, if available, and problem solving for technical difficulties and establishment of the cause of cardiac arrest) [*see Figure 2*]. The two core drugs for asystole management are epinephrine (repeated every 3 to 5 minutes for as long as the patient is pulseless) and atropine (up to 3 mg over time). As with PEA, vasopressin appears to be a reasonable and possibly beneficial substitute for epinephrine in asystole. A single dose of aminophylline (250 mg I.V.) may also be beneficial in atropine-resistant asystole.[78] Potentially treatable causes of asystole include hypoxia, acidosis, hypothermia, hypokalemia, hyperkalemia, and drug overdose. Resuscitation efforts should stop if asystole persists for longer than 10 minutes despite optimal CPR, oxygenation and ventilation, and epinephrine or atropine administration; if extenuating circumstances (e.g., hypothermia, cold-water submersion, or drug overdose) are not present; and if no other readily treatable condition is identified.

Immediate Postresuscitation Care

Even when the resuscitation is successful, the patient's situation remains tenuous and continued meticulous patient care is essential. When the cardiac monitor indicates what should be a perfusing rhythm, the rescuer should immediately confirm that the patient has a palpable pulse. If there is a pulse, the patient's blood pressure is then obtained. Simultaneously, resuscitation team members need to quickly reassess the adequacy of the patient's airway, the ET tube position, oxygenation and ventilation, and the patient's level of consciousness and comfort.

If the patient is hypotensive, appropriate blood pressure management depends on the presence or absence of fluid overload, as judged at the bedside. If the patient is clinically volume overloaded or in frank pulmonary edema and hypotensive, dopamine is started at inotropic doses (5 μg/kg/min I.V.) and titrated to a target systolic blood pressure of 90 to 100 mm Hg. If the patient's clinical status suggests normovolemia or hypovolemia, intravenous crystalloid boluses (in 250 to 500 ml increments) can be administered instead of dopamine to support adequate tissue perfusion. In patients who are regaining consciousness, their level of comfort mandates careful assessment and administration of analgesia and sedation, as appropriate.

If the arrest rhythm was either VT or VF, the parenteral antiarrhythmic drug used immediately before the return of spontaneous circulation is continued as a maintenance infusion (amiodarone, 1 mg/min for 6 hr, then 0.5 mg/min for 18 hr as blood pressure allows; or lidocaine, 2 to 4 mg/min). If an antiarrhythmic drug has not yet been administered, it is usually started at this point to prevent the recurrence of VF or pulseless VT. There are important exceptions to this guideline, however. If the perfusing postarrest arrhythmia is an idioventricular rhythm or third-degree heart block accompanied by an idioventricular escape rhythm, an antiarrhythmic medication should not be started at this time, because the antiarrhythmic agent could eliminate the ventricular perfusing focus and return the patient to a pulseless state.

Initial postresuscitation studies usually include an ECG; portable chest radiography; and measurement of ABGs, a serum electrolyte panel, fingerstick or blood glucose, serum magnesium and cardiac enzyme levels, and hemoglobin and hematocrit. The resuscitated patient requires urgent transfer to the optimal site for continued definitive care. Depending on the circumstances, this may be either the cardiac catheterization laboratory or the intensive care unit.

Ongoing research continues to look at optimal postresuscitation management strategies to improve neurologic outcome and survival to hospital discharge.[79] Hyperthermia and hyperglycemia compromise postresuscitation neurologic outcome, whereas mild to moderate induced hypothermia appears to improve neurologic outcome and decrease mortality.[80-83]

Ending a Resuscitation Attempt

Throughout the resuscitation, the team leader must speak with calmness and authority, and all resuscitations should be orchestrated with clarity and finesse. If possible, the code captain should make clinical decisions without directly performing specific procedures. Cardiac arrests are emotionally charged, but the leader must insist on a composed, orderly, and technically sound resuscitation. It is appropriate to invite suggestions from team members and to ensure that all members are comfortable with the decision to stop the resuscitation, should that time arrive.

The decision whether to stop a cardiac resuscitation is burdensome. Clearly, the circumstances of the event, patient comorbidities, the nature of the lethal arrhythmia, and the resuscitation team's ability to correctly identify and treat potential contributing causes of the arrest are all important considerations. Resuscitation efforts beyond 30 minutes without a return of spontaneous circulation are usually futile unless the cardiac arrest is confounded by intermittent or recurrent VF or pulseless VT, hypothermia, cold-water submersion, drug overdose, or other identified and readily treated contributing conditions.[84,85]

With nontraumatic cardiac arrest in the prehospital setting (assuming proper equipment and medications are available and no extenuating circumstances suggest otherwise), full resuscitation efforts take place at the scene of the arrest in preference to rapid transport to an emergency department. A prehospital resuscitation that has been appropriately conducted but has not resulted in at least temporary return of spontaneous circulation to the patient may be discontinued. It is important that certain criteria are adhered to, however, including the following: high-quality CPR provided, an adequate airway successfully placed, appropriate oxygenation and ventilation delivered, intravenous access established, appropriate medications specific to the arrest scenario administered, and resuscitation attempted for at least 10 minutes; in addition, the patient must not be in persistent VF, and there can be no extenuating circumstances that mandate in-hospital continuation of the resuscitation (e.g., hypothermia, drug overdose). The decision whether to cease resuscitation efforts in the field is bolstered by direct discussion with EMS physicians. It is also essential that social services be available to provide immediate assistance and support to the family and loved ones of the patient who has now died.

Discontinuing in-hospital resuscitations is advisable when three criteria are met: (1) the arrest was unwitnessed, (2) the ini-

tial rhythm was other than VF or VT, and (3) spontaneous circulation does not return after 10 minutes of ongoing resuscitation.[86] In a study of this three-component decision rule, only 1.1% of patients (three out of 269) who met these criteria survived to hospital discharge, and none of the three survivors were capable of independent living.[87] In a study of 445 prospectively recorded resuscitation attempts in hospitalized patients, no patient survived who suffered a cardiac arrest between 12 A.M. and 6 A.M. if the arrest was unwitnessed and if it occurred in an unmonitored bed.[38]

A resuscitation attempt in a persistently asystolic patient should not last longer than 10 minutes, assuming all of the following conditions apply: asystole is confirmed through proper rhythm monitoring and assessment; high-quality CPR is taking place; ET intubation is correctly performed and confirmed; adequate oxygenation and ventilation are provided; intravenous access is secured; appropriate medications (epinephrine or vasopressin and atropine) have been administered; and the patient is not the victim of hypothermia, cold-water submersion, drug overdose, or other readily identified and reversible cause.

After all resuscitation attempts, the code-team captain should debrief the team so that all may learn from the experience. Finally, marked empathy and skill are needed to carefully and compassionately inform family members about the outcome of the resuscitation.[88]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

IV PREOPERATIVE ASSESSMENT AND CARE OF THE SURGICAL PATIENT

MICHAEL F. LUBIN, M.D., F.A.C.P.

Surgery is changing, and so too is the preoperative evaluation of surgical patients. Newer surgical procedures (e.g., laparoscopic cholecystectomy), along with many common, well-established procedures, are being done in outpatient facilities and on increasingly older and much sicker patients. Increasing numbers of patients are having elective surgical procedures. The evaluation of a patient who is being considered for surgery has changed a great deal in the years since the first papers on cardiac risk assessment were published in the late 1970s.[1] Despite much progress and new data, expert opinion and clinical judgment are still critical in this area of medicine. This chapter reviews risk assessment and provides current recommendations for the evaluation and management of perioperative medical problems [*see Sidebar* Approach to the Preoperative Consultation].

Goldman and coworkers developed the first systematic method to evaluate surgical patients for potential cardiac complications [*see Table 1*].[1] Their cardiac risk index for noncardiac surgery factored in decompensated heart failure, recent myocardial infarction, and arrhythmias, all of which were found to significantly contribute to the risk of cardiac complications and cardiac death. Impairment of pulmonary, renal, or hepatic function added additional risk; other risk factors included age, certain surgical sites (e.g., abdomen, thorax, and aorta), and emergency procedures. A subsequent study confirmed these risk factors and emphasized that severe and unstable angina added significantly to the risk of cardiac complications and cardiac death [*see Table 2*].[2]

Although these methods could identify groups of patients for whom surgery posed higher risk, they were not very helpful in selecting out individual patients who were at increased risk. Except in the highest risk group, the chances of cardiac complications varied from only 1% to 11%, and the risk of death varied from 0 to 2%[2]; these data demonstrate that a large majority of patients can tolerate surgery without problems, even if they have higher risk scores. Since the original indices were published, other methods to assess risk have been developed that employ a variety of information.[3,4] Although the use of any of these indices yields results that are better than the results that come from chance alone, all of them have a high false positive rate that limits their usefulness.[5]

How then should a physician proceed in evaluating a patient for surgery? Initially, two very important questions that have nothing to do with individual risk assessment need to be asked: First, is the surgical procedure being contemplated important to the patient's health and well-being? Second, what are the intrinsic risks of the anesthesia and proposed surgery?

It is quite clear that in a young patient who has a compound fracture, surgical repair is essential to the patient's health, and the risk of the surgery itself is rather low. On the other hand, extensive liposuction in a patient with advanced heart failure who also has renal failure is unlikely to have an acceptable risk-to-benefit ratio no matter how stable the patient appears to be. Many procedures fall between these two extremes, however, and risk assessment in such cases can be much more challenging. For example, bypass surgery for moderately severe angina in an 80-year-old patient with diabetes may or may not be useful, and the risks of the operation are not low.

Therefore, the decision to proceed with surgery requires the input of all the medical personnel involved. The internist or family physician has a critical role in assessing the findings from the history and physical examination; such an assessment will determine the degree of risk in the contemplated operation and the need for further testing to define risk. The surgeon must evaluate the risk-to-benefit ratio for the proposed procedure. The anesthesiologist needs to evaluate the risks of anesthesia and present this assessment to the patient. Finally, of course, the patient will have to understand the risks of the procedure and have confidence that they are outweighed by the potential benefits.

Approach to the Preoperative Consultation*

Assessment

Cardiac risk

- Use Goldman or Detsky score [*see Tables 1 and 2*] but provide explanation if the score does not reflect the true assessed risk (e.g., patient does not have angina but has many risk factors, including being wheelchair bound)

Pulmonary risk

- Assess as low, medium, or high, using clinical judgment

Other risks

- Hypertension (well or poorly controlled)
- Diabetes mellitus
- Heart failure (uncontrolled)
- Bleeding risk
  - Use of aspirin or other NSAIDs
- DVT risk
  - Assess as low, medium, or high [*see 1:XVIII Venous Thromboembolism*]

Plan

Cardiac risks

- Use routine cardiac monitoring or monitor as if for stable coronary disease; consider perioperative beta blockade

Pulmonary risks

- Use routine pulmonary care or preoperative and postoperative incentive spirometry with or without preoperative and postoperative chest physiotherapy

Hypertensive patients

- Continue hypertensive medications; hold diuretics on day of surgery

Diabetic patients

- Monitor blood glucose and treat with sliding-scale regular insulin, q. 4 hr, or give NPH insulin half dose, then follow with sliding-scale regular insulin

Thrombosis risk

- Hold aspirin for 5 days preoperatively; if DVT prophylaxis is necessary, give low-dose heparin, 5,000 U q. 12 hr, or LMWH

*This sidebar presents an example of possible assessments and plans.
DVT—deep vein thrombosis LMWH—low-molecular-weight heparin
NSAIDs—nonsteroidal anti-inflammatory drugs

Table 1 Calculating Operative Morbidity and Mortality[1]

Information Source	*Criterion*	*Points*
History	Age > 70 yr	5
	MI < 6 mo ago	10
	Chronic liver disease	3
	Bedridden	3
Physical examination	S_3 heart sound or JVD	11
	Significant aortic stenosis	3
Electrocardiogram	Rhythm other than sinus or PACs; > 5 PVCs/min	7
Laboratory tests	P_{O_2} < 60 mm Hg or P_{CO_2} > 50 mm Hg	3
	Serum potassium < 3 mmol/L	3
	Serum bicarbonate < 20 mEq/L	3
	Serum creatinine > 3 mg/dl	3
	BUN > 50 mg/dl	3
	Elevated AST	3
Intended operation	Peritoneal, thoracic, or aortic	3
	Emergency	4

Risk Class (Total Points)	*Morbidity*	*Mortality*
1 (0–5)	0.7%	< 0.2%
2 (6–12)	5%	2%
3 (13–25)	11%	2%
4 (> 25)	22%	56%

AST—aspartate aminotransferase BUN—blood urea nitrogen JVD—jugular venous distention MI—myocardial infarction PAC—premature atrial contraction PVC—premature ventricular contraction

Decisions about proceeding to surgery require good clinical judgment. High-risk patients need individual assessment. Despite high risk, those with life-threatening indications, such as an uncontrollable upper gastrointestinal bleed, will usually proceed to surgery. Less important procedures that are not likely to sustain or enhance life will more likely be postponed to permit treatment of alterable conditions, replaced with a lower-risk procedure, or canceled if the risks appear to be too high and the benefits not high enough.

Clinical Evaluation

In determining surgical risk, the history and physical examination are of great importance. The systems most involved in postoperative morbidity and mortality are the cardiovascular and pulmonary systems.[1,2] It is also essential to evaluate renal, hepatic, and endocrine function.

ASSESSING CARDIOVASCULAR RISK

The most critical parts of the cardiac assessment are those that involve heart failure and coronary artery disease (CAD). Assessment of anginal chest pain is particularly important because proper management of CAD can decrease the risks of surgery. On the other hand, extensive cardiac testing in a patient who is unlikely to have significant CAD will delay procedures that may be important and will increase the cost of care.

Heart Failure

Uncontrolled heart failure is the most important risk factor for cardiac death or complications. A history of functional limitation appears to be the most helpful of all the historical points in this assessment. Patients who can perform activities that require four metabolic equivalents (METs) have a good chance of survival for most surgical procedures [*see Table 3*]; such patients require no further testing. Some authors have used stair climbing to assess patients' functional capacity; the ability to walk up approximately two flights of stairs or to walk four level city blocks has proved helpful.[6] The presence of such symptoms as orthopnea and paroxysmal nocturnal dyspnea in a patient with poor functional capacity increases the likelihood of heart failure but does not have predictive value for perioperative outcome.

The physical examination should identify signs of heart failure, such as distended neck veins, an S_3 gallop, rales, and edema. Other signs of cardiovascular disease, such as hypertension, decreased pulses, or bruits, should be recorded. These signs will help identify patients with ventricular dysfunction and peripheral vascular disease that may increase overall risk.

The use of echocardiography as a predictive tool is controversial. Although many experts advocate echocardiography as a good tool for assessing heart failure control, the procedure may provide little prognostic information beyond that available from a careful history and physical examination.

The most important preoperative use of echocardiography is in the differentiation of systolic dysfunction from diastolic dysfunction in patients with new-onset heart failure. A careful history and physical examination can suggest which is more likely, but the echocardiographic differentiation is significantly more reliable. The distinction is important, because data clearly show that systolic dysfunction, in a patient with substantial clinical manifestations (i.e., overt congestive failure), adds significantly to the risk of surgery.[1] On the other hand, there are no data showing that echocardiographic evidence of systolic dysfunction in a patient without symptoms or signs of heart failure has any prognostic implications.[7]

There are also no good data indicating that diastolic dysfunction increases risk significantly. Although diastolic dysfunction probably adds some degree of risk, patients with echocardiographic findings of diastolic dysfunction but who have no signs and symptoms are probably not at substantially higher risk. Thus, there is no reason to order preoperative echocardiography when the diagnosis of diastolic dysfunction has already been established.

Patients who are able to perform tasks that require more than four METs can undergo most surgery without a significant increase in risk[8]; therefore, such patients would not benefit from an echocardiogram. Additionally, patients who have no clear-cut symptoms or signs of heart failure are unlikely to benefit from the test. Patients who do have symptoms and signs (e.g., elevated neck veins, S_3 gallop, orthopnea, or paroxysmal nocturnal dyspnea) are definitely at increased risk; preoperative echocardiography is unnecessary in such cases because it provides no additional information on risk.[7] Treating the heart failure until the symptoms have stabilized and the signs have improved will lower risk substantially.

Coronary Artery Disease

The preoperative evaluation of the patient with established or probable CAD is of great importance. In general, most patients who will be having cardiac surgery or major vascular

surgery are evaluated by cardiologists. Recent myocardial infarction is second only to decompensated heart failure as a risk factor for perioperative complications.[1] Decisions regarding the evaluation of chest pain in patients without a history of CAD can be difficult under any circumstance. Preoperatively, a decision must be made about the likelihood of CAD; again, if the chances of having the disease are low, there will be many false positive tests [*see* General Laboratory Testing, *below*], delays in surgery, and interventions that will not help many patients and may actually harm some of them. If a patient has known CAD or if angina is a serious consideration, however, then the severity and stability of the CAD must be ascertained. The clinician should then proceed with the evaluation process (see below).

The American College of Cardiology and the American Heart Association (ACC/AHA) have developed guidelines for preoperative cardiovascular evaluation for noncardiac surgery (http://www.acc.org/clinical/guidelines/perio/clean/perio_index.htm).[8] These guidelines are widely used. The ACC/AHA guidelines include an eight-step algorithm for patient risk stratification and subsequent determination of appropriate cardiac evaluation[9]; this algorithm is available on the ACC Web site (www.acc.org/clinical/guidelines/perio/update/fig1.htm).

The American College of Physicians has also developed guidelines on the perioperative assessment and management of risk from CAD.[10] Perhaps the most important message in the ACP's clinical guideline is the following: most patients who do not have an independent clinical need for coronary revascularization can proceed to surgery without further cardiac investigation.[10] In other words, if there is no prior reason to perform coronary artery bypass surgery, further cardiac investigation usually does not need to be carried out for the anticipated surgery, unless there is some other overriding consideration. This guideline does not apply to the patient with significant peripheral vascular disease, particularly if the patient is to undergo major vascular surgery.

Unstable angina or severe angina needs evaluation before surgery if the procedure is not immediately lifesaving. For patients who have stable, less than severe angina and for those whose symptoms occur only after significant exertion (e.g., walking at 4 miles an hour or engaging in moderate lifting), it is not necessary to proceed with coronary artery evaluation for most surgical procedures.[8] This is particularly true if the operative procedure is of low risk (see above). It may also be true in those at moderately higher risk when the following factors are considered: there may be an unacceptable increase in risk because of the delay induced by the bypass surgery, if such surgery is done before the anticipated operation (e.g., resection of potentially curable lung cancer or repair of a hip fracture); the combined mortality of bypass surgery and of the planned procedure may exceed the risk of simply proceeding with the operation (e.g., hip arthroplasty or herniorrhaphy).

The preoperative use of noninvasive testing for CAD is controversial. Despite the indications given in the ACC/AHA algorithm, it is important to consider the consequences of doing these tests, along with their rate of false positive and false negative results. Specifically, it is important to determine whether bypass surgery is truly an option before testing for CAD; if it is not an option, there is no need to test, because surgery will not be done no matter what the result. Some patients refuse bypass surgery even when significant disease is found.

Another consideration is the reliability and accuracy of the test or tests being considered. Exercise tests can be helpful, but only for those patients who can exercise enough to have a valid result. Those whose capacity to exercise is limited by weight, age, arthritis, or other physical or mental ailments will not achieve the level of exercise necessary to give valid results.

Thallium testing, particularly in women, can also be quite difficult. The specificity of these tests may be as low as 50% in

Table 2 Calculating the Likelihood of Postoperative Events[2]

Risk Factor	*Points*
CAD	
MI < 6 mo ago	10
MI > 6 mo ago	5
Canadian CVS angina	
Class III	10
Class IV	20
Unstable angina < 6 mo	10
Alveolar pulmonary edema	
< 1 wk	10
Ever	5
Critical aortic stenosis	20
Arrhythmia	
Other than sinus or PACs	5
> 5 PVCs/min	5
Poor medical status	5
Age > 70 yr	5
Emergency surgery	10

Class (Total Points)	*Likelihood Ratio**
1 (0–15)	0.42
2 (16–30)	3.58
3 (> 30)	14.93

*Likelihood ratio for postoperative events, defined as myocardial infarction, pulmonary edema, ventricular tachycardia or fibrillation, and cardiac death.
CAD—coronary artery disease CVS—Cardiovascular Society MI—myocardial infarction PAC—premature atrial contraction PVC—premature ventricular contraction

Table 3 Metabolic Equivalents of Selected Activities*

Activity	*METs*
Baking	2
Golfing with cart	2.5
Playing a musical instrument (various)	1.8–2.3
Mowing lawn (power mower)	3
Bicycling (leisurely)	3.5
Calisthenics (no weights)	4
Golfing without cart	5
Chopping wood	5

*A metabolic equivalent (MET) is an approximation of the energy expenditure involved in a particular physical activity, expressed as a unit of oxygen uptake; 1 MET is defined as 3.5 ml O_2/kg/min. Representative levels are as follows: 1 MET, resting; 2 METs, walking on level ground at 2 mph; 4 METs, walking on level ground at 4 mph.

women[11]; that is, half of the patients without disease may test positive. These patients will be subjected to invasive catheterization despite the absence of clinically significant disease.

Dobutamine echocardiography is now being used to identify patients with reversible ischemia. This test appears to have fairly good sensitivity and specificity when an adequate test can be done, but it is not definitive, and no controlled studies have proved its usefulness.[12,13] The results of dobutamine echocardiography may also be less accurate in patients in whom the study is difficult (e.g., obese patients).

ELECTROCARDIOGRAPHY

There is general agreement on indications for electrocardiography, and there is some additional clinical support for its use.[1,2] ECG testing is recommended for men older than 45 years and women older than 55 years, although these age limits are arbitrary. Many elderly patients (arbitrarily defined as those older than 65 years) will have ECG abnormalities even without a history of any cardiovascular disease.[14] The ECG has been shown to have modest predictive value in anticipating morbidity and mortality; it is also useful as a baseline to guide care in patients who develop postoperative symptoms or complications. In addition, any patient with hypertension, cardiovascular disease, or pulmonary disease should have an ECG. For these latter indications, it is probable that an ECG done within the past 3 to 6 months can be used, provided there has been no intervening clinical change.

ASSESSING PULMONARY RISK

The pulmonary evaluation process is unfortunately much more subjective than the cardiac evaluation. Despite many attempts to find methods to identify patients at increased pulmonary risk, no method has been shown to be definitively useful for an individual patient; thus, clinical judgment is critical. The importance of the surgery is often the deciding factor, even in those who are thought to be at high risk.

Significant lung disease, particularly from smoking, is often identified at the time of surgery. For that reason, taking a smoking history is an important part of the preoperative assessment. In the pulmonary assessment, it is important to note any dyspnea on exertion, wheezing, or coughing with sputum production, particularly if acute. Acute reversible disease, such as asthma or a respiratory tract infection, must be identified so that it can be treated and reversed before the procedure, if possible. Patients who can exercise without significant symptoms are at low risk.[3] Shortness of breath on exercise, in the absence of heart disease, identifies patients at higher risk. In general, the ability to climb a flight of stairs or walk several blocks without stopping indicates a lower risk level. Advancing age is a minor risk factor.[1,2] On physical examination, a respiratory rate above normal; poor chest wall movement; use of accessory muscles on inspiration; and poor breath sounds, wheezes, or rales on lung auscultation suggest significant underlying disease.

Clinical detection of obstructive airway disease has not been carefully studied. One study in 309 patients found only four clinical elements that were significantly associated with the diagnosis of obstructive airway disease: smoking for more than 40 pack-years, a self-reported history of chronic obstructive airway disease, a maximum laryngeal height of 4 cm (corrected) or less, and an age of 45 years or older.[15] In this study, the presence of all four findings indicated obstructive airways disease (likelihood ratio, 220); the absence of all four ruled out obstructive airways disease (likelihood ratio, 0.13). In patients with more severe chest disease, formal testing of respiratory function is indicated.

Pulmonary Function Tests

Preoperative use of pulmonary function tests (PFTs) is controversial.[16,17] PFTs do not readily identify individual patients who are at prohibitive risk for mortality; there is poor correlation between PFT results and mortality, despite some statistical correlation.[18] If the history and physical examination do not suggest significant pulmonary disease, there is no advantage in performing PFTs. If the intended surgery is of major importance, such surgery will have to be done regardless of the PFT results. The most important place for PFTs is in patients whose surgery may be of some benefit but whose risks may be prohibitively high. Many patients with very poor PFT results have been shown to survive surgery despite serious underlying disease.[19]

Exercise tolerance may be a good way to test for risk of death from pulmonary causes. It appears that for patients who can walk up two to four flights of stairs without stopping, the risk associated with major surgery is reasonable.[18]

Patients with chronic obstructive pulmonary disease and asthma should have their condition under the best possible control before surgery is attempted. In those whose symptoms are not controlled, surgery should be delayed until control is maximized; if this is not possible, additional drugs, including steroids, can be given before admission or in hospital to achieve as much control as possible before the procedure. It may be necessary to admit patients to the hospital one day or more before the operation to control their disease if it is particularly resistant to treatment.

Chest X-ray

Most experts believe that any patient older than 60 years should have a baseline chest x-ray. This has been shown to be clinically useful in elderly patients, who often have abnormalities that would not have been expected from history and physical examination.[20] Although the results of the chest x-ray may have little impact on preoperative risk assessment, I have found them to be useful in the care of patients who have postoperative pulmonary complications.

Clearly, any patient with cardiovascular or pulmonary disease needs a chest x-ray. Those with acute pulmonary symptoms and perhaps those with a history of tuberculosis or tuberculosis exposure probably derive some benefit from a chest x-ray. Again, in the absence of a change in symptoms or signs, a recent x-ray is usually adequate; a repeat x-ray is not needed in the immediate preoperative period.

ASSESSING RENAL RISK

Decreased renal function, most commonly defined as a serum creatinine concentration of approximately 2.0 mg/dl or higher, increases the risk of morbidity and mortality.[3] Because most renal disease results from hypertension and diabetes, a history of these diseases should lead to testing of renal function. Polyuria and nocturia may also indicate underlying kidney disease.

ASSESSING FOR LIVER DISEASE

Although significant liver disease is not common, failure to identify underlying liver disease can lead to catastrophic complications, particularly bleeding. The leading cause of significant liver disease is ethanol, so a history of alcohol intake is very

important. Hepatitis B and C are also important risk factors for impaired hepatic function; these diseases may be suggested by a history of bleeding episodes, transfusions, drug abuse, or sexual promiscuity.

ASSESSING FOR ENDOCRINE DISEASE

Endocrine abnormalities affect surgical risks. Diabetes is the most common endocrine abnormality; it is especially important because of its association with cardiovascular disease, which may be silent in diabetic patients.[21] Consequently, a history of hyperglycemic symptoms should be sought.

A history of thyroid disease is important, although most patients with hypothyroidism are at low risk unless they are profoundly affected.[22,23] On the other hand, identifying patients with undiagnosed or undertreated hyperthyroidism is very important, because it is well known that surgery can precipitate thyroid storm.[24] Thus, a history of hyperthyroidism or its symptoms (e.g., tremor, palpitations, weight loss, and anxiety) must be sought. Physical findings of tremor, lid lag, hyperreflexia, and tachycardia are useful clues. If there is any indication that the patient may be hyperthyroid, the thyroid-stimulating hormone level should be measured.

Addison disease is uncommon but can be deadly with the stress of surgery.[25] Profound weakness, orthostatic hypotension, and hyperpigmentation suggest adrenal insufficiency. For patients with adrenal insufficiency and those receiving long-term corticosteroid therapy, supplementary doses of corticosteroids must be given during the perioperative period.

ASSESSING FOR NEUROLOGIC DISEASE

Neurologic disease may significantly increase surgical risks. The most common and important neurologic disease is cerebrovascular disease. Hypertension, atherosclerosis, and diabetes are important antecedent processes. A history of episodic or fixed neurologic deficits, as well as a history of stroke, is important to identify. A history of memory loss or other cognitive deficits must also be sought, because strokes and dementia increase the risk of postoperative delirium.[26]

On examination, neurologic deficits must be noted and an etiology sought. I believe a baseline mini–mental status examination should be done on any patient suspected of having a dementing illness. With elderly patients, I recommend a mini–mental status examination even in those with no clear evidence of dementia. Particularly in elderly patients, any signs of dementia on mental status examination should be noted and clearly documented so that any suspected change after surgery can be compared with the presurgical state.

Medication Review and Adjustment

Review of medications, particularly in the elderly, is critical. In some cases, it may be necessary to discontinue a drug or adjust its dosage before surgery. As a side benefit, the medication review may reveal that the patient is taking unnecessary medications; this may be especially likely in elderly patients, many of whom are on multiple medications. Stopping unnecessary drugs simplifies the care of all patients.

The most commonly prescribed medications that require adjustment of dosages with surgery are those for hypertension and diabetes. Diuretics and oral diabetic medications are usually not administered on the day of surgery.[27,28]

Anticoagulant therapy obviously requires thoughtful perioperative management [*see* Thrombosis, *below*]. There are good reviews of the management of perioperative anticoagulation.[29] Because of their antiplatelet actions, nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, should be discontinued 5 days before surgery. NSAIDs also increase the risk of acute renal failure, particularly in patients with renal insufficiency.

Many patients take over-the-counter medications or herbal remedies. It is important to specifically ask about such products when taking a medication history. These products may affect coagulation or interact with medications the patient will receive perioperatively. All such products should be stopped before surgery.

The clinician should review any previous surgery the patient has undergone. This review may reveal problems with anesthetic agents, such as malignant hyperthermia, that might otherwise be missed.

General Laboratory Testing

Laboratory testing before surgery has been studied extensively over the past 2 decades. Unfortunately, there are few data to help clinicians determine which patients truly need specific tests; most published recommendations are based on expert opinion. Many clinicians worry about the medicolegal risks of not performing tests before surgery, but preoperative testing also has drawbacks. Testing subjects the patient to increased risks from more invasive procedures such as catheterization and may even erroneously indicate disease that is not present.

Noninvasive tests are often far from perfect for predicting the presence or absence of disease. Most of these tests have rather good sensitivity but only moderate specificity. The lower the prevalence of a disease in the population being tested for it, the greater the odds of false-positive results, which almost inevitably lead to further costly, invasive, and perhaps risky testing. This limitation of testing underlines the importance of a good history and physical examination for selecting patients for testing. Methods for calculating the likelihood of disease on the basis of a given test result are discussed in detail elsewhere [*see CE:VIII Quantitative Aspects of Clinical Decision Making*.]

For many years, most preoperative patients at most institutions underwent a standard panel of tests: a complete blood count (CBC), including platelets; electrolytes and renal panel; extended serum chemistry studies with liver function tests; prothrombin time and partial thromboplastin time; and chest x-ray and electrocardiogram. Kaplan and colleagues showed that many tests were not needed for the care of these patients and that many of the abnormal test results were only slightly out of the normal range.[30] Almost all of those abnormal results were ignored without consequence or were pursued with no benefit to the patients. Pursuing these abnormal results simply added more tests and caused delays in surgery. A number of subsequent studies confirmed these findings.[31,32]

Most experts agree that patients who are older than 60 years and those undergoing procedures that pose a substantial risk of bleeding should have their hematocrit measured. It is not clear, however, that even this limited testing makes a clinical difference. Obviously, patients with a history of anemia should have a CBC; those with any underlying disease associated with anemia should also be tested. Measurement of renal function and electrolyte levels may be indicated for all patients older than 60 years, but there are no data to support this recommendation. Such tests should be performed on the following patients: those

with hypertension, diabetes, cardiovascular disease, or renal disease; those who are taking diuretics, angiotensin-converting enzyme (ACE) inhibitors, or angiotensin receptor blockers (ARBs); and those who will undergo bowel preparation for surgery. The Cockcroft-Gault equation should to used to estimate renal function from the serum creatinine; this equation estimates creatinine clearance, corrected for age and weight:

$$\text{Creatinine clearance (ml/min)} = \frac{(140 - \text{age}) \times \text{wt (in kg)}}{(\text{serum creatinine} \times 72)}$$

Routine measurement of the platelet count, prothrombin time, and partial thromboplastin time are not necessary.[30] Indications for testing include a history of prolonged bleeding, easy bruising, postoperative bleeding, or a family history of bleeding.[33] Patients on anticoagulants obviously also need testing.

Other areas of testing are more controversial. Liver enzyme, bilirubin, and albumin measurements are not needed unless there are indications of liver dysfunction on history and physical examination. Other serum chemistry tests, such as calcium and phosphate concentrations, are rarely indicated.

Management of Surgical Risk Factors

CORONARY ARTERY DISEASE

It is now clear that the use of perioperative beta blockers can prevent complications after surgery, both short term and long term.[34-36] Patients with known CAD who can tolerate beta blockers should already be taking these drugs. If they are not, a beta blocker should be started. Many experts recommend starting beta blockade before surgery in patients at high risk for CAD; such patients include those older than 70 years and those who have symptomatic heart failure, a history of stroke, renal insufficiency (i.e., a serum creatinine concentration greater than 2.0), or diabetes.[20] A number of agents have proved useful for perioperative treatment, including labetolol, esmolol, and bisoprolol. Because only a few studies have been done, no specific recommendations can be made; both intravenous and oral regimens have been used with success.[36]

BLOOD PRESSURE

Patients with diastolic blood pressures below 110 mm Hg are not at significant added risk and do not require specific blood pressure management.[1] For elective surgery, however, I believe it is useful that blood pressure be reasonably controlled (i.e., that diastolic blood pressure be lower than 100 mm Hg). It is clear that in patients with poorly controlled blood pressure who undergo surgery, blood pressure may swing widely, both in hypertensive and hypotensive directions. High blood pressure and low blood pressure can each cause problems perioperatively. Unless surgery is urgent or emergent, hurried attempts at blood pressure control are not advised. Excessive diuretic use can lead to volume depletion and hypokalemia; heavy doses of other medications can lead to unanticipated hypotension. Maintaining reasonable control for a period of about a week on an outpatient basis appears to be quite safe. Diuretics are usually withheld on the day of surgery to avoid preoperative volume decrease.[27] Other antihypertensive medications should be taken as usual. Patients with very high blood pressure who need surgery may require treatment with intravenous doses of drugs such as nitroprusside, labetalol, or enalaprilat.

RENAL INSUFFICIENCY

Although patients with significant renal disease are known to be at increased risk for perioperative morbidity and mortality, including increased cardiac complications,[1,2] there is little that can be done to decrease the risks for most of these patients. Foreknowledge aids in watching for complications, however. Perhaps the most common problem seen is volume depletion from high doses of diuretics. A blood urea nitrogen:creatinine ratio of approximately 10 is usually optimal; higher levels should increase suspicion of volume depletion. The presence of such signs as tachycardia, orthostatic changes in blood pressure and pulse, and poor skin turgor help to confirm this suspicion.

Other problems that are seen frequently in patients with renal insufficiency include hyponatremia, hyperkalemia, volume overload, and metabolic acidosis. These abnormalities should be treated to the extent possible before the operation. In patients with acute renal insufficiency, acute complications should be anticipated. Delirium from uremia, serositis (particularly pericarditis), and severe acidosis may be present or may develop quickly. Some of these patients may require dialysis before surgical intervention.

The management of patients on replacement therapy can be quite complicated. In general, to be in optimal condition for the operation, most patients undergo dialysis either on the day before or the day of surgery.

HYPERGLYCEMIA AND DIABETES MELLITUS

Hyperglycemia can lead to poor wound healing and perioperative infections, particularly wound infections.[37] Control of blood sugars to below approximately 200 mg/dl appears to be sufficient. There is now evidence that controlling blood sugars, even in patients without previous diabetes, can improve outcomes in patients in intensive care units.[38]

Oral antidiabetic agents should be discontinued on the day of surgery. In patients whose diabetes is controlled by diet and oral agents, normoglycemia can usually be maintained by giving regular insulin every 4 hours on a sliding scale, until diet and oral medications can be resumed.[39] Patients on insulin generally must be given insulin during and after surgery. It is best to perform surgery in the morning in these patients so that the dose of insulin can be more easily determined.

There are a number of methods of giving insulin.[39] There are no good studies to prove that one method gives better clinical results than another. The most expensive and time consuming but the one that provides the best glucose control is an intravenous drip of regular insulin. This method is probably not necessary in most cases, but in difficult, brittle cases, it will give the best glucose control. In most cases, it is reasonable to give one half to two thirds of the usual dose of neutral protamine Hagedorn (NPH) or other long-acting insulin, monitor regularly, and give regular insulin or glucose as needed.[39] Patients with hyperglycemia or acidosis will require more intensive dosing with regular insulin.

DECREASED HEMATOCRIT

The hematocrit level necessary for minimizing surgical risk has been controversial for many years. There are no good data to support any specific limits for all patients, although young, healthy patients clearly can tolerate much lower hematocrits than older patients with multiple underlying diseases, particularly those of the heart, vascular system, and lungs. Most patients without underlying disease can tolerate surgery if their

hematocrit is above 28%; those with underlying heart or lung disease, particularly elderly patients, may need to undergo transfusion to raise the hematocrit above 35%.[40] Transfusion appears to decrease the development of postoperative delirium.

THYROID DISEASE

Patients with hypothyroidism do not have significant problems with surgery and do not require special treatment, provided they are functional.[23] Patients who are clinically hyperthyroid are at risk for thyroid storm perioperatively, so hyperthyroidism should be well controlled before surgery is undertaken. If surgery is necessary, it is best to consult an endocrinologist to manage the hyperthyroidism perioperatively.[41]

LIVER DISEASE

Underlying liver disease does not appear to be a major risk factor for surgery under most circumstances,[1] nor do elevated levels of liver enzymes appear to be associated with increased risk. Active inflammation from alcoholic hepatitis, however, substantially increases the risk of mortality. Patients with fever, elevated white blood cell counts, and jaundice should not have surgery unless their condition is clearly not the result of alcoholic hepatitis and they are facing a surgical emergency.[42] The main risks from underlying liver disease are variceal bleeding in patients with varices and hepatic encephalopathy in those at risk. Ascites also presents difficult management problems, with many complicated issues that are beyond the scope of this chapter [*see 4:IX Cirrhosis of the Liver*].

CORTICOSTEROID THERAPY

Patients who are taking corticosteroids (e.g., for rheumatic disease or asthma) usually need replacement therapy perioperatively.[25] In normal persons, the daily output of cortisone is approximately 30 mg; peak stress levels are approximately 300 mg a day. Unfortunately, no good studies have been done to determine which patients definitely need supplementation and how long the increase in dose should be maintained. Current practice is to give additional medication to patients who are taking the equivalent of 30 mg or more of hydrocortisone a day. For patients at lower dose ranges, supplemental doses (e.g., 50 mg) given twice daily are adequate; for those taking more than 150 mg a day, three doses a day of 50 to 100 mg are usually recommended. It is unusual to give more than 100 mg three times a day. For most patients, the dose can be tapered back to baseline in 2 to 3 days.

ALCOHOL ABUSE

Patients who abuse alcohol are at risk for withdrawal syndromes when admitted for surgery. It is best to get patients to stop drinking at least a week before surgery. If efforts to get a patient to stop do not succeed (or if such efforts were not made, because the patient gave a misleading drinking history), then therapy should be begun for withdrawal as soon as the initial signs and symptoms are noted. Most often, these consist of tremor and tachycardia with agitation. Oral benzodiazepines (e.g., chlordiazepoxide, lorazepam, diazepam), are the usual choice for treating withdrawal; they may be given every 4 to 6 hours until symptoms abate.[43] The dose will depend on the patient's alcohol consumption; the dose can be remarkably high, as compared with the dose in patients who do not abuse alcohol. Requiring the equivalent of 400 mg of chlordiazepoxide is not uncommon.

THROMBOSIS

All surgical procedures increase the risk of deep vein thrombosis (DVT), and most major surgery carries a significant risk of both DVT and pulmonary embolism. Patients older than 40 years who will have an operation lasting longer than 30 minutes will require DVT prophylaxis. Most general and gynecologic surgery patients require low-dose heparin at 5,000 U every 12 hours; some experts believe that 5,000 U every 8 hours should be given for patients having long and complicated surgical procedures. In orthopedic surgery, particularly hip and knee operations, low-molecular-weight heparin is the agent of choice. There is increasing and convincing evidence that continuing DVT prophylaxis, particularly after orthopedic hip and knee surgery, for 4 to 6 weeks postoperatively prevents morbidity and mortality from late thromboses and pulmonary emboli. This is particularly true in light of the shorter hospitalizations of patients after surgical procedures.[44,45] Warfarin can be used as well. For surgical procedures in which any increased risk of bleeding is unacceptable (e.g., neurosurgery or open prostatectomy), intermittent compression stockings are most often used to prevent DVT.

ADVANCED AGE

Surgery in elderly patients has become routine over the past decade or so. Improvements in anesthetic techniques, better understanding of the management of medical diseases, and improved and less invasive surgical techniques have allowed older and much sicker patients to undergo surgery. Many studies have shown that an elderly patient can undergo most procedures that are important to survival or quality of life without being exposed to a large increase in perioperative risk.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

V BIOTERRORISM

Jeffrey Duchin, m.d.

Well before the 2001 anthrax outbreak, public health and government leaders in the United States recognized the need for increased preparedness to detect and respond to acts of biologic terrorism. Concern about the vulnerability of the United States to a biologic attack grew with revelations about the offensive biologic weapons programs of the former Soviet Union and Iraq, as well as uncertainty about the whereabouts of and accountability for biologic agents produced through those programs; the successful chemical attack on the Tokyo subway system by the Aum Shinrikyo cult, coupled with information that the cult was actively experimenting with biologic agents; and information about the potential for domestic bioterrorism.[1-5]

In April 2000, the Centers for Disease Control and Prevention (CDC) published a strategic plan for preparedness and response to biologic and chemical terrorism.[6] This subsection describes the clinician's role in recognizing and responding to biologic terrorism, as presented in the CDC plan; summarizes current information on the diagnosis and management of the most likely agents of bioterrorism; and describes current resources for authoritative information and guidelines related to bioterrorism.

The Clinician's Role in Bioterrorism Preparedness and Response

For clinicians, the response to a bioterrorism attack is in many ways the same as the response to naturally occurring outbreaks of communicable disease.[7,8] Both situations typically require early identification of ill or exposed persons, rapid implementation of preventive therapy, special infection control considerations, and collaboration or communication with the public health system. Examples of naturally occurring communicable diseases that require such a response include meningococcal disease[9]; enteric infection with *Escherichia coli* 0157:H7, *Salmonella,* or *Shigella*[10]; pertussis, rubella, measles, or chickenpox occurring in health care facilities and clinics[11-14]; unusual or newly emerging infections such as West Nile virus and hantavirus pulmonary syndrome[15-17]; and the inevitable reappearance of pandemic influenza.[18] The 2002 outbreak of severe acute respiratory syndrome (SARS) exemplifies the type of unexpected, naturally occurring disease for which the need for preparedness and the impact on clinicians have much in common with that of biologic terrorism.[19,20]

The first indication of an unannounced biologic attack will likely be an increase in the number of persons seeking care from primary care physicians. In the 2001 anthrax outbreak, as well as in outbreaks of *E. coli* 0157:H7 disease and hantavirus pulmonary syndrome in 1993 and West Nile virus in 1999, alert clinicians initiated the public health response by recognizing an unusual clinical syndrome, ordering appropriate laboratory tests, and notifying public health officials.[10,16,17] Similarly, primary care physicians and subspecialists alike must be familiar with both the specific clinical syndromes associated with agents of bioterrorism and the ways to rapidly notify public health authorities. In addition to identifying cases and treating ill patients, clinicians also play a critical role in managing postexposure prophylaxis and its complications, as well as psychological and mental health problems brought on by the event.

During both bioterrorism attacks and naturally occurring outbreaks, clinicians are faced with the challenge of excluding the outbreak disease in persons who are worried about potential exposure or who are ill with signs and symptoms similar to those of the outbreak disease. The clinician must have knowledge of the signs and symptoms, modes of transmission, incubation periods, and communicable periods of these diseases, as well as skill in both clinical evaluation and eliciting an appropriate and thorough history, including relevant occupational, social, and travel information. In both the 2001 anthrax bioterrorism attack and the 2002 SARS outbreak, the epidemiologic setting of cases played an important role in guiding clinical management, diagnostic tests, and treatment.[21-23] The primary care clinician has the best opportunity to obtain relevant information early in the evaluation; this is important because such information may be more difficult to obtain as time goes on, particularly if the patient's condition deteriorates.

Physicians and other health care providers should have a working knowledge of the basic classes of isolation and infection control measures recommended for patients exposed to agents of potential bioterrorism. Again, these measures are also used in the management of common communicable diseases.[14,24-26]

Recognition of Potential Bioterrorism Agents

The CDC has developed a list of bacteria, viruses, and toxins thought to pose the greatest risk for use in a bioterrorist attack [*see Table 1*].[27] Agents were included in the list on the basis of their ability to cause disease that (1) is easily disseminated or transmitted from person to person; (2) has high mortality, with potential for major public health impact; (3) may result in panic and social disruption; and (4) requires special action for public health preparedness. Category A agents are thought to pose the highest immediate risk for use as biologic weapons; and category B agents, the next highest risk. Category C agents are thought to pose a potential, but not immediate, risk for use as biologic weapons.

As in naturally occurring outbreaks, early recognition of a bioterrorist attack is critical for rapid implementation of preventive measures and treatment. Early recognition can be challenging, however, because patients presenting for medical care after exposure to a biologic agent may initially exhibit nonspecific symptoms, and pathogens that ordinarily occur in the community, particularly enteric organisms, may be used in a biologic attack.[28,29] A heightened level of suspicion, plus knowledge of the relevant epidemiologic clues, should help physicians recognize changes in illness patterns, including clusters and increases in observed cases over the number expected [*see Table 2*].[30] Physicians should also be able to recognize diagnostic clues in single cases of a syndrome of concern (e.g., inhalational anthrax, plague and tularemia, botulismlike illness, and possible smallpox).[31] Familiarity with the clinical features of diseases from potential bioterrorist agents and diseases prevalent in the community will allow recognition of potentially significant differences from naturally occurring cases. One of the most important lessons learned from the 2001 anthrax attack was that clinical ill-

Table 1 Critical Biologic Agent Categories for Public Health Preparedness

Category	*Biologic Agent*	*Disease*
A (highest immediate risk)	Variola major	Smallpox
	Bacillus anthracis	Anthrax
	Yersinia pestis	Plague
	Clostridium botulinum (botulinum toxins)	Botulism
	Francisella tularensis	Tularemia
	Filoviruses and arenaviruses (e.g., Ebola virus, Lassa virus)	Viral hemorrhagic fevers
B (next highest risk)	*Coxiella burnetii*	Q fever
	Brucella species	Brucellosis
	Burkholderia mallei	Glanders
	Burkholderia pseudomallei	Melioidosis
	Alphaviruses (VEE, EEE, WEE)	Encephalitis
	Rickettsia prowazekii	Typhus fever
	Toxins (e.g., ricin, staphylococcal enterotoxin B)	Toxic syndromes
	Chlamydia psittaci	Psittacosis
	Food-safety threats (e.g., *Salmonella* species, *E. coli* 0157:H7)	
	Water-safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)	
C (potential, but not immediate, risk)	Emerging-threat agents (e.g., Nipah virus, hantavirus)	

EEE—eastern equine encephalitis VEE—Venezuelan equine encephalitis WEE—western equine encephalitis

ness caused by agents prepared as biologic weapons may differ from typical natural infections.

The identification of a bioterrorist attack requires clinicians to be prepared, alert, and open-minded [*see Sidebar* Internet Resources on Bioterrorism]. Many local and state health departments post current information about communicable diseases on their Web sites and distribute informational newsletters with relevant data. The CDC's weekly bulletin, *Morbidity and Mortality Weekly Report (MMWR),* contains current information on medical conditions of public health importance in the United States. Subscriptions to MMWR are available online at http://www.cdc.gov/mmwr/mmwrsubscribe.html.

Communication with Authorities

Once a potential outbreak or significant cluster or event has been detected, prompt consultation with appropriate medical specialists and public health authorities is indicated. Clinicians must have reliable, around-the-clock contact information for emergency resources in the geographic area where they practice; these resources include specialist consultants (e.g., consultants in infectious disease, dermatology, or pulmonary medicine) and infection control professionals or hospital epidemiologists. All clinicians should know how to contact their local or state public health department 24 hours a day to report suspicious or otherwise immediately notifiable cases or for consultation. Many local and state health departments have such contact numbers on their Web sites. Clinicians should have these numbers readily accessible and keep them current.

Clinicians must also ensure that they have a reliable way to promptly receive urgent communications from public health authorities, both for naturally occurring outbreaks of local significance and for a bioterrorist event or outbreak. Increasingly, public health authorities are disseminating health alerts over the Internet, through Web sites and e-mail listserves.

Smallpox

Smallpox is caused by variola virus, an orthopox virus unique to humans. No known animal or insect reservoirs or vectors exist.[32] Related orthopox viruses infecting humans include vaccinia (smallpox vaccine), monkeypox, and cowpox. Smallpox existed in two forms: variola major, which accounted for most morbidity and mortality, and a milder form, variola minor. Variola major is the type of concern in the context of biologic terrorism.

Smallpox was declared eradicated in 1980, 3 years after the last naturally occurring case was reported from Somalia. Stocks of smallpox virus were retained, however, by World Health Organization (WHO) reference laboratories at the Institute of Virus Preparations in Moscow, Russia, and at the CDC in Atlanta, Georgia. In the late 1990s, allegations were published describing the production of large quantities of smallpox virus by the former Soviet Union. These stores, which may have become dis-

Table 2 Epidemiologic Clues of a Biologic Attack

- Presence of a large epidemic
- Unusually severe disease or unusual routes of exposure
- Unusual geographic area, unusual season, or absence of normal vector
- Multiple simultaneous epidemics of different diseases
- Outbreak of zoonotic disease
- Unusual strains of organisms or antimicrobial-resistance patterns
- Higher attack rates in persons with common exposures
- Credible threat, as determined by authorities, of biologic attack
- Direct evidence of biologic attack

seminated after the breakup of the Soviet Union, would presumably be the source for a bioterrorist attack involving smallpox.

Smallpox is stable and highly infectious in the aerosol form. The risk for a smallpox attack currently is considered low but not zero.[1,4,33,34]

CLASSIFICATION

On the basis of a study from India, the WHO has classified smallpox into five clinical forms: ordinary, flat-type, hemorrhagic, modified, and sine eruptione.[35] These forms reflect different host reactions to the same strain of virus.

Ordinary Smallpox

Ordinary smallpox is the most common form seen in nonimmune persons; it accounted for 90% of cases in the WHO study and had an average case-fatality rate of 30%. The incubation period is 7 to 17 days (mean, 10 to 12 days). Symptoms of the prodromal phase include the acute onset of high fever, malaise, headache, backache, and prostration. Other prominent symptoms include vomiting and abdominal pain.

Figure 1 **Lesions of smallpox.**

The characteristic rash occurs 2 to 3 days later, appearing first on the face and forearms. An enanthem involving the oropharyngeal mucosa precedes the rash by a day. The rash progresses slowly, from macules to papules to vesicles and pustules and finally to scabs, with each stage lasting 1 to 2 days. The lesions are firm, discrete vesicles or pustules (4 to 6 mm in diameter) deeply embedded in the dermis; they may become umbilicated or confluent as they evolve [*see Figure 1*]. The patient remains febrile throughout the evolution of the rash, which may become painful as pustules enlarge. A second fever spike 5 to 8 days after onset of the rash may signify a secondary bacterial infection. Pustules remain for 5 to 8 days, after which umbilication and crusting occur. Lesions are in the same stage of development on any given part of the body. They are peripherally distributed, more concentrated on the face and distal extremities than on the trunk, and may involve the palms and soles. Scarring occurs with scab separation from destruction of sebaceous glands.

Experience during the global smallpox eradication program suggests that the onset of communicability coincides with the development of rash, approximately 2 days after the onset of the acute febrile prodrome. However, because the oropharyngeal enanthem and associated release of virus into oral secretions may precede rash onset, it is recommended that for the purposes of postexposure management, anyone who has contact with smallpox patients from the time of onset of fever should be considered potentially exposed [*see* Infection Control, *below*].[36]

Complications of smallpox include fluid and electrolyte disturbances; extensive desquamation that clinically resembles burns; bronchitis and pneumonitis; panophthalmitis and blindness from viral keratitis or secondary infection of the eye; arthritis (developing in up to 2% of children); and encephalitis (less than 1% of cases). Death results from toxemia associated with circulating immune complexes and variola antigens.[37]

Other Forms of Smallpox

Flat-type (or malignant) smallpox occurs in 5% to 10% of cases and is severe, with a 97% case-fatality rate among unvaccinated persons. In this form, lesions are flat and become densely confluent, evolving slowly and coalescing with a soft, velvety texture. Hemorrhagic smallpox was reported in less than 3% of cases, occurring particularly in pregnant women. It is a severe, rapidly progressive, uniformly fatal illness. A dusky erythema develops, followed by hemorrhages into the skin and mucous membranes. Both hemorrhagic and flat-type smallpox have an accelerated and more severe prodromal phase and are thought to be associated with underlying immune dysfunction.

Modified smallpox is a mild form that accounted for 2% of cases in unvaccinated patients and 25% in previously vaccinated patients. This form rarely resulted in death, and these patients had fewer, smaller, more superficial, and more rapidly evolving lesions. Smallpox sine eruptione (without rash) occurs in previously vaccinated persons or children with maternal antibodies to smallpox. It is a mild or asymptomatic illness that has not been documented to be transmissible.[35,37-39]

DIAGNOSIS

A suspected case of smallpox is a public health emergency. Local and state health authorities, the hospital epidemiologist, and other members of a hospital response team for biologic emergencies should be notified immediately (see the CDC Interim Smallpox Response Plan and Guidelines at http://www.bt.cdc.gov/documentsapp/SmallPox/RPG/ContactInfo.asp).

The differential diagnosis of smallpox includes other illnesses that can cause fever and a rash [*see Table 3*]. Severe varicella is the disease most likely to be confused with smallpox. However, familiarity with the clinical features of the two diseases, particularly the rash, should help differentiate them [*see Table 4*]. Additional information that may be useful in differentiating smallpox from chickenpox includes a history of exposure to persons with chickenpox, a personal history of chickenpox, a history of vaccination against varicella or smallpox, and the clinical course of illness.

If shingles or disseminated herpes infection is a consideration, direct fluorescent antibody testing for varicella-zoster virus can rapidly confirm varicella-zoster virus and herpes simplex virus infection in patients not considered at high risk for smallpox. Such testing should not be done in patients who are considered at high risk, to avoid exposing laboratory workers to smallpox virus. Certain laboratories can also perform polymerase chain reaction (PCR) testing for herpes simplex virus and varicella-zoster virus. Consultation with an infectious disease specialist, a dermatology specialist, or both is recommended.

Flat-type and hemorrhagic smallpox may be difficult to recognize because of the absence of the characteristic rash of ordinary smallpox, yet these cases are highly infectious. Hemorrhagic smallpox cases may be mistaken for meningococcemia or acute leukemia. All patients with potential smallpox should be asked about their travel history, history of varicella and vaccinia vaccination, level of immunocompetence, and current medications.

The local or state health department should be contacted to facilitate specimen collection for smallpox testing (http://www.statepublichealth.org). Protocols for specimen collection for smallpox testing have been published by the CDC and are available on the Internet (http://www.cdc.gov).

Diagnostic testing is available at designated biosafety level 4 (BSL-4) laboratories and includes electron microscopy, immunohistohemical tests, and viral culture with PCR and restriction fragment length polymorphism (RFLP) testing. Only personnel who have undergone successful smallpox vaccination recently (within 3 years) and who are wearing appropriate barrier protection (gloves, gown, and shoe covers) should be involved in specimen collection for suspected cases of smallpox. Respiratory protection is not needed for personnel with recent, successful vaccination. Masks and eyewear or face shields should be used if splashing is anticipated. If unvaccinated personnel must collect specimens, only those who are without con-

Table 3 Diagnosis of Smallpox

Incubation Period	*Clinical Presentation*	*Differential Diagnosis*	*Diagnostic Testing*
7–17 days; mean, 10–12 days	Severe, acute febrile prodrome 1–4 days before rash onset, with temperature ≥ 101° F (38.3° C), headache, backache, chills, vomiting, abdominal pain, prostration Enanthem on oropharyngeal mucosa, followed by rash on face, forearms, distal extremities, then trunk; lesions most concentrated on face and distal extremities Lesions evolve slowly from macules to papules to deep-seated, firm, nodular, round, well-circumscribed vesicles or pustules to scabs over 1–2 days per stage; are in same stage of evolution on a given area of the body; may become umbilicated or confluent Hemorrhagic smallpox: bleeding into skin and mucous membranes Flat-type/malignant smallpox: lesions remain soft and flattened, coalesce Modified smallpox: less severe with fewer, more superficial and rapidly evolving lesions	Varicella (chickenpox); disseminated herpes zoster and simplex; drug eruptions; erythema multiforme; enteroviral infections; secondary syphilis; contact dermatitis; impetigo; scabies; molluscum contagiosum Hemorrhagic smallpox: meningococcemia, Rocky Mountan spotted fever, ehrlichiosis, gram-negative bacterial sepsis, severe acute leukemia Malignant smallpox: hemorrhagic chickenpox	Diagnostic testing at BSL-4 laboratory, including skin biopsy, electron microscopic examination of vesicular and pustular fluid, culture, PCR; serology Appropriate infection control precautions

Note: The clinical manifestations of infections acquired during a biologic attack may differ from those of naturally occurring infections. Clinicians should remain alert for compatible syndromes that vary from the descriptions given.
BSL-4—biosafety level 4 PCR—polymerase chain reaction

Table 4 Differentiating Features of Smallpox and Chickenpox

Clinical Feature	*Smallpox*	*Chickenpox*
Prodromal illness	Febrile prodrome lasting 1–4 days; patient appears ill or toxic	No or mild prodrome; patients typically do not appear ill
Appearance of lesions	Firm, round, well-circumscribed, deep-seated lesions; may be umbilicated	Superficial lesions
Stage of lesions on any one part of the body	Lesions are all at the same stage of development on a given area of the body	Lesions occur in crops with various stages of development evident on a given area of the body
Initial lesions	Oral mucosa, face, or forearms	Face, then trunk
Oral lesions	Early; may not be evident	May occur
Severity of illness	Typically severe	Typically not severe
Distribution of rash	Centrifugal: lesions concentrated on the face and extremities, with relative sparing of the trunk	Centripetal: lesions concentrated on the trunk with relative sparing of the face and extremities
Lesions on palms or soles	Lesions on palms and soles in majority of cases	Lesions on palms and soles uncommon
Rate of evolution of rash	Slow evolution of lesions from macules to papules to pustules over days	Rapid evolution from macules to papules to crusted lesions within 24 hours
Presence of pruritus	Lesions may be painful and are not usually pruritic until scabbing occurs	Often pruritic, typically not painful in the absence of secondary infection
Hemorrhagic lesions	Can occur	Can occur

traindications to vaccination should do so, because they would require immediate vaccination if the diagnosis of smallpox were confirmed. Vesicular or pustular fluid, scabs, punch biopsies of skin lesions, blood, and tissue from autopsy specimens should be obtained, packaged, and transported according to CDC protocol (http://www.bt.cdc.gov/labissues/PackagingInfo.pdf; http://www.bt.cdc.gov/documentsapp/SmallPox/RPG/index.asp).[36,39]

The CDC has developed a protocol in poster format for evaluating patients with an acute vesicular or pustular rash illness and for determining the risk of smallpox. The protocol, including color pictures of smallpox lesions, is available on the Internet at the CDC smallpox Web site (http://www.bt.cdc.gov/agent/smallpox/index.asp).

INFECTION CONTROL AND POSTEXPOSURE ISOLATION

In the event of a limited outbreak, patients should be admitted to the hospital and confined to rooms that are under negative atmospheric pressure and equipped with high-efficiency particulate air (HEPA) filtration. Standard, contact, and airborne precautions, including use of gloves, gowns, and masks, should be strictly observed. Unvaccinated personnel caring for patients suspected of having smallpox should wear fit-tested N95 or higher-quality respirators. Once successful vaccination is confirmed, care providers are no longer required to wear an N95 mask.[39] Patients should wear a surgical mask and be wrapped in a gown or sheet to cover the rash when they are not in a negative-airflow room. All laundry and waste should be placed in biohazard bags and autoclaved before being laundered or incinerated. Surfaces that may be contaminated with smallpox virus can be decontaminated with disinfectants that are used for standard hospital infection control, such as hypochlorite and quaternary ammonia.

Persons suspected of being infected with smallpox should be immediately isolated, and all their household members and others who have had face-to-face contact with the infected patient after the onset of fever should be vaccinated and placed under surveillance. Because persons who have had contact with an infected patient would not be contagious until the onset of rash, they should take their temperatures at least once daily, preferably in the evening. Any temperature higher than 101° F (38.3° C) during the 17-day period after the last exposure to the infected patient would suggest the possibility of the development of smallpox. This would be cause for immediate isolation until the diagnosis can be determined clinically, by laboratory examination, or both.

In the event of an outbreak, the following high-risk groups should be given priority for vaccination: (1) persons exposed to the initial release of the virus; (2) contacts of suspected or confirmed smallpox patients; (3) personnel who are directly involved in medical or public health evaluation of suspected or confirmed smallpox patients, as well as the care or transportation of such patients; (4) laboratory workers involved in the collection or processing of possible smallpox specimens; (5) other persons who may be in contact with infectious material, such as hospital laundry, medical waste, and mortuary workers; (6) other groups essential to response activities, such as law enforcement, emergency response, or military personnel; and (7) all persons in a hospital where there is a smallpox patient who is not isolated appropriately. Employees for whom vaccination would be contraindicated (see below) should be furloughed.[36,39]

Smallpox Vaccine

Vaccinia vaccine does not contain smallpox (variola) virus. The only currently available vaccine was prepared from calf lymph with a seed virus derived from the New York City Board of Health (NYCBOH) strain of vaccinia virus (Dryvax vaccine, Wyeth Laboratories, Marietta, Pennsylvania). A supply of licensed Dryvax vaccine was used in 2003 to immunize smallpox health care and public health teams as part of the National Smallpox Vaccination Plan. A reformulated vaccine, produced by using cell-culture techniques, is being developed.

The immune status of those vaccinated more than 27 years ago is not clear. Studies have demonstrated persistence of T cell and humoral responses, but absolute levels of neutralizing antibodies decline substantially during the first 5 to 10 years after vaccination. Interpretation of the data is complicated by the fact that the laboratory correlates of immunologic protection against smallpox infection are not currently established. Epidemiologic studies demonstrate that an increased level of protection against smallpox persists for less than 5 years after primary vaccination, and substantial but waning immunity can persist for longer than 10 years. Antibody levels after revaccination can remain high longer, conferring a greater period of immunity than occurs after primary vaccination alone.[32,35]

Complications of smallpox vaccination Current data on complication rates after primary vaccination are derived from observations made when smallpox vaccine was in routine use in the United States, over 30 years ago, and from the initial reports from the 2002 to 2003 United States military and civilian smallpox vaccination programs, involving 450,293 and 38,257 vaccinees, respectively. In these vaccination programs from 2002 to 2003, licensed undiluted Dryvax vaccine was used.[32,40-42] No cases of eczema vaccinatum or progressive vaccinia or vaccine-attributable deaths occurred. These reports suggest that for selected healthy vaccinees who have been carefully screened for vaccine contraindications and educated about adverse effects, adverse-event rates can be comparable to or less than historical rates. Should smallpox vaccine need to be administered to the general public, higher rates of vaccine complications could occur, given the increased number of persons with vaccine contraindications, including atopic dermatitis and other medical conditions, as well as the number of persons receiving medications that compromise the immune system. Contact transmission of vaccinia from immunized persons to close contacts, particularly those at risk for serious adverse events, is of particular concern.[43] Twenty-one cases of contact transmission were reported from the military program (47 per million vaccinees); no cases of transmission from health care providers to patients occurred.

Cell-mediated immunity is important in controlling smallpox and vaccinia infection. However, the level of immunosuppression that correlates with increased risk of adverse events is not known with certainty. In HIV-infected persons, progressive vaccinia infection after smallpox vaccination is the adverse event of greatest concern (see below); the risk presumably correlates with CD4 cell count.[44] During the 2002 to 2003 United States military smallpox vaccination program, 10 service members with HIV infection and CD4 cell counts ranging from 303 to 752 cells/μl were inadvertently vaccinated before recognition of their HIV infection. All 10 responded successfully to vaccination without adverse events.[40]

Moderate and severe complications of vaccinia vaccination include eczema vaccinatum, generalized vaccinia, progressive vaccinia, and postvaccinial encephalitis. These complications are rare but are at least 10 times more common after primary vaccination than after revaccination; they occur more frequently in infants than in older children and adults.

The most common complication of smallpox vaccination, occurring in 529.2 cases per million doses, is localized vaccinia infection resulting from inadvertent transfer (autoinoculation) of vaccinia from the vaccination site to other parts of the body. In addition, transmission of vaccinia virus can occur when a recently vaccinated person has contact with a susceptible person; in one study, approximately 30% of eczema vaccinatum cases were persons who had had such contact.[32,45] Inadvertent transfer of vaccinia from the vaccination site to other parts of the body can be prevented by careful hand washing after touching the vaccination site and by keeping the site covered.

Figure 2 **Progressive vaccinia (vaccinia necrosum) at the site of smallpox vaccination in a 64-year-old man.**

Eczema vaccinatum (38.5/million doses) is a localized or systemic dissemination of vaccinia virus that occurs in persons who have eczema or a history of eczema or other chronic or exfoliative skin conditions (e.g., atopic dermatitis). Illness is usually mild and self-limited but can be severe or fatal. Severe cases have also been observed in persons with active eczema or a history of eczema, after contact with recently vaccinated persons.

Generalized vaccinia (241.5/million doses) is characterized by a vesicular rash of varying extent that can occur in persons without underlying illness. The rash is generally self-limited and requires minor or no therapy except in patients whose condition might be toxic or who have serious underlying immunosuppressive illnesses.

Progressive vaccinia (vaccinia necrosum, 1.5/million doses) is a severe, potentially fatal illness characterized by progressive necrosis in the area of vaccination, often with metastatic lesions [*see Figure 2*]. It has occurred almost exclusively in persons with cellular immunodeficiency.

The most common serious complication is postvaccinial encephalitis (12.3/million doses). It occurs mostly in infants younger than 1 year and, less often, in adolescents and adults receiving a primary vaccination. Rates of this complication were influenced by the strain of virus used in the vaccine and were higher in Europe than in the United States. The principal strain of vaccinia virus used in the United States—the NYCBOH strain—was associated with the lowest incidence of postvaccinial encephalitis. Approximately 15% to 25% of affected vaccinees with this complication die, and 25% have permanent neurologic sequelae.

Fatal complications caused by vaccinia vaccination are rare, with approximately one death per million primary vaccinations and 0.25 deaths per million revaccinations. Death is most often the result of postvaccinial encephalitis or progressive vaccinia.

In 2003, cases of myocarditis, pericarditis, or both (myopericarditis) occurred at higher than expected rates in both the civilian and the military smallpox vaccination programs. Cases of cardiac ischemic events, including myocardial infarction and angina, were also reported in persons who had received vaccinations; however, the rates of ischemic events were not clearly elevated above expected background rates, and the association between smallpox vaccination and cardiac ischemic events is unclear.[46,47]

Among 450,293 United States military service members vaccinated from December 2002 to May 2003, 37 cases of suspected, probable, or confirmed myopericarditis were observed; the rate was 1:12,195 among male primary vaccinees 21 to 33 years of age. No cases were reported among 132,836 previously vaccinated vaccinees.[40] Through May 9, 2003, 21 cases of myopericarditis (90% of revaccinees) were reported among 36,217 civilian vaccinees, representing a rate of 1:1,700 vaccinees (the rate decreases to 1:36,000 vaccinees when vaccinees without elevations in cardiac enzyme levels are excluded).[46]

Symptoms of myopericarditis after smallpox vaccination began 7 to 19 days after vaccination (range, 1 to 42 days). Symptoms included prodromal myalgias, arthralgias, or both, as well as subsequent pleuritic precordial chest pain with variable shortness of breath, dry cough, or both. Electrocardiogram findings varied; such findings included ST segment and T wave abnormalities and dysrhythmias, including paroxysmal atrial fibrillation, atrial ectopy, supraventricular tachycardia, and ventricular ectopy. ECG findings included pleural effusion and wall motion abnormalities; these findings were not seen in all patients. All patients among the United States military vaccinees, as well as one civilian patient, were reported to have had elevated cardiac enzyme levels. All the patients who were reported to have myopericarditis recovered. In cases where alternative etiologies were sought, none were established, and in no case was a virologic diagnosis made. The biologic mechanism for myopericarditis after smallpox vaccination is not established; it may involve the viral cytopathic effect, an immune-mediated reaction, or both.[47] A surveillance case definition for myopericarditis has been developed to monitor smallpox vaccine adverse events (this definition is not to be used for clinical diagnosis). That survillance case definition is available on the Internet.[46]

In response to these reports, new cardiovascular screening and exclusion criteria were published for use of smallpox vaccine in persons not exposed to smallpox.[48] Vaccinees experiencing chest pain, shortness of breath, or other symptoms of cardiac disease within 2 weeks of smallpox vaccination are advised to seek medical attention. Although myopericarditis after smallpox vaccination had been previously reported, a causal association with the vaccine had not been recognized.

Focal folliculitis and generalized folliculitis were reported after smallpox vaccination in 7.4% and 2.7%, respectively, of 148 primary vaccinees enrolled in a clinical trial of a smallpox vaccine that is not currently in use but that was derived from the same strain of vaccinia virus as the NYCBOH strain used in Dryvax.[49] Follicular erythematous papules developed from 9 to 11 days after vaccination; these papules progressed to pustules that lasted 3 to 5 days. Lesions appeared primarily in areas where there were larger numbers of hair follicles or sebaceous glands (e.g., the extremities, face, and back); concurrent lesions were in different stages of development. Vaccinia was not isolated from specimens that were available for culture. This new observation is significant because of the potential for this apparently benign condition to be confused with generalized vaccinia.

Contraindications Groups at special risk for complications include persons with eczema or other acute, chronic, or exfoliative skin conditions; patients with immune system suppression, including leukemia, lymphoma, or generalized malignancy who are receiving therapy with alkylating agents, antimetabolites, radiation, or large doses of corticosteroids; patients with HIV infection and persons with hereditary immune disorders; children younger than 1 year; and women who are pregnant or breast-feeding (because of the risk of contact transmission to the child). On the basis of reports of adverse cardiac events in 2003, persons should currently be excluded from preexposure smallpox vaccination if they have known underlying heart disease or three or more known cardiac risk factors (i.e., hypertension, smoking, diabetes, hypercholesterolemia, and heart disease occurring by 50 years of age in a first-degree relative). Deferring vaccination of persons with active inflammatory disease of the eye requiring steroid treatment is advised until the condition resolves and treatment is complete.[48] In persons with contraindications who require vaccination because of exposure to smallpox virus from a bioterrorist attack, the risk of complications can be reduced by giving vaccinia immune globulin (VIG; see below) simultaneously with the vaccine. However, current stores of VIG are insufficient to allow its prophylactic use. Even if VIG is not available, vaccination may still be warranted, given the far higher risk of an adverse outcome from smallpox than from vaccination.

Current information about smallpox vaccine, including recommendations for vaccine use, contraindications, screening of potential vaccinees, prevention of contact transmission, and management of adverse effects, is available on the CDC Web site (http://www.cdc.gov).

Vaccinia immune globulin Complications of vaccinia vaccination can be prevented or treated with VIG, which is an isotonic sterile solution of the immunoglobulin fraction of plasma from persons vaccinated with vaccinia vaccine. For prophylactic use, in persons with contraindications who require vaccination, VIG is given along with vaccinia vaccine.[32] Very large amounts are required: VIG is administered intramuscularly in a dose of 0.3 ml/kg (e.g., 22.5 ml I.M. for a 75 kg patient) At present, however, supplies of VIG are so limited that its use should be reserved for treatment of patients with the most serious vaccine complications.

For treatment of vaccinia vaccination complications, VIG is administered intramuscularly; 0.6 ml/kg is given in divided doses over a 24- to 36-hour period. A repeat dose may be given 2 to 3 days later if improvement does not occur. VIG is effective for treatment of eczema vaccinatum and certain cases of progressive vaccinia; it might be useful also in the treatment of ocular vaccinia resulting from inadvertent implantation. VIG is contraindicated for the treatment of vaccinial keratitis. VIG is recommended for severe generalized vaccinia if the patient is extremely ill or has a serious underlying disease. VIG provides no benefit in the treatment of postvaccinial encephalitis and has no role in the treatment of smallpox.[32,36]

Anthrax

Anthrax is a zoonotic disease caused by the spore-forming bacterium *Bacillus anthracis,* a large, nonmotile, nonhemolytic, gram-positive rod [*see 7:IV Infections Due to Gram-Positive Bacilli*]. The organism is distributed worldwide in soil. Animals, pri-

marily herbivores, become infected through grazing in contaminated areas. Under natural conditions, humans contract the disease after close contact with infected animals or contaminated animal products such as hides, wool, or meat.[50] Hardy spores resistant to heat and environmental degradation are the usual infective form. The spores develop in response to exposure to ambient air. On exposure to favorable, nutrient-rich environmental conditions such as tissues or blood of an animal or human host, the spores germinate, producing vegetative cells.[51]

CLASSIFICATION AND EPIDEMIOLOGY

Anthrax occurs in three clinical forms in humans: inhalational, cutaneous, and gastrointestinal. In a biologic attack, aerosol exposure to anthrax spores would be most likely.[33] Only 18 cases of inhalational anthrax were reported in the United States in the 20th century, none of them after 1976. Sixteen of these cases were attributable to an industrial source of infection, and two cases were laboratory associated.[52] Before 2001, exposure to powdered anthrax spores in an envelope or package was not thought to be an efficient means of causing inhalational disease. However, exposure to anthrax spores sent through the United States mail in the 2001 anthrax attack resulted in 11 cases of inhalational anthrax and 11 cases of cutaneous disease.[21,53,54] Recent research has demonstrated the unanticipated potential for significant dispersion of respirable aerosol particles of spores through opening of a contaminated envelope.[55] In addition, expected clinical findings based on previous experience with naturally occurring anthrax infections did not entirely correspond to the clinical presentation in persons exposed to anthrax in the context of a biologic attack, although there was considerable overlap between the two.

Cutaneous anthrax accounts for the majority of naturally occurring anthrax cases worldwide. It results from inoculation of spores subcutaneously through a cut or abrasion.[56] Given that cutaneous anthrax cases occurred during the 2001 anthrax outbreak, it is possible that a bioterrorist attack could be detected through recognition of cutaneous anthrax cases.[21] Gastrointestinal and oropharyngeal anthrax occur in rural parts of the world where anthrax is endemic. They result from ingestion of meat contaminated with spores or large numbers of vegetative cells.[57] No cases of gastrointestinal anthrax occurred during the 1979 accidental release of anthrax from a military facility in Sverdlovsk, Russia, in which 77 inhalational cases occurred, or during the 2001 outbreak in the United States. Because of the logistic difficulty of effectively contaminating food and water supplies, it is thought that this form of anthrax would be less likely to occur as a result of a biologic attack.[33]

PATHOPHYSIOLOGY

Anthrax is a toxin-mediated disease. In inhalational anthrax, 1 to 5 μm particle–bearing spores are deposited in the terminal airways or alveoli, phagocytized by alveolar macrophages, and transported to mediastinal and peribronchial lymph nodes. Spores may stay in the mediastinal lymph nodes for extended periods and can germinate for up to 60 days or longer.[58] Cases of inhalational anthrax occurred up to 43 days after exposure in the Sverdlovsk outbreak.[59] Spores germinate into vegetative cells, which escape from the macrophages, multiply in the lymphatics, and ultimately gain access to the bloodstream, where they can reach high concentrations (107 to 108 organisms per milliliter of blood). Hemorrhagic meningitis is a complication of bacteremic spread; it develops in up to one half of cases.

In anthrax, tissue damage is mediated by two toxins: edema toxin and lethal toxin. These two toxins are composed of various combinations of edema factor, lethal factor, and protective antigen. The three components of edema toxin and lethal toxin are produced by vegetative cells. Vegetative cells also produce an antiphagocytic capsule that is necessary for virulence.[60] Lethal toxin is a combination of lethal factor and protective antigen that interferes with cellular protein synthesis; it causes macrophages to release tumor necrosis factor and interleukin-1. In severe cases, it contributes to sudden death from toxemia. Edema toxin is a combination of edema factor and protective antigen that causes increased cellular levels of cyclic adenosine monophosphate (cAMP) and altered water homeostasis, resulting in massive edema. Together, edema toxin and lethal toxin cause edema, hemorrhage, necrosis, and shock. In cutaneous and gastrointestinal anthrax, toxin production results in a similar pathophysiologic process that causes edema and hemorrhagic necrosis in the skin and gastrointestinal mucosa, respectively. Pathologic studies of eight cases of inhalational anthrax related to the bioterrorism attack of 2001 demonstrated hemorrhagic mediastinitis without pneumonia; pulmonary infiltrates seen on chest radiographs corresponded to pulmonary edema and hyaline membrane formation. Large numbers of anthrax bacilli and cell wall and capsular antigens were observed in pleural tissues—findings that related to persistent pleural effusions seen clinically.[61]

INHALATIONAL ANTHRAX

Clinical Presentation and Diagnosis

Recent information on the clinical manifestations of inhalational anthrax from the 2001 anthrax outbreak both confirms many of the features reported in naturally occurring anthrax cases and reveals unanticipated differences.[52,58,62-64] The infectious dose of anthrax is not known with certainty. Animal data suggest that the median lethal dose (LD_{50}, which is the dose sufficient to kill 50% of exposed subjects) is 2,500 to 55,000 inhaled spores. Data from naturally occurring cases and from two cases in the 2001 outbreak suggest that the infectious dose may be very low in some persons, particularly those with underlying pulmonary disease.[58,63,65]

Clinical symptoms develop rapidly after germination of anthrax spores. The incubation period for inhalational disease is most commonly reported as 1 to 6 days but may be prolonged by antibiotic administration or, presumably, a low infectious dose.[66,67] In the 2001 anthrax outbreak, the median incubation period was 4 days (range, 4 to 6 days) for the six cases in which it could be calculated.

Inhalational anthrax has been described as a two-stage disease. The initial stage is a nonspecific, flulike illness lasting from several hours to a few days. In the 2001 bioterrorism-associated anthrax cases, symptoms at presentation included some combination of fever, chills, weakness, cough, dyspnea, chest discomfort, nausea or vomiting, myalgia, and headache. Profound malaise and drenching sweats were prominent symptoms, and most patients reported nausea or vomiting. Tachycardia was the most consistent clinical sign. Fever was documented in the majority of patients, although it was sometimes low grade. Sore throat, nasal symptoms, and abdominal pain were common. Classically, the initial stage is followed 1 to 3 days later, sometimes after brief improvement, by the rapidly progressive second stage, characterized by fever, dyspnea, diaphoresis,

Figure 3 **Chest x-ray of a patient with inhalational anthrax showing mediastinal widening and a small left pleural effusion.**

cyanosis, and shock. In the 2001 cases, no brief improvement between stages was observed.

Laboratory studies are nonspecific or unremarkable during the early stage of disease. The majority of patients experienced elevations in hepatic transaminase levels; neutrophilia without leukocytosis; hyponatremia; hypoalbuminemia; and hypocalcemia.[62,68] Chest x-rays were abnormal on initial presentation in all 11 recent cases, although one patient had subtle abnormalities that were initially interpreted as normal. Only seven patients had the classic finding of mediastinal widening [*see Figure 3*]. Pleural effusions were present in all cases. These effusions were often small on presentation and were progressive, requiring drainage in the majority of patients. In contrast to previous descriptions, seven patients had pulmonary infiltrates consistent with pneumonia at presentation, and one patient was thought to have heart failure with pulmonary congestion. Other abnormalities included paratracheal and hilar fullness. The CT scan was valuable in further characterizing abnormalities in the lungs and mediastinum and was more sensitive than the chest x-ray in revealing mediastinal changes. Blood cultures can be diagnostic, although appropriate antibiotic therapy rapidly reduces the likelihood of isolating the organism. In the 2001 cases, *B. anthracis* was isolated from blood cultures obtained before antibiotic therapy was given, but not from those obtained afterward.

The initial manifestations of inhalational anthrax are nonspecific and are consistent with flulike illnesses caused by a variety of respiratory viruses, as well as with community-acquired bacterial infections. Adults can average one to three episodes of flulike illness a year, and millions of cases occur throughout the United States.[69] Because of the high frequency of flulike illnesses and the low likelihood of inhalational anthrax in a given patient, a combination of epidemiologic, clinical, and (if indicated) laboratory testing should be used to evaluate potential cases of inhalational anthrax [*see Figure 4*]. According to CDC guidelines, consideration of inhalational anthrax hinges on a history of exposure or occupational/environmental risk within 2 to 5 days before illness onset.[19] Whenever possible, exposure and risk determinations should be made in consultation with public health authorities before initiating treatment or preventive therapy.

The clinical presentation of inhalational anthrax may be difficult to distinguish from that of community-acquired pneumonia.[68] According to the CDC, diagnostic testing for anthrax should be done in patients whose signs and symptoms are consistent with anthrax and when one or more of the following conditions are present: a history of a recent anthrax case or outbreak in the community; a credible threat of anthrax exposure, as determined by law enforcement and public health authorities; a cluster of anthraxlike cases characterized by rapid deterioration. Anthrax should also be considered in any patient with compatible symptoms and rapid deterioration. Alternatively, a set of five symptoms that are compatible with inhalational anthrax, in combination with fever and tachycardia, have been suggested as criteria for pursuing additional diagnostic evaluation for patients with possible inhalational anthrax who are without epidemiologic risk factors.[70] All cases of *suspected* anthrax should be reported immediately to local or state public health authorities and the hospital epidemiologist (http://www.statepublic health.org). The clinical laboratory should also be alerted when diagnostic specimens of suspected anthrax are submitted to ensure that appropriate precautions are taken to protect laboratory staff, facilitate proper evaluation of the isolate, and expedite confirmatory testing at the nearest laboratory that belongs to the public health Laboratory Response Network.[6]

There is no rapid screening test to diagnose inhalational anthrax in its early stages. In persons with a compatible clinical illness for whom there is a heightened suspicion of anthrax based on clinical and epidemiologic data, the appropriate initial diagnostic tests are a chest x-ray or chest CT scan, or both, and culture and smear of peripheral blood. On chest x-rays, the posteroanterior and lateral view may be more sensitive than the anteroposterior (portable) view in detecting pulmonary abnormalities. Mediastinal widening or hyperdense mediastinal lymphadenopathy (secondary to hemorrhagic lymph nodes) on a nonenhanced CT scan should raise the suspicion of pulmonary anthrax [*see Figure 5*]. Most persons with flulike illnesses do not have radiologic findings of pneumonia; such findings occur most often in the very young, the elderly, and persons with chronic lung disease.

Pleural fluid and cerebrospinal fluid, as well as biopsy specimens taken from the pleura and lung, are also potentially useful for culture and other testing when disease is present in these sites, whereas sputum culture and Gram stain are unlikely to be useful. In highly suspicious cases, local or state health departments can arrange for additional diagnostic testing, including immunohistochemical staining and PCR at the CDC. Serologic testing is not useful in clinical management but may be used in epidemiologic investigations. Similarly, nasal swabs are of potential value in epidemiologic investigations for determining the route and extent of spread of anthrax in a population, but they have no role in clinical management.

A rapid influenza test can be used when influenza itself is a consideration in a patient with flulike illness, but these kits have limited value because their sensitivity can be relatively low (45% to 90%). However, rapid influenza testing with viral culture can help indicate whether influenza viruses are circulating among certain populations, and this epidemiologic information can be useful in diagnosing flulike illnesses.[69]

Treatment

Early intravenous antibiotic treatment may improve survival in inhalational anthrax.[71] In contrast to the reported case-fatality

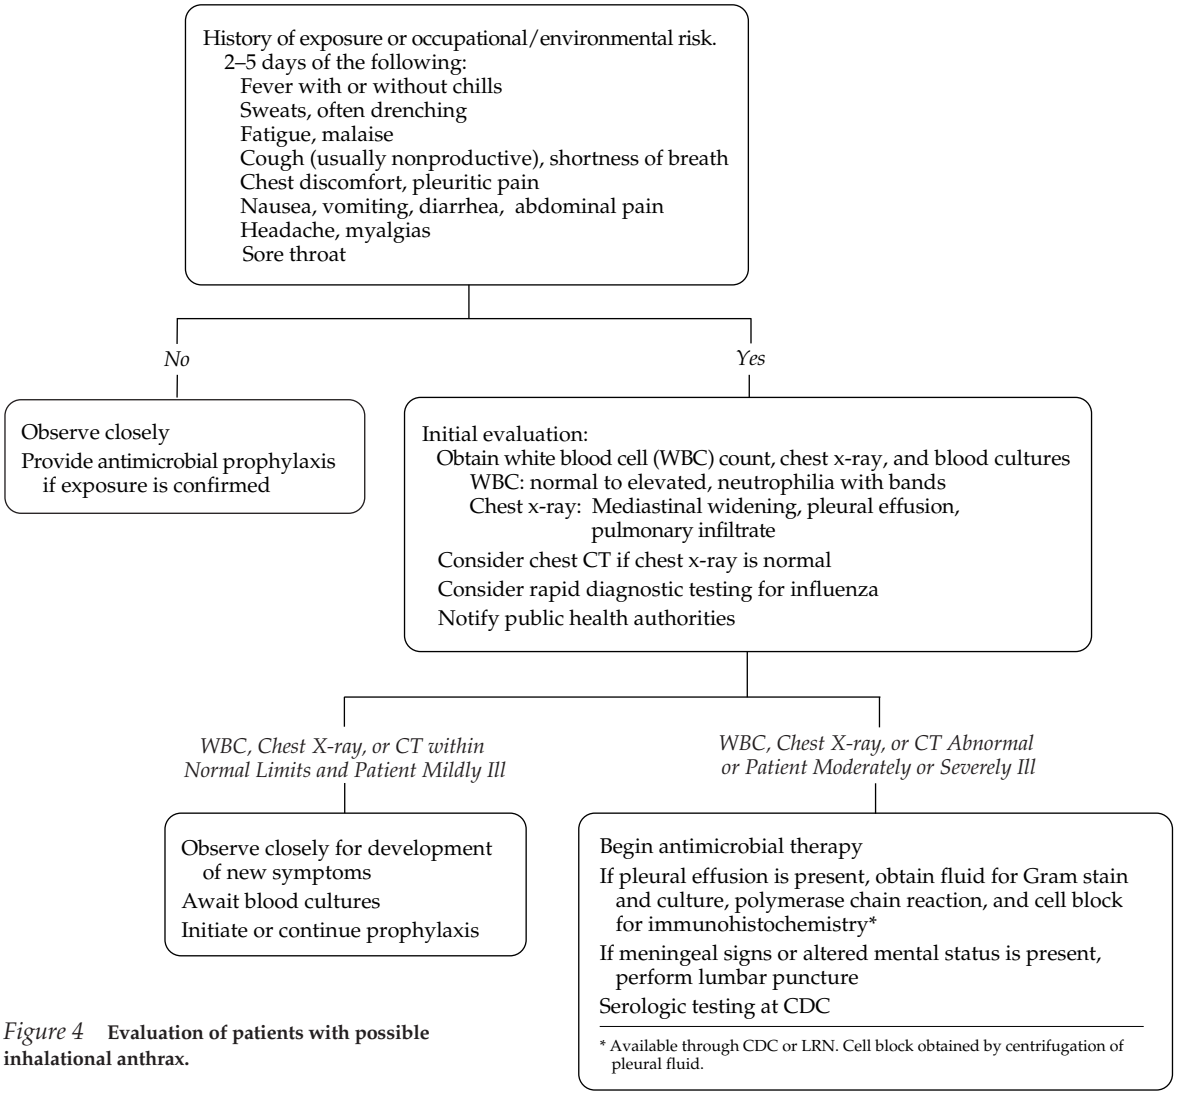

Figure 4 **Evaluation of patients with possible inhalational anthrax.**

rate of 85% for 20th-century inhalational anthrax cases, 6 of 11 patients in the 2001 outbreak survived; all the survivors presented during the initial phase of the illness and received treatment the same day with antibiotics active against *B. anthracis.* Fatal cases occurred in patients who had severe disease by the time they first received antibiotics with activity against *B. anthracis.* Aggressive supportive care—including attention to fluid, electrolyte, and acid-base disturbances and drainage of pleural effusions—also played an important role in treatment.[62]

Current CDC treatment recommendations and related guidelines and information can be obtained at http://www.bt.cdc.gov/HealthProfessionals/index.asp. Before initiating treatment, clinicians should review this site to stay informed of revisions and updates. The Working Group on Civilian Biodefense has published similar recommendations with a detailed accompanying text.[58]

At present, intravenous ciprofloxacin or doxycycline plus one or two additional antimicrobials with in vitro activity against *B. anthracis* are recommended for initial empirical treatment [*see Table 5*]. Antibiotic therapy should be modified according to the results of antimicrobial susceptibility testing to ensure that the most effective and least toxic regimen is used. The duration of antimicrobial therapy should be at least 60 days. Once clinical improvement occurs, it may be possible to complete the course of treatment with one or two agents given orally. Corticosteroid therapy has been suggested as adjunct therapy for inhalational anthrax associated with extensive edema, respiratory compromise, and meningitis.[21,56,58]

Prevention

Ciprofloxacin and doxycycline are recommended first-line agents for prophylaxis in persons exposed to inhalational anthrax. In vivo data suggest that other fluoroquinolone antibiotics would have efficacy equivalent to that of ciprofloxacin.[58] High-dose amoxicillin is an option when ciprofloxacin or doxycycline is contraindicated [*see Table 6*]. Postexposure prophylaxis should continue for at least 60 days.[72] Given the uncertainty about the length of time viable spores can persist in the lungs, patients should be instructed to seek prompt medical evaluation if symptoms compatible with anthrax develop after discontinuance of postexposure prophylaxis. Because of uncertainty about the length of time that anthrax spores can remain viable in the lungs, the United States Department of Health and Human Services made two additional options available for preventive treatment for persons exposed to inhalational anthrax in the 2001 outbreak. These options were to follow a 60-day course of antibiotic treatment with either (1) an additional 40 days of an-

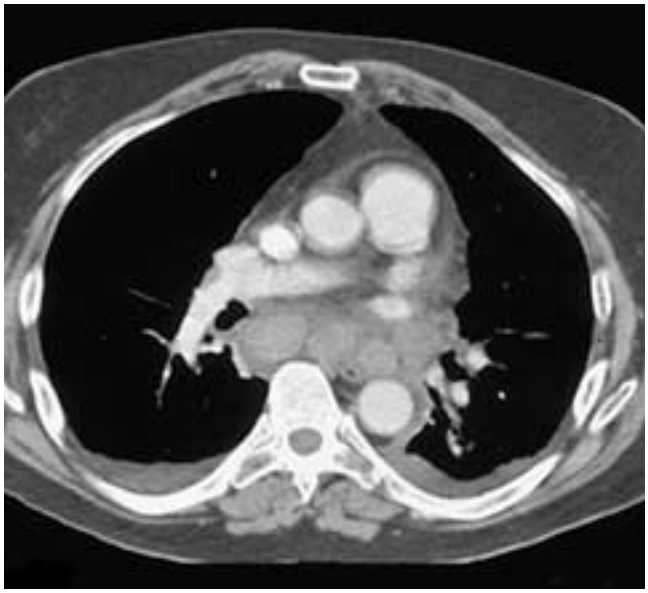

Figure 5 **CT scan of the chest of a patient with inhalational anthrax showing mediastinal lymphadenopathy and small bilateral pleural effusions.**

tibiotic treatment or (2) an additional 40 days of antibiotic treatment plus three doses of anthrax vaccine over a 4-week period.[73]

Anthrax vaccine The only licensed human anthrax vaccine available in the United States is anthrax vaccine adsorbed (AVA). This is an inactivated, cell-free filtrate of a nonencapsulated attenuated strain of *B. anthracis* (BioPort Corporation, Lansing, Michigan).[67] Primary vaccination consists of three subcutaneous injections at 0, 2, and 4 weeks and three booster vaccinations at 6, 12, and 18 months. To maintain immunity, the manufacturer recommends an annual booster injection. The basis for this recommended schedule of vaccination is not well defined.

Vaccination of adults with the licensed vaccine induced an immune response, as measured by indirect hemagglutination, in 83% of vaccinees 2 weeks after the first dose and in 91% of vaccinees who received two or more doses. Approximately 95% of vaccinees undergo seroconversion after three doses, with a fourfold rise in titers of IgG against protective antigen (the principal antigen responsible for inducing immunity). However, the precise correlation between antibody titer (or concentration) and protection against infection is not defined. The vaccine has shown efficacy in experiments involving animal models of inhalational anthrax in preexposure settings and, in combination with antibiotics, in postexposure settings.[58,69]

Anthrax vaccine is considered acceptably safe by the Advisory Committee on Immunization Practices and the Institute of Medicine.[67,74] Supplies of anthrax vaccine are limited and are held by the United States Department of Defense. A combination of antibiotics and anthrax vaccine, if available, is recommended for exposed persons after a biologic attack.[58,75,76] At this time, preexposure use of anthrax vaccine is recommended only for certain laboratory workers and others at occupational risk for repeated exposures to *B. anthracis* spores; it is not recommended for the general public.

CUTANEOUS ANTHRAX

After an incubation period of approximately 7 days (range, 1 to 12 days), the primary lesion of cutaneous anthrax appears as a nondescript, painless, pruritic papule, usually on an exposed area such as the face, head, neck, or upper extremity. The papule enlarges and develops a central vesicle or bullae with surrounding brawny, nonpitting edema. The central vesicle enlarges and ulcerates over 1 to 2 days, becoming hemorrhagic, depressed, and necrotic and leading to a central black eschar [*see Figure 6*]. Satellite vesicles may be present. The eschar dries and falls off over the next 1 to 2 weeks. The findings of a painless lesion and edema out of proportion to the size of the lesion and the fact that pustules are rarely present in cutaneous anthrax are clinically useful. Tender regional lymphadenopathy, fever, chills, and fatigue may occur. Systemic disease has been

Table 5 Treatment of Inhalational Anthrax

Patients	*Medication and Dosage*	*Comments*
Adults, including pregnant women and immunocompromised persons	Ciprofloxacin, 400 mg I.V., q. 12 hr *or* Doxycycline, 100 mg I.V., q. 12 hr *and* One or two additional antimicrobials*	If meningitis is suspected, doxycycline may be less optimal because of poor central nervous system penetration Modify regimen on the basis of susceptibility testing of isolate; can switch to p.o. after patient is clinically stable; continue treatment for at least 60 days Consider corticosteroids for meningitis, severe edema, or respiratory compromise
Children, including those who are immunocompromised	Ciprofloxacin, 10–15 mg/kg I.V., q. 12 hr, not to exceed 1 g/day *or* Doxycycline If > 8 yr and > 45 kg, give adult dosage If ≤ 8 yr or if > 8 yr but ≤ 45 kg, give 2.2 mg/kg q. 12 hr (maximum, 200 mg/day) *and* One or two additional antimicrobials*	If meningitis is suspected, doxycycline may be less optimal because of poor central nervous system penetration Modify regimen on the basis of susceptibility testing of isolate; can switch to p.o. after patient is clinically stable; continue treatment for at least 60 days Consider corticosteroids for meningitis, severe edema, or respiratory compromise

Note: Treatment recommendations may change over time and according to antimicrobial susceptibility test results during a biologic attack and to availability of selected antimicrobial agents. Before initiating treatment, clinicians should consult with an infectious disease specialist and public health authorities and should check for revisions and updates at http://www.bt.cdc.gov/index.asp. This information is adapted from CDC and Working Group on Civilian Biodefense recommendations and may not represent FDA-approved uses.
*Other agents with in vitro activity against anthrax include rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin.

Table 6 Postexposure Prophylaxis for Anthrax in the Setting of a Bioterrorist Attack

Patients	*Medication*	*Comments*
Adults, including immunocompromised persons	Ciprofloxacin, 500 mg p.o., q. 12 hr *or* Doxycycline, 100 mg p.o., q. 12 hr *or, if strain proved susceptible,* Amoxicillin, 500 mg p.o., q. 8 hr	Give prophylaxis for at least 60 days
Pregnant women	Ciprofloxacin, 500 mg p.o., q. 12 hr *or, if strain proved susceptible,* Amoxicillin, 500 mg p.o., q. 8 hr	Give prophylaxis for at least 60 days
Children, including those who are immunocompromised	Ciprofloxacin, 10–15 mg/kg p.o., b.i.d., not to exceed 1g/day *or, if strain proved susceptible,* Amoxicillin If ≥ 20 kg: 500 mg p.o., q. 8 hr If < 20 kg: 80 mg/kg/day p.o., in divided doses q. 8 hr (maximum, 500 mg/dose)	Give prophylaxis for at least 60 days

Note: Prophylaxis recommendations may change over time and according to antimicrobial susceptibility test results during a biologic attack and to availability of selected antimicrobial agents. Before initiating prophylaxis, clinicians should consult with an infectious disease specialist and public health authorities and should check for revisions and updates at http://www.bt.cdc.gov/index.asp. This information is adapted from CDC and Working Group on Civilian Biodefense recommendations and may not represent FDA-approved uses.

reported to have a mortality of 20% if untreated. Cutaneous anthrax of the face or neck may lead to respiratory compromise from massive edema.[56,58,60,77]

The differential diagnosis of cutaneous anthrax includes other causes of eschar and ulceration and the ulceroglandular syndrome.[75] Guidelines for the diagnosis of cutaneous anthrax have been published by the American Academy of Dermatology (http://www.aad.org/BioInfo/anthrax.html).

For patients with the typical appearance and progression of cutaneous anthrax, a Gram stain and culture of the skin lesion should be obtained using a dry swab for unroofed vesicle fluid and a moist swab for the base of the ulcer and edges underneath the eschar. Blood cultures are also recommended. If the patient is taking antimicrobial drugs or if the Gram stain and culture are negative for *B. anthracis* or clinical suspicion remains high, two punch biopsies for culture (with the specimen placed in saline) and immunohistochemical staining should be performed; PCR (with the specimen placed in formalin) should be performed, or both should be considered [*see Figure 7*]. Immunohistochemical staining and PCR testing at the CDC should be arranged through local public health authorities.[21,58]

Management

Antibiotic treatment is curative in cutaneous anthrax and can be initiated pending confirmation of anthrax infection. Ciprofloxacin and doxycycline are first-line agents for the empirical treatment of cutaneous anthrax and may be administered orally. Intravenous therapy with multiple drugs, as for inhalational anthrax (see above), is recommended for patients with signs of systemic involvement, extensive edema, or lesions of the face and neck.[71]

GASTROINTESTINAL AND OROPHARYNGEAL ANTHRAX

Symptoms appear 2 to 5 days after ingestion of contaminated food and include nausea, vomiting, fever, malaise, and abdominal pain. Severe bloody diarrhea with rebound abdominal tenderness develops. Ulcerative lesions occur primarily in the terminal ileum and cecum. Gastric ulcers with hematemesis, hemorrhagic mesenteric lymphadenitis, and marked ascites may occur. Mediastinal widening has also been reported with gastrointestinal anthrax. Morbidity results from blood loss, fluid and electrolyte imbalances, and shock. The case-fatality rate is reportedly greater than 50%; death results from toxemia or intestinal perforation.[33,57,58]

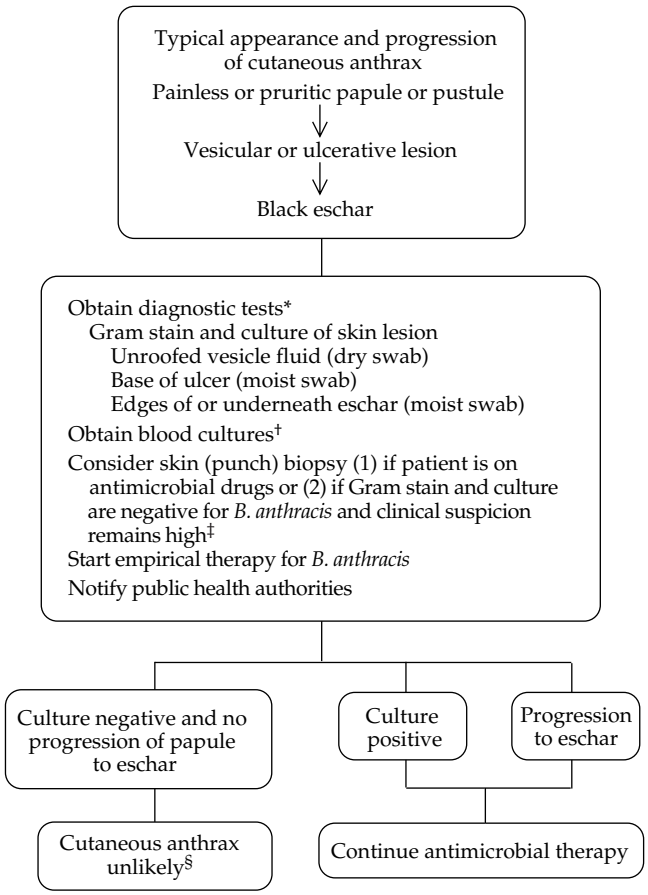
Oropharyngeal anthrax is characterized by sore throat, fever, dysphagia, and marked edema and lymphadenitis. Ulcerative lesions may have an associated pseudomembrane. Specimens for diagnosis of gastrointestinal anthrax may include ascitic fluid for Gram stain and culture, blood cultures, and tissue samples from affected mucosal sites.

Treatment for gastrointestinal anthrax and oropharyngeal anthrax is the same as that for inhalational anthrax (see above).

INFECTION CONTROL

Person-to-person transmission of anthrax is not known to occur. Patients may be hospitalized in a standard hospital room

Figure 6 **Cutaneous anthrax lesion, 11 days old.**



* Serologic testing available at CDC may be an additional diagnostic technique for confirmation of cases of cutaneous anthrax.

† If blood cultures are positive for *B. anthracis*, treat with antimicrobials as for inhalational anthrax.

‡ Punch biopsy should be submitted in formalin to CDC. Polymerase chain reaction can also be done on formalin-fixed specimen. Gram stain and culture are frequently negative for *B. anthracis* after initiation of antimicrobials.

§ Continue antimicrobial prophylaxis for inhalational anthrax for 60 days if aerosol exposure to *B. anthracis* is known or suspected.

Figure 7 **Evaluation of patients with possible cutaneous anthrax.**

with standard barrier isolation precautions. No treatment is necessary for contacts of cases.

The microbiology laboratory should be notified upon suspicion of anthrax to ensure that appropriate precautions are taken under BSL-2 conditions when specimens are processed for culture.[78] Sporicidal solutions approved for use in hospitals and commercially available bleach or a 0.5% hypochlorite solution (1:10 dilution of household bleach) are effective for decontamination of contaminated areas. Precautions should be taken during autopsies, and cremation of human remains should be considered to prevent further transmission of disease.[24]

Plague

Plague is caused by the gram-negative coccobacillus *Yersinia pestis,* of the family Enterobacteriaceae. Wild rodents are the animal reservoir for the disease. Under natural conditions, plague is transmitted to humans by the bite of an infectious flea and, less frequently, by direct contact with infectious body fluids or tissues of an infected animal or by inhaling infectious droplets.[79] Plague has a long history of use and development as a biologic weapon, including the catapulting of plague victims' corpses over the walls of a besieged city in the 14th century. The most likely presentation after a biologic attack is primary pneumonic plague.[33] Additional information on plague, including the nonpneumonic forms (bubonic and septicemic plague), microbiology, and pathogenesis, is available elsewhere [*see 7:XI Infections Due to Brucella, Francisella, Yersina Pestis, and Bartonella*].

CLINICAL PRESENTATION

Plague is a severe febrile illness. Pneumonic plague, the most fatal form of the infection, can develop from inhalation of plague bacilli (primary pneumonic plague) or from hematogenous spread secondary to septicemic plague. Approximately 12% of cases of bubonic and primary septicemic plague develop into secondary pneumonic plague. Conversely, septicemic plague can be secondary to primary pneumonic plague.

The incubation period for pneumonic plague is typically 2 to 4 days (range, 1 to 6 days). Presenting symptoms typically include the acute onset of malaise, high fever, chills, headache, chest discomfort, dyspnea, and cough concomitant with or followed rapidly by clinical sepsis. Hemoptysis is a classic sign that should suggest plague in the appropriate clinical context, but sputum may be watery or purulent. Gastrointestinal symptoms may be prominent with pneumonic plague; these include nausea, vomiting, diarrhea, and abdominal pain. A cervical bubo is infrequently present.

The disease is rapidly progressive, with increasing dyspnea, stridor, and cyanosis. Rapidly progressive respiratory failure and sepsis within 2 to 4 days of onset of illness is typical of pneumonic plague. Abnormalities on chest x-ray are variable but frequently show bilateral patchy infiltrates or consolidation. The mortality for pneumonic plague is reported to be 57% and is extremely high when initiation of treatment is delayed beyond 24 hours after symptom onset.[80] Complications of septicemic plague include disseminated intravascular coagulation (DIC), purpuric skin lesions and gangrene of extremities (so-called black death), acute respiratory distress syndrome (ARDS), meningitis, and multiorgan failure with shock.[33,81-83]

DIAGNOSIS

During a confirmed outbreak of pneumonic plague after a biologic attack, a presumptive diagnosis can be made on the basis of symptoms, especially if there is a high index of suspicion. However, other causes of severe pneumonia or rapidly progressive respiratory infection with or without sepsis should be considered. Suspected cases of plague should be immediately reported to the local public health department and the hospital epidemiologist.

There are no widely available, rapid confirmatory tests for *Y. pestis.* Specimens for bacteriologic and serologic testing should be collected before initiating therapy. Sputum, blood, and lymph node aspirate should be submitted for Gram stain and culture. Microscopic examination of clinical specimens or buffy coat may show a gram-negative coccobacillus; Wright, Giemsa, or Wayson stains may show bipolar (safety pin) staining. Sera for acute and convalescent antibody detection should be obtained, but findings are primarily of epidemiologic value. Additional diagnostic testing, including antigen detection, IgM immunoassay, immunostaining, PCR testing, and antimicrobial susceptibility testing, is available through the CDC and through designated public health laboratories (http://www.

Table 7 Antimicrobial Treatment of Pneumonic Plague

Patients	*Drug*	*Comments*
Adults	Streptomycin, 1 g I.M., b.i.d. *or* Gentamicin, 5 mg/kg I.M. or I.V., q.d., or 2 mg/kg loading dose followed by 1.7 mg/kg I.M. or I.V., t.i.d. *Alternative choices:* Doxycycline, 100 mg I.V., b.i.d., or 200 mg I.V., q.d. Ciprofloxacin, 400 mg I.V., b.i.d. Chloramphenicol, 25 mg/kg I.V., q.i.d.	Treat for 10 days; during a community outbreak of pneumonic plague, all persons developing a temperature ≥ 101.3° F (38.5° C) or a new cough should begin parenteral antibiotic treatment; oral treatment may be given when resources for parenteral treatment are limited; pregnant women should not receive streptomycin or chloramphenicol; tetracycline may be substituted for doxycycline
Children	Streptomycin, 15 mg/kg I.M., b.i.d. (maximum, 2 g/day) *or* Gentamicin, 2.5 mg/kg I.M. or I.V., t.i.d. *Alternative choices:* Doxycycline: if ≥ 45 kg, adult dosage; if < 45 kg, 2.2 mg/kg b.i.d. (maximum, 200 mg/day) Ciprofloxacin, 15 mg/kg I.V., b.i.d. Chloramphenicol, 25 mg/kg I.V., q.i.d.; maintain serum concentration between 5 and 20 μg/ml	Use chloramphenicol in plague meningitis

Note: Treatment recommendations may change over time and according to antimicrobial susceptibility test results during a biologic attack and to availability of selected antimicrobial agents. Before initiating treatment, clinicians should consult with an infectious disease specialist and public health authorities and should check for revisions and updates at http://www.bt.cdc.gov/index.asp. This information is adapted from CDC and Working Group on Civilian Biodefense recommendations and may not represent FDA-approved uses.

statepublichealth.org). Specimen submission should be arranged through local public health authorities. The laboratory should be notified whenever plague is suspected, to help prevent exposures to staff and to facilitate appropriate testing.[33,80,83]

Laboratory findings are consistent with the systemic inflammatory response syndrome. The leukocyte count is elevated and the differential shows a neutrophil predominance, including immature forms. Platelets may be normal or low. Coagulation abnormalities include increased fibrin degradation products, hypofibrinogenemia, and prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT). Elevated liver function tests and abnormal renal function tests are seen with systemic disease.

TREATMENT

When plague is suspected, antibiotic treatment should begin before laboratory confirmation of the diagnosis [*see Table 7*]. Whenever possible, specimens should be collected for bacteriologic and serologic testing before the start of therapy. Antibiotic resistance is rare with naturally occurring *Y. pestis* but may be present in strains used as biologic weapons. Treatment should be continued for 10 days or for 3 days after defervescence and improvement in symptoms. The route of administration can be changed from intravenous to oral after the patient is clinically stable. The choice of antibiotic may be modified after microbial sensitivity testing is completed. The CDC bioterrorism Web site or local public health authorities should be consulted for updated treatment recommendations.[33,80,83]

Postexposure Prophylaxis for Pneumonic Plague

All persons potentially exposed to aerosolized *Y. pestis* and all persons in close contact with pneumonic plague patients (close contact is defined as exposure within 2 m [6.5 ft]) should be treated for 7 days after the last exposure [*see Table 8*]. Persons receiving prophylactic antibiotic treatment should seek medical evaluation immediately if fever or illness with cough develops.

There is no currently available vaccine for pneumonic plague. The previously available licensed plague vaccine in the United States was discontinued in 1999. That vaccine was demonstrated to reduce the severity of illness with bubonic plague but not pneumonic plague.[81]

Communicability and Infection Control Considerations

Pneumonic plague is transmitted person to person through respiratory droplets. Aerosol transmission has not been demonstrated. For patients with pneumonic plague, respiratory droplet precautions as well as standard precautions are recommended, including the use of gowns, gloves, eye protection, and surgical masks for the first 48 hours of antimicrobial therapy and until clinical improvement occurs. Hospitalized patients should remain in isolation for the first 48 hours of antimicrobial therapy and until clinical improvement occurs. Hospitalized patients should wear a mask during transport.

Y. pestis is rapidly destroyed by sunlight and drying. Environmental surfaces can be decontaminated with a standard disinfectant. Persons exposed to aerosolized plague bacilli during a biologic attack should shower with warm water and soap. Clothing of persons exposed to an aerosol of *Y. pestis* and linens of plague patients should be washed in hot water.[24,81,82]

Botulism

Botulism is a paralytic illness caused by a potent neurotoxin produced by *Clostridium botulinum,* an anaerobic, spore-forming bacterium. Natural forms of the disease are foodborne botulism, wound botulism, and infant botulism. Foodborne botulism results from ingestion of improperly processed foodstuffs containing preformed toxin produced by *C. botulinum.* Wound botulism results from production of botulinum toxin by *C. botulinum* organisms that contaminate wounds. Infant botulism results from the colonization of the intestinal tract of infants after ingestion of spores. Botulinum toxin has been developed as

a biologic weapon. An aerosol attack is considered the most likely use of botulinum toxin for bioterrorism, although intentional contamination of food supplies is possible.[33,84] Additional information about the pathogenesis and epidemiology of noninhalational forms of botulism is available elsewhere [*see 7:V Anaerobic Infections*].

Botulinum toxin is the most potent lethal toxin known. The estimated toxic dose of type A botulinum toxin is 0.001 μg/kg of body weight. There are seven distinct antigenic types of botulinum neurotoxins—types A through G—produced by different strains of *C. botulinum.* Human botulism is caused primarily by toxin types A, B, and E. Botulinum toxin acts to block neurotransmission by binding irreversibly to the presynaptic nerve terminal at the neuromuscular junction and preventing the release of acetylcholine, resulting in bulbar palsies and skeletal muscle weakness. The toxin is colorless, odorless, and presumably tasteless.[33,85,86]

CLINICAL PRESENTATION

The incubation period for foodborne botulism is 2 hours to 8 days; the typical incubation period is 12 to 72 hours. The incubation period for inhalational botulism is not established. Aerosol exposures of monkeys and accidental aerosol exposure of humans have resulted in clinical illness developing 12 to 80 hours after exposure. Type A toxin is associated with more severe disease and a higher fatality rate than type B or E. The neurologic features of all forms of botulism are similar.[33,85,86] Although initial symptoms in foodborne botulism may include nausea, vomiting, abdominal cramps, and diarrhea, these symptoms are thought to result from other bacterial metabolites in contaminated food and may not occur in inhalational botulism.

The so-called classic triad of botulism summarizes the clinical presentation: an afebrile patient, symmetrical descending flaccid paralysis with prominent bulbar palsies, and a clear sensorium.[85-87] Symptoms of cranial nerve abnormalities nearly always begin in the bulbar musculature; patients typically present with difficulty seeing, speaking, or swallowing. Clinical hallmarks include ptosis, blurred vision, and the so-called four Ds: diplopia, dysarthria, dysphonia, and dysphagia. Cranial nerve abnormalities and bulbar weakness are followed by symmetrical descending weakness and paralysis with progression from the head to the arms, thorax, and legs. The extent of paralysis and rapidity of onset of symptoms are proportional to the dose of toxin absorbed into the circulation. Recovery depends on the regeneration of new motor axon twigs to reinnervate paralyzed muscle fibers; recovery may take weeks to months.

Anticholinergic symptoms are common, including dry mouth, ileus, constipation, nausea and vomiting, urinary retention, and mydriasis. Other symptoms include dizziness and sore throat. Sensory findings are not present, with the exception of circumoral and peripheral paresthesias secondary to hyperventilation resulting from anxiety. Botulinum toxin does not cross the blood-brain barrier. Cranial nerve dysfunction and facial nerve weakness may make communication difficult; these symptoms may be mistaken for lethargy and signs of central nervous system involvement.

DIAGNOSIS

Initiation of treatment with botulinum antitoxin should be based on the clinical diagnosis and should not await laboratory confirmation. A clinician who suspects botulism should immediately contact the local or state health department to facilitate procurement of antitoxin for treatment; arrangements should be made for confirmatory diagnostic testing and initiation of an epidemiologic investigation to identify the source of infection. In cases of potential foodborne botulism, any leftover foodstuffs or containers should be held for testing by the public health laboratory.

Demonstration of botulinum toxin in serum samples by mouse bioassay is diagnostic. Samples of serum (in adults, > 30 ml blood in a tiger-top or red-top tube) obtained before administration of botulinum antitoxin should be submitted for testing. For potential foodborne botulism, samples of stool, gastric aspirate, emesis, and suspect foods should also be submitted.[86] The likelihood of finding toxin in the sera of affected patients decreases with time; it is detectable in only 13% to 28% of patients more than 2 days after ingestion.[88]

The possibility of a bioterrorist attack should be considered in any outbreak of botulism. A bioterrorist attack should especially be considered when a cluster of cases occurs; when an outbreak has a common geographic location but there is no common dietary exposure (suggestive of possible aerosol exposure); when there is an outbreak of an unusual botulinum toxin type; or when multiple simultaneous outbreaks occur. A careful dietary and travel history must be taken to help identify the

Table 8 Postexposure Prophylaxis of Pneumonic Plague

Patients	*Drug*	*Comments*
Adults, including pregnant women	Doxycycline, 100 mg p.o., b.i.d. Ciprofloxacin, 500 mg p.o., b.i.d. *Alternative:* Chloramphenicol, 25 mg/kg p.o., q.i.d.	Asymptomatic household contacts, hospital contacts, or other close contacts should receive postexposure prophylaxis for 7 days; contacts who develop fever or cough while receiving prophylaxis should begin antibiotic treatment for plague.
Children	Doxycycline: if ≥ 45 kg, adult dosage; if < 45 kg, 2.2 mg/kg p.o., b.i.d. (maximum, 200 mg/day) Ciprofloxacin, 20 mg/kg p.o., b.i.d. *Alternative:* Chloramphenicol, 25 mg/kg p.o., q.i.d.	Asymptomatic household contacts, hospital contacts, or other close contacts should receive postexposure prophylaxis for 7 days; contacts who develop fever or cough while receiving prophylaxis should begin antibiotic treatment for plague.

Note: Prophylaxis recommendations may change over time and according to antimicrobial susceptibility test results during a biologic attack and to availability of selected antimicrobial agents. Before initiating prophylaxis, clinicians should consult with an infectious disease specialist and public health authorities and should check for revisions and updates at http://www.bt.cdc.gov/index.asp. This information is adapted from CDC and Working Group on Civilian Biodefense recommendations and may not represent FDA-approved uses.

source. Patients should be asked if they know of others with similar symptoms.

The differential diagnosis of botulism includes stroke and other neuromuscular disorders.[85,86] A CT scan of the head may be used to exclude cerebrovascular accident, although it is relatively insensitive in early ischemic stroke [*see 11:IV Cerebrovascular Disorders*]. Patients with myasthenia gravis will often have characteristic electromyographic findings and serum antibody tests. A test dose of edrophonium (Tensilon) may briefly reverse paralysis in patients with myasthenia gravis but also, reportedly, in some cases of botulism. Guillain-Barré syndrome typically results in ascending paralysis and sensory abnormalities. Cerebrospinal fluid protein is normal in patients with botulism and is normal or elevated in patients with Guillain-Barré syndrome. The rare Miller-Fisher variant of Guillain-Barré syndrome is characterized by descending paralysis and may be confused with botulism. Other conditions that mimic botulism include tick paralysis; poliomyelitis; Eaton-Lambert syndrome; paralytic shellfish poisoning; pufferfish ingestion; and anticholinesterase intoxication with organophosphates, atropine, carbon monoxide, or aminoglycosides.

The electromyogram (EMG) can help distinguish different causes of paralysis. The EMG in botulism demonstrates normal nerve conduction velocity, normal sensory nerve function, and small amplitude motor potentials with facilitation to repetitive stimulation at 50 Hz.[89]

TREATMENT

The mainstay of treatment for botulism is supportive care, including intensive care, mechanical ventilation, and parenteral nutrition. Morbidity and mortality are usually from pulmonary aspiration secondary to loss of the gag reflex and dysphagia leading to inability to control secretions, respiratory failure secondary to inadequate tidal volume from diaphragmatic and accessory respiratory muscle paralysis, and airway obstruction from pharyngeal and upper airway muscle paralysis. Careful and frequent monitoring of the gag and cough reflexes, swallowing, oxygen saturation, vital capacity, and inspiratory force are critical. Airway intubation is indicated for inability to control secretions and impending respiratory failure. Secondary infections are common and should be sought in patients who develop fever.

Trivalent (ABE) equine antitoxin is available from the CDC through state and local health departments and should be administered as soon as possible after clinical diagnosis. Antitoxin can prevent progression of disease caused by subsequent binding of toxin but does not reverse the effects of already bound toxin. For this reason, antitoxin is not useful if the patient is no longer showing progression of disease or is improving from maximum paralysis. The amount of neutralizing antibody present in the standard treatment dose of antitoxin far exceeds maximum serum toxin concentrations in foodborne botulism patients, and repeat doses are usually not required. In a biologic attack, however, patients may be exposed to unusually high concentrations of toxin, so serum toxin levels should be assessed after initiation of treatment in such cases to determine the need for repeat doses. Botulism caused by toxin types other than A, B, or E would not respond to the trivalent antitoxin. Limited quantities of an investigational heptavalent (A-G) antitoxin are held by the United States Army. However, because of the time delay involved in typing the toxin, the utility of this product in a biologic attack is probably minimal.[85,87]

Hypersensitivity reactions, including anaphylaxis, have occurred after administration of botulism antitoxin. For that reason, all patients should undergo a skin test before receiving the antitoxin, and resuscitation equipment should be immediately available. Patients showing a positive hypersensitivity reaction on the skin test can be desensitized over several hours.[90,91]

Before administering antitoxin, physicians should carefully review the package insert for dosage and adverse effects. Standard regimens can be used in children, pregnant women, and immunocompromised persons with botulism. Botulism immune globulin intravenous is an investigational human-derived neutralizing antibody that is available only for treatment of infant botulism from the California Department of Health Services, Berkeley. The CDC bioterrorism Web site or local public health authorities should be consulted for updated treatment recommendations.[33,85,86]

Transmissibility and Infection Control

Botulism is an intoxication, not an infection, and thus is not transmitted from person to person. Botulinum toxin does not penetrate intact skin. Standard infection-control precautions are adequate unless meningitis is suspected, in which case droplet precautions are indicated. Clothes of persons exposed to an aerosol release of botulinum toxin should be removed and washed. Exposed persons should shower with soap and hot water. Exposed environmental surfaces can be decontaminated with 0.1% hypochlorite bleach solution.[86]

Tularemia

Tularemia is a zoonotic infection caused by *Francisella tularensis,* a small, nonmotile, gram-negative, pleomorphic coccobacillus. The disease is typically acquired through contact with blood or tissue fluids of infected animals or through the bite of an infected deerfly, tick, or mosquito.[92] Inhalation of organisms aerosolized from the environment and the drinking of contaminated water can also result in human infection.[93] *F. tularensis* was developed for use as a biologic weapon by the United States (before its offensive biologic weapons program was terminated) and other countries.[33] The epidemiology, pathogenesis, and clinical manifestations of the naturally occurring forms of tularemia are discussed in more detail elsewhere [*see 7:XI Infections Due to Brucella, Francisella, Yersina Pestis, and Bartonella*].

CLINICAL PRESENTATION

Tularemia can take several forms in humans, depending on the route of infection. Ulceroglandular, oculoglandular, glandular, typhoidal, and pharyngeal tularemia are discussed elsewhere [*see 7:XI Infections Due to Brucella, Francisella, Yersina Pestis, and Bartonella*]. Inhalational tularemia is a term used to describe infection resulting from an aerosol release of *F. tularensis*.[94] Most patients with inhalational tularemia develop pleuropulmonary tularemia (tularemia pneumonia), but many patients may present with an undifferentiated febrile illness. The infectious dose is as low as one to 50 organisms, and the incubation period is typically 3 to 5 days (range, 1 to 14 days).[33]

The clinical course of inhalational tularemia is less rapidly progressive than that of pulmonary anthrax or plague. Illness onset is acute, with some combination of fever, chills, sweats, myalgias, headache, coryza, and sore throat. Nausea, vomiting, diarrhea, and abdominal pain are common. Anorexia and weight loss may occur as the illness continues. Cough may be

dry or mildly productive. Hemoptysis is uncommon. Pleuritic chest pain, substernal chest discomfort, and dyspnea may be present. Chest x-rays may be normal or minimally abnormal or show a variety of abnormalities, including peribronchial patchy infiltrates, effusions, and hilar adenopathy.[95]

F. tularensis infection may be mild and nonspecific or rapidly progressive. Any form of tularemia may result in hematogenous spread with secondary pleuropneumonia, sepsis, and, rarely, meningitis. If left untreated, tularemia can progress to respiratory failure; liver, kidney, and splenic involvement; meningitis; sepsis; shock; and death. There is usually complete recovery with early diagnosis and treatment. Mortality is less than 2% if the patient is treated; it can be as high as 60% for untreated severe disease and pneumonia.[94,96,97]

DIAGNOSIS

A clustering of sudden, severe pneumonias in previously healthy patients should raise the possibility of an intentional aerosolized release of tularemia. Clusters of patients with tularemia and cases in which there is no natural explanation for the disease should be reported immediately to the local or state health department (http://www.statepublichealth.org). There are no rapid confirmatory tests for *F. tularensis*. Gram stain of sputum is not diagnostic but may identify other potential etiologies.[97,98] In the context of a known or suspected outbreak, a presumptive diagnosis can be made on the basis of symptoms. A chest x-ray should be obtained for patients with suspected pleuropulmonary tularemia. The x-ray may show infiltrates, effusion, hilar adenopathy, or subtle abnormalities, or it may be normal. Recent experience with inhalational anthrax suggests that chest CT scans of patients with tularemia may show pulmonary abnormalities, including infiltrates, effusions, and adenopathy, before they are evident on x-ray.[62]

Specimens of respiratory secretions and blood for bacteriologic and serologic testing should be collected before initiating therapy. Pharyngeal washings, sputum specimens, fasting gastric aspirates, and blood can be cultured for *F. tularensis*. Growth may be slow, so cultures should be held for 10 days. Cysteine-enriched culture media should be used to improve yield. Direct examination (by direct fluorescent antibody staining or immunohistochemical testing, antigen detection, microagglutination antibody testing, PCR, and other research tests) is available through designated public health laboratories. Acute and convalescent serologies are valuable for epidemiologic purposes.[94,98]

TREATMENT AND POSTEXPOSURE PROPHYLAXIS

When the index of suspicion is high, antibiotic treatment should be started before diagnosis is confirmed. Streptomycin or gentamicin is the preferred agent. All persons potentially exposed to aerosolized *F. tularensis* should be treated with doxycycline or ciprofloxacin. Close contacts of patients with tularemia pneumonia do not need prophylactic antibiotics. No vaccine for tularemia is currently available. The CDC bioterrorism Web site, local public health authorities, or both should be consulted for updated treatment recommendations.[33,94,99]

Transmissibility and Infection Control

Tularemia is not transmitted from person to person, and isolation of patients with tularemia is not necessary. Standard precautions are recommended for all patients with tularemia. Microbiology staff must be alerted when tularemia is suspected, so they can take precautions to prevent laboratory-acquired infection from culture plates and other infectious materials. Contaminated environmental surfaces can be disinfected with a 10% bleach solution followed by cleansing with 70% alcohol.[94]

Hemorrhagic Fever Viruses

Hemorrhagic fever viruses (HFVs) are RNA viruses classified in several taxonomic families. HFVs cause a variety of disease syndromes with similar clinical characteristics, referred to as acute hemorrhagic fever syndromes [*see 7:XXXI Viral Zoonoses*]. The pathophysiologic hallmarks of HFV infection are microvascular damage and increased vascular permeability. HFVs that are of concern as potential biologic weapons include Arenaviridae (Lassa, Junin, Machupo, Guanarito, and Sabia viruses, which are the causative agents of Lassa fever and Argentine, Bolivian, Venezuelan, and Brazilian hemorrhagic fevers, respectively); Filoviridae (Ebola and Marburg viruses); Flaviviridae (yellow fever, Omsk hemorrhagic fever, and Kyasanur Forest disease viruses); and Bunyaviridae (Rift Valley fever [RVF]). Under natural conditions, humans are infected through the bite of an infected arthropod or through contact with infected animal reservoirs. Hemorrhagic fever viruses are highly infectious by aerosol; are associated with high morbidity and, in some cases, high mortality; and are thought to pose a serious risk as biologic weapons.[33] All suspected cases of HFV infection should be reported immediately to the local or state health department and the hospital epidemiologist.

PATHOPHYSIOLOGY

The exact pathogenesis for HFVs varies according to the etiologic agent. The major target organ is the vascular endothelium. Immunologic and inflammatory mediators are thought to play an important role in the pathogenesis of HFVs. All HFVs can produce thrombocytopenia, and some also cause platelet dysfunction. Infection with Ebola and Marburg viruses, Rift Valley fever virus, and yellow fever virus causes destruction of infected cells. DIC is characteristic of infection with Filoviridae. Ebola and Marburg viruses may cause a hemorrhagic diathesis and tissue necrosis through direct damage to vascular endothelial cells and platelets with impairment of the microcirculation, as well as cytopathic effects on parenchymal cells, with release of immunologic and inflammatory mediators. Arenaviridae, on the other hand, appear to mediate hemorrhage via the stimulation of inflammatory mediators by macrophages, thrombocytopenia, and the inhibition of platelet aggregation. DIC is not a major pathophysiologic mechanism in arenavirus infections.[100,101]

CLINICAL PRESENTATION

The incubation period of HFVs ranges from 2 to 21 days. The clinical presentations of these diseases are nonspecific and variable, making diagnosis difficult. It is noteworthy that not all patients will develop hemorrhagic manifestations. Even a significant proportion of patients with Ebola virus infections may not demonstrate clinical signs of hemorrhage.[102]

Initial symptoms of the acute HFV syndrome may include fever, headache, myalgia, rash, nausea, vomiting, diarrhea, abdominal pain, arthralgias, myalgias, and malaise. Illness caused by Ebola, Marburg, Rift Valley fever virus, yellow fever virus, Omsk hemorrhagic fever virus, and Kyasanur Forest disease virus are characterized by an abrupt onset, whereas Lassa fever and the diseases caused by the Machupo, Junin, Guarinito, and Sabia viruses have a more insidious onset. Initial signs may include fever, tachypnea, relative bradycardia, hypotension

(which may progress to circulatory shock), conjunctival injection, pharyngitis, and lymphadenopathy. Encephalitis may occur, with delirium, seizures, cerebellar signs, and coma. Most HFVs cause cutaneous flushing or a macular skin rash, although the rash may be difficult to appreciate in dark-skinned persons and varies according to the causative virus. Hemorrhagic symptoms, when they occur, develop later in the course of illness and include petechiae, purpura, bleeding into mucous membranes and conjunctiva, hematuria, hematemesis, and melena. Hepatic involvement is common, and renal involvement is proportional to cardiovascular compromise.[33,100,102,103]

Laboratory abnormalities include leukopenia (except in some cases of Lassa fever), anemia or hemoconcentration, and elevated liver enzymes; DIC with associated coagulation abnormalities and thrombocytopenia are common. Mortality ranges from less than 1% for Rift Valley fever to 70% to 90% for Ebola and Marburg virus infections.[33,100,102-104]

DIAGNOSIS

The nonspecific and variable clinical presentation of the HFVs presents a considerable diagnostic challenge. Clinical diagnostic criteria based on WHO surveillance standards for acute hemorrhagic fever syndrome include temperature greater than 101° F (38.3° C) of less than 3 weeks' duration; severe illness and no predisposing factors for hemorrhagic manifestations; and at least two of the following hemorrhagic symptoms: hemorrhagic or purple rash, epistaxis, hematemesis, hematuria, hemoptysis, blood in stools, or other hemorrhagic symptom with no established alternative diagnosis. Any suspected case of HFV should result in immediate notification of the hospital epidemiologist, local public health department, and clinical laboratory personnel.[101,105] Laboratory testing is currently available only at the CDC and the United States Army Medical Research Institute for Infectious Diseases. Laboratory techniques for the diagnosis of HFVs include antigen detection, IgM antibody detection, isolation in cell culture, visualization by electron microscopy, immunohistochemical techniques, and reverse transcriptase–polymerase chain reaction. Submission of clinical specimens, including processing and transport, should be arranged through consultation with local public health authorities. The CDC's Packaging Protocols for Biologic Agents/Diseases are available at (http://www.bt.cdc.gov/agent/vhf/index.asp).

TREATMENT

Therapy for HFVs is largely supportive. Treatment of other suspected causes of infection should be administered pending confirmation of HFV infection. Hypotension and shock may require early administration of vasopressors and hemodynamic monitoring with attention to fluid and electrolyte balance, circulatory volume, and blood pressure. HFV patients tend to respond poorly to fluid infusions and rapidly develop pulmonary edema.

Secondary infections may occur and should be diagnosed and treated. Intravenous lines, catheters, and other invasive procedures should be avoided unless they are clearly indicated. The management of bleeding is controversial. Recent recommendations include not treating mild bleeding and use of replacement therapy and heparin for severe bleeding with DIC.[33] Intramuscular injections and medications that interfere with platelet function or coagulation should be avoided.

No treatments of HFVs have been approved by the Food and Drug Administration. Ribavirin is a nucleoside analogue with activity against some Arenaviridae and Bunyaviridae (including the viruses that cause Lassa fever, Argentine hemorrhagic fever, and Crimean-Congo hemorrhagic fever) but not against Filoviridae or Flaviviridae. Ribavirin may be used under an IND protocol for the empirical treatment of HFV patients while awaiting identification of the etiologic agent. Current treatment protocols and dosing recommendations for ribavirin should be obtained through local public health authorities or the CDC's bioterrorism Web site.

Postexposure Prophylaxis

Postexposure prophylaxis is currently recommended only for persons potentially exposed to HFV and for known high-risk contacts or close contacts of HFV patients who develop fever or other clinical criteria of HFV infection with no alternative diagnosis, unless the etiologic agent is known to be a filovirus or a flavivirus.[100]

Infection Control Considerations

Ebola virus, Marburg virus, Lassa fever virus, and the New World arenaviruses are transmissible from person to person through direct contact with blood and body fluids. Airborne transmission of HFVs is unlikely but cannot be completely ruled out. The risk of person-to-person transmission is highest during the latter stages of illness, which are characterized by vomiting, diarrhea, shock, and, often, hemorrhage. The most important step in preventing transmission of HFVs is strict attention to implementation of appropriate barrier infection control measures, including double gloves, impermeable gowns, face shields, eye protection, and leg and shoe coverings.

Airborne precautions are recommended during care of patients with possible HFV infections. Airborne precautions include high-efficiency particulate respirators such as N-95 masks or powered air-purifying respirators (PAPRs) for all persons entering the patient's room. Patients should be placed in a negative-pressure isolation room with 6 to 12 air changes per hour.[101,106]

High-risk contacts of HFV patients include persons having contact with mucous membranes (e.g., through kissing or sexual intercourse) or with secretions, excretions, or blood (through percutaneous injury) of the infected person. Close contacts are persons who have other direct contact with the patient (e.g., shaking hands or hugging), provide medical care to the patient, or process laboratory specimens from a patient with HFV before initiation of infection-control precautions.

Persons potentially exposed to HFVs in a bioterrorist attack and their close and high-risk contacts should be placed under medical surveillance for 21 days from the day of exposure. Temperatures should be recorded twice daily, and any temperature of 101° F (38.3° C) or higher should be reported to the designated clinical or public health authority. Therapy with ribavirin should be initiated promptly unless an alternative diagnosis is established or the etiologic agent is known to be a filovirus or a flavivirus [*see* Treatment, *above*].[100]

HFVs are highly infectious in the laboratory setting through small-particle aerosols generated through procedures such as centrifugation. Laboratory personnel should be alerted when HFV infections are suspected, and appropriate personal-protection precautions and laboratory biosafety procedures should be implemented.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VIII ASSESSMENT OF THE GERIATRIC PATIENT

HELEN K. EDELBERG, M.D.

The conventional medical approach, which focuses on single diseases and organ systems, does not meet the complex medical and psychosocial needs of many elderly patients. Over the past 20 years, geriatric assessment (GA) has evolved as a way to account for the atypical or nonspecific presentation of illness, the impact of medical comorbidity, and the influence of psychosocial stressors on the health of elderly persons.[1,2]

Different models of GA have been devised, utilizing a variety of settings, personnel, and approaches. Most models also include treatment and follow-up of some kind. Hence, the term assessment is something of a misnomer; these would more accurately be described as evaluation and management programs. Despite their diversity, many GA programs have resulted in improved diagnostic accuracy, functional status, affect, cognition, placement outcomes, and survival. They have also had a beneficial effect on health care utilization, reducing the number of hospital admissions (and readmissions) and institutionalization, as well as total health care costs. A recent multicenter randomized, controlled trial of 1,388 frail elderly persons reported significant reductions in functional decline with inpatient GA and improvements in mental health with outpatient GA, with no increase in costs.[2]

Studies suggest that for a GA program to be successful, it should be targeted to those patients most likely to benefit from the intervention.[3] For all intents and purposes, frail patients (i.e., those 80 years of age and older and those suffering from multiple medical and psychosocial problems) can be considered appropriate candidates for GA programs that focus on rehabilitation or chronic disease management and improved care coordination.[4,5] A number of criteria can be used for the selection of these high-risk elderly patients [*see Table 1*]. In contrast, GA programs that aim to identify risk factors for functional decline and develop interventions to prevent or delay impairment are more likely to benefit low-risk elderly persons.[6]

Principles of Geriatric Assessment

General features of GA include the following: (1) an interdisciplinary team approach to patient care; (2) a focus on prevention, including the prevention of decline (maintaining functional status); and (3) a feedback loop to promote adherence to recommendations by other health care providers, patients, and caregivers, as well as to promote patient self-efficacy or confidence in the ability to perform specific activities.[7]

TEAM APPROACH

The traditional components or functional domains of GA are physical, cognitive, psychological, and social [*see Table 2*]. Teams are more effective in assessing these domains and creating an effective care plan than are professionals working alone.[8] The core disciplines of GA are medicine, nursing, and social work. Other professionals—such as a physical, occupational, or speech therapist; a pharmacist; a psychologist; a nutritionist; a dentist; a visiting nurse; a podiatrist; or a member of the clergy—may participate in the GA team or serve as consultants. The composition and structure of the team reflect the treatment goals and resources of the specific setting, whether it is a specialized geriatric ward, consultation service, outpatient clinic, patient's home, or a nursing home.

In general, team leadership rotates, with the key provider of care reporting on the patient's progress. For example, if the major concern is the medical condition of the patient, a physician should lead the team meeting and introduce the team to the patient and family members. To be effective team members, physicians must be knowledgeable about geriatric medicine, familiar with the patient, dedicated to the team process, and have good communication skills. As team members, physicians explain the medical conditions and differential diagnoses that affect care, incorporate the team advice into medical orders, and alert the patient, family members, and caregivers about team decisions.[8] To create, monitor, or revise the care plan, interdisciplinary teams must communicate openly, freely, and regularly. Core team members must collaborate with trust and respect for the contributions of others and coordinate (i.e., delegate, share accountability, and jointly implement) the care plan. Some team members work together at the same site, so communication can be informal and expeditious. Teams should set deadlines for reaching their goals and have regular meetings to discuss team structure, process, and communication. Team effectiveness should be defined by specific goals at the outset and monitored by continuous quality-improvement measures.[8]

When formal teams do not exist, physicians may be able to achieve the benefits of an interdisciplinary approach by assembling informal teams through referrals to other professionals and community-based organizations, such as adult day programs and home care agencies. The Eldercare Locator service (1-800-677-1116), operated by the National Association of Area Agencies on Aging, provides information on and refers callers to local

Table 1 Suggested Criteria for Geriatric Assessment

Impairment of activities of daily living
Incontinence
Confusion or dementia
Chronic and disabling illness that prevents patient self-care
Impaired mobility
Malnutrition or weight loss
Falls
Depression
Socioeconomic or family problems
Sensory impairment (e.g., visual or hearing)
Cerebrovascular accident
Prolonged bed rest
Restraints
Pressure sore
Polypharmacy

Table 2 Domains of Geriatric Assessment

Physical health	Illness Incontinence Balance and gait Falls Nutrition Dental Hearing Vision Sexual functioning Polypharmacy Prevention
Mental health	Cognition Depression Anxiety Psychosis

Environmental adequacy	Safety Impact of climate

services for elderly persons. Resources are also available on the Internet [*see Table 3*].

FOCUS ON PREVENTION

Primary and secondary prevention for the elderly have become increasingly important as the population has continued increasing in average age and average life expectancy.[9] Because primary care practice guidelines do not always address the specific needs of elderly persons, physicians may be compelled to rely on clinical judgment to modify preexisting recommendations that were designed for middle-aged adults.[10] Assessment categories unique to elderly patients include functional status (e.g., activities of daily living [ADL] and instrumental ADL) [*see Table 4*], sensory perception, and injury prevention.[11] Interventional areas that are common to other age groups but have special implications for elderly patients include immunizations, diet and exercise, and sexuality [*see Table 5*]. Cognitive ability and mental health issues should also be evaluated within the context of the individual patient's social situation—not by screening all patients but by being alert to the occurrence of any change in mental function. The prevalence of undetected, correctable conditions and comorbid diseases is high in elderly persons. The American College of Physicians has advocated incorporating GA into routine medical care for elderly persons, particularly patients 75 years of age and older.[12]

FEEDBACK LOOP

Communication among team members and with patients and caregivers—whether it is face to face or by telephone, e-mail, or fax—is the key to effective GA programs. The team and patient must develop ways to communicate honestly, to prevent the patient from suppressing an opinion and agreeing to every suggestion. For example, patients can help the team to set goals (e.g., advance directives and end-of-life care). They can also discuss drug treatment, rehabilitation, dietary plans, and other forms of therapy. If the team learns that the patient will not take a particular drug or change certain dietary habits, the care plan can be modified accordingly. Caregivers, including family members, may help by identifying realistic and unrealistic expectations on the basis of the patient's habits and lifestyle.[8]

Settings for Geriatric Assessment

GA originated in the inpatient setting, but it has since taken on significance in the outpatient setting and across the continuum of care in integrated delivery systems. It may play a critical role in hospital discharge planning and during the transition from independent living to assisted living or nursing home. Formal GA programs are available on a limited basis only, because of the nationwide shortage of trained geriatricians, and are more likely to be found in large regional or academic medical centers. Local community hospitals, visiting nurse agencies, adult day programs and senior centers may provide some of the resources necessary to provide comprehensive geriatric care, such as social work support, home nursing care and safety evaluations, and physical and occupational therapy.

INPATIENT MODELS

Community Hospital

The benefits of GA at a community rehabilitation hospital were first reported in 1990, in a 1-year randomized, controlled trial involving 155 functionally impaired elderly patients recovering from acute medical or surgical illnesses and considered at

risk for nursing home placement. Compared with usual care, treatment in a GA unit resulted in improved function and decreased risk of nursing home placement. The beneficial effects of inpatient GA on mortality and function appeared greatest for patients at a moderate rather than high risk of nursing home placement.[13] The researchers of this study also found that improved outcomes from GA required an investment in rehabilitation that was not totally offset by decreased institutional charges in the following year.[14] Since then, less costly and labor-intensive approaches to inpatient GA have been developed and implemented, including limited support from a geriatric nurse practitioner and use of current hospital personnel to educate attending nurses and staff physicians.[15] These options include wards or beds assigned to elderly patients and consultation services dedicated to the care of elderly persons.

Geriatric Acute Care Units

In 1990, the University Hospitals of Cleveland established an Acute Care for Elders (ACE) unit that reengineered the process of caring for elderly patients to improve functional outcomes. This program comprised four key elements: (1) a specially prepared environment (e.g., uncluttered hallways, large clocks and calendars, and handrails); (2) patient-centered care emphasizing independence, including specific protocols for prevention of disability and for rehabilitation; (3) discharge planning with the goal of returning the patient to his or her home; and (4) intensive review of medical care to minimize the adverse effects of procedures and medications. A randomized, controlled trial of 651 acutely ill patients 70 years of age or older demon-

Table 5 Evidence-Based Preventive Services Recommended for the General Population 65 Years of Age and Older[9]

Service	*Activity*	*Frequency*	*Condition to Detect or Prevent*
Screening	Blood pressure	At least annually	Hypertension
	Mammography	Every 2–3 yr	Breast cancer
	Fecal occult blood testing	Annually	Colorectal cancer
	and/or		
	Flexible sigmoidoscopy	Every 3–5 yr	—
	or		
	Colonoscopy	Once	—
	Pap smear	Every 3 yr or less*	Cervical cancer
	Height and weight	At least annually	Obesity, malnutrition
	Alcoholism questionnaire	†	Alcoholism
	Serum lipids in persons with angina, prior MI, DM	Annually	Risk factor for CAD
	Vision testing	Annually	Visual impairment
	Hearing testing	Annually	Hearing loss
Counseling	Low-fat, well-balanced diet	Annually	Obesity, CAD
	Adequate calcium intake	Annually	Osteoporosis
	Physical activity	Annually	Immobility, CAD, osteoporosis
	Injury prevention	Annually	Falls, motor vehicle accidents, burns, other injuries
	Smoking cessation	‡	COPD, many cancers, CAD
	Regular dental visits	Annually	Malnutrition, oral cancers, endentulism
Immunization	Influenza vaccination	Each fall	Influenza
	Pneumococcal vaccination	§	Pneumococcal disease
	Tetanus booster	Every 10 yr	Tetanus
Chemoprophylaxis	Discussion, implementation of HRT in women	¶	Osteoporosis
	Aspirin therapy after MI	Daily	Additional MI, TIA, or stroke

*May stop screening at age 65 if patient had regularly normal smears up to that age; if never tested before age 65, may stop after two normal annual smears.

†Perform at initial visit and whenever problem drinking is suspected.

‡Discuss at every visit of patients who smoke.

§Immunize once at age 65 for immunocompetent patients; revaccinate high-risk immunocompromised patients after 7–10 yr.

¶Discuss at menopause and at least one time after age 65.

CAD—coronary artery disease COPD—chronic obstructive pulmonary disease DM—diabetes mellitus HRT—hormone replacement therapy MI—myocardial infarction TIA—transient ischemic attack

Table 6 Checklist for Assessing Environmental Hazards in the Home

House or rooms	Lack of cleanliness Inadequate insulation Inadequate lighting Hot-water temperature not regulated at 110° F Inaccessible entries and exits
Stairs or furniture	Unsafe stairs Steps with sharp or broken edges Pointed, broken, or hanging furniture (e.g., suspended chairs) Wheels on furniture
Bathroom	Absence of handrails or secure railings Absence of skid strips for bathtub Outdated prescription drugs Absence of working toilet or acceptable substitute
Signs of neglect	Old food in refrigerator Unwashed dishes Insufficient supply of food Accumulated clothing or newspapers Other signs of disrepair
Obvious dangers	Loose, frayed, or worn carpets; scatter rugs Loose or waxed flooring Absence of smoke alarm Frayed electrical cords or overloaded outlets Exposed pipes and radiators

strated that at the time of hospital discharge, patients admitted to the ACE unit were better able to perform basic ADL and more likely to return home. However, by 90 days after discharge, the functional status of ACE patients was similar to that of standard care patients.[16] However, the costs to the hospital for ACE unit care were less than those for usual care.[17] A recently published trial of 1,531 community-dwelling patients found that an ACE unit in a community hospital improved the process of care and patient and provider satisfaction without increasing hospital length of stay or costs.[18] Publications such as *The ACE (Acute Care for Elders) Manual: Meeting the Challenge of Providing Quality and Cost-Effective Hospital Care to Older Adults*[19] provide valuable information and practical advice for health care providers interested in establishing an ACE unit at their local hospital.

Geriatric Evaluation and Management Units

In the United States, the Department of Veterans Affairs helped to pioneer inpatient geriatric evaluation and management units (GEMUs), which undertake interdisciplinary diagnosis to improve the health of frail elderly patients. The GEMU team, consisting of a geriatrician, a social worker, and a nurse, follows standard protocols for geriatric evaluation and management, with specific instructions in five areas: (1) complete the history taking and physical examination, including screening for geriatric syndromes such as falls or incontinence; (2) develop a list of problems; (3) assess the patient's functional, cognitive, affective, and nutritional status; (4) evaluate the caregiver's capabilities; and (5) assess the patient's social situation. A care plan is developed on the basis of that evaluation, and the team meets at least twice a week to discuss the plan. Preventive and management services (e.g., physical and occupational therapy, nutrition, clinical pharmacy) are coordinated to address the problems identified, with a general emphasis on maintaining functional status.[2] Although the Department of Veterans Affairs mandated that every VA facility have a GEMU by 1996, there are at present only 110 GEMUs functioning in the United States.[20] In the United Kingdom, the counterpart to the GEMU, the geriatric day hospital, continues to play a major role in the multidisciplinary assessment and rehabilitation of elderly people, despite limited evidence to support its efficacy.[21]

Inpatient Consultation Services

If GA is performed as a consultation, special care must be taken in transmitting the findings and recommendations to the primary care provider.[6] The transition between the GA team and the primary care physician frequently presents the greatest obstacle to achieving optimal care of the elderly patient.[3] The GA literature depicts a range of consulting services, from single-focus services (addressing delirium, falls, and other geriatric syndromes) to more comprehensive programs. For example, the Hospital Elder Life Program, developed by Inouye and colleagues, employs an interdisciplinary team that works closely with primary nurses. The team includes a geriatric nurse specialist and an elder life specialist. The latter is a team member with a bachelor's degree in human services or a health care–related field who has experience in geriatrics and management; this person is responsible for program operations, interventions, and volunteer coordination. The Elder Life Program is unique in its hospital-wide focus, in providing skilled staff and volunteers to implement interventions, and in targeting practical interventions toward evidence-based risk factors. In elderly persons who are cognitively impaired, sleep deprived, immobile, dehydrated, and vision or hearing impaired, the program has successfully implemented a nonpharmacologic sleep protocol, documented a reduction in incidence delirium, and prevented cognitive and functional decline.[22]

OUTPATIENT MODELS

Primary Care

Outpatient GA programs may be used as an adjunct to or a substitute for routine primary care. A consultative or primary care team—usually consisting of a physician, nurse (or nurse practitioner), and social worker—provides GA services in the ambulatory setting. Whenever appropriate, referrals are made to other providers (e.g., podiatry, neurology, physical therapy). These programs utilize self-administered questionnaires to screen for common conditions in elderly persons. Patients can complete these questionnaires in the waiting room or with the assistance of a trained receptionist.[23] For example, Moore and colleagues developed and tested a 10-minute office-staff administered screening measure to evaluate malnutrition or weight loss, visual impairment, hearing loss, cognitive impairment, urinary incontinence, depression, physical limitations, and reduced leg mobility. In a large randomized, controlled trial, the measure was associated with more frequent detection and assessment of hearing loss but did not appear to affect detection and management of other conditions included in the screen or health status at 6 months.[24]

Preventive medical care may be provided by the medical staff and psychosocial issues addressed by the nurse or social worker. Lachs and colleagues proposed a short, simple approach that primary care providers in office practice can use to routinely screen

the functional status of elderly patients. The approach focuses on a limited number of functions that often cause problems for elderly patients but that conventional histories and physical examinations often fail to uncover. The screening instrument, which employs brief questions and easily observed tasks, consists of carefully selected tests of vision, hearing, arm and leg function, urinary incontinence, mental status, instrumental and basic ADL, environmental hazards, and social support systems; and it may be administered by a physician or nurse.[25]

Outpatient GA can benefit caregivers as well as patients. In a randomized trial of 568 high-risk, community-dwelling elderly persons who received outpatient GA or usual care for 6 months, caregivers of participants in the GA group were less than half as likely as the usual-care group (16.7% versus 38.5%)to report increased burden during the 1-year follow-up period.[26] Moreover, participants given outpatient GA were significantly less likely than the usual-care patients to lose functional ability, to experience increased health-related restrictions in their daily activities, to have possible depression, or to use home health care services during the 12 to 18 months after randomization. Mortality, use of most health services, and total Medicare payments did not differ significantly between the two groups. The intervention cost $1,350 a person.[27]

In 1997, Beck and colleagues described another GA model for use in primary care. In this model, elderly patients with high health services utilization and one or more chronic conditions had monthly group visits with their primary care physician and nurse. Visits included health education and prevention measures, along with opportunities for socialization, mutual support, and one-to-one consultations with physicians, when necessary. A 12-month randomized, controlled trial of 321 chronically ill HMO enrollees 65 years of age and older showed that group visits resulted in reduced repeat hospital admissions and emergency care use, reduced cost of care, more effective delivery of certain preventive measures, and increased patient and physician satisfaction.[28]

Veterans Affairs Medical Centers

There is a long-established tradition of GA within the VA system. In a randomized, controlled trial involving 160 frail elderly outpatients that compared ongoing outpatient GA through the VA system with usual care, GA proved significantly more effective in reducing mortality, increasing patient satisfaction, and improving the quality of health and social care. It did not, however, reduce health care utilization or costs.[29] In a recent 2-year randomized, controlled trial, 128 veterans 65 years of age or older were treated with outpatient GA or usual care. GA resulted in greater improvement in perceived health; smaller increases in numbers of clinic visits and impairment in instrumental ADL; improved social activity; and greater improvement in measures of depression, general well-being, life satisfaction, and cognitive status. There were no significant treatment effects in ADL scores, number of hospitalizations, or mortality.[30]

Consultation Services

GA can be a consultative service provided through hospital-based outpatient clinics. In a 12-month multicenter, randomized, controlled trial of outpatient consultative GA versus usual care in 442 elderly patients with a health problem or recent change in health status, outpatient consultative GA led to significantly improved diagnosis of cognitive impairment, depression, and incontinence; to psychological and emotional benefits for patients; and to reduced levels of caregiver stress.[31]

Even a single outpatient GA consultation, coupled with subsequent intervention to improve adherence to consultative recommendations, can be beneficial in elderly patients with identified problems.[32,33] In a 15-month randomized, controlled trial of 363 community-dwelling elderly persons in whom screening identified one or more specific geriatric conditions (falls, urinary incontinence, depressive symptoms, or functional impairment), intervention not only prevented functional and health-related quality-of-life decline but also was cost effective.[32]

In-Home Geriatric Assessment

GA in the home may be provided as part of an ongoing office-based program, as an extension of hospitalization through a post–acute care program,[34-36] or as a freestanding entity.[37] In-home GA includes the assessment of environmental hazards, which can serve an important preventive function [*see Table* 6].

The physician's role in in-home GA is to serve as a member of an interdisciplinary team composed of nurses, therapists (speech, physical, occupational, and respiratory), social workers, personal care attendants, home medical equipment suppliers, and informal caregivers (e.g., family members and friends).[38] In-home GA is used to establish a baseline, monitor the course of an illness, and evaluate the effects of an intervention. A recent meta-analysis of 18 randomized, controlled trials found that preventive home-visitation programs (based on multidimensional GA that included multiple follow-up home visits) helped prevent nursing home admission and functional decline, particularly in low-risk elderly persons.[39]

INTEGRATED DELIVERY SYSTEMS

GA programs have been developed and implemented by health systems to improve the evaluation and management of older adults. Managed care organizations and other integrated delivery systems have employed registered nurses, nurse practitioners, social workers, or public health workers as care or case managers to follow, organize, and coordinate care for elderly persons.[40,41] Chronic disease management programs incorporate the basic principles of GA in a variety of different settings, including outpatient clinics, senior centers, and home care.[42-44]

Programs of All-Inclusive Care for the Elderly (PACE)

More than 6,000 Medicare nursing home certifiable beneficiaries receive care from PACE, a program designated for expansion under the Balanced Budget Act of 1997.[45] PACE replicates the model of comprehensive, community-based geriatric care pioneered by On Lok. This model enrolls frail elderly persons who meet states' criteria for nursing home care and uses interdisciplinary teams to assess the participants and to deliver care in appropriate settings. Analysis of data from PACE's minimum data set reveals that short-term hospital utilization among PACE participants is lower than that for other older and disabled populations.[46]

Reimbursement

There is currently no explicit Medicare reimbursement mechanism to cover hospital or physician GA services in the United States. Elderly persons can receive GA in the context of hospitalization for acute illness, provided that the assessment does not prolong the hospital length of stay. A number of Diagnostic Related Groups (DRGs) of the Medicare system apply to frail elderly patients and can be used to justify the hospitalization of pa-

tients with coexisting conditions who require GA. Documentation of the need for hospitalization is critical.[47] As managed care, PACE receives capitated payment from Medicare and Medicaid on the basis of the rate structure of the Medicare+Choice payment system, adjusted for the comparative frailty of PACE enrollees and other factors deemed to be appropriate by the Secretary of Health and Human Services.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

IX MANAGEMENT OF COMMON CLINICAL DISORDERS IN GERIATRIC PATIENTS

Robert M. Palmer, m.d.

The process of aging predisposes elderly patients to homeostatic failure, chronic disease, and a loss of independence in the performance of daily activities (functional decline). Consequently, clinical disorders often manifest as geriatric syndromes, which are multifactorial health conditions that occur when the accumulated effect of impairments in multiple systems renders a person vulnerable to situational challenges.[1] Geriatric syndromes increase in frequency and clinical importance in advanced age, growing more prevalent in patients older than 75 years. These syndromes are frequently encountered by physicians in ambulatory, hospital, and long-term care settings.

Geriatric syndromes reflect the presence of common chronic conditions in the elderly population. In the United States, an estimated 90 million people live with at least one chronic condition that threatens their independent self-care or compromises the quality of their lives. Rates of chronic conditions are highest among the elderly, 88% of whom have at least one chronic condition.[2] By identifying, evaluating, and treating these common conditions, physicians can help older patients maximize their physical and mental status.

Delirium

Common causes of cognitive dysfunction in elderly patients are delirium, dementia, and depression. Dementia and depression are discussed elsewhere [*see CE:X Symptom Management in Palliative Medicine, 11:IV Cerebrovascular Disorders, 11:VII Anoxic, Metabolic, and Toxic Encephalopathies, 11:XI Alzheimer Disease and the Dementias, 11:XIV Pain, and 13:II Depression and Bipolar Mood Disorders*].

Delirium, an acute disorder of attention and global cognitive function, is a common and potentially preventable cause of adverse health outcomes. Elderly patients who develop delirium are at risk for future functional decline (a loss of independence in their performance of daily activities), cognitive decline, and increased mortality.[3,4] Delirium is also associated with prolonged hospitalization, increased risk of nursing home placement, persistent functional decline, and debilitating complications (e.g., falls, injury, and immobility).

The criteria for delirium caused by a general medical condition include the following: disturbance of consciousness (i.e., reduced awareness of the environment) with reduced ability to focus, sustain, or shift attention; change in cognition (e.g., memory deficit, disorientation, language disturbance) or perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia; increased or reduced psychomotor activity; disorganized sleep-wake cycle; acute onset of disturbance (usually hours to days) with fluctuation over the course of the day; and evidence from the history, physical examination, or laboratory findings that the disturbance is caused by an etiologically related general medical condition.[5,6] The cognitive disturbances contribute substantially to problems in identifying and managing delirium.

epidemiology

Medical Illness

Delirium is most often identified in hospitalized patients. It is present in 10% to 15% of older patients at hospital admission for treatment of medical illnesses, and it develops in 10% to 15% of older medical patients during hospitalization.[3] Independent risk factors for delirium in elderly medical patients during hospitalization include the use of psychoactive medications, severe illness, cognitive impairment (dementia), vision impairment, and a high ratio of blood urea nitrogen to creatinine, implying dehydration.[3,7] Precipitating factors for delirium in hospitalized elderly persons include the use of physical restraints, more than three medications added to the patient's drug regimen, bladder catheterization, and any iatrogenic event (e.g., unintentional injury).[8] Benzodiazepines, opioids (meperidine), and medications that have central anticholinergic effects, including diphenhydramine, are most often associated with incident delirium.[9] These findings establish ways to both identify high-risk patients and prevent incident delirium through appropriate medical, behavioral, and pharmacologic approaches.

Postoperative Delirium

Postoperative delirium occurs in 10% to 15% of older general surgery patients and in 30% to 60% of older patients admitted with hip fractures or who are undergoing knee arthroplasty.[10] The incidence of delirium or other cognitive impairments is not related to the type of anesthesia administered, whether general or epidural. In a large prospective study, postoperative cognitive dysfunction was present in 25.8% of patients 60 years of age and older 1 week after surgery.[11] Although both surgery and anesthesia are factors contributing to the development of both short-term and long-term postoperative cognitive impairment, uncertainty remains about the specific factors that contribute to postoperative delirium. Putative risk factors for postoperative delirium include polypharmacy, the use of preoperative anticholinergic drugs, cognitive impairment, and older age.[10] Other contributing factors are intraoperative hypoxemia, perioperative hypotension, and postoperative complications.

Among low-risk adult patients undergoing elective noncardiac surgery, postoperative delirium occurred in 9% and was independently correlated with an age of 70 years or older, self-reported alcohol use, poor cognitive status, poor functional status, markedly abnormal preoperative serum sodium level, and thoracic surgery.[12] In these patients, the postoperative use of meperidine and benzodiazepines increased the risk of delirium.[12]

risk factors and etiology

Virtually any acute physical stress can precipitate delirium in elderly patients, particularly those with risk factors [*see Table 1*]. In medically ill patients, delirium is most commonly associated with acute infections, such as pneumonia and urosepsis; hypoxemia; hypotension; and use of psychoactive medications.[13] The last include many antiarrhythmic agents, tricyclic antidepressants, neuroleptics, gastrointestinal medications, and antihistamines. These agents used in large doses or in combination at therapeutic doses

Table 1 Prevention and Management of Delirium

	Predisposing or Precipitating Factors	*Interventions*
Prevention	Psychotropic medications Benzodiazepines Alcohol Anticholinergic agents Opiates	Avoid or discontinue antihistamines (e.g., diphenhydramine) and benzodiazepines Observe for possible alcohol withdrawal Titrate doses of opiates to achieve analgesia Promote sleep by applying relaxation techniques and keeping hallways quiet at night
	Preexisting cognitive impairment or dementia Alzheimer disease Vascular cognitive impairment Major depressive disorder	Orient to date, place, caregivers, and upcoming events Use psychotropic medications judiciously to treat specific symptoms Encourage visits by family members or sitters
	Dehydration High BUN-to-creatinine ratio Hypotension Poor skin turgor	Prescribe fluids, and monitor intake and discharge Utilize intravenous hydration if oral intake is inadequate Have nursing staff assist with eating and drinking Monitor basic electrolytes
	Severe illness High fever Infection Hypotension	Diagnose illness quickly and follow with empirical therapy (e.g., intravenous antibiotics for community-acquired pneumonia) Optimize hemodynamic status (ensure adequate oxygenation and cardiac output)
	Sensory impairment Vision Hearing	Utilize visual aids (e.g., corrective lenses, large-print books, diffuse illumination) Utilize hearing aids (e.g., portable amplifying devices, cerumen disimpaction)
	Immobility/physical restraint Bed-rest orders Mechanical or chemical restraints	Ambulate or apply bedside exercises Obtain physical therapy consultation for gait assessment and strengthening exercises Obtain occupational therapy consultation for functional assessment and adaptive devices
	Interventions	*Suggested Guidelines*
Management	Medications Neuroleptics Anxiolytics Opiates	Judiciously use neuroleptics to treat disturbing psychiatric symptoms (e.g., delusions, hallucinations, aggressiveness) Administer haloperidol, 0.5–1.0 mg orally or parenterally, every 6–8 hr (higher doses are justified when there is a risk that patient will disrupt life-sustaining therapies) Administer risperidone, 0.5–1.0 mg orally daily in divided doses, when long-term neuroleptic therapy is warranted Administer lorazepam, 0.5–1.0 mg every 6–8 hr orally or parenterally, to patients with disturbing anxiety (higher doses for benzodiazepine or alcohol withdrawal) Control acute pain with morphine sulfate, administered slowly in low initial doses (e.g., start with 2–4 mg parenterally every 3 hr); monitor pain relief with visual analogue scale Avoid meperidine
	Nursing care	Keep sitter at bedside Move patient closer to nurses' station Implement preventive measures Educate patient and family about delirium
	Environmental measures	Keep hallways or corridors quiet Dim lights at night Provide recreational activities outside patient's room Reduce clutter in rooms and hallways

BUN—blood urea nitrogen

may induce delirium. Antibiotics (e.g., ciprofloxacin), analgesics (e.g., nonsteroidal anti-inflammatory drugs), opiates (e.g., meperidine), and H_2 receptor antagonists (e.g., cimetidine) have been associated with delirium.[14] Other important causes of delirium include alcohol and drug intoxication and withdrawal and neurologic illness (e.g., stroke, tumor, or infection).

PATHOPHYSIOLOGY

The pathophysiology of delirium in elderly patients is complex. Patients with risk factors for delirium are regarded as vulnerable on the basis of the hypothetical assumption of limited homeostatic (brain) reserves. Global functional disturbances are associated with neurotransmitter disturbances (e.g., acetylcholine, dopamine, and serotonin). For example, depressed acetylcholine transmission secondary to anticholinergic drugs with central effects can disturb normal cognition.[14] Patients with Alzheimer disease appear to be sensitive to the central anticholinergic effects of various drugs and show improved cognition after treatment with cholinesterase inhibitors, which potentiate the effects of acetylcholine. In some conditions, such as he-

patic encephalopathy, the presence of delirium correlates with the accumulation of toxic metabolites (e.g., ammonia). Disturbances in the elaboration of cytokines, including interleukin-1 (IL-1) and IL-2, have also been associated with delirium.[15]

DIAGNOSTIC EVALUATION

Clinical Features

The patient with delirium presents with an acute change in mental status and clinical features of disturbed consciousness, impaired cognition, and a fluctuating course. The patient has a reduced ability to focus (i.e., sustain or shift) attention, which is associated with incoherent or tangential speech and disorganized or erratic thought processes. Perceptual disturbances, such as misperceptions, illusions or frank delusions, and hallucinations, are often accompanied by increased psychomotor activity. Most patients with delirium vacillate between hypoalertness and hyperalertness. However, the majority of elderly patients with delirium have a so-called quiet confusion, with fluctuations in behavior and level of cognition throughout the day (e.g., increased confusion in the evening, referred to as sundowning).

Several instruments or scales have been found to have significant likelihood ratios and reasonable specificity for the diagnosis of delirium.[3] Of these tools, the confusion assessment method is often used to make a diagnosis in clinical studies and is practical for bedside application.[3] The diagnosis of delirium by the confusion assessment method requires (1) the presence of inattention that has an acute onset and a fluctuating course and (2) disorganized thinking or altered level of consciousness, or both [*see Table 2*]. The confusion assessment method has been adapted for use in patients who are admitted to intensive care units.[16]

Table 2 Confusion Assessment Method for Diagnosis of Delirium*

Factor	*Assessment*
1. Delirium of acute onset and fluctuating course	Indicated by positive response to the following questions: Is there evidence of acute change in the patient's mental status? Does the abnormal behavior fluctuate during the day (appear to come and go or increase or decrease in intensity)?
2. Inattention	Indicated by positive response to the following questions: Does the patient have difficulty focusing attention? Does the patient have difficulty keeping track of what is being said?
3. Disorganized thinking	Indicated by positive response to the following questions: Is the patient's thinking disorganized or incoherent (rambling, irrelevant conversation, unclear or illogical flow of ideas, unpredictable changes in topic)?
4. Altered level of consciousness	Indicated by an answer other than "alert" to the following question: Overall, how would you rate this patient's level of consciousness? Normal = alert Hyperalert = vigilant Drowsy, easily aroused = lethargic Difficult to arouse = stupor Unarousable = coma

*The diagnosis of delirium requires the presence of features 1 and 2 and either 3 or 4.

Table 3 Differential Features of Delirium and Dementia

Feature	*Delirium*	*Dementia*
Onset	Rapid	Insidious
Duration	Hours to days (transient)	Months to years (persistent)
Attention	Decreased (digit span test ≤ 4 words, distractible, fluctuating)	Usually normal (mild to moderate dementia)
Awareness	Always impaired	Usually normal
Alertness	Fluctuates	Usually normal
Consciousness	Depressed	Normal
Memory	Impaired (varies)	Impaired (recent is better than remote)
Language	Normal or incorrect naming	Aphasia, anomia, paraphasia
Perception	Misperceptions, illusions, hallucinations (common)	Usually normal (or delusions)
Psychomotor activity	Increased, decreased (varies)	Usually normal
Sleep-wake pattern	Disrupted (reversal)	Normal or fragmented

Laboratory Tests

The evaluation of a patient with delirium focuses on a search for the most probable etiologies and the need to treat life-threatening illnesses. Often, the precipitant of delirium is obvious, but careful monitoring is needed to exclude other causes or contributing conditions (e.g., pneumonia accompanied by hypoxemia, electrolyte imbalance, and adverse drug effects). A neuroimaging head scan is rarely useful unless patients have focal neurologic findings. Because infection is so frequently the precipitant of delirium, a complete blood count and a chemistry panel are obtained for all patients when infection cannot be excluded. In select cases, blood and urine cultures are warranted, as are a chest x-ray, an electrocardiogram, arterial blood gas analysis, a lumbar puncture, a computed tomographic scan of the head, and an electroencephalogram. The lumbar puncture is rarely diagnostic in patients who are not immunocompromised or in patients with no signs suggesting a serious diagnosis (e.g., meningitis). Although the EEG is useful in distinguishing delirium from depression or dementia, it only occasionally suggests a diagnosis (e.g., partial-complex seizure disorder) that could not be established on the basis of clinical findings.[3,15]

DIFFERENTIAL DIAGNOSIS

Delirium is often misdiagnosed as dementia, depression, or functional psychosis. The clinical features of delirium and dementia may overlap, but the findings of inattention and altered level of consciousness and the duration of symptoms usually enable a separation of these two diagnoses [*see Table 3*]. Psychosis caused by late-onset schizophrenia or major depression is not characterized by impaired attention or altered level of consciousness and fluctuating mental status. Although many depressed patients perform poorly on formal tests of cognition, they remain alert and attentive, and they do not display the fluctuating course of delirium. The depressed patient often refuses to complete a mental status test or gives many "I don't know" responses. Likewise, many anxious patients have impaired concentration and may appear inattentive, but they do not have the fluctuating course and altered level of consciousness seen in delirium.

Protocols Targeted at Risk Factors

Delirium can be prevented in patients who are at risk for the disorder [*see Table 1*]. In the Elder Life Program, patients at risk for incident delirium were identified shortly after hospital admission and followed daily with the confusion assessment method.[17] An array of protocols targeted at specific risk factors served to optimize cognitive function (reorientation and therapeutic activities), prevent sleep deprivation (relaxation and noise reduction), avoid immobility (ambulation and exercises), improve vision (visual aids and illumination), improve hearing (hearing devices), and treat dehydration (volume repletion). In 852 patients studied, the incidence of delirium was 9.9% in the intervention group, compared with an incidence of 15% in the usual-care group. The total number of days and number of episodes of delirium were also significantly reduced in the intervention group, but no significant effects were seen on the severity of delirium or on recurrence rates. The prevention of postoperative delirium in patients undergoing hip surgery for fracture was demonstrated in a pilot study. Geriatric consultation accompanied by targeted recommendations resulted in an incidence of delirium of 32% in intervention-group patients, compared with an incidence of 50% in usual-care patients.[18]

Increased Socialization

Other nursing and environmental interventions that are often helpful in the management of delirium include placement of a patient in a room near the nurses' station for greater observation and socialization; social visits with family members, a caregiver, or hired sitter; the avoidance of physical restraints, which can aggravate agitation; and the promotion of normal sleep cycles through noise control and dim lighting at night.

Pharmacotherapy

Pharmacologic interventions are often warranted for patients with specific indications, including bothersome hallucinations and delusions, physical aggression and risk of harm to self or others, or severe personal distress or discomfort. Pharmacologic interventions are often utilized in patients in whom disruption of medical therapy must be avoided, such as those who are critically ill. However, no agents have been approved by the Food and Drug Administration specifically for the treatment of delirium. Definitive clinical trials of the drug therapy for elderly patients with delirium are lacking. As a general recommendation, for patients with bothersome symptoms, haloperidol is the usual drug of choice. It is administered in dosages of 0.5 to 1.0 mg given orally or intramuscularly every 6 to 8 hours. Higher doses or more frequent administration (e.g., every 30 minutes) may be needed to control agitation when patients require endotracheal intubation or other lifesaving procedures. Once the agitation is relieved, the doses of haloperidol should be gradually tapered over several days. Adverse effects of neuroleptics include extrapyramidal effects, dystonic reactions, and torsade de pointes, which is associated with high doses of intravenous haloperidol.

For treatment of withdrawal from alcohol or benzodiazepine use or severe anxiety and sleep disturbance, lorazepam, in doses of 0.5 to 1.0 mg given orally or parenterally every 6 to 8 hours, is the usual drug of choice; higher doses are often required for treatment of alcohol withdrawal.

A neuroleptic such as haloperidol or risperidone, 0.5 to 1.0 mg/day given orally, can be used as an adjunct to control psychotic symptoms associated with withdrawal. Haloperidol and lorazepam may also be useful in preparing patients for neuroimaging scans or when invasive or supportive therapies are necessary (e.g., insertion of a central line). Adverse effects of benzodiazepines include paradoxical confusion, amnesia, and falls. Severe pain associated with agitation should be treated parenterally with morphine sulfate with lower than usual adult dosages (e.g., 4 to 6 mg every 3 hours; with lower doses used in very old or frail patients). In general, repeated doses of meperidine should be avoided to prevent the neurotoxic effect of its metabolite, normeperidine. Novel approaches to the prevention or reversal of delirium (e.g., use of cholinesterase inhibitors and newer neuroleptics) await clinical trials.

PROGNOSIS

Treatment of the underlying cause of delirium usually results in rapid improvement, although full resolution of cognitive symptoms can take several days to several months. Functional and cognitive deficits often persist after hospital discharge. In a multicenter cohort study, delirium that occurred in hospitalized elderly patients was associated with an increased risk of nursing home admission and mortality, underscoring the seriousness of the diagnosis of delirium and the need to closely monitor such patients after discharge from the hospital.[6] The persistence of cognitive deficits may be related to underlying conditions, especially dementia.

Urinary Incontinence

Urinary incontinence, the involuntary loss of urine of sufficient severity to be a social or health problem, is a common, costly, and potentially disabling condition that is never a consequence of normal aging; it is always treatable and often curable.[19] Urinary incontinence is a source of social embarrassment for older patients, results in a loss of self-esteem and physical independence, and increases the patient's risk of institutionalization.

EPIDEMIOLOGY

The prevalence of urinary incontinence increases from approximately 10% to 15% in women 65 years of age to more than 25% in men and women 85 years of age and older.[19] The prevalence of incontinence approaches 50% in nursing home residents and frail homebound elderly patients. Despite the publication of guidelines for screening and management of incontinence, this condition is still underrecognized and undertreated by primary care physicians.[20]

RISK FACTORS AND ETIOLOGY

Urinary incontinence in older patients results from an interaction of age-related changes in the genitourinary tract, comorbid conditions, altered cognition, impaired mobility, and environmental barriers to toileting. An overactive bladder associated with changes in the smooth muscle of the bladder, prostatic hyperplasia in men, bladder wall relaxation or prolapse in women, medication side effects, and cognitive impairment are the most common factors predisposing older patients to urinary incontinence. Fecal impaction and urinary tract infections (UTIs) are common causes of acute incontinence, which resolve with appropriate treatment.

PATHOPHYSIOLOGY

Incontinence results from neurologic or anatomic defects that

interfere with normal urinary micturition. The urinary bladder is responsible for the storage and emptying of urine. Lesions that interfere with bladder contraction or emptying will predispose patients to urinary incontinence. Urine storage occurs when the muscular wall (detrusor) relaxes, and micturition occurs when the detrusor contracts. Bladder relaxation and filling are promoted by sympathetic stimulation via the hypogastric plexus (T11-L2), which inhibits parasympathetic tone and augments beta-adrenergic tone. Bladder contraction is initiated through parasympathetic (cholinergic) stimulation via the sacral complex (S2-4) and relaxation of the pelvic floor musculature (external sphincter), which is under control of the somatic (pudendal) nerve. As the urinary bladder fills, contraction of the detrusor muscle is inhibited by closure of the bladder neck under sympathetic tone, somatic innervation of pelvic floor muscles and striated muscles around the urethra, and activation of inhibitory pathways from the brain stem and cerebral (frontal) cortex. Detrusor pressure increases, resulting in involuntary contractions and the subjective sensation of a need to void. During voluntary urination, the increase in detrusor pressure overcomes inhibitory pathways and exceeds urethral resistance.

Lesions that interfere with bladder contraction and emptying (e.g., sensory neuropathy) predispose patients to incontinence. Contractions of the detrusor muscle at low bladder filling volumes (detrusor overactivity or instability) may occur in patients with lesions of the central nervous system (e.g., stroke) or with increased sensory stimulation from the bladder, which may be seen in UTI or prostatic hyperplasia. Incompetence of the internal urethral sphincter (e.g., caused by pelvic relaxation or intrinsic sphincter deficiency) allows urine to leak from the bladder (stress incontinence) whenever intra-abdominal pressure exceeds urethral resistance. Loss of detrusor contractility (acontractile bladder) or bladder outlet obstruction may result in a distended bladder and leakage of urine (overflow incontinence) with or without a subjective sensation of urinary urgency.

DIAGNOSTIC EVALUATION

Incontinence may present as either an acute (transient) or chronic (established) condition. The clinical type and most likely cause of urinary incontinence can be determined by a focused medical history and physical examination, a few laboratory studies, and simple office procedures.[21]

Clinical Features

Acute incontinence Acute incontinence typically has a sudden onset and is associated with an acute illness (e.g., infection or delirium) or iatrogenic event (e.g., polypharmacy or restricted mobility). UTI is the most commonly recognized cause of transient incontinence in ambulatory elderly patients. In hospitalized patients, delirium or acute confusion, excessive infusions of intravenous fluids, and metabolic disorders, such as hyperglycemia with glucosuria, will predispose the patient to incontinence. Acute urinary incontinence is also associated with functional impairments such as an inability to toilet quickly enough or a lack of awareness of the need to urinate (e.g., in patients with dementia or acute confusion). Despite the common distinction between acute and chronic causes of incontinence, the two are often difficult to distinguish and often share a similar pathophysiology.

Established incontinence Four basic types of established urinary incontinence occur in elderly patients: stress, urge, overflow, and functional incontinence [*see Table 4*]. Urinary incontinence is often caused by a combination of two or more of the subtypes of incontinence, in which case it is classified as mixed incontinence.

Medical History

The medical history, the key to diagnosis, includes a description of the onset, duration, and characteristics of incontinence; the most significant symptoms; the frequency, timing, and quantity of episodes; and the precipitants of incontinence, such as the relationship of incontinence to exercise, previous surgery, or onset of acute diseases. In men, symptoms related to prostatism should be elicited (i.e., nocturia, dysuria, hesitancy, or decreased stream). The patient's bowel habits (e.g., constipation or impaction) and fluid intake should be noted. A written record or diary of incontinent episodes recorded for 7 days (or a continence record for nursing home residents) is a reliable measure of the frequency of incontinent episodes; it also provides clues to the etiology and severity of urinary incontinence.[22]

Physical Examination

The physical examination focuses on conditions affecting genitourinary function. The abdominal examination seeks abdominal masses caused by bladder distention or fecal impaction. The rectal examination evaluates patients for fecal impaction, rectal masses, and, in men, abnormalities of the prostate gland. The pelvic examination evaluates women for pelvic organ prolapse, genital atrophy, and urethral abnormalities. Neuromuscular examination identifies patients with impaired mobility or diseases of the central nervous system that predispose to urinary incontinence (e.g., stroke, Parkinson disease, or dementia). Sacral root integrity is evaluated by assessment of anal sphincter tone, anal wink, and perineal sensation.

Laboratory Tests

The laboratory evaluation of an incontinent elderly patient is driven by the clinical type, frequency, and significance of the incontinence. Patients with acute urinary incontinence associated with a UTI should first be treated with antibiotics before further urodynamic evaluation. Although many patients with established incontinence have asymptomatic bacteriuria, there is no evidence that treatment of the infection will lead to resolution of the incontinence.[23] A urinalysis will suggest the presence of infection, possible inflammation, or the need for further diagnostic evaluation to rule out tumor or stones (e.g., if the patient has hematuria or pyuria).

In patients with established incontinence, blood tests should measure renal function, electrolytes, blood glucose, and serum calcium, all of which help to exclude polyuric conditions that may cause incontinence.

The most useful bedside test of lower urinary tract function is measurement of the postvoiding residual (PVR) urine. Accurate measurement of the PVR is most often accomplished by straight catheterization of the urinary bladder after the patient attempts complete voiding. Pelvic ultrasonography and portable bladder scanning are safe and accurate alternative methods of estimating PVR.[24] A PVR of less than 50 ml of urine is considered normal. A PVR of greater than 150 ml is abnormal even in elderly patients and indicates the need for further urologic evaluation or repeat measurement of PVR.

When the cause of incontinence is not apparent after these tests, additional studies often performed by urologic specialists

Table 4 Types, Characteristics, and Treatments of Urinary Incontinence

Types	*Characteristics*	*Treatments*		
		Nondrug	*Drug*	*Precautions*
Stress	Associated with urethral hypermobility or intrinsic sphincter deficiency (ISD); urinary leakage with an increase in intra-abdominal pressure resulting from coughing, sneezing, or physical exertion; continuous leakage with ISD	*Behavioral:* pelvic muscle exercises (repeated contraction of pelvic muscles); scheduled toileting (urinate at defined intervals), bladder training (interrupt urination, avoid straining) *Surgical:* needle bladder neck suspension for urethral hypermobility; vaginal sling or periurethral (collagen) injections for ISD	Estrogens Conjugated, 0.3–0.625 mg orally daily (plus progestin if uterus is intact) Topical, 0.5–1.0 g/application Alpha-adrenergic agonists Pseudoephedrine, 30–60 mg three times daily	Oral estrogens increase the risk of endometrial cancer, elevated blood pressure, and venous thrombosis Alpha-adrenergic agonists are not FDA-approved treatment of stress incontinence; they may increase the risk of stroke, hypertension, headache, and tachycardia
Urge	Urinary urgency and frequency (small to moderate volumes); overactive bladder caused by detrusor instability	Bladder training (scheduled or prompted voiding), pelvic muscle rehabilitation (contraction and relaxation of pelvic muscles), biofeedback (reduction of intensity of uninhibited contractions)	Anticholinergics/bladder relaxants Oxybutynin, 2.5–5.0 mg three times a day (or a single dose at night for nocturia and urgency) Oxybutynin XL, 5–10 mg every day Tolterodine, 1–2 mg twice a day (or a single dose at night for nocturia and urgency) Tolterodine LA, 2–4 mg every day	Common side effects are dry mouth, constipation, and blurred vision; potential risk of increased intraocular pressure, delirium, and tachyarrhythmias
Overflow	Associated with either an acontractile bladder or bladder outlet obstruction (BPH, stricture, or bladder neck constriction); bladder distention with frequent or constant dribbling, with or without urgency	Intermittent or continuous catheter drainage for acontractile bladder Surgical relief of urethral obstruction (prostatectomy) Bladder retraining and scheduled toileting can be attempted after acute urinary retention	Cholinergic agonist Bethanechol, 10–30 mg three times daily (initiate with lower doses) $Alpha_1$-adrenergic antagonists Terazosin, 1–5 mg at night Doxazosin, 1–4 mg at night Tamsulosin, 0.4–0.8 mg at night	Cholinergic agonists should be used judiciously for acontractile bladder; bethanechol may exacerbate bradycardia, hypotension, bronchoconstriction, and peptic ulcer exacerbation $Alpha_1$-adrenergic antagonists should be used only for mild outlet obstruction caused by BPH; possible side effects are postural hypotension, fatigue, and sexual dysfunction
Functional	Associated with inability or unwillingness to perform toileting (physical disability, environmental barriers, or psychiatric illness)	*Behavioral:* toileting schedule and prompted voiding; assisted toileting, bedside commode or urinal; assistive devices to aid ambulation and toileting (canes, walkers, rails, grab bars); discontinue physical restraints; increase exercise *Medical:* absorbent pads and garments; indwelling catheters for severely debilitated patients	Change treatments (reduce diuretic and vasodilator dosages) Treat depression Treat Parkinson disease	Minimize use of drugs that worsen functional impairments (e.g., neuroleptics with extrapyramidal side effects and vasodilators that cause postural hypotension)

Note: Elderly patients frequently have mixed incontinence (urge and stress) and functional impairments that precipitate incontinence. Treatments should not be started until after a basic evaluation is completed to exclude reversible causes of acute incontinence and overflow incontinence. Many frail patients have detrusor hyperactivity with impaired contractility presenting with urinary urgency and small-volume voids.
BPH—benign prostatic hyperplasia LA—long acting XL—extended length

are warranted. Outpatient cystometry is able to determine bladder filling capacity, detrusor compliance and contractility, and PVR. A detailed urodynamic evaluation may be needed to determine the cause and most appropriate treatment of incontinence, particularly before operative treatments of incontinence. For example, stress incontinence is diagnosed and categorized according to abdominal-leak point pressures.[25] Urodynamic studies are essential for making a definitive diagnosis of urinary obstruction or detrusor hyperactivity with impaired contractility and for determining the type of stress incontinence.

MANAGEMENT

Strategies for the management of urinary incontinence include behavioral modification techniques, medications, patient and caregiver education, surgical procedures, catheter placement, and incontinence supplies [*see Table 4*].[21] The acute onset of incontinence should be evaluated and treated promptly. UTI, acute urinary retention, stool impaction, and adverse effects of medications (e.g., diuretics) should be excluded. After the initial diagnostic evaluation, most patients should be treated on the basis of the most likely type of incontinence. This empirical ap-

proach will lead to successful management of a large percentage of incontinent patients.[26]

Stress Incontinence

In female outpatients, behavioral interventions (e.g., anorectal biofeedback, which helps patients identify pelvic floor muscles so as to relax them selectively), bladder training, and pelvic muscle exercises are effective first-line therapies for established stress incontinence.[27-29] Daily repeated pelvic floor exercises will strengthen the voluntary periurethral and perivaginal muscles, augment urethral pressure, and inhibit urinary leakage. Pelvic muscle exercise is assumed to enhance urethral resistance by increasing the strength and endurance of the periurethral and perivaginal muscles and by improving the anatomic support to the bladder neck and proximal urethra.

Pelvic muscle exercises entail tensing the perivaginal muscles and anal sphincter as if to control urination or defecation while applying minimal contraction of abdominal, buttock, or inner thigh muscles. Typically, pelvic floor exercises are conducted for 10-second intervals several times a day for at least 8 weeks—most often, indefinitely. Another technique for exercising pelvic muscles is to interrupt midstream voiding by contracting the urinary sphincter while keeping the other muscles relaxed. The effectiveness of these exercises depends on patient compliance; benefits may not be seen for several weeks. Vaginal cones and electrical stimulation are sometimes used as adjuncts to exercises, with less certain results. For mild cases of stress incontinence, elevation of the urethra with a foam pessary often suffices.

Medications play a modest role in the treatment of stress incontinence. Middle-aged women with stress incontinence and hypoestrogenism may benefit from intravaginal, oral, or transdermal estrogen replacement therapy.[19] However, current concerns regarding the long-term risks of estrogen replacement therapy on cardiovascular disease, cancer, and venous thromboembolism limit the role of these treatments in elderly women.[30] Alpha-adrenergic agonists (e.g., pseudoephedrine, 15 to 30 mg) are thought to reduce the frequency of stress incontinence by increasing internal sphincter tone and bladder outflow resistance. These agents have potential side effects, including exacerbation of hypertension, and should be used with caution in elderly patients.

Surgical options for treatment of urethral hypermobility include bladder neck resuspension (colposuspension) or vaginal slings. The long-term effectiveness of percutaneous needle operations has been disappointing and suggests that conservative approaches should be fully explored before resorting to major operations.[31] Vaginal slings or periurethral injections of collagen are the treatments of choice for patients with intrinsic sphincter deficiency. In one study, collagen-injection therapy for intrinsic sphincter deficiency in women showed excellent 1-year responses. Of 94 patients, 67% achieved continence, 38.3% became dry, and 28.7% became socially continent.[25] Long-term studies find collagen to be a safe and moderately effective therapy; however, many women experience recurrent leakage that may not resolve with reinjection.[32]

In elderly men, stress incontinence is usually caused by intrinsic sphincter deficiency resulting from trauma to the bladder outlet, most commonly secondary to prostatectomy. Stress incontinence caused by intrinsic sphincter deficiency may be treated with either periurethral injections or the placement of an artificial sphincter.[19] Success rates with collagen are less impressive in men than in women. However, very high continence rates have been reported in men in whom artificial sphincters (especially models having a double cuff) have been implanted for treatment of postprostatectomy incontinence.[33]

Urge Incontinence

Elderly women with detrusor instability with urge incontinence often respond to behavioral therapies, such as bladder training (i.e., a combination of patient education, scheduled voiding, urge-suppression techniques, and pelvic muscle exercises)[34]; biofeedback has been shown to work well in younger and cognitively intact women.[27] Bladder training is assumed to improve cortical inhibition over lower urinary tract functioning and has been used primarily in the treatment of urge incontinence. Cognitively impaired patients also benefit from bladder training with scheduled toileting (e.g., beginning every 2 hours and progressing to every 3 to 4 hours); prompted voiding in which the caregiver toilets the patient may also be useful. Bladder-relaxant medications that also have anticholinergic properties are the most effective drug therapies for urge incontinence. Most commonly, either oxybutynin or tolterodine is used for treating detrusor overactivity.[19] Oxybutynin is short acting and often produces significant anticholinergic side effects of constipation, dry mouth, and exacerbation of glaucoma. A long-acting preparation of oxybutynin (Ditropan XL) may enhance compliance and reduce the incidence of anticholinergic side effects.[35] Tolterodine is available in both short-acting and long-acting forms.[36] Direct comparison of the extended-release preparations of oxybutynin and tolterodine in women with an overactive bladder showed similar reductions in incontinence episodes, with only minor differences in side effects.[37] Because of anticholinergic side effects, these agents need to be used cautiously in cognitively impaired patients, especially patients taking cholinesterase inhibitors for treatment of Alzheimer disease.

For the frail elderly, behavioral and environmental interventions are most effective in the treatment of urge incontinence. Strategies that maintain or improve mobility may prevent incontinent episodes.[19] Devices, including urinals, bedside commodes, or other external collecting devices, may help these patients to achieve continence. Other helpful aids are canes, walkers, or wheelchairs for patients with impaired ambulation; elevated toilet chairs; and the avoidance of physical or chemical restraints that impede the patient's toileting ability. For patients with intractable incontinence, absorbent undergarments or adult diapers are frequently used.

Combined Stress and Urge Incontinence

Because mixed forms of urinary incontinence are common in women, patients may benefit from both behavioral therapies and medications. One randomized clinical trial contrasted a biofeedback-based behavioral approach with both drug treatment (oxybutynin chloride, 2.5 to 5.0 mg three times daily) and a placebo.[28] Women 55 years of age or older with urge or mixed urge-stress incontinence were assigned to behavioral treatment consisting of anorectal biofeedback and pelvic muscle exercises performed at home. Episodes of incontinence decreased nearly 81% on average with behavioral treatment, which was significantly better than the decreases that occurred with drug treatment (68.5%) or placebo (39%). A toileting schedule may also be effective in combination with behavioral and pharmacologic approaches. Patients should be encouraged to urinate at regular intervals and before physical exertion. As in treatment of stress incontinence, vaginal cones, electronic devices, pessaries, or ele-

vating devices (e.g., surgical sling procedures) can be useful for individual patients with mixed incontinence, although their long-term effectiveness has not been established.[38]

Overflow Incontinence

Overflow incontinence occurs when there is either bladder outlet obstruction or an underactive (acontractile) bladder. Acute urinary retention is a common cause of overflow incontinence in hospitalized elderly patients. It is often precipitated by medications (e.g., anticholinergic drugs), anesthesia, or urethral manipulation, and it may be treated with intermittent urethral catheterization until the acute precipitating event subsides. The most common cause of bladder outlet obstruction in men is prostatic hyperplasia; less common causes are carcinoma and urethral stricture. Patients with incontinence resulting from bladder outlet obstruction will require either surgical correction or intermittent catheterization. Occasionally, men with prostatic hyperplasia respond to alpha-adrenergic antagonists, which may reduce internal sphincter tone. In women, overflow incontinence occurs as a complication of anti-incontinence operations or severe pelvic organ prolapse. An underactive or acontractile bladder may occur secondary to neurologic diseases such as diabetic neuropathy, spinal cord injury, and idiopathic detrusor underactivity.

Intermittent self-catheterization is ideal in patients who have atonic or neurogenic bladders. Long-term indwelling urinary catheterization is usually reserved for patients who cannot be catheterized intermittently because of discomfort or terminal illness. External (condom) catheters for males are used selectively because they often fail and can lead to local skin infection or UTI.

Functional Incontinence

Patients with neuropsychiatric diseases may experience functional incontinence in the absence of bladder disease. Immobile patients may suffer incontinence when they are unable to toilet because of physical illness, restraints, or environmental barriers. If urinary retention with overflow incontinence is excluded, patients with functional incontinence can be managed through exercise, toileting schedules, and assistive devices that enhance toileting ability.

Fecal Incontinence

Fecal incontinence is the continuous or recurrent uncontrolled passage of fecal material for at least 1 month. Acute and chronic fecal incontinence occur commonly in elderly patients with comorbid conditions and are often a socially embarrassing and incapacitating problem.[39]

EPIDEMIOLOGY

The prevalence of fecal incontinence increases with age, occurring in 3% to 7% of all persons 65 years of age and older,[39] in up to 50% of elderly patients in nursing homes,[40] and in 30% of elderly patients in hospitals.[41] Constipation (i.e., the passage of infrequent, hard, or difficult-to-pass stools) is often associated with incontinence, particularly in patients with fecal impactions.

RISK FACTORS AND ETIOLOGY

Fecal incontinence is most often a result of fecal impaction caused either by constipation or dysfunction of the internal or external anorectal sphincters. Factors that contribute to the risk of fecal incontinence include disordered muscle integrity, decreased rectal sensation or compliance, declining mental function, and loss of physical mobility.[39] Common causes of constipation include a diet low in fiber and fluids, dehydration, immobility, and medications.[41]

PATHOPHYSIOLOGY

The process of normal defecation requires the integrity of skeletal and striatal muscles involved in anal sphincter function, cognitive awareness and ability to get to the toilet, and normal function of the pelvic floor muscles and nerves.[41] A disruption of any of these links predisposes the patient to incontinence. Rectal trauma, pudendal nerve injury, autonomic neuropathies, rectal prolapse, hyperosmolar diets, and fecal impaction are common physiologic factors contributing to incontinence.[41] Fecal impaction occurs most often in the distal or rectosigmoid colon. Mucus and fluids are secreted proximal to the impaction and leak around the mass or are passed after therapeutic disimpaction. Medications, especially opiates and anticholinergic agents, are common causes of constipation, impaction, and incontinence. Acute fecal incontinence may be seen in diarrheal states, and intermittent incontinence is often seen in patients with dementia, delirium, pelvic floor denervation, or excessive laxative use.[42]

Table 5 Fecal Incontinence: Prevention and Management

	Intervention	*Example*
Prevention of Constipation	Physical activity	Aerobic exercises (e.g., walking, water aerobics)
	High-fiber (8–12 g daily) diet* (to induce bulking effects, alter microbial ecology) plus fluids	High-fiber vegetables, bran supplements, psyllium supplement, methylcellulose supplement
	Laxatives (when fiber is ineffective or not tolerated)	Lactulose or sorbitol preferred (osmolar agents); irritant laxatives (for patients intolerant of osmolar agents): bisacodyl, senna; enemas (for patients with colonic dysfunction)
	Avoid constipating medications or use judiciously	Anticholinergic agents; antispasmodics, antiparkinsonian drugs, tricyclic antidepressants, neuroleptics, iron supplements, opiates, calcium channel blockers (verapamil)
Management of Fecal Incontinence	Treatment of fecal impaction†	Enemas: saline, water, sodium phosphate, bisphosphonate; colonic irrigation; high-fiber diet (after disimpaction); oral hyperosmolar solutions
	Treatment of colitis (e.g., from radiation, inflammatory bowel disease)	Medical: soluble fiber supplements, opiates (loperamide)
	Modification of behavior	Biofeedback (motivated, cognitively intact patients), toileting schedule for physically or cognitively impaired patients
	Treatment of anatomic abnormalities	Surgical repair of rectal prolapse or anal sphincter

*Fiber should be avoided until fecal impaction resolves.
†Often, a combination of soluble fiber, hyperosmolar agents, and periodic enemas is needed to prevent impaction in bedridden patients and those with chronic colonic dysfunction (e.g., chronic laxative use, diverticular disease).

DIAGNOSTIC EVALUATION

Medical History and Physical Examination

The evaluation of fecal incontinence includes a careful review of the patient's cognitive status, anorectal and neurologic function, and a rectal examination. In hospitalized or institutionalized patients, the diagnosis of a fecal impaction is suggested by the passage of watery stools laden with mucus. This suspicion is confirmed by rectal examination, which generally reveals firm or hard stool in the ampulla, often associated with a patulous rectum. With high impactions, feces may be palpable during abdominal examination or confirmed by x-ray of the abdomen. Mental status examination identifies the patient with dementia or delirium who has lost self-toileting capacity. The absence of anal sphincter tone or anal wink may suggest denervation of the pudendal nerve (S2-4), resulting from a local or spinal cord lesion. The rectal and abdominal examinations also help identify inflammatory diseases or tumors as causes of incontinence.

Laboratory Tests

Diagnostic studies are needed when either the diagnosis or the appropriate management of the incontinent patient remains uncertain. Useful studies include anoscopy or flexible sigmoidoscopy for confirmation of masses or inflammation. Infrequently, anorectal manometry to measure intraluminal pressure, anal endosonography to identify mass lesions, pudendal nerve conduction measurement to diagnose neuropathy, or defecography to define intrinsic lesions are needed to ascertain the cause of fecal incontinence.[39]

PREVENTION AND MANAGEMENT

The prevention of fecal incontinence begins with an assessment of risk factors for fecal impaction and functional incontinence. The most common approaches to the prevention of fecal incontinence and constipation include changes in diet, increased physical activity, the judicious use of laxatives and enemas, and surgical correction in patients with anatomic abnormalities (e.g., rectocele) [*see Table 5*]. Biofeedback can be effective in highly motivated and cognitively normal patients with sphincteric dysfunction.

Laxatives

Laxatives are prescribed for patients with incontinence resulting from constipation. Stimulant laxatives (e.g., senna and bisacodyl), hyperosmolar laxatives (e.g., sorbitol and lactulose), rectal suppositories (e.g., glycerin and bisacodyl), or enemas (e.g., tap water) are often sufficient to treat constipation. Saline laxatives (e.g., milk of magnesia) can also be used, but hypermagnesemia limits their usefulness in patients with renal insufficiency.[39] Fecal disimpaction can be performed manually with an anesthetic lubricant or by mineral oil enemas. Mixed electrolyte solutions containing polyethylene glycol, a major hyperosmolar laxative,[39] are effective in relieving fecal impactions; the electrolyte solution is given orally, usually in large amounts (e.g., 2 to 3 L/day in divided doses). Sodium phosphate solution should be avoided in most elderly patients with fecal impaction because of its increased absorption and the risk of electrolyte disturbances associated with its use.

High-Fiber Diet

Once the impaction is resolved and colonic function is restored, patients should be placed on a high-fiber diet or given fiber supplements (e.g., psyllium or methylcellulose) along with liquids. If constipation is associated with hard stools, fiber and fluids should be gradually increased over several weeks to ensure a soft stool. The role of diet in the prevention of impaction is unclear; diet is probably not as important as colonic cleansing in preventing impaction.[39]

Suppositories and Enemas

The intermittent use of glycerin or bisacodyl suppositories is warranted if rectosigmoid outlet delay or difficult passage of a soft stool is the primary concern.[37] Patients unable to retain a suppository can be treated with periodic enemas or hyperosmolar solutions.

Falls and Gait Disturbances

Accidental falls, defined as unintentionally coming to rest on the ground, floor, or other lower level, are common and potentially preventable causes of morbidity and mortality in elderly adults. The risk factors for falls and the effectiveness of multifactorial interventions to prevent recurrent falls in carefully targeted patients are well established.[43] Falls often result from an interaction of conditions that involve host (intrinsic) or environmental (extrinsic) predisposing or situational risk factors [*see* Risk Factors, *below*].[44] Falls can be associated with syncopal or presyncopal episodes, resulting from cardiac arrhythmias, postural hypertension, or postprandial hypotension [*see 1:I Approach to the Cardiovascular Patient*].

EPIDEMIOLOGY

Each year, falls occur in about one third of community-dwelling persons older than 65 years and in about half of persons 80 years of age or older. About half of these individuals who fall experience multiple falls. Falls account for serious injuries that include hip fractures and soft tissue trauma and often lead to an older person's loss of functional independence and a fear of falling.[43] Unintentional injury, most often attributed to falls, is the seventh leading cause of death in elderly persons. About 5% of falls by community-dwelling elderly persons result in a fracture. Falling increases the probability of hospitalization, nursing home placement, and death. About half of falls by elderly patients result in soft tissue injuries such as bruises, lacerations, and abrasions. Less common complications are subdural hematomas and cervical fractures. Most hip fractures that occur in elderly people result from falls. More than half of the survivors of hip fracture are discharged to a nursing home, and half of those remain in a nursing home a year later. After hip fracture, fewer than 30% of patients regain their prefracture level of physical functioning.

RISK FACTORS

Intrinsic risk factors include lower extremity weakness, poor grip strength, gait and balance deficits, impaired performance of daily activities, visual impairment, cognitive impairment, and depression.[44] Extrinsic risk factors include use of four or more prescription drugs and environmental impediments such as poor lighting, loose carpets, and absence of bathroom-safety equipment.[44] Risk factors for hip fractures resulting from falls include low bone mineral density, use of long-acting benzodiazepines (e.g., diazepam), vision impairment, reduced mobility and physical independence, and cognitive dysfunction. About a third of fallers develop a fear of falling that is itself predictive of

an increased risk of balance and gait problems, a decline in self-care abilities, and an increased risk of falling.[45]

ETIOLOGY

Accidental falls stem from the combination of environmental hazards and the increased susceptibility to falls related to aging or diseases. Accidents, simple slips, and trips are the most common causes of falls occurring in the community-dwelling elderly population and are usually associated with environmental hazards. In nursing home patients, however, environmental factors are the most common immediate cause of falls, followed by weakness, gait or balance disturbances, drop attacks, dizziness or vertigo, and confusion. Less common causes of falls are postural hypotension, syncope [*see 1:I Approach to the Cardiovascular Patient*], acute illness (e.g., infection), and medications. Gait impairments with falls are associated with lower extremity weakness from deconditioning, stroke, cardiovascular disease (e.g., arrhythmias), and neurologic disease (e.g., Parkinson disease). Dizziness, vertigo, delirium, postural hypotension, visual disorders, alcohol use, and medications (e.g., psychotropic agents) are other causes of falls.[43] Medications associated with falls most notably include those that cause postural hypotension, such as loop diuretics, vasodilators, or adrenergic antagonists, and those with psychotropic properties, such as antidepressants and sedative-hypnotic agents.

PATHOPHYSIOLOGY

The maintenance of normal balance and gait requires the successful integration of sensory (afferent), central nervous (brain and spinal cord), and musculoskeletal systems. A disturbance in sensory input (e.g., peripheral neuropathy), central nervous system functioning (e.g., dementia), or motor function (e.g., arthritis or muscle weakness) will predispose elderly patients to falls. The aging process may also predispose patients to falls by increasing postural sway and reducing adaptive reflexes. Postural-stability limits appear to decrease with aging. However, changes in gait, such as slowing of walking speed, reduced stride length, and prolonged double support, which are often attributed to the aging process, likely represent adaptations to the fear of falling.

DIAGNOSTIC EVALUATION

Patients at risk for falls can be identified through a medical history, physical examination, and a few laboratory studies. A review of risk factors, medications (e.g., vasodilators, adrenergic blockers, and psychotropic agents), and screening instruments (vision, mental status, balance, and gait) help identify patients at risk. Older persons should be asked at least once a year whether they experience falls.[42] For those persons reporting a fall, a review of the circumstances surrounding the fall, including symptoms before and after the event, provides clues to the likely causes. For example, vertigo may precede loss of balance and a fall; a

Table 6 Interventions to Reduce the Risk of Falls

Risk Factors	*Interventions*
Medications Use of ≥ 4 medications Alcohol reduction Use of any benzodiazepine or other sedative-hypnotic agent Vasodilators (arterial and venous)	Review medications, and reduce, taper, or discontinue use of alcohol and psychotropics (benzodiazepines and sedative-hypnotics); if necessary, replace with antidepressants (for insomnia, depression, or anxiety) Use nonpharmacologic therapy for sleep disorders (sleep restriction, no long daytime naps, aerobic exercise early in day, utilization of relaxation techniques such as music and massage) Use alternatives to vasodilators (beta blockers and calcium channel blockers)
Postural hypotension Drop in systolic blood pressure ≥ 20 mm Hg Postural dizziness or light-headedness	Change doses of medications (e.g., loop diuretics, vasodilators) If syncopal or presyncopal, consider workup for autonomic nervous system or hemodynamic causes If venous pooling occurs in legs, try leg pumps, salt repletion, or graded compression stockings
Lower-extremity weakness Generalized decreased strength of quadriceps, knee extensors, or flexors Deconditioning resulting from recent illness, hospitalization, or immobility	Low-intensity resistive exercises (bands, tubes, pulleys, or weights) under therapist supervision Endurance exercises (walking, biking, or water exercise)
Balance/gait impairment Postural instability Inability to transfer safely to bathtub or toilet Antalgic gait Fear of falling	Physical-therapy consultation for gait assessment Prescription of assistive devices (canes, walkers) Training in transfer skills Gait training and balance exercises (e.g., Tai chi) Analgesics for pain relief Environmental alterations (raised toilet seats, commodes, grab bars, and handrails)
Sensory impairments Hearing Vision	Hearing aids (headset microphones, reduced background noise) Visual aids (corrective lenses, improved illumination of room)
Environmental hazards Uneven surfaces Frayed rugs Loose cords Poor lighting Uneven steps or stairs	Occupational-therapy consultation (home visit, safety evaluation) Diffuse illumination of rooms Install handrails and grab bars Resurface slippery floors Install ramps Rearrange furniture Remove frayed rugs and cords

loss of consciousness preceding the fall suggests a diagnosis of syncope.

Observation of the patient's balance and gait is the most useful aspect of the examination. Performance-based measures have been validated and are predictive of gait and balance impairments. The timed get-up-and-go test is particularly useful, is quickly performed, and appears to be predictive of falling. The test requires a patient to stand up, walk 10 ft, turn, walk back, and sit down. Older adults at risk for falls require more than 20 seconds to complete this task. During the test, postural instability, lower extremity weakness, reduced steppage, increased lateral sway, stride variability, and ataxia can be easily identified. Individuals who have difficulty with this task or demonstrate unsteadiness require further assessment.[45] In the outpatient setting, patients who have had two or more falls or who experience balance or gait difficulties should have a detailed assessment of the factors that predispose them to falls [*see Table 6*].[44]

The further diagnostic evaluation is based on the circumstances surrounding the fall and a judgment about the most likely causes. An examination of the patient's vision, gait and balance, lower extremity strength and function, and mental status, as well as a basic neurologic examination, is recommended.[45] An extensive diagnostic workup is not usually warranted in nonsyncopal falls. However, in the emergency evaluation of an elderly faller, the history of head trauma and the finding of focal neurologic deficits suggest the need for a neuroimaging procedure (e.g., CT scan of the head).

PREVENTION AND MANAGEMENT

Multicomponent Interventions

The most consistently effective interventions to prevent recurrent falls have been targeted at both intrinsic and extrinsic risk factors [*see Table 6*].[44] Successful components of interventions used in clinical trials include review and alterations of medications, balance and gait training, muscle-strengthening exercises, improvement of postural hypotension, home-hazard modifications, and specific medical and cardiovascular treatments.[44] In a clinical trial involving community-residing persons 70 years of age or older with risk factors for falling, those who received interventions that included an adjustment of medications, behavioral instructions, and an exercise program (e.g., balance exercises, gait training, and low-intensity resistive exercises) had fewer falls in the subsequent year than did control subjects.[46] Meta-analyses support the effectiveness of multicomponent interventions to prevent falls.[47]

Balance and Strengthening Exercises

Tai Chi exercise Tai Chi exercises to enhance balance and body awareness when combined with balance training may also reduce the rate of falls.[48] A randomized trial of Tai Chi exercise for 15 weeks in 200 persons 70 years of age and older resulted in a 47% decrease in falls after a 4-month follow-up. Fear of falling is reduced as well, which may account for the benefits of exercise rather than improved postural balance.[6,49]

Therapist-conducted exercise In one study, home visits of women 80 years of age and older made by a physiotherapist led to a 41% reduction in self-reported falls in 1 year, a decreased risk of fall with injury, and improved balance.[50,51] The therapist conducted an exercise program designed to increase balance and muscle strength. Benefits persisted for 2 years in compliant patients.

Resistive exercise Clinical trials demonstrate the effectiveness of both low-intensity and progressive high-intensity resistive exercise in improving lower-extremity strength.[44,47] Bands, tubes, pulleys, and weight machines have been used under therapist supervision in various studies.[52]

Prevention of Hip Fractures Caused by Falls

Hip protectors have been found to reduce the risk of hip fracture in nursing home patients.[53] Studies of community-residing older people have produced mixed results.[54,55] In part, this reflects the low level of adherence to the use of hip protectors, as well as differences in the efficacy of available brands.

Recommended Treatment Plan

Clinicians who are evaluating an elderly patient with a history of falls should begin with a discussion of the circumstances surrounding the falls and determine if the falls were syncopal or nonsyncopal. If the falls were nonsyncopal, the next step is to review the patient's medications, perform a test of mobility such as the get-up-and-go test, and evaluate the patient's muscles and joints (especially knees, hips, and ankles) for range of motion, strength, and stability. If the causes of falls remain unclear and the falls occur primarily at home, the clinician should consider a home-safety evaluation by a physical therapist. For patients with lower extremity weakness, a referral of the patient to a physical therapist for gait assessment and muscle strengthening is advisable. The referral should request a gait assessment and low-intensity resistive exercises of the lower extremities, including hip and knee extensors. Clinicians should also treat comorbid conditions that increase the risk of injurious falls, notably osteoporosis, drug intoxication, and being underweight.

Immobility

Prolonged bed rest produces many physiologic changes, including decreases in blood volume and cardiac output, orthostatic hypotension, hypoxemia, muscle atrophy and generalized weakness, and decreased muscle oxidative capacity. In hospitalized elderly patients, immobility increases the risks of functional dependency; nursing home placement after discharge; and medical complications, including deep vein thrombosis, urinary incontinence, pressure sores, joint contractures, cardiac deconditioning and muscle weakness, and falls. Immobile patients in hospitals or nursing homes are at risk for pressure ulcers.

Pressure Ulcers

A pressure ulcer occurs when soft tissue is compressed between a bony prominence and an external surface for a sustained period. Pressure ulcers result in substantial morbidity, increased health care costs, and reduced quality of life for older patients.[56] Pressure ulcers are common in immobilized patients and increase in incidence with aging. Early-stage ulcers should be identified and managed aggressively to prevent their progression to more severe stages. The National Pressure Ulcer Advisory Panel[57] has defined four stages of pressure ulcers:

Stage I: nonblanchable (persistent) erythema of intact skin.
Stage II: partial-thickness skin loss involving the epidermis, the dermis, or both.

Stage III: extension into subcutaneous tissues to the deep fascia with or without undermining.
Stage IV: extension into muscle, bone, or both.

EPIDEMIOLOGY

The prevalence of stages II, III, and IV ulcers in patients in acute care hospitals ranges from 3% to 11%, with an incidence during hospitalization of 1% to 3%. The rate is higher in bedridden patients. Stage I and stage II pressure ulcers are the most common. The prevalence of pressure ulcers in nursing home residents in one study was 11.3% for stage II, III, or IV pressure ulcers.[55] For residents admitted to the nursing home without pressure ulcers, the incidence was 13.2% at 1 year and increased to 21.6% after 2 years of nursing home stay.[58] About 80% of pressure ulcers in nursing home patients develop over the sacrum or coccyx, hips (femoral trochanter), ischia, and heels.[59]

RISK FACTORS AND ETIOLOGY

Most prospective studies of stage II, III, or IV pressure ulcers in hospitalized patients have implicated impaired mobility, incontinence, undernutrition, and impaired consciousness as significant risk factors for pressure ulcers.[59] In hospitalized patients who are bedridden or chairbound, risk factors include hypoalbuminemia, fecal incontinence, and fractures.[59] A prospective study of hospitalized patients with activity limitation (e.g., bedridden or hip fracture) identified the following five independent predictors of incident pressure ulcers in patients 55 years of age or older: nonblanchable erythema (stage I ulcer), lymphopenia, immobility, dry skin, and decreased body weight.[59] In general, impaired mobility is the most important risk factor for pressure ulcers.

PATHOPHYSIOLOGY

Four factors have been implicated in the pathogenesis of pressure ulcers: pressure, shearing forces, friction, and moisture. Sustained pressure over bony prominences (e.g., for more than 2 hours) results in ischemic damage to muscle and subcutaneous tissues. Shearing forces are tangential forces that lower the amount of pressure required to cause damage to the epidermis. Shearing forces occur, for example, when a patient is shifted in bed and dragged across underlying sheets. Repeated exposures to pressure will cause skin necrosis at lower pressures. The loss of subcutaneous tissue also lowers the threshold for skin breakdown caused by pressure. Friction is the force that results in skin abrasion when a patient is dragged across bedsheets, for instance. Moisture secondary to incontinence or perspiration can result in skin maceration and predispose the patient to pressure ulcers.[59] Any disease process leading to immobility and limited activity levels increases the risk of pressure ulcers. The aging skin predisposes patients to pressure ulcers: it is more susceptible to shearing forces, has decreased vascularity, and, in malnourished patients, has decreased subcutaneous fat. Furthermore, patients with cognitive impairment, depression, or spinal cord injury are likely to be immobile or unable to report symptoms of pain and discomfort, thereby delaying detection of an ulcer.

DIAGNOSTIC EVALUATION

Although stage I ulcers are not true ulcerations, their identification and early treatment are critical to prevent progression to stage II, III, or IV. Full-thickness injury is often manifested by eschar, which must be removed before staging can be completed. The most common sites for pressure ulcers in elderly patients include the scapula, iliac crest, sacrum, ischium, trochanter, lateral malleolus, heel, and lateral edge of the foot.[59] Pressure ulcers often present as a skin blister, which evolves to frank ulceration with exudate or plaque eschar over several days. The ulcer represents the tip of the iceberg as the ischemic injury extends in a widening triangular fashion down to subcutaneous tissue. Clinically, the lesion is identified as a stage III ulcer when the injury extends beneath the dermis to involve muscle fascial structures. In stage IV ulcers, undermining and sinus tracts may be present. Sinus tracts in stage IV lesions can be identified by probing the ulcer margin. Pressure ulcers also can become colonized by bacteria, resulting in cellulitis or bacteremia, especially in debilitated or immunocompromised patients.

PREVENTION AND MANAGEMENT

Preventive strategies for pressure ulcers include recognizing risk factors, decreasing the effects of pressure, assessing nutritional status, avoiding excessive bed rest, and preserving the integrity of the skin.[60] Patients at risk for an ulcer can be identified with the use of the Norton or Braden scales. These scales relate the risk of pressure ulcer to impaired sensory perception, increased skin moisture, decreased physical activity, immobility, poor nutrition, and friction and shearing force.[56]

Treatment principles include assessing the severity of the wound; reducing pressure, friction, and shearing forces; optimizing wound care; removing necrotic debris; managing bacterial contamination; and correcting nutritional deficits.[60] For all stages of pressure ulcers, the first step is to reduce pressure. The principles of stage I ulcer management apply to all patients with stage II, III, or IV ulcers [*see Table 7*].[61] For stage II, III, or IV ulcers, necrotic tissue is eliminated by either medical or surgical debridement.[56] Necrotic tissue is a barrier to epithelialization and serves as a nidus for infection.

The prevention and treatment of pressure ulcers in hospitalized and nursing home patients is a measure of quality of care. A multicenter study of hospitals in the United States identified six processes of care for prevention of pressure ulcers in at-risk patients: use of daily skin assessment; use of a pressure-reducing device; documentation of being at risk; repositioning for a minimum of 2 hours; nutritional consultation initiated for patients with nutritional risk factors; and staging of pressure ulcer.[62]

Wound Care

Wound management strategies such as use of wound dressings, debridement techniques, physical therapies, antibiotics, and antiseptics are used in the management of pressure ulcers. Occlusive dressings such as transparent films in hydrocolloid dressings or topical collagen improve healing of stage II pressure ulcers. The dressings remain in place for several days and facilitate epithelial migration.[58] Topical hydrocolloid and collagen treatments were found to have similar healing outcomes in a study of nursing home patients with stage II or III ulcers, in whom healing occurred in most cases within 8 weeks; however, hydrocolloid dressing has the advantage of being less expensive and is changed weekly rather than daily.[63]

A 2-week trial of a topical antibiotic such as silver sulfadiazine can be considered for clean pressure ulcers that are not healing or are continuing to produce exudate after 2 to 4 weeks of optimal management. Povidone-iodine should not be used, because it is toxic to fibroblasts. When necrotic tissue is present, debridement should be performed. Debridement can be accomplished

Table 7 Stages and Usual Treatments for Pressure Ulcers

Stage	*Presentation*	*Usual Treatment*
I	Nonblanchable erythema of intact skin; the heralding lesion of skin ulceration	Reduce pressure over ulcer and bony prominence; bedridden patients with sacral, ischial, or back ulcers are repositioned (e.g., side-to-side at 30° angle) at least every 2 hr. For chair-bound patients, use pressure-reducing device (e.g., foam, gel, or air), reposition hourly; treat dry skin with moisturizers (e.g., creams, lotions, ointments, or lubricants); protect skin from moisture; maintain proper positioning, transferring, and turning techniques; provide nutritional support; apply semipermeable polyurethane film (change weekly)
II	Partial-thickness skin loss involving epidermis, dermis, or both; the ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater	Debride devitalized tissue. Medical debridement: cleanse wound with saline; use wet-to-dry saline dressing, thin-film polymer dressing, or hydrocolloid dressing (wet-to-dry saline dressings when exudate is present, wet-to-moist when ulcer base is free of exudate and eschar; change hydrocolloid dressing every 4–7 days [reduces caregiver time]); schedule exercise for patients able to walk Surgical debridement: use scalpel if eschar or advancing cellulitis is evident; use thick foam mattress or air mattress as a support surface
III	Full-thickness skin loss involving damage or necrosis of subcutaneous tissue, which may extend down to but not through underlying fascia; the ulcer presents clinically as a deep crater with or without undermining of adjacent tissue	Intervention for stage II ulcers Medical: use hydrogel or alginate, moist gauze packs (saline), enzymatic debridement (noninfected ulcers), or topical antibiotic (if exudate or nonhealing persists after ≥ 2 wk of optimal care) for 2 wk (gram-negative, gram-positive, anaerobic coverage) Surgical: debride large eschar and devitalized tissue; use air-fluidized bed or low-air-loss bed (for deep, large, or multiple ulcers) as a support surface
IV	Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon or joint capsule)	Interventions for stage II–III ulcers Medical: systemic antibiotics for bacteremia, sepsis, advancing cellulitis, or osteomyelitis; suspect osteomyelitis in patients with deep ulcers that fail to heal with appropriate therapy and in patients with elevated temperature and white blood cell count or abnormal bone scan Surgical: create myocutaneous flap (after debridement) of large (wide) ulcers; use split-thickness skin grafts

with a sharp blade; by mechanical approaches such as wet-to-dry dressings, hydrotherapy, irrigation, or dextranomers; by enzymatic approaches (collagenase); or by autolytic techniques (synthetic dressing cover).[56,61] Once an ulcer is clean and epithelialization occurs, a moist wound environment should be maintained; wet-to-dry dressings are avoided. Hydrocolloid dressings or gels are continued until healthy skin appears.

Most stage I and stage II pressure ulcers heal within 60 days with the usual optimal therapies. The choice of dressings and debridement techniques has little impact on this good prognosis. In general, a moist saline gauze wound dressing is as effective as the application of hydrogel dressings. The choice of treatment for these ulcers is based on considerations of cost, convenience, and caregiver preferences.

Stage III and IV ulcers are often slow to heal or refractory to usual medical therapies. A promising technique for curing these ulcers is the sequential use of calcium alginate dressings and hydrocolloid dressings. The sequential approach has been shown to promote faster healing of ulcers than treatment with hydrocolloid dressings alone.[64] Another promising therapy is the use of topical treatment of pressure ulcers with nerve growth factor. In a 6-week clinical trial, compared to standard care, daily application of a solution of nerve growth factor on foot ulcers produced acceleration of ulcer healing.[65]

Pressure Relief

Pressure relief can contribute to prevention of pressure ulcers by two principal methods: (1) use of a conforming support surface to distribute the body weight over a large area and (2) use of an intermittent support surface in which inflatable cells are alternately inflated and deflated. Treatment of pressure ulcers also requires reduction of pressure to the damaged skin. Special support surfaces aimed at pressure redistribution (e.g., beds, mattresses, and cushions) are widely used.[66] Air or foam products may be helpful, but some patients require the use of specialized beds, such as an air-fluidized bed or a low-air-loss bed. Air-fluidized beds contain microspheres of ceramic glass, and warm pressurized air is forced up through the beads, causing them to take on the characteristics of a fluid. Patients float on the beads, with pressure reduced under prominences. Low-air-loss beds consist of large fabric cushions that are constantly inflated with air. The cushions of low-air-loss beds are fitted on a regular hospital bed frame, which is more practical for patient transfers. The use of these beds should be considered when patients have large, multiple, or full-thickness (stage III or IV) pressure ulcers; when an individual has fewer than two turning surfaces free of pressure ulcers; or when a patient has experienced recurrent ulceration and an inability to heal on a static pressure-reducing device.[66] In a clinical trial conducted in nursing homes, low-air-loss beds provided significantly better healing rates of stage II or greater pressure ulcers than foam mattresses.[67]

Malnutrition

EPIDEMIOLOGY

In the United States, protein-calorie malnutrition, also known as protein-energy undernutrition, is uncommon among community-residing elderly persons. In community surveys, however, the prevalence of nutrient-specific malnutrition is greater in people older than 65 years.[68] In the National Health and Nutrition Examination Survey III, median energy intake for elderly adults was below the recommended levels, with higher intakes for whites than for African Americans. Minorities tended to have

lower median energy, dietary, and mineral intakes than whites.[65] A survey of patients 65 years of age and older who were admitted to general medicine, orthopedic, general surgery, and neuroscience services revealed that 41% were well nourished, 44% had moderate risk for malnutrition, and 15% were malnourished.[69]

In long-term care, malnutrition has been identified in 50% of residents and is an independent predictor of subsequent mortality. Poor nutritional status and protein-calorie malnutrition have been associated with altered immunity, impaired wound healing, reduced functional status, increased health care utilization, and increased mortality. Weight loss of 5% or more of usual body weight is associated with increased morbidity and mortality.

RISK FACTORS AND ETIOLOGY

Nutritional disorders in older patients may be caused by numerous intrinsic and extrinsic factors. Many acute and chronic diseases predispose older patients to malnutrition (e.g., hyperthyroidism, diabetes, cancer, diseases of malabsorption, cardiovascular disease, renal disease, chronic obstructive pulmonary disease, and conditions associated with increased tumor necrosis factor or cachectin). Dementia is a common cause of undernutrition, as are adverse effects of medications (e.g., digoxin, some antidepressants). Furthermore, dysgeusia can be caused by medications (e.g., antihistamines, angiotensin-converting enzyme inhibitors, levodopa, lithium), zinc deficiency, and changes in sense of smell and taste resulting from physiologic aging. Inflammatory bowel disease, pancreatic insufficiency, and gluten enteropathy can cause malabsorption.[67] Other factors contributing to malnutrition include poor oral dentition, ill-fitting dentures, dry mouth, functional disability, and impaired vision. Less common causes are endocrine disorders (e.g., thyrotoxicosis or uncontrolled diabetes mellitus).

Studies of involuntary weight loss suggest that depression, cognitive impairment (dementia), gastrointestinal disorders (peptic ulcer or motility disorders), and cancer are the most common causes. Often, inflammation caused by infections and catabolic states contributes to the weight loss, hypoalbuminemia, and other serum markers of chronic disease.[70]

Psychosocial factors contribute to the risk of inadequate nutrition in older adults. Many older patients live on fixed incomes, have reduced access to food (social isolation), have poor knowledge of nutrition, or are dependent on others (caretakers or institutions) for food preparation. They may also suffer from depression, bereavement, dementia, or alcohol use. Other contributing factors that affect shopping for food and selecting or preparing food are impaired strength and impaired mobility.

PATHOGENESIS

During middle age, there is an increase in body mass and percentage of body fat in both men and women. At 70 years of age and beyond, declines in both lean body mass (sarcopenia) and body fat occur. Normal aging is associated with many physiologic changes that have a great impact on nutrition, notably in the gastrointestinal, sensory, hormonal, renal, and musculoskeletal systems. The complex interaction between these physiologic changes, chronic illness, and psychosocial and environmental factors determines the overall nutritional health of the elderly adult.[70]

Sarcopenia

The relevant changes associated with usual aging are a decrease in lean body mass (both skeletal and visceral), bone density, and total body water and an increase in total fat. From 25 to 75 years of age, lean body mass declines 19% in males and 12% in females, probably because of both inactivity and decreases in protein synthesis. Sarcopenia, or skeletal muscle wasting, results from a constellation of factors, including biologic changes associated with aging, inactivity, protein-calorie malnutrition, and catabolic diseases (e.g., congestive heart failure, chronic obstructive pulmonary disease, cancer, and hyperthyroidism). In both frail elderly and healthy elderly adults, type II, or fast-twitch, fibers are the only type of muscle fiber to atrophy. This selective atrophy of the type II fibers suggests that sarcopenia is caused by disuse, implying the potential for prevention. Sarcopenia, which is the result of a physiologic process, has to be differentiated from cachexia, a loss of both fat and muscle associated with chronic diseases such as malignancy.[70]

Anorexia of Aging

Anorexia of aging is a physiologic concept that explains the decrease in nutritional intake in old age; it can be regarded as a syndrome of inadequate nutritional consumption.[70] Anorexia of aging is caused by a combination of factors that interfere with the normal regulation of appetite and food consumption. Decreased olfactory discrimination, altered taste perception, and xerostomia diminish the flavor of food, which discourages the consumption of an adequate total caloric intake. Abnormal gastric emptying, decreased adaptive relaxation, and decreased gastric acid secretion probably caused by atrophic gastritis can interfere with absorption of vitamin B_{12} and iron, resulting in micronutrient deficiencies.

DIAGNOSTIC EVALUATION

Clinical Features

Major indicators of poor nutritional status include significant weight loss over time (10% or more of body weight in 6 months or involuntary weight loss), significantly low weight for height (e.g., 20% below desirable weight, or a body mass index of less than 19 kg/m^2), serum albumin of less than 3.5 g/dl, change to dependence in two activities of daily living (e.g., bathing and dressing), sustained inappropriate food intake (e.g., excessive alcohol use or dietary imbalance), reduction in midarm circumference to less than 10th percentile of ideal circumference, decrease in triceps skinfold thickness to less than 10th percentile of ideal thickness, and presence of nutrition-related disorders (e.g., osteoporosis, vitamin B_{12} deficiency, or folate deficiency).

Laboratory Tests

The serum albumin level is generally the most reliable, although nonspecific, indicator of chronic malnutrition. An albumin level below 3.5 g/dl, an unexplained normocytic anemia, and a very low serum cholesterol level (< 160 mg/dl) are compatible with a diagnosis of protein-calorie malnutrition. Reduced levels of serum transferrin and prealbumin and a low total lymphocyte count also suggest protein-calorie malnutrition.

PREVENTION AND MANAGEMENT

For healthy older people, a well-balanced diet is recommended and includes adequate amounts of calories, protein and essential amino acids, essential fatty acids, fiber, and complex carbohydrates and sufficient amounts of minerals and vitamins. The food-guide pyramid may be used as a general guideline for counseling patients about a balanced diet (http://www.nal.

usda.gov/fnic). Patients who are chronically ill, who have recent weight loss resulting from illness or surgery, or who have an unbalanced diet should be advised to take a multivitamin and mineral supplement daily. Calcium supplementation to ensure a daily consumption of 1 g or more of elemental calcium, along with vitamin D supplementation, is advisable. When treating chronically ill patients, education of the patient and family caregivers is an important step in preventing malnutrition. Patients should take advantage of nutritional programs available in the community, such as Meals on Wheels (http://www.projectmeal.org) and Title III nutrition services. A referral to the local office on aging or the Area Agency on Aging (http://www.aoa.dhhs.gov) will enable the patient to access these services.

Patients with social, physical, and psychological risk factors for malnutrition can be readily identified using screening instruments and a targeted physical examination.[70] Subjective global assessment (SGA), a validated measure of nutritional status based on medical history and physical examination findings, accurately classifies patients as severely malnourished, moderately nourished, or well nourished. SGA combines elements of the patient's nutritional history (weight loss in previous 6 months) and physical examination (e.g., muscle wasting) to generate a valid and subjective impression of nutritional status (http://www.eneph.com/feature_archive/nutrition/v25n4p190.html).[70,71] When combined with a review of biochemical indicators of nutritional status, this information should drive the process of further evaluation and treatment of protein-calorie malnutrition.

Balanced Diet and Nutritional Supplements

A well-balanced diet with calorie-dense foods should be prescribed, along with vitamin and mineral supplements. Commercially available canned nutritional supplements containing 250 to 350 calories of a nutritionally balanced formula are recommended as between-meal supplements (e.g., midmorning and midafternoon) for undernourished older patients. In hospitalized or community-dwelling elderly patients, oral protein and energy supplements reduce all-cause mortality.[72] Available interventions include frequent meals and snacks, enhanced flavors of favorite foods, protein-calorie supplements, multivitamins, appetite stimulants, and enteral and parenteral nutrition [*see Table 8*]. In a randomized, controlled trial of 88 nursing-home patients, an oral supplement was well accepted and resulted in increased daily protein and energy intake, body weight, and nutritional status in most malnourished patients and in those at risk for malnutrition.[73]

Acutely ill, delirious, or demented patients are at great risk for oropharyngeal dysphagia and aspiration pneumonia. A swallowing evaluation may help enhance the safety and success of oral feeding.

Despite their effectiveness, nutritional oral or enteral supplements are often underutilized in hospitalized patients. A prospective cohort study found that 20% of elderly patients had an average daily in-hospital nutrient intake of less than 50% of their calculated maintenance energy requirements. These patients often had orders for nothing by mouth, and canned supplements were often ordered but not consumed by the patients.[74]

Nutritional Support

High caloric intake is recommended for ill adults (i.e., 25 to 30 kcal/kg/day in women and 30 to 35 kcal/kg/day for men). Even higher amounts of calories are needed in severely malnourished or catabolic individuals.[72] Nutritional support (i.e., nonoral feeding) is considered if prevention or treatment of protein-calorie malnutrition will improve prognosis or quality of life and if the nutritional requirements cannot be met with oral foods and supplements [*see Table 8*].[75] If the gastointestinal tract is functional, enteral nutrition (via nasogastric or nasoenteric tubes) is preferred over parenteral nutrition. Percutaneous tube placement is indicated when long-term tube feeding is not anticipated for weeks to months or for patient comfort. Total parenteral nutrition (intravenous feeding) is essential for survival in patients who cannot eat for extended periods of time and who are not candidates for enteral support (e.g., because of bowel obstruction). However, gastrostomy tube feedings are not recommended for patients with severe dementia, given the absence of data to show that tube feedings improve clinical outcomes in such patients.[76]

Table 8 Nutritional Support

Route	*Patient Characteristics*	*Nutritional Intervention*
Oral	Alert, normal swallowing, mildly to moderately malnourished	High-calorie, high-protein diet; calorie-dense foods (high fat); nutritional supplements between meals
Intravenous fluids	Acutely ill, decreased oral fluid intake, unable to swallow	Glucose solution with electrolytes for ≤ 48 hr as sole nutritional source
Enteral	Oropharyngeal dysphagia, cognitive dysfunction, critically ill (e.g., intubated), or severely malnourished; ability to resume oral feeding within a few weeks (or cyclic use)	Nasoenteric tube feedings (continuous or cyclic) with lactose-free enteral feeding solutions (normal-calorie or normal-calorie, high-nitrogen solutions)
Peripheral parenteral nutrition	Oral and nasoenteric routes temporarily contraindicated (e.g., acute pancreatitis, bowel obstruction)	Peripheral intravenous infusion with isotonic glucose-electrolyte-lipid solution
Total parenteral nutrition	Severely malnourished; hypermetabolic state (e.g., sepsis syndrome); enteral route contraindicated or inadequate	Central intravenous catheter (e.g., in subclavian vein): infusion of high-calorie, hypertonic, balanced (protein, carbohydrate, and amino acid) solutions
Percutaneous endoscopic gastrostomy	Severely malnourished; oropharyngeal dysphagia contraindicates oral feeding (e.g., stroke or advanced dementia) for prolonged time (e.g., ≥ 2 mo) or indefinitely*	Enteral solutions: isotonic or hypertonic (limited by diarrhea; high- or normal-nitrogen formulas)

*Severely demented patients not included.

Correction of Nutrient Deficiencies

Specific nutrient deficiencies result from dietary imbalance, chronic disease, or medications. The most commonly recognized examples are vitamin B_{12} (cobalamin), calcium, and iron deficiencies. Cobalamin deficiency can occur in the absence of classic hematologic or neurologic findings of pernicious anemia. A low serum cobalamin level accompanied by an elevated serum level of methylmalonic acid supports the diagnosis of B_{12} deficiency. Dietary calcium deficiency is common in elderly women. Dietary supplementation is often needed to maintain a daily consumption of 1.2 to 1.5 g of elemental calcium. Vitamin D supplementation, 800 IU daily, is often recommended for the treatment of elderly patients who lack sun exposure or have evidence of osteoporosis or osteomalacia. Iron deficiency is more common in the elderly because of long-term internal or external causes of blood loss.

Sensory Impairment

Hearing and visual losses are the most important and common sensory impairments in elderly people. However, they often go undetected because physicians frequently do not screen for them. Sensory impairments adversely affect the older patient's physical, cognitive, and social functioning. In community-dwelling elders, mood and social relationships are particularly affected by vision impairment, and performance of daily activities is strongly reduced by hearing impairment.

HEARING IMPAIRMENT

Epidemiology

Hearing loss affects between 25% and 40% of the population 65 years of age or older. The prevalence rises with age, ranging from 40% to 66% in patients older than 75 years and more than 80% in patients older than 85 years.[77] Significant hearing loss has been reported in 70% to 90% of nursing-home residents. Hearing loss is associated with emotional and social dysfunction, including depression and social isolation.[77]

Etiology

Hearing loss is categorized as sensorineural, conductive, or mixed. Sensorineural hearing loss is caused by cochlear or retrocochlear diseases and is characterized by decreased thresholds for both air and bone conduction. Presbycusis is the most common cause of sensorineural hearing loss in elderly patients. Other causes include ototoxicity from medications (e.g., aminoglycosides and chemotherapeutic agents), infections involving the eighth cranial nerve, and injury caused by vascular events or tumors of the eighth cranial nerve. Most hearing loss in older adults is sensorineural and caused by presbycusis; however, cerumen impaction and chronic otitis media may be present in up to 30% of elderly patients with hearing loss.[78]

Presbycusis is a bilateral, symmetrical cause of hearing loss at high frequencies, especially at frequencies above 2,000 Hz, and is associated with impaired speech discrimination and loudness recruitment. Presbycusis begins in middle age and causes hearing loss that is typically gradual and bilateral. The most severe changes occur in the inner ear, which is responsible for sensitivity, sound, understanding of speech, and maintenance of equilibrium. Signs and symptoms of presbycusis include a history of progressive high-frequency hearing loss and difficulty in understanding speech, especially in noisy environments. The cause of presbycusis remains uncertain. Presbycusis is also associated with an auditory processing disorder, which makes understanding speech more difficult than would be predicted on the basis of loss of peripheral hearing sensitivity.

Conductive hearing loss occurs when there is impairment of sound transmission to the inner ear. Lesions of the external or middle ear may cause conductive hearing loss. Typically, bone-conduction thresholds are better than air-conduction thresholds. The most common causes of conduction hearing loss are cerumen impaction and otosclerosis. Less common causes include tumors and degenerative disorders (e.g., Meniere disease), trauma, vasculitis, and hemorrhagic disorders.[79]

Diagnostic Evaluation

Hearing impairment may be obvious during casual conversation with the patient. Patients with hearing impairments should be first examined for cerumen impaction. Six independent factors for hearing loss can be identified by brief self-reports of patients 55 to 74 years of age. These factors are (1) age 70 years or older, (2) male gender, (3) 12 or more grades of education, (4) having seen a doctor for deafness or hearing loss, (5) inability to hear a whisper across a room, and (6) inability to hear a normal voice across the room.[80] Several office measures of hearing impairment are useful to clinicians. The whisper test can be performed by asking patients to repeat a short list of whispered numbers from an examiner positioned 2 ft behind them. Although a reasonably sensitive measure, the whisper test lacks reproducibility. A more quantitative approach is a handheld otoscope with a built-in audiometer. This device has high sensitivity and specificity but is expensive and requires some skill to be used correctly.

Patients with hearing loss should undergo formal audiologic assessment. The evaluation includes a pure-tone audiogram to document the decibel loss across frequency ranges and to determine whether the loss is sensorineural or mixed.

Management

Management of hearing loss may be surgical, medical, or rehabilitative. Patient education is important with any treatment. The treatment of presbycusis entails referral to specialists for counseling regarding hearing strategies, emotional support from family members and health care professionals, and the use of hearing aids or various types of assistive listening devices. Referrals for hearing loss are made to audiologists, otolaryngologists, or both. Audiologists have expertise in hearing testing, use of assistive listening devices (e.g., telephone amplifiers, infrared systems, pocket talkers, and visual/tactile alerts for the doorbell, telephone, and smoke alarm), and the selection and fitting of hearing aids.[77] Surgical approaches are indicated for patients with obstructive lesions of the external auditory canal and remedial causes of conductive hearing loss. Stapedectomy is the most common surgical intervention for otosclerosis. Cochlear implants are of value to patients with profound sensorineural deafness for whom a conventional hearing aid is not feasible.[77,79] A change in medical treatments may be indicated for patients who experience sensorineural hearing loss. Serial evaluations of hearing are helpful for patients who are receiving high doses of potentially ototoxic drugs (e.g., anticancer drugs and high-dose loop diuretics).

Most patients with sensorineural or cochlear disease will benefit from aural rehabilitation. Aural rehabilitation includes treatment modalities such as hearing aids, auditory training, and

training in lip reading. Hearing aids remain the usual treatment of patients with sensorineural hearing loss. A variety of devices are available, including programmable hearing aids and amplification circuits that reduce distortion. Hearing aids may fit entirely within the external auditory canal, attach over the patient's earlobe, or sit behind the ear.[77] Assistive listening devices include television listening systems, alerting devices, telephone amplifiers, large-area amplification systems, and remote microphone systems. Remote microphone systems with headsets can be purchased at radio supply stores. They are inexpensive, practical, and capable of improving communication with even severely hearing-impaired patients.

To improve communication with a hearing-impaired patient, an attempt should be made to get the listener's attention before speaking, to face the listener directly to afford visual cues, to reduce background noise, to use facial expressions and gestures, to speak slowly and clearly, to speak only slightly louder than normal and not shout, to rephrase the message if the listener does not understand rather than repeating it, to alert the listener to changes in the topic, and to not turn and walk away while talking.

VISION IMPAIRMENT

Age-related changes in vision, especially presbyopia or farsightedness, are common causes of increasing vision impairment. Other important changes that affect vision include reduced pupillary dilatation, which contributes to poor night vision; discoloration of the crystalline lens; and changes in the vitreous fluid, which may produce dots in the visual field. With normal aging and refractive error, little change occurs in acuity that cannot be corrected or compensated for with ease. Major causes of vision impairment associated with low vision or blindness (i.e., vision worse than 20/200 in either one or both eyes with correction) include cataracts, glaucoma, macular degeneration, and diabetic retinopathy [*see 9:VI Diabetes Mellitus*].

In a study of older adults from three communities, the prevalence of functional blindness increased from 1% in persons 71 to 74 years of age to 17% in those 90 years of age and older. Functional vision impairment increased from 7% in persons 71 to 74 years of age to 39% in those 90 years of age and older.[81] Racial differences are reflected in patterns of vision loss, with whites being more likely to have age-related macular degeneration and African Americans being more likely to have primary open-angle glaucoma. African Americans have a twofold greater prevalence of blindness and vision impairment than whites; there is no difference in prevalence by gender. In nursing homes, the prevalence of bilateral blindness is 17% and the prevalence of vision impairment (i.e., worse than 20/40 but better than 20/200) is 19%. The prevalence of blindness is 29% in nursing-home residents 90 years of age and older.[82]

Cataract

A cataract is an opacity or clouding of the crystalline lens that may affect visual acuity, contrast sensitivity, and light perception. Senile cataracts are often classified as cortical, subcapsular, or nuclear. Although the prevalence of opacification of the lens increases with aging to nearly 100% of those older than 90 years, functional impairment occurs in only half of people with cataracts. Cortical or cuneiform cataracts present as translucent spokes, flakes, or wedges of opacity around the nucleus. Cortical cataracts progress slowly and may eventually involve the entire cortex of the lens. Subcapsular cataracts are more common in younger patients and are associated with use of corticosteroids. They often appear as irregular granules and crystals with various colors. Nuclear cataracts are the most common in elderly white patients; they appear as a yellow or brown discoloration and are associated with increasing myopia and vision deterioration.

Risk factors and etiology The possible risk factors for cataract include exposure to ultraviolet B radiation, a history of diabetes mellitus, alcohol consumption, cigarette smoking, a vitamin-deficient diet, and corticosteroid use.[83] The prevalence of age-related cataract increases from less than 5% in persons younger than 65 years to 46% in persons 75 to 85 years of age.[83] Cigarette smoking has been shown to be an important independent risk factor for age-related cataract. In a prospective cohort study of nearly 21,000 physicians free of cataract at baseline, the relative risk of age-related cataract in men was 36% lower in those who never smoked. Smoking cessation appears to reduce the risk of cataract primarily by limiting total dose-related damage to the lens.[84]

Diagnostic evaluation Initial symptoms of a cataract include glare and poor contrast sensitivity. Contrast sensitivity is the ability to discern subtle variations in shade. It can be tested through the use of figures that vary in contrast, luminance, and spatial frequency.[85] The glare is caused by excess refraction of light rays penetrating the clouded lenses and is most troublesome in bright sunlight or during night driving. Decreased contrast sensitivity is manifested by difficulty distinguishing field objects in poorly illuminated settings. Near visual acuity is more often reduced in posterior subcapsular cataract, and patients often complain of disabling glare during daytime. Patients with cortical cataract complain of glare with oncoming headlights while driving at night. A nuclear sclerotic cataract affects distance vision more than near vision. Nuclear and cortical cataracts have distinct characteristics on examination. Nuclear cataract may be invisible against the red reflex until the cataract is fairly mature. The cataract then appears as a poorly defined central fog. The cortical cataract is typically composed of radially oriented, sharply defined, spokelike opacities.[83]

Management Symptomatic cataracts are managed surgically. The decision whether to perform cataract surgery is based on the likely degree of visual improvement that will occur and its impact on the quality of life weighed against the risks and cost of surgery. A cataract is considered to be clinically significant if it causes a decrease in visual acuity or function that interferes with the patient's performance of activities of daily living.[85] Older drivers with cataracts are at greater risk of vehicular crashes than are cataract-free drivers. Drivers who undergo cataract surgery, compared to those who elect not to have surgery, have a 50% reduction in the risk of a motor vehicle accident.[86] Most cataract surgery in the United States is performed under regional or local anesthesia in an ambulatory setting. Extracapsular cataract surgery with implantation of a posterior chamber lens implant is the procedure of choice. Approximately 95% of patients without other ocular comorbidity who undergo cataract extraction achieve a visual acuity of 20/40 or better.

Glaucoma

Glaucoma is a chronic progressive optic neuropathy characterized by excavation of the optic nerve head and loss of visual

field in the midperiphery. Two anatomic classifications of glaucoma are based on whether the angle of the anterior chamber is open or narrow; the more common open-angle glaucoma is a chronic disease, whereas the less common angle-closure glaucoma is usually an acute disease.

Risk factors and etiology The major risk factor for open-angle glaucoma is thought to be elevation of the intraocular pressure beyond the statistical norm of 21 mm Hg.[87] The high intraocular pressure originates from an increased resistance to drainage of aqueous humor through the trabecular meshwork.[87]

However, many patients with glaucoma have normal-pressure glaucoma characterized by pressures of less than 21 mm Hg.[87] Putative risk factors for open-angle glaucoma include high intraocular pressure, African-American ancestry, positive family history, myopia, and possibly diabetes and systemic hypertension.[87]

Angle-closure glaucoma results from obstruction of aqueous humor flow from the posterior chamber through the pupil into the anterior chamber through the pores of the Schlemm canal. Production of aqueous humor continues, resulting in very high intraocular pressures. The main characteristic of the angle-closure glaucomas is a relative pupillary block with a forward bulging of the iris face, thereby obstructing the aqueous humor flow at the chamber angle.[86] Acute angle-closure glaucoma can be precipitated by the use of dilating eyedrops and is a medical emergency. In contrast, primary open-angle glaucoma is an insidious disease most often discovered during routine examinations.

Diagnostic evaluation Symptoms of glaucoma include seeing halos around lights and experiencing reduced vision under low levels of illumination. Glaucoma is frequently asymptomatic and detected only during ophthalmologic examination; unless it comes to clinical attention, glaucoma will cause progressive loss of visual field and eventually lead to blindness. The diagnosis of glaucoma is based on an eye examination that includes tonometry, gonioscopy (which examines the angle of the anterior chamber), inspection of the optic disk and nerve fiber layer, and visual-field testing. With injury to the optic nerve, there is the appearance of cupping of the optic disk, with an increase in the cup-to-disk ratio and visual dysfunction in the midperipheral field of vision. As the disease progresses, deterioration of central visual functions, including acuity, becomes evident.

Intraocular pressure is measured by determination of the force required to flatten the central cornea (applanation). Applanation tonometry can be performed with an optical measuring device or an electrical strain gauge.

Management The treatment of glaucoma includes both medical and surgical approaches. Intraocular pressure is reduced either by decreasing the amount of aqueous humor produced by the ciliary body or by increasing its outflow through the trabecular meshwork, through the uveoscleral pathway, or through a surgically created path.[85] Medical treatments are targeted at the physiology of intraocular pressure. The cell membranes of the nonpigmented ciliary epithelial cells contain α-adrenoceptors and β-adrenoceptors, carbonic anhydrase, and sodium and potassium activated adenosine triphosphatases (ATPases). By stimulation or inhibition of these enzymes or receptors, the active transport of aqueous humor across the blood-aqueous barrier can be modulated to reduce intraocular pressure.[87]

Topical eyedrops are the most common medical treatment of open-angle glaucoma. Agents either decrease the production of aqueous or increase its outflow and absorption. Therapeutic options include: topical carbonic anhydrase inhibitors (e.g., brinzolamide); beta-adrenergic blockers (e.g., timolol, betaxolol); alpha$_2$-adrenergic agonists (e.g., brimonidine); and prostaglandin analogues (e.g., latanoprost and bimatoprost).[88,89]

The aim of medical treatment is to obtain a target pressure at which progression of visual-field defects is halted.[85] Combinations of these therapies can be attempted if treatment with one of these agents fails to reduce or maintain target pressures or if there is progression of visual-field defects.

Surgical therapy for glaucoma includes iridectomy to enhance flow of aqueous humor in the treatment of angle-closure glaucoma and, for open-angle glaucoma, argon-laser therapy to improve outflow through the trabecular meshwork. Surgery for glaucoma is usually reserved for patients in whom target pressures cannot be achieved with medical or laser therapy. Good success rates have been described with argon-laser trabeculectomy, but additional surgery is often needed.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) causes sudden worsening and distortion of central vision, or scotoma, progressing rapidly over weeks or months until scarring is complete and no further vision is lost (legal blindness).[90] AMD impairs central vision that is required for reading, driving, face recognition, and all fine visual tasks. The insidious loss of central vision results in the initial symptoms of reduced visual perception and visual sensitivity to light and gradual progression to legal blindness despite preservation of peripheral vision.

Risk factors and etiology Epidemiologic studies show that cigarette smoking increases the risk for the development of AMD and the consumption of dietary carotenoids and vitamins A, C, and E may prove protective. However, cigarette smoking is the only modifiable risk factor for AMD and maculopathy that has been consistently identified in cohort studies.[91,92]

Diagnostic evaluation AMD is highlighted by the presence of abnormalities in the macular area. These abnormalities include soft drusen, yellow-white deposits of extracellular material containing debris external to the retinal pigment epithelium, and hyperpigmentation or hypopigmentation (or both) of the retinal pigment epithelium. Neurosensory detachment, retinal hemorrhages, and retinal scarring gradually result in decreased visual function of photoreceptors in the central vision.[93] Late maculopathy includes both dry and neovascular AMD. The dry form of AMD is more common and occurs with atrophy of the retinal pigment epithelium. Neovascular, or exudative, AMD is characterized by choroidal neovascularization with vascular leakage into subretinal spaces. Recognition of the less common exudative AMD is important because argon-laser photocoagulation is effective in reducing loss of visual acuity.[93]

Management There is no effective treatment of the dry form of AMD. Clinical trials, however, have found that laser photocoagulation of exudative forms of AMD decreases the rate of severe vision loss and preserves contrast sensitivity.[93] Laser photocoagulation therapy is the only treatment of AMD with proven long-term benefit. However, other therapies have shown promise, including photodynamic therapy (verteporfin), which delays or prevents loss of vision during at least 1 year of

follow-up in patients with predominantly classic neovascular lesions.[93] To identify patients who may benefit from laser therapy, home monitoring for symptoms of scotoma or distorted vision is performed with the use of an Amsler grid.[93]

Treatment of AMD with oral antioxidants may prove effective for subgroups of nonsmoking patients who have either (1) extensive intermediate-size drusen and noncentral geographic atrophy in one or both eyes or (2) advanced AMD or unilateral vision loss caused by AMD.[91] In a clinical trial, supplementation with vitamins C and E, β-carotene, and zinc slowed progression to advanced AMD.[91]

Iatrogenic Illness

Iatrogenic, or physician-induced, illness results from a diagnostic procedure or therapeutic intervention that is not a natural consequence of the patient's disease.[94] Iatrogenic illnesses include complications of drug therapy and of diagnostic or therapeutic procedures, nosocomial infections, fluid and electrolyte disorders, and trauma.[95]

POLYPHARMACY

The most common documented cause of iatrogenic illness is adverse drug reactions, usually associated with polypharmacy.[95] Adverse drug events are more likely to occur in elderly patients because of the age-related changes in drug metabolism, the occurrence of multiple comorbidities, and the use of polypharmacy. The incidence of adverse drug reactions increases with advancing age and number of chronic diseases requiring drug therapy. The concomitant use of several medications increases the risk of drug interactions, unwanted effects, and adverse reactions. Drug-drug interactions resulting in hospitalization have been attributed to hypoglycemia associated with use of the oral hypoglycemic agent glyburide, digoxin toxicity associated with use of the antibiotic clarithromycin, and hyperkalemia in patients treated with angiotensin-converting enzyme inhibitors.[96] Suboptimal drug prescribing, including the inappropriate use or underuse of medications, is common in older outpatients and inpatients and is associated with significant morbidity.[97] Adverse drug events occur in nursing-home patients treated with opioids, antidepressants, antipsychotic agents, and antiseizure medications.[98] A United States consensus panel has identified medications or medication classes that should generally be avoided in persons 65 years age or older because the agents are either ineffective or pose unnecessarily high risk for older persons when safer alternatives are available.[99] The panel's recommendations also included medications to be avoided in older persons known to have specific medical conditions.[99] Many of these agents are psychotropic and anticholinergic drugs (http://www.seniorcarepharmacist.com/inappropriate).

Age-Related Changes in Drug Metabolism

Many medications should be used with special caution in elderly patients because of age-related changes in drug pharmacokinetics (drug disposition) and pharmacodynamics (target-tissue effects). Although drug absorption is not reduced in healthy elderly persons, absorption of medications can be reduced by disease states (e.g., malabsorption) or concomitant administration of drugs that decrease absorption of medications (e.g., antacids). Drug distribution is altered by aging, primarily because of body-composition changes, with a decrease in total body water and lean body mass and a relative increase in body fat. Consequently, water-soluble drugs achieve a higher serum concentration, whereas lipid-soluble drugs have a prolonged elimination half-life. This change is especially important in regard to drugs that are lipid soluble and penetrate the blood-brain barrier (e.g., diazepam). Although serum protein levels are not significantly affected by aging, many elderly patients have reduced levels of serum albumin resulting from acute or chronic disease or malnutrition. Consequently, displacement of a drug by one that binds very highly to albumin enhances the delivery of that agent to the target site, thereby increasing the risk of an adverse reaction. For example, bleeding (excessive anticoagulation) may occur when patients treated with warfarin are given drugs such as sulfas or phenytoin.

A decrease in hepatic blood flow with usual aging will decrease the rate of metabolism of drugs that undergo a high degree of first-pass extraction (e.g., propranolol). Aging and diseases affect phase I hepatic metabolism, the microsomal enzyme mixed-function oxidase system. Active metabolites of drugs that undergo phase I metabolism may prolong the effects of the parent medication (e.g., diazepam). Phase II metabolism, the conjugation of drugs, is not significantly affected by aging. Consequently, the elimination of agents that undergo phase II metabolism is unaffected by normal aging.

Drug elimination is mainly influenced by renal function. The age-associated decrease in renal function, which results in decreased creatinine clearance, necessitates lower maintenance doses of renally excreted drugs in elderly patients.

The effect of aging on target-organ responsiveness to medications is less well established. However, decreased beta-adrenergic receptor sensitivity and increased sensitivity to opiates is well established. Many elderly patients are also more susceptible to the adverse effects of anticholinergic drugs, notably constipation, dry mouth, and delirium.

Diagnostic Evaluation

Because of unpredictable effects of aging on the metabolism of drugs, physicians should suspect an adverse drug reaction whenever any new symptom occurs. Also, blood levels of medications that have narrow therapeutic windows (e.g., aminoglycosides) should be considered.

Prevention and Management

The prevention of iatrogenic illness from inappropriate drug prescribing begins with an understanding of the rational use of medications in elderly patients. Consensus criteria for appropriate drug prescribing offer useful guidelines.[99]

In general, prescribing the fewest medications at the lowest needed dosage is a rational approach to the prevention of iatrogenic illness. Knowing the pharmacology of prescribed drugs and the age-related alterations in drug disposition and tissue sensitivity and using lower than standard doses of most drugs when the therapeutic dose is uncertain should help physicians avoid adverse drug reactions. When prescribing a new medication for an elderly patient, a practical approach is to use the following criteria:

1. Determine whether the drug is lipid or water soluble.
2. Determine whether the drug is highly bound to albumin.
3. Determine whether the drug undergoes cytochrome P-450 metabolism (substrate, inducer, or inhibitor of microsomal enzymes).

Table 9 Long-term Care Options

Site	*Patient Characteristics*	*Comments*
Home (independent living, house, apartment)	Independent performance of ADL; stable chronic diseases; adequate social support network	Acute medical illness may require short-term home care (skilled nursing services); home safety evaluation for environmental hazards
Home with formal support services	Needs assistance with performance of ADL (e.g., bathing, dressing); adequate social support network; acute illness or convalescence from hospitalization; requires skilled nursing care or physical therapy	Skilled services covered for limited period by Medicare; custodial services not covered long-term (e.g., home health aide); risk of elder abuse or neglect because of caregiver strain or loss of informal supports (e.g., illness of spouse)
Community services	Physically or cognitively impaired (limits performance of ADL); limited finances; limited informal supports; caregivers need respite (relief from caregiving)	Options: adult day care; nutritional programs (e.g., Meals-on-Wheels); protective services (suspected elder abuse); transportation services; case management services (professionally coordinated); categorized services (e.g., PACE) for eligible patients
Residential care facilities (assisted living, continuing care retirement communities)	Patients for whom independent living is either no longer desired or feasible; retirees, persons able to perform ADL with minimal or no assistance	Assisted living is ideal for demented patients who are too functional for a nursing home but are unable to safely live at home; retirement communities are vertically integrated, permitting residents to move from independent living (apartment) to assisted living or nursing care as needed
Rehabilitation/hospital	Categorical illness (e.g., stroke or hip fracture); able to tolerate physical therapy (e.g., ≥ 3 hr daily); good informal home supports; likely return home	Interdisciplinary care with focus on returning patient to independent living; patients must be able to participate in rehabilitative services and demonstrate potential to improve ambulation and performance of ADL
Skilled nursing facility	Dependence in ADL or ambulation preventing discharge to home; requires skilled nursing care or physical therapy; too impaired for rehabilitation hospital (noncategorical illness, cannot perform therapy for ≥ 3 hr daily); inadequate social supports at home	The choice of skilled nursing facility, home care, or subacute care unit is often an issue of patient choice, disease severity, availability of services (geographic), and family or caregiver availability; limited Medicare coverage for skilled services forces many patients to eventually enter a long-term care facility or return home
Subacute care unit	Similar to patients in skilled nursing care but typically requiring augmented professional services (e.g., hyperalimentation, respiratory care, peripheral intravenous catheters, or increased nursing staff time)	Subacute care units bridge the gap between acute hospitalization and the patient's return home; market forces have encouraged growth of these units (e.g., hospitals reduce patient length of stay and are reimbursed for cost-based skilled nursing care); short-term stay (< 2 mo) is typical
Long-term care facility	Dependent in performance of ADL; unable to return home (temporarily or permanently) to independent living; ineligible for skilled, subacute, or rehabilitative services; inadequate social supports (e.g., lives alone, no caregivers)	Self-pay and Medicaid are usual sources of payment; many states offer a Medicaid waiver program to provide home services to frail patients who would otherwise require nursing home placement
Palliative (hospice) care	Patients with terminal illness (prognosis ≤ 6 mo) (e.g., metastatic cancer or end-stage heart or renal failure)	Provides comfort measures in home (or inpatient unit where available); Medicare covers palliative (comfort-related) not curative (e.g., elective surgery) services; underutilized by patients (delayed recommendation by physician; home hospice services limited compared with skilled nursing care)

ADL—activities of daily living PACE—Program for All-inclusive Care of Elderly

4. Determine whether the drug is renally excreted (use lower maintenance doses in older patients and in patients with renal insufficiency).

This information can be found by literature searches, a review of newsletters on drug prescribing, or consultation with a pharmacologist or clinical pharmacist.

MEDICAL ERRORS

Medical errors are common in the care of elderly hospitalized patients. These errors often involve incorrect drug dispensing that sometimes causes patient morbidity or mortality. Most medical errors are the result of systems errors in hospitals. Concerns over the reported incidence of medical errors led the Institute of Medicine to release a report advocating dramatic, systemwide changes in hospitals, such as the use of computerized medical information systems and other support systems, to reduce the rate of errors.[100] Computerized medical information systems improve antibiotic selection, limit the emergence of antibiotic-resistant pathogens, and lessen the risk of adverse drug events.[100]

NOSOCOMIAL INFECTION

Nosocomial pathogens are primarily transmitted through contact with hospital or nursing home personnel. Urinary tract, skin (intravascular), lung, and wound infections are common examples of nosocomial infection. Of growing concern for elderly patients are infections with resistant strains of gram-negative bacilli, methicillin-resistant *Staphylococcus aureus*, and vancomycin-resistant enterococci. Resistant urinary tract infections are common after prolonged indwelling urinary catheterization.

Risk Factors and Etiology

Factors promoting nosocomial pneumonia include gastric aspiration, spread of pathogens by poorly cleansed hands of medical and nursing personnel, fecal-oral spread of pathogens, and cross-contamination from other patients. Patients with physical debility, patients who have had a prolonged hospital stay, and

patients who have been exposed to broad-spectrum antibiotics are at risk for nosocomial infections.

Vancomycin-resistant enterococci are likely transmitted from patient to patient by the unwashed hands of health care workers, by contaminated medical equipment, or on environmental surfaces (e.g., bed rails or blood pressure cuffs). Nosocomial pneumonia results from colonization of the upper respiratory and gastrointestinal tracts and occurs most often in critically ill and ventilator-dependent patients.

Prevention and Management

Nosocomial infection can be prevented by washing hands and cleaning medical equipment (e.g., stethoscopes) between patient contacts, wearing gloves during invasive procedures or contact with wounds or mucous membranes, using aseptic techniques when inserting or changing urinary catheters, isolating infected patients (e.g., in nursing homes), elevating the patient's head (to lessen the risk of aspiration), replacing broad-spectrum antibiotics with narrow-spectrum antibiotics on the basis of bacterial-sensitivity reports, and limiting the use of urinary catheters. Prophylactic antimicrobial therapies and routine catheter replacement are not recommended.[95]

Long-term Care

Long-term care refers to the provision of comprehensive health care services, including personal health and social services, delivered over an extended period to people with limited functional capacity.

AVAILABLE CARE SERVICES

The spectrum of long-term care ranges from home and social services provided to patients living in the community to residential and long-term care facilities [*see Table 9*].

In the United States, most elderly persons live in the community. Only 5% at any time are residing in long-term care facilities (i.e., nursing homes). However, the probability of nursing home use increases sharply with age: 25% of persons 85 years of age and older reside in nursing homes, and the lifetime risk of entering a nursing home for people who turned 65 years of age in 1990 is estimated at 40%.[101] About 25% of individuals in the United States will spend at least 1 year in a nursing home, with more women than men having total lifetime nursing home use of 5 years or more.[101] The high cost of institutional care and the growing number of frail Americans have provided an impetus to develop less expensive levels of care (e.g., residential care facilities), ambulatory health centers (e.g., Program for All-inclusive Care of Elderly [PACE]), and community services that will enable the frail elderly patient to remain at home [*see CE:IX Palliative Medicine*].

ADVANCE DIRECTIVES

Health care institutions are required to ascertain whether patients have advance directives and to include copies of them in the medical record. A living will is an advance directive by which a person specifies the circumstances in which life-sustaining treatment is to be provided or discontinued in the event of terminal illness if the person is unable to communicate with health professionals. A durable power of attorney for health care is an advance directive by which a person designates a proxy to represent his or her wishes if he or she loses decision-making capacity. In discussions with physicians, patients should communicate their wishes for end-of-life care, including cardiopulmonary resuscitation, intensive care (e.g., ventilator support), and nutritional support during acute or end-stage illness [*see CE:IX Palliative Care*].[102]

The author participates in the speakers' bureau of Pfizer, Inc.

The drug haloperidol, which is discussed in this chapter, has not been approved by the FDA for use as a treatment of delirium.

X REHABILITATION OF GERIATRIC PATIENTS

Stephanie Studenski, m.d., m.p.h.
Cynthia J. Brown, m.d., p.t.

The Role of the Generalist in Rehabilitation

The generalist plays a key role in the recovery of function in older patients who have had disabling illnesses. In most health care settings other than formal inpatient rehabilitation units, the primary care physician is the coordinator of medical rehabilitation services. Access to and duration of rehabilitation services are undergoing rapid change as Medicare and managed-care policies become more restrictive. Medicare has converted rehabilitation services in the inpatient, postacute, and home settings to prospective payment systems with extensive regulatory and documentation requirements.[1] The primary care physician must be able to assess rehabilitation potential, determine specific patient needs, and match them with the appropriate setting to optimize patient care.

To fulfill this responsibility, the physician must be able to assess the degree of disability, the effect of comorbidity on function, the possibility of recovery, and the indications for specific rehabilitation therapies.[2] Rehabilitation service planning is usually based on a model of diagnosis and treatment that differs from that of traditional medical care. The revised World Health Organization International Classification of Functioning, Disability and Health (ICIDH-2) can be used to assess the causes of disability, plan treatment approaches, and determine the outcomes of care [*see Figure 1*].[3] In this framework, abnormalities in organ system structure or physiologic function are called impairments. They lead to difficulties with individual activities and participation in society. Environmental factors (e.g., stairways and crosswalks) and personal factors (e.g., culture and education) can influence the effect of organ system impairments on activities and participation. Thus, a patient who has recently had a stroke may have impairments of sensory, motor, and language function that limit mobility and self-care, and these limitations can interfere with work and family roles.

The rehabilitation assessment includes evaluation of impairments in body structure and function, as well as the patient's activity limitations and participation goals. The treatment plan includes efforts to reverse or modify impairments, such as decreased strength, and to enable the patient to adapt to activity limitations, such as difficulty in walking. An evaluation of the effectiveness of the service may include measurement of gains in organ function, activities, and participation. The evaluation should also take into account environmental and personal factors. The generalist team can also implement early exercise-rehabilitation services during hospitalization for acute illness. This practice has been shown to contribute to improved function.[4] A form of preventive rehabilitation termed prehab has recently been shown to reduce the onset of new disability in high-risk older adults, but this service is not currently covered by Medicare.[5]

Stroke

Each year, more than 700,000 people in the United States suffer a stroke. Stroke is the leading cause of major long-term functional limitation. Each year, more money is spent in the rehabilitation of stroke patients than is spent on the rehabilitation of any other patient group. Guidelines for poststroke rehabilitation have been developed by an interdisciplinary panel. These guidelines consist of evidence-based recommendations for assessment, referral, and patient management.[6]

Assessment

The primary care physician should assess the type of stroke, the extent of neurologic deficits [*see Table 1*], the presence or absence of comorbid conditions, and the patient's prestroke functional status. Stroke guidelines provide extensive recommendations to help assess these features, measure recovery, and determine the benefits of rehabilitation.[6] A compendium of the recommended assessments has been gathered into a so-called stroke toolbox, which can be found on the Internet (http://www2.kumc.edu/coa/Stroke_Toolbox/stroke-tool.htm).[7]

Selecting the Best Setting for Care

The setting for rehabilitation should be determined as soon as the patient's neurologic function and medical condition are reasonably stable. The appropriate setting is determined by the presence, severity, and complexity of the patient's functional limitations; cognitive status (especially ability to learn); ability to tolerate up to 3 hours of therapy daily; need for close medical monitoring; and the availability of social support [*see Figure 2*]. Under managed care, stroke rehabilitation is shifting from settings that provide acute rehabilitation to settings that provide subacute care, sometimes with a negative effect on outcome. Prospective payment in all settings has led to shorter duration of service, with unclear effects on recovery of function.[1,8,9] Community-based rehabilitation programs may be appropriate at some point in the recovery process for many persons with stroke and can lead to improved rates of personal care independence.[10]

Organized inpatient multidisciplinary stroke care is defined

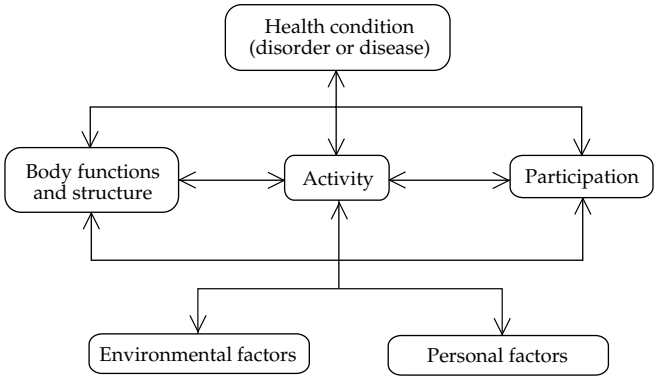

Figure 1 **Current understanding of interactions between the components of ICIDH-2.**[3]

Table 1 Selected Results of the Neurologic Examination of a Patient with Stroke[6]

Type of Deficit	*Tests Used*	*Key Findings*	*Effect of Persistent Deficit on Rehabilitation*
Altered level of consciousness	Repeated observation and testing of responses to external stimuli; Glasgow Coma Scale	Drowsiness, stupor, coma	An altered level of consciousness is a contraindication to rehabilitation
Cognitive deficits in higher functions, memory, ability to learn	Observation; questions to probe mental functions; standardized screening test	Various degrees and types of deficits	A severe deficit is a contraindication to rehabilitation; a moderate deficit may impede rehabilitation and must be incorporated into the rehabilitation management plan
Motor deficits	Tests of strength and tone in muscles of the upper and lower extremities and face	Various degrees and sites of weakness, incoordination, abnormal movements	Motor deficits are the primary indications for rehabilitation; absence of any voluntary movement is a sign of poor prognosis
Disturbances in balance and coordination	Tests of coordination, sitting, standing, walking	Various degrees and types of deficits	Deficits impede but are not a contraindication to rehabilitation
Somatosensory deficits	Specific tests for sensory modalities (e.g., pain, touch); complex sensory tests	Various degrees and types of deficits	Deficits impede but are not a contraindication to rehabilitation
Disorders of vision	Tests of pupillary responses, ocular motility, optic fundus, visual fields, acuity	Visual loss or field defect; conjugate gaze deficits	Severe visual loss or ocular motility disturbances impede rehabilitation
Unilateral neglect	Observation; description of complex picture by patient; sensory testing	One side of body or external environment is ignored (often clears spontaneously)	Neglect impedes but is not a contraindication to rehabilitation
Speech and language deficits	Observation of spontaneous speech and language use, including language comprehension and, if possible, simple reading and writing skills	Aphasia, dysarthria, apraxia of speech	Severe problems in communication impede rehabilitation; treatment becomes an integral part of rehabilitation
Swallowing disorder (dysphagia)	History; test of ability to swallow liquids and solids; cineradiography with barium swallow	Abnormal swallowing mechanism; aspiration	Dysphagia requires careful attention if aspiration and pneumonia are to be prevented
Affective disorder	History; observation; depression screening test	Symptoms of depression	Depression may impede rehabilitation if it is not treated
Pain	Description of pain by patient; observation of restrictions in range of motion; observation of facial expressions or resistance to movement	Location, severity, and precipitating causes of pain	Pain impedes rehabilitation and may require specific treatment or medication

as care from a team of physicians, nurses, and therapists whose work is coordinated through regular weekly meetings and is dedicated to rehabilitation. A systematic review has shown that organized inpatient multidisciplinary stroke care, compared with conventional inpatient medical care or multidisciplinary care in a different setting, reduces mortality, institutionalization, and dependency. For every 100 patients receiving organized inpatient multidisciplinary stroke rehabilitation, an additional five will return home in an independent state.[11] A large multisite observational study showed that adherence to Agency for Health Care Policy and Research (AHCPR) stroke rehabilitation care guidelines results in improved motor recovery and increased patient satisfaction.[12,13] A pooled analysis found that the use of care pathways to enhance adherence to guidelines appears to improve stroke recovery, but evidence is limited to observational studies.[14] Coordinated discharge planning with support for patients' needs after release can shorten length of stay without short-term adverse effects on disability or need for institutionalization. However, the effect of early discharge on long-term outcome is not known.[15]

Age itself does not influence recovery. Problems such as memory loss, diminished ability to follow instructions, urinary or fecal incontinence, and visuospatial deficits such as unilateral neglect (i.e., ignoring one side of the body or failing to be attentive to people and objects on one side of the body) are associated with poorer outcome.[16] The prognosis is also affected by coexisting or associated medical problems, such as delirium and fecal impaction. Simple assessment measures such as the Orpington Prognostic Scale [*see Figure 3*], which contains items for motor function, sensory function, balance, and cognition, can be completed in 5 to 10 minutes and are easily obtained in the first weeks after stroke.[7] The initial Orpington score is a strong predictor of functional status at 3 and 6 months. A score of 2.4 or less, suggesting mild deficits in the first 2 weeks after stroke, is associated with an 80% chance of being independent in personal care and homemaking activities at 6 months, whereas a score of 4.4 or higher, suggesting more severe early deficits, is associated with about a 20% chance of achieving independence in these activities.[17] Motor evoked potentials elicited by transcranial magnetic stimulation may be able to predict potential for motor recovery after stroke, according to preliminary studies.[18]

KEY ASPECTS OF REHABILITATION

Optimal rehabilitation for stroke starts in the acute care setting. Mobilization and efforts at self-care should be instituted as soon as they are medically feasible. Urinary continence and bladder function programs should be initiated; indwelling catheters should not be used unless they are medically necessary, as in cases of urinary retention or cases involving wounds that must be kept clean. An educational program aimed at informing the patient and the patient's family about stroke and stroke recovery should be started.

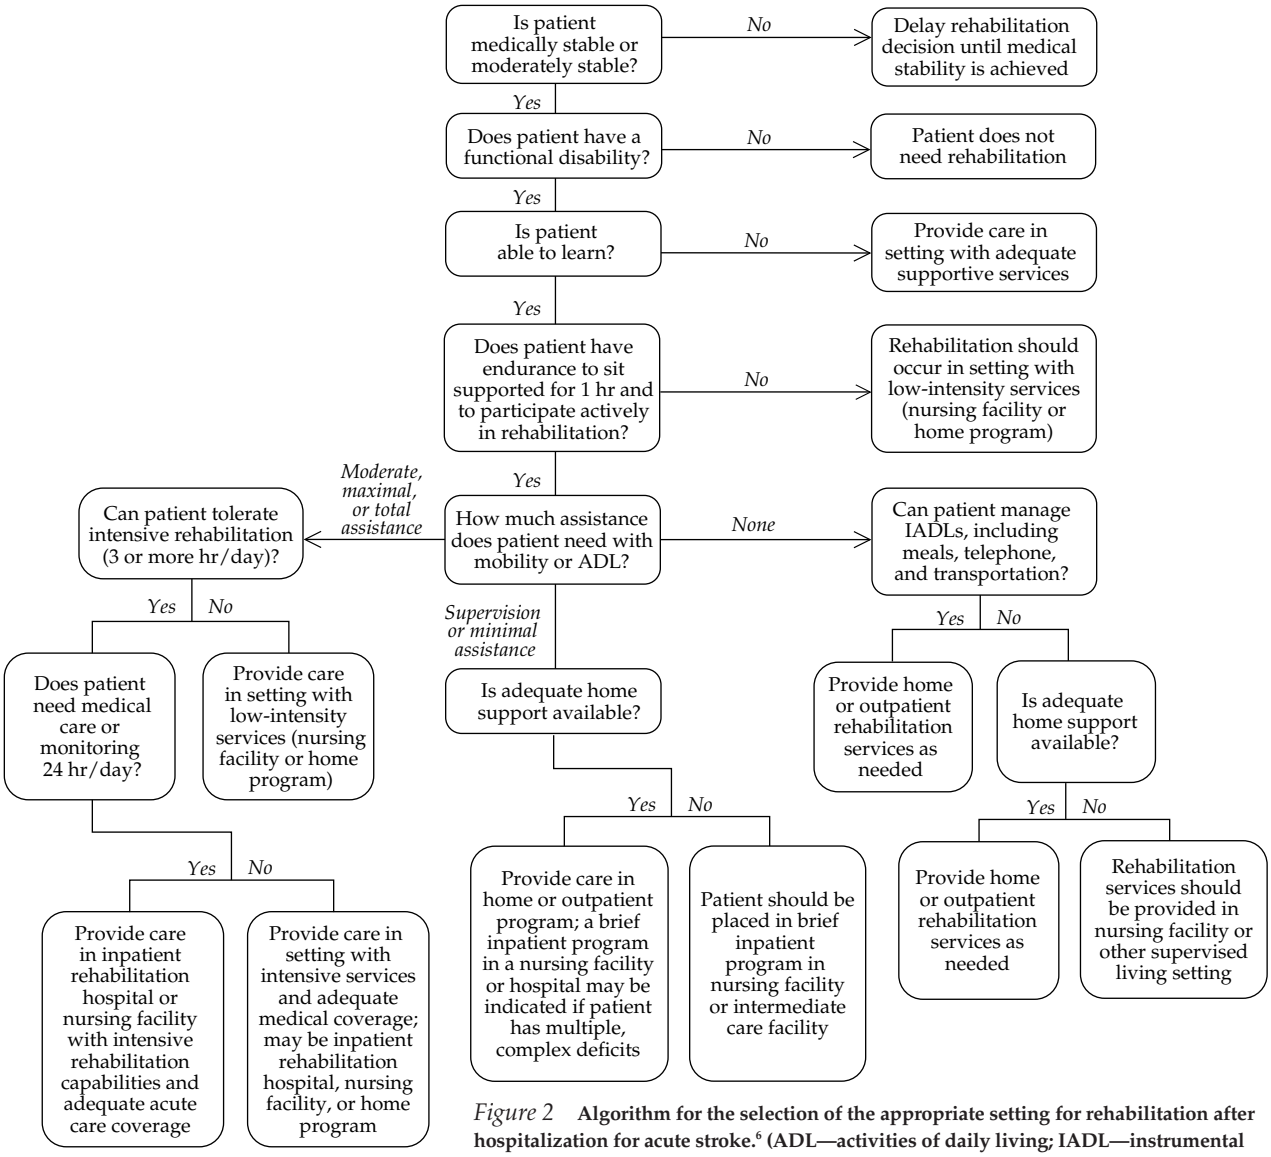

Figure 2 **Algorithm for the selection of the appropriate setting for rehabilitation after hospitalization for acute stroke.[6] (ADL—activities of daily living; IADL—instrumental activities of daily living)**

The next stage in rehabilitation is the defining of functional goals on the basis of the patient's own goals, deficits, and potential. Therapies are devised to ameliorate impairments in strength, range of motion, endurance, balance, sensorimotor coordination, and mobility; to facilitate self-care and household maintenance; to relieve pain; and to educate the patient and caregivers on maintaining functional gains. There are many proposed approaches to physiotherapy after stroke, and no single strategy is superior.[19] However, a clinical trial comparing usual home health care with an intensive home-based program that included endurance training, strengthening, balance, and upper extremity activities found greater gains in mobility, balance, and endurance in the intensive-therapy group.[20] High-intensity strength training improves functional performance after stroke.[21] Complex areas of cognition, such as attention, are affected by stroke[22]; formal cognitive rehabilitation interventions are under development, but results have been inconsistent.[23,24] Adaptive devices can help the patient eat, bathe, use the toilet, dress, walk, transfer between the bed and chairs and commode, and engage in leisure activities. Other aspects of treatment include further education and involvement of the patient and family and attention to the emotional and psychological sequelae of stroke.[25,26] Telephone support for caregivers may improve caregiver skills and satisfaction with the health care system.[27] Good coordination and communication must be maintained during transitions between rehabilitation settings.

Until recently, there was little scientific basis for stroke rehabilitation practice. Previously, it was believed that nerve cells were irreplaceable and that their death led inevitably to losses of neurologic function. Studies in animal models and in humans have now demonstrated, however, that after nerve cells die, their functions can be taken over by other nerve cells. Thus, after destruction of motor neurons controlling the hand, specific rehabilitation approaches can induce new motor neurons to control hand movement. Neuroplasticity in the adult after neurologic injury has been demonstrated by use of functional magnetic resonance imaging and transcranial magnetic stimulation.[28] The potential for neuroplastic change is revolutionizing approaches to neurologic rehabilitation.[29] Systematic studies of treatment approaches that maximize neural reorganization are

INSTRUCTIONS: Circle the appropriate response.

A. Motor deficit in arm
Lying supine, patient flexes shoulder to 90° and is given resistance.

0.0 = MRC Grade 5	(normal power)
0.4 = MRC Grade 4	(diminished power)
0.8 = MRC Grade 3	(movement against gravity)
1.2 = MRC Grade 1–2	(movement with gravity eliminated or trace)
1.6 = MRC Grade 0	(no movement)

B. Proprioception (eyes closed)
Locates affected thumb:
0.0 = Accurately
0.4 = Slight difficulty
0.8 = Finds thumb via arm
1.2 = Unable to find thumb

C. Balance
0.0 = Walks 10 ft without help
0.4 = Maintains standing position (unsupported for 1 min)
0.8 = Maintains sitting position
1.2 = No sitting balance

D. Cognition
Score 1 point for each correct answer:

_____ 1. Age of patient
_____ 2. Time (to the nearest hour)
I am going to give you an address, please remember it and I will ask you later: *42 West Street*

Figure 3 **The Orpington Prognostic Scale is useful for estimating stroke recovery.[82]**

under way. One successful approach is based on intensive, repetitive practice using rhythm or robot aids for the upper extremity and treadmill training for the lower extremity.[30,31] Another method is to force the use of the damaged extremity by limiting the use of the uninvolved extremity, an approach termed constraint-induced movement therapy.[32]

The potential for neural reorganization is also changing the timing of neurologic rehabilitation. Previously, rehabilitation focused on the immediate poststroke period, because the natural history of recovery suggests that neurologic status plateaus 6 months after injury. However, studies have now documented significant gains in function in stroke patients with long-term impairment who undergo treatments that focus on repetitive and forced practice.[33-35]

Neuropharmacologic interventions that promote neural reorganization are being studied as a means to enhance neurologic recovery. One area of interest is the use of stimulants such as amphetamines, which have been shown to accelerate motor and sensory recovery in animal models. It is postulated that increased central noradrenergic—rather than serotoninergic or dopaminergic—mechanisms are the neurochemical basis for motor and sensory recovery secondary to treatment with amphetamines. Human studies have been small and have yielded inconsistent results.[36,37] A small trial has suggested that levodopa treatment after stroke may enhance motor recovery.[38]

PREVENTING COMPLICATIONS AND FUTURE STROKES

Stroke and other disabling conditions can have physical, functional, and psychological complications [*see Table 2*]. Mobilization of the patient is always preferable to inactivity; when in-

activity is inevitable, however, bed exercise and skin care protocols should be instituted. Prevention of deep vein thrombosis during immobilization is a standard component of care after stroke. Low-dose or low-molecular-weight heparin is the preferred treatment, but warfarin, intermittent pneumatic compression, and elastic stockings are acceptable alternatives [*see 1:XVIII Venous Thromboembolism*].[39]

In patients with a swallowing disorder, long-term enteral feeding and cessation of oral feeding may prevent aspiration; however, this measure is not always effective and has many ethical implications for quality of life. Incontinence may be exacerbated by one or more factors: a mobility problem that prevents the patient from getting to the bathroom, constipation, a urinary tract infection, or drug-induced urinary retention.[40] Stroke can cause an uninhibited bladder, characterized by frequent episodes of urgency and incontinence. Treatment with bladder relaxants may help, but these drugs can worsen confusion.

Seizures can occur at any time after a stroke as a result of scarred brain tissue, which serves as a focus of irritation. Standard anticonvulsants are indicated. Major depression occurs in at least one third of patients after stroke. The guidelines for poststroke rehabilitation emphasize the need to screen for and treat this commonly overlooked complication.[6] Increased socialization, counseling, and medication are appropriate. Prophylactic antidepressant medication has been proposed for the prevention of depression after stroke and is currently under study.[41,42] Cognitive impairment caused by poststroke depression may improve with treatment of the depression.[43] Preferred medications are those that cause less sedation and fewer anticholinergic side effects, such as most selective serotonin reuptake inhibitors or low-level anticholinergic tricyclic antidepressants such as nortriptyline. Methylphenidate, given in the morning and at noon, can reduce apathy and increase motivation early in poststroke rehabilitation. It has a rapid onset of effect [*see Table 3*].

Shoulder pain and dislocation are especially likely in the patient with a flaccid upper extremity, because the joint capsule is normally stabilized by the surrounding muscles. Measures to prevent dislocation include supporting the shoulder in a normal position, using a pull sheet rather than the underarm to reposition the patient in bed, and restricting range of motion to 90° of flexion and abduction. Reflex sympathetic dystrophy (chronic regional pain syndrome) occurs in as many as 25% of patients with hemiplegia. Early signs are exquisite cutaneous sensitivity and diffuse swelling of the hands. Treatment includes the use of compression gloves, anti-inflammatory agents, steroids, analgesics, injections for sympathetic nerve blockade, and, most important, aggressive and consistent range-of-motion exercises.[44] Spasticity is a common long-term complication of stroke. Because stroke is a form of upper motor neuron lesion, gradually increasing sensitivity of the lower motor neuron after stroke can lead to hypertonia, muscle spasm, pain, and functional limitations. Current treatments for spasticity (e.g., surgery or medications such as baclofen) have limited benefit. Botulinum toxin injections have been tested in clinical trials, with mixed results.[45-47]

Stroke recurs in 7% to 10% of survivors every year. Screening

Table 2 Assessment and Management of Complications of Stroke and Other Disabling Conditions[6]

Complication	*Cause*	*Assessment*	*Intervention*
Pressure sores	Immobility, malnutrition, incontinence	Monitor skin over pressure sites	Mobilize patient; provide protective bedding and pads; keep skin dry; maintain good nutrition and local skin care
Deep vein thrombosis	Inactivity, loss of muscle pump action in calf	Look for swelling and pain in leg; however, there are often no findings	Prevent with low-dose or low-molecular-weight heparin
Swallowing disorders	Cranial nerve dysfunction	Observe swallowing; listen for hoarse, wet voice; perform cineradiography	Reposition patient; alter food consistency; suggest chewing adaptations; switch to enteral feeding
Incontinence	Mobility problems, infection, impaction, drug side effects, urinary retention, outlet obstruction	Assess frequency and volume of incontinent episodes; assess postvoiding residual volume and ability to get to toilet; perform urinalysis and rectal examination; monitor drugs	Treat superimposed problems; institute toileting program; give oxybutynin for uninhibited bladder
Depression	Local brain effects, sensory isolation, situational factors	Administer depression screens	Give antidepressants
Shoulder pain	Loss of muscle tone around the shoulder, poor repositioning technique	Monitor symptoms and shoulder stability	Use careful positioning technique; give analgesics; conduct ROM exercises
Contractures	Increased muscle tone, immobility	Look for brisk DTRs, clonus, reduced ROM of joints	Conduct ROM exercises; use appropriate braces, heat/cold modalities, antispasticity drugs (baclofen), motor point blocks, botulinum injections, serial casting
Deconditioning	Immobility, depression, malnutrition	Test for reduced endurance and orthostatic hypotension; look for lack of motivation and poor exercise tolerance	Mobilize patient; conduct graded exercise program with scheduled rest breaks
Secondary osteoporosis	Dietary factors, smoking, immobility, medication	Test functional status; perform the following laboratory tests: vitamin D level, CBC, TFT, PTH level, 24 hr urine; measure bone mass	Modify diet; begin hormone therapy; conduct weight-bearing exercises and mobilize patient
Obesity	Dietary factors, immobility	> 20% of ideal body weight	Institute aerobic program; modify diet

CBC—complete blood count DTR—deep tendon reflex PTH—parathyroid hormone ROM—range of motion TFT—thyroid function tests

Table 3 Pharmacologic Therapy for Poststroke Depression

Drug Class	*Drug Name*	*Initial Dose*	*Maintenance Dose*	*Controlled Trial Evidence in Stroke*	*Side Effects*	*Advantages*	*Comments*
Heterocyclics	Nortriptyline	10–25 mg	25–100 mg	Yes	Sedation, orthostasis	Blood levels measurable; goal, 50–150 ng/ml	—
	Desipramine	10 mg	25–100 mg	No	Orthostasis	Less sedation; blood levels measurable; goal, 125–300 ng/ml	—
	Trazodone	25–50 mg	25–200 mg	Yes	Hypotension; sedation	Useful in sleep disturbance	—
Selective serotonin reuptake inhibitors	Fluoxetine	5–10 mg	5–60 mg	No	Nausea; tremor; insomnia	Long half-life	Morning dosing
	Sertraline	25 mg	—	No	Nausea; tremor; insomnia	Few drug interactions; not sedating	Morning dosing
	Citalopram	10 mg	20–40 mg	Yes	Nausea; tremor	Few drug interactions	Morning dosing
	Paroxetine	5–10 mg	5–40 mg	No	Nausea; tremor	Mild sedation	Evening dosing
Stimulants	Methylphenidate	2.5 mg morning and noon	5–30 mg	Yes	Nervousness; insomnia; anorexia	Rapid onset; useful in early period for treatment of apathy	Recommended for short-term use during rehabilitation only; change to other preparation for long-term use

and intervention to prevent recurrence must be considered in all patients except, perhaps, those with severe brain damage.[35] Carotid endarterectomy may be indicated if stenosis of 70% or more is detected in a vessel that feeds a large area of viable brain tissue. Anticoagulation with warfarin in patients with atrial fibrillation significantly reduces risk of stroke; in one meta-analysis, patients receiving warfarin had a third as many strokes as did control subjects.[48] Warfarin therapy is the standard of care for patients with atrial fibrillation who are not at increased risk of bleeding or falls. For an acceptable risk-to-benefit ratio, the international normalized ratio (INR) should be maintained at 2 to 3. Antiplatelet agents such as aspirin, ticlopidine, clopidogrel, and combinations of aspirin and dipyridamole can be used instead of warfarin. Control of hypertension and hyperlipidemia and smoking cessation reduce the risk of stroke.

Peripheral Vascular Disease and Amputation

REHABILITATION FOR PERIPHERAL VASCULAR DISEASE

Although little is known about the benefits of exercise in patients with critical leg ischemia, multiple prospective studies have demonstrated the effectiveness of exercise training in patients with claudication. Enrollment in a medically supervised training program, as well as treadmill testing before the initiation of training, is recommended because patients often have other comorbidities, such as coronary artery disease or diabetes, that put them at higher risk for an adverse event during exercise. The exercise training entails walking until the patient experiences a moderate degree of discomfort; after the onset of discomfort, the patient takes a short rest, then resumes walking. Three to five such sessions are conducted each week of training. The ultimate goal is for the patient to perform 50 minutes of intermittent walking. Improvement has been noted in pain-free walking time, maximal walking distance, and the ability to carry out routine daily activities.[49] Despite use of exercise, pharmacotherapy, angioplasty, and bypass surgery, 5% to 10% of patients with peripheral vascular disease will ultimately require amputation.

SELECTING CANDIDATES FOR PROSTHESES

About 50,000 lower-extremity amputations are performed each year in the United States. In the past, most amputations were performed because of trauma; today, as many as 90% are performed because of peripheral vascular disease. Lower-extremity ischemia often occurs in the setting of widespread atherosclerosis, which includes cerebrovascular, cardiovascular, and renovascular disease. Patients with diabetes are at increased risk for amputation because of vascular disease, peripheral neuropathy that causes the feet to become insensitive, and an increased vulnerability to infection. Thus, the candidate for amputation is very likely to have potentially disabling comorbid conditions.[50]

Prosthetic rehabilitation is most likely to succeed in patients who are ambulatory before undergoing amputation, can bear weight on the contralateral leg, have stabilized medical conditions, and are able to follow the caregiver's instructions. In patients with prostheses, the presence of a natural knee joint significantly reduces the energy cost of walking; therefore, every effort should be made to preserve the joint by performing a below-the-knee procedure, even though this procedure is associated with a higher risk of poor wound healing than above-the-knee amputation. The prognosis for successful prosthetic ambulation is best for patients who undergo unilateral below-the-knee amputation. Patients who undergo a second amputation or

those in whom other major disabling conditions develop are most likely to regain the ability to walk if they were able to walk after the initial amputation. Older patients who undergo bilater-al above-the-knee amputation rarely learn to walk with prostheses.

KEY ASPECTS OF REHABILITATION

Rehabilitation comprises three phases: preoperative preparation, postoperative wound healing, and prosthetic ambulation. Before undergoing amputation, the patient should be educated about the healing and mobilization process and be prepared for life as an amputee. After surgery, the primary care physician should focus attention on the common problems of the hospitalized older patient, including polypharmacy, immobility, delirium, and depression. Measures that promote proper wound healing should be instituted and the stump prepared for weight bearing and mobilization. Traditionally, weight bearing on the residual limb was discouraged until full healing took place; this sometimes resulted in prolonged inactivity for the patient. It is now recognized that earlier mobilization using a rigid, removable dressing and sometimes a temporary artificial leg can simultaneously protect the fragile healing tissues and prevent the complications caused by prolonged immobility.[50] Such complications include deconditioning and flexion contractures, which may limit the patient's success with a prosthesis.

Successful prosthetic ambulation depends on selection of an appropriate device, progressive mobilization, and management of concurrent problems. The permanent prosthesis for an older adult must be lightweight and easy to put on and take off. A comfortable prosthesis fits snugly and has one or more liners, socks, sleeves, or removable attachments. There are many options available for the components (materials, feet, and suspensions) of prostheses. The primary care physician should form a relationship with a reputable prosthetist who can integrate the technical issues involved in designing a prosthesis with the medical and functional status of the older amputee. The prosthetic limb should be adapted to existing comorbidity; for example, patients with heart failure or advanced renal disease often have wide variations in limb edema that must be accommodated by altering the size of the socket and by use of fillers. Progressive mobilization is accomplished by gradually lengthening the period during which the prosthesis is worn and changing the means of external support from parallel bars to walker to cane. Because increasing activity affects diabetes control, salt and water balance, myocardial oxygen demand, and local weight-bearing tissues, the physician should monitor the patient's glucose levels, weight, orthostatic blood pressure, and anginal symptoms and should adjust therapy as needed. The stump must be examined for signs of skin breakdown, edema, and infection.

PREVENTING COMPLICATIONS AND FUTURE AMPUTATIONS

About 25% of patients who undergo unilateral amputation because of peripheral vascular disease and 50% of patients who undergo the procedure because of diabetes will need to have the other leg amputated within 5 years.[51] Care of the contralateral extremity is essential; every amputee should have a program of regular foot care, should check for foot lesions, and should practice control of peripheral vascular disease. Footwear should protect and support the foot. Shoes should be wide at the toe and very roomy, and they should have cushioned soles or inserts. Many athletic shoes meet these criteria. Measures used to control vascular disease include cessation of smoking, control of diabetes, management of cholesterol levels, and a program of exercise of the lower extremity.[52] Invasive treatment of claudication can either delay or prevent the development of critical ischemia, which may lead to a decreased rate of amputation; however, further study of this approach is needed.[53,54]

Hip Fracture

CONSEQUENCES OF HIP FRACTURE

Each year in the United States, hip fracture occurs in about 250,000 persons, of whom 75% are women. Age-adjusted rates of hip fracture are higher in nursing home residents and patients with dementia.

Hip fracture in elderly patients results in increased mortality and loss of functional independence. One-year mortality is nearly 25%.[55] In those who survive, early decline in function is common; up to 50% require temporary nursing home stays. Although most survivors return to their original functional status within 1 year, about 25% require long-term care.[56]

TYPES OF HIP FRACTURE AND REPAIR

Hip fractures occur at the femoral neck in about one third of cases. Such fractures are likely to disrupt the blood supply to the femoral head, particularly if the fractures are displaced; this in turn may lead to avascular necrosis or nonunion. Nondisplaced fractures of the femoral neck are usually treated by internal fixation with pins or nails, whereas displaced fractures may be treated either by reduction and fixation or by hemiarthroplasty with a prosthetic femoral head. Selected patients with significant underlying bony acetabular disease may benefit from complete hip arthroplasty for displaced fracture of the femoral neck.

Two thirds of hip fractures occur across the trochanter. Intertrochanteric fractures are often associated with significant bleeding into the surrounding soft tissue. Surgical treatment usually consists of open reduction and internal fixation with a variety of mechanisms, such as compression screws or sliding nails.

Preoperative stabilization of concurrent medical problems and early surgical intervention is usually recommended. Complications such as deep vein thrombosis, pneumonia, pressure sores, urinary tract infection, malnutrition, delirium, and deconditioning should be prevented or treated.[57] Delirium has been shown to be an independent predictor of poor outcome up to at least 1 year after injury.[58]

KEY ASPECTS OF REHABILITATION

Rehabilitation should be offered to all patients in the absence of near-terminal conditions or possibly to bedridden patients with end-stage dementia. Such patients may be treated nonsurgically with early mobilization from bed to chair, control of pain, and treatment of complications. Patients with mild to moderate dementia can benefit from rehabilitation after fracture.[59,60]

After hip fracture, the care setting may not influence outcome as much as it does in stroke; in an observational study, outcomes in settings involving intensive rehabilitation were not better than outcomes in subacute programs.[61,62] Well-defined home-based programs can be effective.[63] Coordinated multidisciplinary approaches to inpatient rehabilitation of older patients have been found to have borderline effectiveness, with about a 10% reduction in combined outcomes such as death or institutionalization.[64]

Early intervention with early surgery, minimal narcotic analgesia, intense daily therapy, and multidisciplinary management reduced length of stay without affecting function or survival.[65]

The goal of rehabilitation is to regain prefracture function. Short-term goals include pain control, prevention of medical complications, maintenance of range of motion and muscle strength in other joints, early mobilization, and gradual improvement in the movement of the affected hip. Early mobilization reduces all the complications of immobility, including bedsores, constipation, loss of strength, and risk of thromboembolism. If a prosthetic femoral head is placed by the posterior approach, the risk of dislocation is reduced by the intentional limitation of hip motion to 90° of flexion, with no internal rotation and no adduction. Shortening of the affected leg can occur after fracture, resulting in an abnormal gait, which can be corrected with shoe lifts.

Weight bearing after hip fracture is controversial. Surgical factors and surgeons' preferences affect recommendations. Pain, the hazards of inactivity, and the practical difficulties in limiting weight bearing must also be considered. In one study, both weight-bearing and non–weight-bearing exercises during hospitalization after a hip fracture resulted in similar improvements in strength, balance, and functional performance.[66] Early mobilization with unrestricted weight bearing after hip fracture results in mild spontaneous weight shifting and accelerates hospital discharge without adversely affecting healing or putting the patient at higher risk for additional surgery.[67,68] A synthesis of clinical trials comparing mobilization strategies after hip fracture, including twice-daily physical therapy, treadmill training, neuromuscular stimulation, and early mobilization, found no significant effects on the outcomes assessed.[69]

Pharmacologic approaches to improving rehabilitation outcomes in hip fracture are also under study. A clinical trial of human growth hormone in the immediate postfracture phase demonstrated reduced functional decline and increased rates of return to independent living in the subset of patients older than 75 years[70]; however, another large trial found that 6 months of oral growth hormone therapy did not improve physical function.[71]

PREVENTING FUTURE FRACTURES

Efforts should be made to prevent future fractures. Preventive practices include treatment of osteoporosis [*see 3:VI Diseases of Calcium Metabolism and Metabolic Bone Disease*], evaluation and management of any tendency toward falling,[72] and instruction on how to avoid injury in the event of a fall.[57] Higher levels of physical activity have been shown to be associated with lower rates of hip fracture in epidemiologic and case-control studies. As yet, no prospective, randomized clinical trials of physical activity as a preventive approach to hip fracture have been carried out. Hip protectors have been extensively studied, with varied results. For patients living in the community, hip protectors do not appear to decrease the incidence of hip fractures. However, for those living in an institutional setting where the incidence of fracture is high, hip protectors may offer some benefit. Compliance remains an issue.[73]

Rheumatoid Arthritis

Management of rheumatoid arthritis involves pain relief, preservation of strength and joint function, and prevention of deformities [*see 15:II Rheumatoid Arthritis*]. Patients with arthritis can safely participate in exercise programs and often experience relief of pain and of disability as a result.[74]

Arthroplasty

Each year, over 100,000 Americans undergo total hip replacement (THR) and over 50,000 have a total knee replacement (TKR). Joint replacement should be considered in persons with structural damage to the joint who experience pain and loss of function despite nonsurgical management. Most candidates have osteoarthritis, are older than 60 years, and have multiple other medical conditions.

Surgical interventions for uncontrolled knee pain and mobility limitation include lavage with or without debridement, osteotomy, and knee replacement. Lavage can produce significant temporary relief. Osteotomy is preferred in active persons younger than 60 years. Knee replacement can be total or limited to one compartment. Joint replacement relieves pain and improves function in most patients, irrespective of their age. A retrospective cohort study examined complication rates, length of stay in acute care facilities, pain scores, and functional abilities

for selected patients older than 80 years who underwent either a hip or knee arthroplasty. Joint replacement in this selected population led to greatly reduced pain and increased function. Given that surgical risk appears to be tolerable in the increasing population of persons older than 80 years who are in good health with stable chronic conditions, age alone should not be used as a criterion for eligibility for joint replacement.[75]

KEY ASPECTS OF REHABILITATION

Hip

Good pain control and anticoagulation with warfarin to prevent thrombosis are the major goals of the immediate THR postoperative period. Weight bearing often begins on the second postoperative day. The rehabilitation program emphasizes progressive range of motion, strengthening, and gait training. Hip abductors, which are often weak as a direct result of surgery, are a focus of the strengthening program. Patients are taught to avoid motions that increase risk of dislocation; such motions include deep squatting and crossing the knees. A raised toilet seat is recommended for use during the first months after surgery to prevent excess hip flexion. The appropriate site and the duration of rehabilitative services are determined on the basis of medical and functional status, as well as on the availability of caregivers. Many low-risk patients can be discharged from the acute care hospital within 5 days.[76] Patients at higher risk (i.e., those older than 70 years or those with two or more comorbid conditions) can benefit from inpatient rehabilitation, beginning as early as the third postoperative day, and can experience faster recovery of mobility and reduced total length of stay.[77]

Knee

Initial goals after TKR are pain control, wound drainage, and joint stabilization. The patient is usually allowed to bear weight with a straight leg by the second postoperative day. Improved range of motion is a critical step in recovery and is often aided by the use of a continuous passive motion (CPM) machine. Early postoperative CPM combined with physical therapy (PT) has been shown to be more effective than PT alone in increasing active range of motion and shortening length of stay. CPM also decreases the need for postoperative manipulation.[78] Therapy with a CPM machine involves gradually increasing passive range of motion in the operated knee over a period of several days. Good recovery of knee motion is represented by full extension and at least 90º of flexion. In a clinical trial, home CPM produced satisfactory range of motion at about half the cost of home physical therapy.[79] Strength training is often deferred for several weeks to promote stable healing of tissues. Isometric and resistive exercise with gradually increasing loads generally can be introduced safely by 8 weeks after surgery. Low-risk TKR patients appear to do well with discharge from acute care on the fourth postoperative day, and high-risk patients benefit from early transfer to intensive rehabilitation.[76,77] Long-term outcomes include significant relief of pain and improved function,[80] although many patients do not achieve levels of strength or mobility comparable to those of age-matched control subjects.[81]

Additional Information

Additional information on topics discussed in this chapter can be found at various Internet sites [*see Sidebar,* Internet Resources Relevant to Geriatric Rehabilitation].

Stephanie Studenski, M.D., M.P.H., has received grants for clinical research from Eli Lilly and Company during the past 12 months.

Cynthia J. Brown, M.D., P.T., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Amphetamine, methylphenidate, and levodopa, which are discussed in this chapter, have not been approved by the FDA for use in promoting stroke recovery. Oral human growth hormone, which is discussed in this chapter, is experimental and has not been approved by the FDA.

II DIAGNOSIS AND TREATMENT OF DYSLIPIDEMIA

JOHN D. BRUNZELL, M.D., F.A.C.P.
R. ALAN FAILOR, M.D.

Disorders of lipoprotein metabolism, in conjunction with the prevalence of high-fat diets, obesity, and physical inactivity, have resulted in an epidemic of atherosclerotic disease in the United States and other developed countries. The interaction of common genetic and acquired disorders of lipoproteins with these adverse environmental factors leads to the premature development of atherosclerosis. In the United States, mortality from coronary artery disease (CAD), particularly in persons younger than 60 years, has been declining since 1970; however, atherosclerotic cardiovascular disease remains the most common cause of death among both men and women.

Formerly, hyperlipidemia was defined as elevation of a lipoprotein level in the population. The recognition that a low level of high-density lipoprotein (HDL) and the presence of small, dense low-density lipoprotein (LDL) are clinically important in the pathophysiology of lipid disorders has led to the use of the term dyslipidemia to describe a range of disorders that include both abnormally high and low lipoprotein levels, as well as disorders in the composition of these particles. Dyslipidemias are clinically important, principally because of their contribution to atherogenesis. Pancreatitis and fatty liver disease are less common but clinically significant manifestations of lipid disorders.

Lipoprotein Physiology

LIPOPROTEIN COMPOSITION AND METABOLISM

Lipoproteins are spherical macromolecular complexes of lipid and protein [*see Figure 1*]. Clinically important lipids in the blood include cholesterol (both unesterified and esterified) and triglyceride (molecules consisting of three fatty acids attached to a glycerol backbone). Cholesterol has three primary functions: it plays a role in the structure of cell membranes, in the synthesis of steroid hormones, and in the formation of bile acids. The major functions of triglyceride are energy storage (in fat) and energy use (by muscle). Because fat cannot readily dissolve in plasma, cholesterol and triglyceride are made miscible by incorporation into lipoproteins (e.g., very low density lipoprotein [VLDL], LDL, and HDL). Apolipoproteins are the protein component of lipoproteins; they aid in the lipid transport and delivery process in three ways: they serve as structural elements, as ligands for receptors, and as regulatory cofactors [*see Table 1*].

LIPOPROTEIN STRUCTURE AND CLASSIFICATION

A mature lipoprotein particle is a sphere consisting of a central core of lipids (triglyceride and cholesteryl ester) surrounded by a monolayer surface of phospholipid, unesterified cholesterol, and apolipoproteins [*see Figure 1*]. Operationally, the lipoproteins can be described on the basis of their size and buoyancy characteristics [*see Figure 2*].

Chylomicron Chylomicrons are the largest of the lipoprotein particles. The major structural protein is apolipoprotein B-48 (apo B-48). The bulk (~80%) of the lipid core consists of triglyceride. Synthesized and secreted from the intestine, chylomicrons transport exogenous cholesterol, fatty acids, and fat-soluble vitamins absorbed from digested food [*see* Exogenous Pathway, *below*].

VLDL This triglyceride-rich particle (~80% of the lipid core consists of triglyceride) is synthesized in the liver, delivers triglyceride to the periphery, and is the precursor for intermediate-density lipoproteins (IDLs) and LDL. The major structural protein of this lipoprotein is apo B-100 [*see* Endogenous Pathway, *below*].

IDL The remnant of VLDL is of IDL density. It is formed after triglyceride in VLDL is hydrolyzed by lipoprotein lipase. The core is roughly 50% triglyceride and 50% cholesteryl ester. Approximately half of the body's IDL particles are cleared from the plasma into the liver; the other half are further processed to form LDL [*see* Endogenous Pathway, *below*]. In clinical practice, assessment of LDL levels includes the determination of cholesterol in both IDL and LDL fractions.

LDL This lipoprotein results from the hepatic processing of VLDL remnants. The core is rich in cholesteryl ester and accounts for the majority of cholesterol circulating in the blood. LDL plays a major role in the development of atherosclerosis [*see* LDL Catabolism, *below*].

HDL HDL forms from the unesterified cholesterol and phospholipid removed from peripheral tissues and the surface of triglyceride-rich proteins [*see* Function and Regulation of HDL, *below*]. The major structural protein is apo A-I; the core is predominantly cholesteryl ester. HDL mediates the return of lipoprotein and tissue cholesterol to the liver for excretion in the process referred to as reverse cholesterol transport. Another of its functions is to shuttle apo E and apo C-II to and from chylomicrons and VLDL.

LIPOPROTEIN ASSEMBLY AND CATABOLISM

Exogenous Pathway

After a meal, intestinal cells absorb fatty acids and cholesterol, esterify them into triglyceride and cholesteryl ester, and incorporate them into the core of chylomicrons.[1] Triglyceride greatly predominates over cholesterol ester in the chylomicron core. The chylomicrons are secreted into plasma, where apo C-II on the chylomicron surface activates endothelial-bound lipoprotein lipase (LPL). LPL in turn hydrolyzes the chylomicron's core triglyceride and releases free fatty acids, which are taken up by adipose tissue for storage and by muscle for energy. During lipolysis, the chylomicron decreases in size, and some surface components are transferred to HDL; the remaining particle is the chylomicron remnant particle. This chylomicron remnant next acquires apo E from HDL and is subsequently taken up by the liver after binding to sites that recognize apo E. It is then degraded, thereby delivering dietary cholesterol to the liver.

Endogenous Pathway

The liver secretes triglyceride-rich VLDL into plasma, where they too acquire apo C-II from HDL. As with chylomicrons,

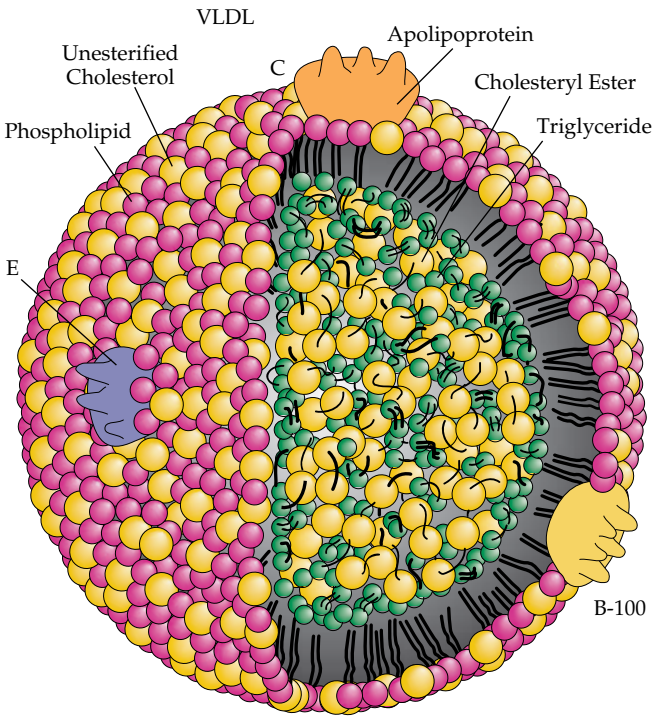

Figure 1 **Lipoproteins transport water-insoluble triglyceride and cholesterol through the bloodstream. All apo B–containing lipoproteins have a structure similar to that shown for very low density lipoproteins (VLDL). The core is composed of triglyceride and cholesteryl ester, whereas the monolayer surface is composed of phospholipid, unesterified cholesterol, and protein in the form of apolipoproteins. VLDL contains apolipoproteins B-100, C-I, C-II, and E. Low-density lipoprotein (LDL), which transports most of the cholesterol found in blood, contains primarily apo B-100.**

VLDL interacts with LPL on the capillary endothelium, and the core triglyceride is hydrolyzed to provide fatty acids to adipose and muscle tissues.[1] About half of the catabolized VLDL remnants (IDL density) are taken up by hepatic receptors that bind to apo E for degradation; the other half—apo B-100 particles, depleted of triglyceride relative to cholesteryl ester— are converted by the liver to cholesteryl ester-rich LDL. As IDL is converted to LDL, apo E becomes detached, leaving only one apolipoprotein, apo B-100. Each particle in this cascade from VLDL to LDL contains one molecule of apo B-100.

In the metabolism of both chylomicrons and VLDL, apo C-II permits the hydrolysis of triglyceride by lipoprotein lipase, and apo E prompts hepatic uptake of remnants. A major difference in the metabolism of these particles is that chylomicrons contain a truncated form of apo B (i.e., apo B-48), whereas VLDL contains the complete form (i.e., apo B-100). Another difference is that chylomicron remnants are degraded after they are absorbed by the liver, whereas many of the VLDL remnants are most likely processed in the hepatic sinusoids to become LDL.

REGULATION OF LIPOPROTEIN METABOLISM

There are four major clinically significant physiologic steps in the lipoprotein cascade from VLDL to LDL—namely, VLDL assembly, hydrolysis by LPL, remnant catabolism, and LDL catabolism [*see Figure 3*].[1,2] Defects at any step in the cascade can lead to hyperlipidemia. These defects can be genetic or acquired (i.e., secondary to disease or the effects of drugs) or the result of an interaction of genetic and acquired factors.

Table 1 Major Apolipoproteins and Their Functions

Apolipoprotein	*Function*
Apo A-I	Structural protein of HDL; activates lecithin-cholesterol acyltransferase
Apo A-II	Structural protein of HDL
Apo B-48	Structural protein of chylomicron
Apo B-100	Structural protein of VLDL, IDL, and LDL; ligand for LDL receptor
Apo C-II	Activator of LPL
Apo C-III	Potential inhibitor of apo C-II and apo E functions
Apo E	Ligand for chylomicron remnant receptor and LDL receptor
Apo(a)	Function unknown; antagonizes plasminogen

HDL—high-density lipoprotein IDL—intermediate-density lipoprotein LDL—low-density lipoprotein LPL—lipoprotein lipase VLDL—very low density lipoprotein

Lipoprotein Assembly

Apo B-100 is synthesized constitutively in the endoplasmic reticulum of the hepatocyte, and much of it is degraded in the endoplasmic reticulum. Triglyceride is added to the surviving apo B that will be secreted as VLDL. It is transported to the Golgi complex, where it acquires additional core lipid, forming the nascent VLDL particle. This particle is secreted into plasma, where it acquires apolipoproteins (e.g., apo C-II and apo E) from HDL.[1]

Abnormalities in VLDL secretion can occur in two genetic forms of hyperlipidemia: familial hypertriglyceridemia (FHTG) and familial combined hyperlipidemia (FCHL). FHTG is characterized by the overproduction of triglyceride contained within a normal number of VLDL particles; this results in each particle's having an excessive amount of triglyceride. In FCHL, an excessive amount of apo B-100 is secreted into VLDL or LDL particles; these particles tend to be smaller than normal.[3]

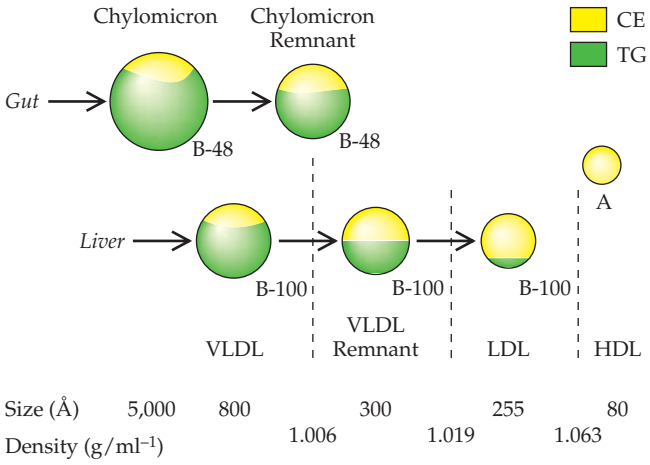

Figure 2 **Size and buoyancy characteristics of lipoproteins. Chylomicrons, which are composed largely of triglyceride, are the largest and most buoyant of the lipoproteins. High-density lipoprotein (HDL) particles are substantially smaller and denser and are composed mostly of cholesteryl ester. (CE—cholesteryl ester; TG—triglyceride)**

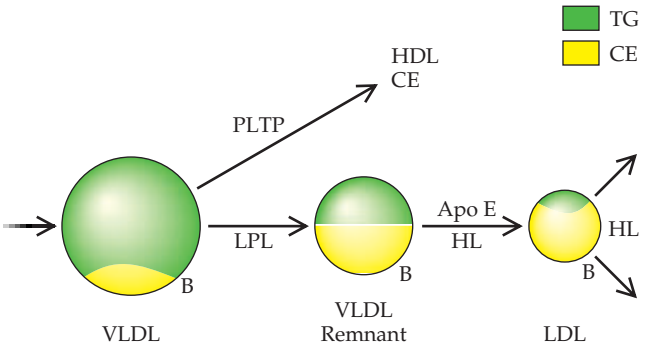

Figure 3 **The apolipoprotein B-100 (apo B-100) cascade. VLDL is secreted from the liver with one apo B on the surface and triglyceride and cholesteryl ester in the core. Core triglyceride is hydrolyzed by lipoprotein lipase and becomes a remnant lipoprotein that is recognized by the liver—in part, by apo E. The remnant lipoprotein is further processed to form LDL, which has a cholesterol-rich core and an intact apo B on its surface. The LDL particle can be removed by peripheral or hepatic LDL receptors. As the VLDL core is hydrolyzed, the unesterified cholesterol and phospholipid are transferred to HDL by phospholipid transfer protein to become the cholesteryl ester of HDL. (CE—cholesteryl ester; HL— hepatic lipase; LPL—lipoprotein lipase; PLTP—phospholipid transfer protein; TG—triglyceride)**

The metabolic syndrome, which is a common condition in the general population, is a component of most cases of FCHL and also contributes to the residual dyslipidemia seen in patients with type 2 diabetes mellitus who have been treated with insulin or insulin secretagogues. The molecular basis of the hepatic triglyceride or apo B oversecretion in these disorders is unknown.

A deficiency in lipoproteins containing apo B is referred to as hypobetalipoproteinemia; an absence of apo B is termed abetalipoproteinemia. Abetalipoproteinemia may occur because of a defect involving both apo B genes that prevents the production of apo B. It also may occur in individuals who are homozygous for mutations in the microsomal triglyceride transport protein, which is critical for apo B transport in the endoplasmic reticulum. Homozygous hypobetalipoproteinemia and abetalipoproteinemia lead to deficiencies in fat-soluble vitamins because each of these conditions results in a shortage of apo B–containing lipoproteins, which are needed to transport fat-soluble vitamins. Hypobetalipoproteinemia, which is characterized by apo B levels of 50% normal, can be caused by a defect in a single apo B gene.[4]

Lipoprotein(a) Lipoprotein(a) [Lp(a)] is a specific class of lipoprotein particles that are synthesized in the liver and that have a lipid composition similar to that of LDL. Lp(a) differs from LDL by the presence of apolipoprotein(a) [apo(a)], a protein whose structure is homologous to plasminogen.[5] The apo(a) protein is bound by a disulfide linkage to apo B-100 to form Lp(a). High levels of Lp(a) are both prothrombotic and atherogenic.[5] Levels of Lp(a) in plasma are almost completely determined by genetic variation in the *Lp(a)* gene.

Lipoprotein Catabolism

Lipoprotein lipase–mediated triglyceride removal LPL is synthesized in adipose tissue and muscle and then transported to the luminal surface of the endothelial lining of the adjacent capillary, where it acts on triglyceride-rich lipoproteins. The fatty acids that are released during the processing of triglyceride-rich particles (i.e., chylomicrons and VLDL) can be used for energy by muscle, or they can be reesterified into triglyceride and stored in adipocytes for later use.[6] Apo C-II, the LPL activator, is carried on the triglyceride-rich lipoproteins chylomicrons and VLDL.

Genetic defects that result in impaired lipoprotein lipase synthesis or function are rare autosomal recessive causes of hyperlipidemia. Usually, these mutations present in neonates or infants as severe hypertriglyceridemia. Heterozygote parents of these children often have mild hypertriglyceridemia. Acquired defects of LPL, such as untreated diabetes or uremia, are more common causes of hyperlipidemia. When an acquired defect of LPL is associated with a disorder characterized by excessive input of VLDL, marked hypertriglyceridemia can ensue. The coexistence of two or more disorders that independently increase the level of triglycerides in plasma (e.g., FHTG or FCHL coexistent with untreated diabetes) can lead to marked hypertriglyceridemia.[6]

Remnant catabolism Both chylomicron and VLDL remnants acquire apo E from HDL before they can bind to hepatic receptors for either uptake and degradation or further processing to LDL. Three alleles of the *APOE* gene (i.e., *APOE*E2, APOE*E3,* and *APOE*E4*) result in six possible combinations. The *APOE*E4* allele product has the greatest affinity for hepatic receptors, followed by the *APOE*E3* allele product; the *APOE2* allele product has markedly reduced receptor affinity.

Individuals who are homozygous for the *APOE*E2* allele (E2/E2) have marked impairment of hepatic remnant lipoprotein uptake, which results in the accumulation of these remnants in the plasma and in very low levels or the absence of LDL. Interestingly, individuals with E2/E2 typically have either normal or low cholesterol levels because of the paucity of LDL particles characteristic of this disorder.[7] If, however, an individual who is homozygous for the *APOE*E2* allele (E2/E2) has a defect—either inherited or acquired—that causes excessive input of VLDL, then excessive accumulation of VLDL remnants and hyperlipidemia occur. This results in remnant removal disease. Because chylomicron and VLDL remnants contain roughly equal amounts of triglyceride and cholesterol, the hyperlipidemia of remnant removal disease is characterized by both hypercholesterolemia and hypertriglyceridemia.[7]

LDL catabolism The final step at which a defect in lipoprotein metabolism can occur is in LDL catabolism. Apo B-100 on the surface of LDL binds to its receptor on the cell surface; LDL is then absorbed into the cell, where it is catabolized [*see Figure 4*]. After hydrolysis of the core lipids, unesterified cholesterol is used by cells for synthesis of membranes, bile acids, and steroid hormones and for various regulatory actions that prevent overaccumulation of cholesterol within the cell. The vast majority of LDL particles in plasma are taken up by the liver by means of the LDL receptor.

Mutations of the LDL receptor (as found in familial hypercholesterolemia [FH]) or, less commonly, mutations in the apo B-100 molecule (as found in familial defective apo B-100) lead to an impairment in the interaction of LDL with its receptor; this can result in elevated LDL levels. LDL levels also can be influenced by dietary factors. For example, dietary cholesterol delivered to the liver by chylomicron remnants can suppress hepatic LDL receptors, leading to impaired LDL removal from plasma. Dietary saturated fats also may reduce LDL receptor activity and may increase LDL production. Hypothyroidism can also be associated with defective LDL receptor–mediated cholesterol removal.[8]

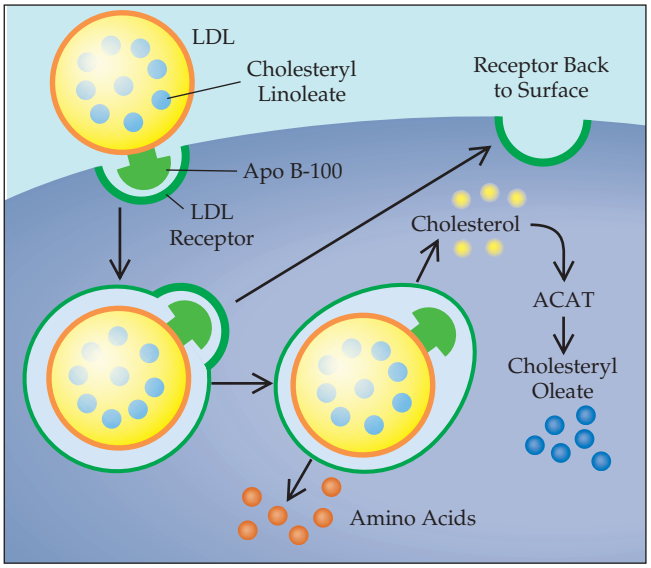

Figure 4 **LDL is absorbed by cells through the LDL receptor. This receptor recognizes apo B-100, the apolipoprotein on the surface of LDL. Once internalized, the lipoprotein is catabolized, releasing cholesterol and amino acids. The free cholesterol is converted to cholesteryl oleate by the enzyme acyl–coenzyme A: cholesterol acyltransferase (ACAT). The LDL receptor is recycled back to the cell surface.**

Function and Regulation of HDL

The major HDL apolipoproteins are apo A-I and apo A-II, which are formed in the liver and small intestine.[9] Apo A-I is secreted with phospholipid in a disklike structure called nascent HDL. Most of the apolipoproteins and phospholipid destined to become nascent HDL are initially secreted on the surface of chylomicrons and VLDL. After LPL hydrolyzes triglyceride in chylomicrons and VLDL, the core lipid content in these lipoprotein particles becomes smaller, and redundancies of unesterified cholesterol and phospholipid occur in the surface layer. These redundant surface components are transferred to HDL by phospholipid transfer protein. Nascent HDL particles also pick up excess unesterified cholesterol and phospholipid from peripheral tissues via the transporter ABCA1. This HDL cholesterol then undergoes esterification by the plasma enzyme lecithin-cholesterol acyltransferase (LCAT). LCAT is activated by apo A-I on the HDL surface to esterify free cholesterol into cholesteryl ester, causing it to move into the core. In this process, the particle becomes the larger, more buoyant HDL_3 particle and progresses to the even larger HDL_2 particle.[9,10] At some point, apo A-II may be added to the HDL_2 particle, which then is directed to deliver cholesteryl ester to the liver by cholesteryl ester transfer protein (CETP). Hepatic lipase activity on the liver surface hydrolyzes the phospholipid and triglyceride in the HDL_2 particle, promoting the decrease in size and density to HDL_3 and then to even smaller HDL particles.[10] Recycling of some of the apo A-I causes the process to repeat itself [*see Figure 5*].

Abnormally high or low levels of HDL cholesterol may be caused, rarely, by genetic defects. Elevations in the HDL cholesterol level may result from genetic hyperalphalipoproteinemia or CETP deficiency. Markedly reduced HDL cholesterol levels may be caused by apo A-I structural mutation; homozygosity for mutations in *ABCA1*,[11] leading to Tangier disease; or homozygosity for mutations in the enzyme LCAT, leading to LCAT deficiency and fish-eye disease. Factors associated with an increase in HDL levels include female sex, aerobic exercise, weight reduction, high-fat diets, and certain drugs (e.g., alcohol, estrogens, fibrates, and nicotinic acid) [*see Table 2*]. Factors associated with a decrease in HDL levels include male sex, central obesity, cigarette smoking, low-fat diets, hypertriglyceridemia, uremia, being heterozygous for Tangier disease, and certain drugs (e.g., androgens, progestins, and some antihypertensive agents) [*see Table 2*]. Low HDL particle number is commonly associated with increased triglyceride levels, as seen in the metabolic syndrome.

Function of Hepatic Lipase

Hepatic lipase is synthesized in the hepatocyte, binds to endothelial surfaces in the liver sinusoids, and acts on lipoproteins.[10] After triglyceride-rich VLDL particles exchange triglyceride for the cholesteryl ester in LDL and HDL, hepatic lipase can hydrolyze the phospholipid and triglyceride in LDL and HDL [*see Figure 6*]. This process leads to the formation of small, dense LDL and converts HDL_2 to HDL_3. This process may be driven by the presence of excessive levels of triglyceride-rich VLDL in the presence of normal hepatic lipase activity or by increases in the level of hepatic lipase. Factors such as male sex and the accumulation of intra-abdominal fat predispose to increased hepatic lipase levels and are associated with an increase in small, dense LDL levels and a decrease in HDL_2 levels. Increased hepatic lipase activity is an important factor in the dyslipidemia of the metabolic syndrome.[10,12] Hepatic lipase also may facilitate hepatic recognition and uptake of chylomicron and VLDL remnant lipoproteins.

Clinical Manifestations of Dyslipidemia

The main clinical consequences of hyperlipidemia are premature atherosclerosis; pancreatitis, which is usually associated with the chylomicronemia syndrome; and nonalcoholic fatty liver disease. Atherosclerosis is most clearly associated with elevated levels of LDL cholesterol and reduced levels of HDL cholesterol. In both pancreatitis and fatty liver disease, the underlying lipid disorder is hypertriglyceridemia.

DYSLIPIDEMIA IN ATHEROSCLEROSIS

There is consensus that elevated plasma LDL levels and reduced HDL levels are associated with an increased risk of atherosclerosis. The role of hypertriglyceridemia as a cardiovascular risk factor is more complex. Hypertriglyceridemia may be a marker for other lipoprotein abnormalities (e.g., increased levels of small, dense LDL particles; low levels of HDL; or remnant accumulation) that are part of the dyslipidemic pattern associated with FCHL, type 2 diabetes mellitus, and the metabolic syndrome. In these settings, hypertriglyceridemia is a predictor of increased premature cardiovascular risk. However, other forms of hypertriglyceridemia may not be associated with premature cardiovascular disease [*see* Familial Hypertriglyceridemia, *below*]. The precise mechanisms whereby increased levels of LDL result in increased atherosclerotic risk are unclear. Very high levels of large, buoyant LDL particles, such as occur in FH and familial defective apo B-100, as well as the presence of more moderate numbers of small, dense LDL particles, are associated with an increased risk of cardiovascular disease. Accumulating evidence suggests that LDL needs to be modified before it becomes atherogenic.[13] Oxidation of LDL may increase its atherogenicity. Oxidized LDL has many biologic properties that may cause it to become atherogenic. The atherogenicity of small, dense LDL particles may result from the ability of LDL to enter the arterial

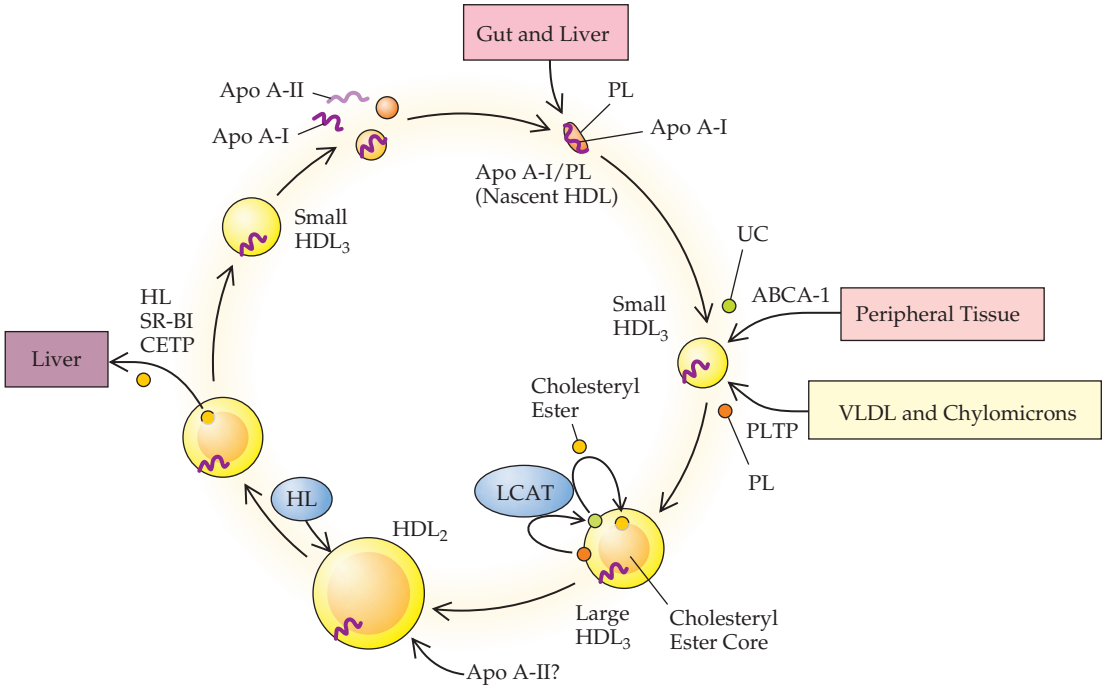

Figure 5 **The circular pathway of HDL formation and degradation.[11] HDL begins as an apo A-1 phospholipid complex. Unesterified cholesterol and phospholipid are added to the nascent HDL via adenosine triphosphate–binding cassette transporter A-1 and phospholipid transfer protein to begin the formation of the smaller HDL_3 particle. LCAT transfers a fatty acid from phospholipid to unesterified cholesterol to cholesteryl ester, which moves to the HDL core. In this process, the HDL particle becomes the larger, more buoyant HDL_3 particle and progresses to the even larger HDL_2 particle. Cholesteryl ester transfer protein contributes to the transfer of cholesteryl ester from HDL_2 to the liver and various lipoproteins; with this loss of cholesteryl ester, the HDL particle shrinks in size. Hepatic lipase hydrolyzes the phospholipid and triglyceride in the HDL_2 particle, promoting the decrease in size and density to HDL_3 and then to even smaller HDL particles, including apo A-1. Recycling of some of the apo A-I causes the process to repeat itself. The role of apo A-II in this process in humans is not clear. (ABCA1—ATP-binding cassette transporter A1; CETP—cholesteryl ester transfer protein; LCAT—lecithin-cholesterol acyltransferase; LPL—lipoprotein lipase; PL—phospholipid; PLTP—phospholipid transfer protein; SR-BI—scavenger receptor BI; UC—unesterified cholesterol)**

intima, where it is retained by matrix molecules and undergoes oxidation more readily than larger, more buoyant LDL particles. The antiatherogenic properties of HDL are probably related to its role in reverse cholesterol transport, and HDL may have anti-inflammatory and antioxidant effects.

DYSLIPIDEMIA IN THE CHYLOMICRONEMIA SYNDROME

Pancreatitis is associated with chylomicronemia, usually with elevated levels of VLDL. The mechanism by which chylomicronemia causes pancreatitis is unclear. Pancreatitis is believed to be caused by the release of free fatty acids and lysolecithin from chylomicrons in excess of their binding capacity in the capillaries of the pancreas by pancreatic lipase.

The chylomicronemia syndrome occasionally occurs when LPL is defective as a result of genetic variation in the enzyme or its cofactor, apo C-II. Much more commonly, chylomicronemia is caused by the coexistence of a genetic form of hypertriglyceridemia combined with an acquired disorder of plasma triglyceride metabolism, the most common being untreated diabetes. Other conditions may be implicated (e.g., hypothyroidism and nephrotic syndrome), as may the use of drugs that raise triglyceride levels.

The chylomicronemia syndrome is associated with abdominal pain, eruptive xanthomas, and transient memory loss. Eruptive xanthomas occur most frequently on the buttocks and the extensor surfaces of the upper limb. A reversible loss of memory, particularly for recent events, and peripheral neuropathy, which sometimes mimics the carpal tunnel syndrome, also may occur. The retinal vessels occasionally demonstrate lipemia retinalis. If the chylomicronemia syndrome is not corrected, it may lead to acute pancreatitis. Acute pancreatitis can be fatal and is often recurrent until low triglyceride levels are maintained. The risk of pancreatitis caused by severe hypertriglyceridemia markedly increases with triglyceride levels over 2,000 mg/dl.

DYSLIPIDEMIA IN NONALCOHOLIC FATTY LIVER DISEASE

Fatty liver disease seems to occur in both genetic and acquired hypertriglyceridemia. It usually is caused by the synthesis of hepatic triglyceride in amounts that are excessive relative to the amount of apo B that is synthesized; this leads to accumulation of triglyceride in the liver, rather than the hepatic secretion of VLDL triglyceride. Fatty liver disease also may occur in heterozygous familial hypobetalipoproteinenemia because of the decreased synthesis of hepatic apo B associated with this disorder. Alcoholic fatty liver disease also occurs with increased hepatic triglyceride synthesis in the face of impaired apo B synthesis.[14] Fatty liver disease has been associated with the metabolic syndrome,[12] which is related to central obesity, insulin resistance, and hypertriglyceridemia.

Any severe form of hypertriglyceridemia with defective VLDL catabolism also can be associated with fatty liver and hepatosplenomegaly. In fact, familial LPL deficiency—a form of hypertriglyceridemia caused entirely by an extrahepatic defect

Table 2 Effects of Selected Drugs on Lipoprotein Levels

*Can cause severe hypertriglyceridemia and chylomicronemia syndrome in patients with a familial form of hypertriglyceridemia or type 2 diabetes mellitus.

in triglyceride hydrolysis—is commonly associated with fatty liver disease; in this setting, fatty liver disease regresses rapidly with restriction of dietary fat. In some patients, fatty liver disease progresses to steatohepatitis that is associated with fibrosis and necrosis; the reasons for such a progression are not clear. Perhaps a second insult is needed for these patients to develop nonalcoholic steatohepatitis and then progress to cirrhosis.

Approach to the Patient with Abnormal Lipid Levels

PATIENTS WITH ISOLATED ELEVATION OF LDL CHOLESTEROL LEVELS

A patient's cholesterol level is said to be "above desirable" in an individual with low atherosclerotic risk if the LDL cholesterol level exceeds 130 mg/dl. High LDL levels are those above 190 mg/dl. The patient's triglyceride level is by definition normal,[15] and the HDL cholesterol level is variable but is often normal. The lipid disorders in these patients are usually discovered through routine cholesterol screening. Although some observers question the cost-effectiveness of screening men and women older than 20 years, the high prevalence of elevated LDL cholesterol in the United States warrants population screening, as recommended by the National Cholesterol Education Program (NCEP) and other authorities.

Severely elevated cholesterol levels are an indication of FH. The ability to diagnose FH is valuable because affected individuals will require drug therapy from a relatively young age [*see* Familial Hypercholesterolemia, *below*].

Isolated hypercholesterolemia may be present intermittently in patients with FCHL. A family history that is strongly positive for premature cardiovascular disease, or the presence of any of the other criteria for FCHL, should provide clues to the diagnosis of this disorder [*see* Familial Combined Hyperlipidemia, *below*]. Not all cases of mild isolated hypercholesterolemia are indicative of FH or FCHL; such cases may result from interactions of acquired and environmental factors, particularly dietary factors, with unknown genetic factors that confer susceptibility to hypercholesterolemia.

Most current treatment guidelines are based primarily on LDL cholesterol levels, because reduction of LDL has been shown to reduce cardiovascular disease by as much as 50%.[16] Reduction in the consumption of dietary saturated fat and cholesterol usually leads to a modest reduction in LDL cholesterol levels; such a reduction depends in part on the baseline diet [*see CE:IV Diet and Exercise*]. Lifestyle changes, including diet and weight loss, will suffice in some individuals for reducing LDL cholesterol levels to an acceptable range. However, this approach is unlikely to suffice in patients with familial forms of dyslipidemia, such as FH or FCHL.

In patients with familial forms of the disease or in patients for whom lifestyle measures alone fail to bring LDL cholesterol levels within guideline goals, cholesterol-lowering drugs should be added to the treatment regimen [*see* Drug Therapy in Dyslipidemia, *below*]. Diet therapy can reduce LDL cholesterol levels an additional 5% to 15% beyond reductions achieved with drugs.[17] Diet therapy can therefore lead to a reduction in the dosages of required drugs and should be used in combination with drug therapy. The major class of drugs used to reduce LDL cholesterol is the statins. However, bile acid–binding resins and drugs that block cholesterol absorption are of value in patients who do not respond adequately to statins alone, and they can be used in combination with statins and other drugs.

PATIENTS WITH ISOLATED ELEVATION OF TRIGLYCERIDE LEVELS

An isolated elevation in triglyceride levels may be caused by a primary disorder of lipid metabolism (e.g., FHTG or FCHL); it

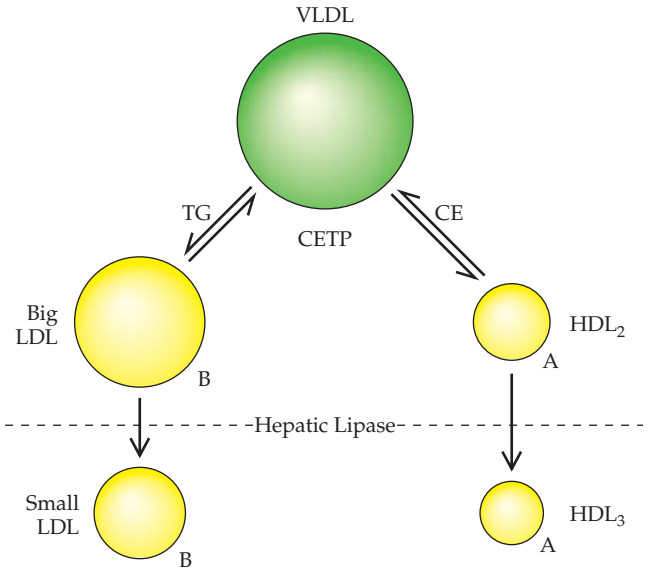

Figure 6 **Dyslipidemia in the metabolic syndrome. Triglyceride-rich VLDL exchanges triglyceride for the cholesteryl ester in LDL and HDL particles. This change in lipoprotein composition is initiated by cholesteryl ester transfer protein. Hepatic lipase hydrolyzes the triglyceride and phospholipid in large LDL and HDL particles, decreasing the size of each particle. (CE—cholesteryl ester; TG—triglyceride; CETP—cholesterol ester transfer protein)**

may arise secondary to the use of therapeutic drugs; or it may be a component of the metabolic syndrome or type 2 diabetes mellitus. Unlike with cholesterol levels, it has been difficult to determine the level of triglyceride at which the risk of CAD increases or decreases. It is valuable to ascertain the cause of the hypertriglyceridemia, because the therapeutic approaches may differ.

For example, it is important to distinguish FHTG, which confers no risk of premature CAD, from FCHL, which is associated with a high incidence of premature atherosclerosis.[17] However, it can be difficult to distinguish these disorders when FCHL is associated with hypertriglyceridemia. A positive personal or family history of premature atherosclerosis suggests FCHL. In addition, patients with FCHL frequently have nonlipid cardiovascular risk factors (i.e., central obesity, hypertension, insulin resistance, impaired glucose tolerance, increased levels of plasminogen activator inhibitor–1, (PAI-1) and increased levels of circulating inflammatory markers). Hypertriglyceridemia present in FCHL indicates the presence of increased numbers of small, dense LDL particles and confers an increased risk of premature cardiovascular disease.[12] Similarly, hypertriglyceridemia associated with type 2 diabetes mellitus and the metabolic syndrome is an important cardiovascular risk factor. Other cardiovascular risk factors are usually present in patients with type 2 diabetes mellitus, the metabolic syndrome, or FCHL. Therefore, the therapeutic strategy must consider factors beyond the lipid disorder.

Patients with FHTG do not appear to be at significantly increased risk for developing premature CAD. However, they are at increased risk for developing the chylomicronemia syndrome when secondary forms of hypertriglyceridemia are present, such as the hypertriglyceridemia caused by the use of triglyceride-raising drugs. The chylomicronemia syndrome occurs in FCHL in combination with other causes of hypertriglyceridemia as well. In patients with pancreatitis caused by hypertriglyceridemia, triglyceride levels are above 2,000 mg/dl and can be much higher. It is recommended that plasma triglyceride levels be maintained below 2,000 mg/dl to prevent recurrent acute pancreatitis. A safe goal would be a level of less than 1,000 mg/dl.

PATIENTS WITH ELEVATIONS IN CHOLESTEROL AND TRIGLYCERIDE LEVELS

Patients with elevations in the levels of both total plasma cholesterol and triglyceride fall into three categories. In the first category, there is an elevation in VLDL and in LDL, as seen in FCHL. In the second category, there is an elevation in VLDL remnants and chylomicron remnants, as in remnant removal disease. The third category consists of patients with very high triglyceride levels in whom the increase in total cholesterol is a result of the cholesterol in VLDL and chylomicrons.

In patients with FCHL, an increase in triglycerides and in LDL cholesterol is often seen. These patients have elevated apo B levels and small, dense LDL particles. Therapy for these individuals often requires several drugs, one aimed at lowering the triglyceride level and one aimed at reducing the amount of small, dense LDL particles [*see* Drug Therapy in Dyslipidemia, *below*].

In patients with remnant removal disease, the levels of plasma cholesterol and triglyceride are often equal. It is important to consider remnant removal disease in these circumstances. Therapy in this case is related to decreasing hepatic lipoprotein secretion with statins, fibrates, or niacin.

In patients with severe hypertriglyceridemia, the increase in total plasma cholesterol is a result of the cholesterol in VLDL and chylomicrons. Fibrates are often the drug of choice. However, it is very important to determine the etiology of the severe hypertriglyceridemia and remove any offending drug [*see Table 2*] or treat any secondary cause for the hypertriglyceridemia.

PATIENTS WITH LOW HDL CHOLESTEROL LEVELS

Many if not most patients with hypertriglyceridemia have a concomitant reduction in HDL cholesterol levels. Therefore, the management of low HDL cholesterol levels should be considered in the context of the management of the underlying disorder (e.g., FCHL or type 2 diabetes mellitus) [*see* Patients with Isolated Elevation of Triglyceride Levels, *above*]. Isolated low HDL cholesterol levels of 20 to 30 mg/dl without concomitant hypertriglyceridemia or other changes in lipid and lipoprotein levels are rare, but such low levels are a risk factor for cardiovascular disease.[9] In the past, these reductions in HDL levels were often not identified; the screening strategies that were employed were based on the assessment of total cholesterol levels, and total cholesterol levels often are not elevated in patients with isolated reductions in HDL. Specific measurement of HDL cholesterol is required to identify these patients. The treatment of the rare patients with isolated low levels of HDL cholesterol remains somewhat controversial. There are no currently available drugs that effectively increase HDL cholesterol levels only.[18] Gemfibrozil, a fibrate that decreases VLDL triglyceride levels, also raises HDL cholesterol levels. Many studies of fibrate therapy for atherosclerosis have been inconclusive. However, the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) demonstrated a reduction in cardiovascular events.[19] Nicotinic acid, which acts at many metabolic sites, also raises HDL cholesterol. It decreased cardiovascular death in the Coronary Drug Project of the 1970s.[20] Few other studies have evaluated the effect of niacin on atherosclerotic events.

PATIENTS WITH ATHEROSCLEROSIS AND NORMAL LIPID LEVELS

On rare occasions, a middle-aged patient with established atherosclerosis is seen to have no detectable lipid or lipoprotein abnormality. In addition to the standard lipid profile, measurement of apo B and Lp(a) will often reveal subtle lipoprotein abnormalities, such as increased numbers of small, dense LDL particles in these patients. Assessment of nonlipoprotein risk factors (e.g., homocysteine and inflammatory markers such as C-reactive protein [CRP]) also may be of value in assessing cardiovascular risk factors. Although the levels of some of these risk factors can be reduced by various strategies (e.g., homocysteine by folate therapy), the use of statins in all categories of high-risk individuals, particularly those who have established vascular disease, has been shown to be of benefit, even if lipid levels are apparently normal.

Genetic Disorders of Lipoprotein Metabolism

Primary disorders of lipoprotein metabolism are those that arise from genetic defects in the metabolic pathways of lipoproteins (i.e., familial disorders caused by increased hepatic secretion of lipoproteins or by catabolic defects). The disorders that cause increased lipoprotein secretion are the metabolic syndrome, familial combined hyperlipidemia, type 2 diabetes mellitus, and FHTG; elevations of Lp(a) can also cause increased lipoprotein secretion. Disorders of LDL catabolism are FH and familial defective apo B-100. Remnant removal disease is a defect in remnant catabolism.

METABOLIC SYNDROME

The metabolic syndrome consists of a central distribution of adiposity or visceral obesity; insulin resistance; elevations in plasma free fatty acid levels; impaired glucose tolerance; hypertension; dyslipidemia; and an abnormal procoagulant state. Many features of this syndrome are known to predispose men and women to premature CAD.[12]

Etiology and Risk Factors

An accumulation of visceral rather than subcutaneous fat has been observed in individuals with the central body fat distribution characteristic of the metabolic syndrome. Men have more visceral fat than premenopausal women, even when matched for body mass index. It has been suggested that these differences in visceral fat and the associated changes in lipoproteins and blood pressure could account, in part, for the difference in risk of premature CAD between men and premenopausal women.[21,22] Increased visceral fat is associated with insulin resistance, hyperinsulinemia, low plasma adiponectin, and elevations in plasma free fatty acid levels.[23] It has been suggested that the accumulation of visceral fat precedes and causes insulin resistance and the resultant hyperinsulinemia, because insulin sensitivity increases and free fatty acid levels fall when visceral fat is decreased after caloric restriction.[24]

The levels of insulin, glucose, triglyceride, HDL cholesterol, blood pressure, PAI-1, and other inflammatory markers are increased above the mean normal in patients with the metabolic syndrome. Although these variables are usually shifted to high levels, some of these variables are in the high-normal range in some affected individuals. HDL levels tend to be lower than mean normal. Genetic and environmental factors appear to affect the distribution of these variables in both normal persons and those with the metabolic syndrome. Because the metabolic syndrome is associated with multiple cardiovascular risk factors, individuals with the metabolic syndrome are at increased risk for CAD. Whether all individuals who meet the NCEP guidelines for the metabolic syndrome[25] [*see* Diagnosis, *below*] are at increased risk for premature CAD is unknown. However, type 2 diabetes mellitus and FCHL are specific disorders of which the metabolic syndrome is a component.[12] These two disorders account for at least 40% to 50% of premature CAD and need to be considered in the context of the metabolic syndrome.

The risk of abdominal fat patterning, dyslipidemia, impaired glucose metabolism, and hypertension—the sentinel symptoms of the metabolic syndrome—increases with age.[26] Central obesity associated with the metabolic syndrome may be evident in young adults after completion of adolescent growth; however, it is more typical for central obesity and insulin resistance to manifest in midlife. Whereas elevations in LDL cholesterol levels may not predict the onset of atherosclerosis in the elderly, central obesity, hypertension, and insulin resistance are risk factors for atherosclerosis, and their prevalence increases with age,[26-30] possibly because of the metabolic syndrome.

Pathophysiology

Although the association of central obesity and insulin resistance with dyslipidemia is well established, the underlying cause remains unclear. One mechanism that would explain the association of central obesity and insulin resistance with dyslipidemia is an increase in portal vein long-chain free fatty acids. Such an increase would inhibit hepatic apo B from undergoing degradation in the endoplasmic reticulum and would increase the likelihood of apo B undergoing hepatic secretion as triglyceride-containing lipoproteins. This would account for the increased levels of triglyceride and the increased number of VLDL and LDL particles seen in patients in insulin-resistant states.[31] Another effect of long-chain free fatty acids is to increase hepatic lipase on the surface of hepatic cells. Hepatic lipase hydrolyzes triglyceride and phospholipid in LDL and HDL, decreasing the size of each particle [*see Figure 6*].[12] However, CETP also contributes to this lipoprotein remodeling process; whether hepatic lipase or CETP has the predominant effect on the size and density of LDL and HDL particles depends on the triglyceride content of VLDL and the secretion rate of VLDL. The differences in LDL particle size and HDL_2 levels between men and premenopausal women can largely be accounted for by differences in visceral fat in men and women.

Diagnosis

The National Cholesterol Education Program Adult Treatment Panel III (NCEP ATPIII) has suggested five clinical variables as diagnostic criteria for the metabolic syndrome: (1) increased waist circumference, (2) increased triglyceride level, (3) decreased HDL cholesterol level, (4) increased blood pressure, and (5) elevated level of fasting plasma glucose [*see Table 3*].[15] A diagnosis of the metabolic syndrome is made when three or more of these clinical variables are present. When these five variables were assessed in a survey of 8,814 adult men and women, approximately 24% of those surveyed met the diagnostic criteria for diagnosis of the metabolic syndrome.[32,33] The World Health Organization (WHO) also has criteria for the metabolic syndrome. An attempt to harmonize the two sets of criteria is in progress.

Visceral obesity and insulin resistance are major contributors to the dyslipidemia associated with the metabolic syndrome. The following lipid abnormalities are associated with the metabolic syndrome: increased levels of triglyceride; increased numbers of small, dense LDL particles; increased apo B levels; and decreased levels of HDL cholesterol. However, in normal, randomly selected populations, isolated visceral obesity and insulin resistance were associated with only a slight increase in triglyceride levels and only a slight decrease in HDL cholesterol levels.[23] In contrast, visceral obesity and insulin resistance can contribute to a more severe dyslipidemia, such as that associated with type 2 diabetes mellitus and FCHL.[12]

The dyslipidemia of the metabolic syndrome can be diagnosed by demonstrating mild to moderate increases in plasma triglyceride and apo B levels, decreased levels of HDL cholesterol, and normal levels of LDL. Although the LDL level is normal in patients with this disorder, the number of LDL particles is generally increased; the predominant form is small, dense LDL

Table 3 Clinical Features of the Metabolic Syndrome[15]

The presence of three or more variables indicates a diagnosis of metabolic syndrome
Abdominal obesity: waist circumference > 35 in (women) or > 40 in (men)
Triglycerides ≥ 150 mg/dl
HDL cholesterol < 50 mg/dl (women) or < 40 mg/dl (men)
Blood pressure ≥ 130/85 mm Hg
Fasting plasma glucose ≥ 110 mg/dl

particles, which are cholesterol poor relative to large, buoyant LDL particles. The presence of small, dense LDL particles can be determined by direct measurement of LDL size or density. The routine measurement of plasma apo B levels in clinical practice is not necessary for the diagnosis of this disorder; however, measurement of plasma apo B levels can indicate the presence of increased numbers of small, dense LDL particles. Similarly, total HDL levels reflect changes in the HDL_2 levels, indicating that HDL subfractions do not need to be measured.[34]

Treatment

Aerobic exercise and a diet low in saturated fat are indicated as therapy for most people with the metabolic syndrome. If the metabolic syndrome is severe or FCHL or type 2 diabetes mellitus is present, more aggressive therapy is indicated [*see CE:IV Diet and Exercise* and *see* Drug Therapy in Dyslipidemia, *below*].

FAMILIAL COMBINED HYPERLIPIDEMIA

FCHL is an autosomal dominant disorder that accounts for up to half of the familial causes of CAD[35]; it was first described in families of survivors of myocardial infarction.[36-38] FCHL is characterized by elevations in triglyceride or cholesterol levels, or both, in affected relatives. In addition to increases in triglyceride and cholesterol levels, patients with FCHL characteristically have elevations in apo B levels and increased numbers of small, dense LDL particles.[39]

Genetic linkage analysis suggests that the inheritance of the lipid phenotype in FCHL involves separate gene effects[40] for the elevation in apo B levels[41] and the increased numbers of small, dense LDL particles that are present in FCHL families. Further evidence for genetic heterogeneity comes from studies that found that in one third of individuals with FCHL, the activity level of LPL in postheparin plasma was reduced by half.[42] Visceral obesity and insulin resistance contribute to the dyslipidemia seen in FCHL but cannot account for the elevation in apo B levels.[43]

In the Familial Atherosclerosis Treatment Study (FATS), intensive lipid-lowering therapy with nicotinic acid or lovastatin in combination with colestipol led to decreased hepatic lipase activity; decreased numbers of small, dense LDL particles; and elevated levels of HDL_2 cholesterol, with subsequent regression of CAD, as evidenced by angiography.[44] Intensive lipid lowering resulted in subsequent regression of atherosclerosis, particularly in individuals with small, dense LDL particles who had FCHL or who had elevated Lp(a) levels at baseline.

An aggressive approach to modify reversible cardiovascular risk factors should be undertaken in individuals affected by this disorder. Diet therapy and therapeutic lifestyle modification that includes physical activity should be undertaken [*see CE:IV Diet and Exercise*], together with lipid-lowering drug therapy [*see* Drug Therapy in Dyslipidemia, *below*][18] and management of other cardiovascular risk factors. Which lipid-lowering drug to use depends to some extent on whether the primary lipid manifestation is hypercholesterolemia, hypertriglyceridemia, or combined elevations of cholesterol and triglyceride. If hypercholesterolemia is the primary manifestation, the approach should be the same as that for the hypercholesterolemic patient [*see* Patients with Isolated Elevation of LDL Cholesterol Levels, *above*]. If hypertriglyceridemia is the major abnormality, the initial approach might be that used for patients with isolated hypertriglyceridemia. However, most patients will have elevations in both triglyceride and LDL levels and will require combination therapy; regimens may combine a statin and niacin, fibrate, or ezetimibe [*see* Drug Therapy in Dyslipidemia, *below*].

TYPE 2 DIABETES MELLITUS

Patients undergoing treatment of type 2 diabetes mellitus characteristically have visceral obesity and insulin resistance. A defect in insulin secretion is present in insulin-resistant individuals who develop hyperglycemia. First-degree relatives of individuals with type 2 diabetes mellitus may be centrally obese and insulin resistant or may experience decreased insulin secretion in response to glucose; first-degree relatives who are both centrally obese and who have a defect in insulin secretion invariably develop type 2 diabetes mellitus. Although the genes contributing to central obesity, insulin resistance, and defective insulin secretion are mostly unknown, type 2 diabetes mellitus is a classic example of an oligogenic disorder. Determining all of the genes involved will require careful phenotypic characterization of subsets of individuals with type 2 diabetes mellitus.

The dyslipidemia of untreated diabetes mellitus and hyperglycemia is discussed later in this chapter under acquired disorders [*see* Endocrine Disorders That Cause Dyslipidemia, *below*]. The dyslipidemia of treated type 2 diabetes mellitus is similar to that of the metabolic syndrome and FCHL; it is characterized by a mild increase in triglyceride levels, decreased HDL_2 cholesterol levels, and increased numbers of small, dense LDL particles. Treatment entails diet therapy, increased physical activity, and lipid-lowering drug therapy [*see* Drug Therapy in Dyslipidemia, *below*].[45]

FAMILIAL HYPERTRIGLYCERIDEMIA

FHTG is a common inherited disorder, thought to be autosomal dominant, that affects about 1% of the population. FHTG is characterized by an increase in triglyceride synthesis resulting in VLDL particles enriched with triglyceride secreted in normal numbers. Affected people have elevated VLDL levels but low levels of LDL and HDL and are generally asymptomatic unless severe hypertriglyceridemia (i.e., chylomicronemia syndrome) develops. FHTG does not appear to be associated with an increase in the risk of premature CAD.[17]

A diagnosis is made by family history and examination of fasting lipoprotein profiles of the patient and relatives. The triglyceride level ranges from 250 to 1,000 mg/dl in approximately one half of first-degree relatives; a strong family history of premature CAD usually is lacking; and elevated LDL levels should not be present.

Patients with FHTG should lose weight if necessary, exercise regularly, and reduce their intake of saturated fatty acids and cholesterol. Alcohol, exogenous estrogens, and other drugs that increase VLDL levels might need to be restricted. Diabetes, if present, should be well controlled. Hypertriglyceridemia in patients with FHTG often responds to these measures. If triglyceride levels exceed 500 mg/dl after 6 months of nonpharmacologic therapy, drug therapy with a fibrate should be considered[19]; at levels above 1,000 mg/dl, drug therapy should be instituted.

Fibrates are the drugs of choice to reduce elevated triglyceride levels in patients with familial hypertriglyceridemia [*see* Drug Therapy in Dyslipidemia, *below*]. In familial combined hyperlipidemia, niacin can be very useful. Niacin has several additional beneficial effects on blood lipids—it increases HDL cholesterol levels; it reduces levels of small, dense LDL particles; and it may reduce Lp(a) levels. Despite having a less dramatic effect on triglycerides than fibrates, statins have been shown to be of value in high-risk patients with moderate hypertriglyceridemia and increased levels of small, dense LDL particles, such as occur in patients with type 2 diabetes mellitus and FCHL.

FAMILIAL HYPERCHOLESTEROLEMIA

FH is an autosomal dominant disorder caused by a mutation in the gene encoding the LDL receptor protein. The extremely rare homozygote with FH has two mutant alleles at the LDL receptor locus, leaving the person with an absolute or nearly absolute inability to clear LDL from the circulation by the LDL receptor.[8] Heterozygotes with FH possess one normal allele, giving them approximately one half of the normal receptor activity. Because the LDL receptor contributes to VLDL remnant clearance from the plasma, a deficiency of LDL receptors may lead to some accumulation of remnant lipoproteins. High concentrations of LDL result in nonreceptor-mediated uptake of LDL by the extracellular matrix, including that of the arterial wall, which leads to the formation of xanthomas and atherosclerosis. The heterozygous form of this disorder has a prevalence of about one in 500 people, making it one of the more common genetic diseases.[8]

Diagnosis

Hypercholesterolemia can be detected at birth in umbilical cord blood. If FH is not detected at birth, various associated conditions may suggest the diagnosis later in life. Tendon xanthomas are a highly specific sign of FH; typically, they begin to appear by 20 years of age and may be present in up to 70% of older patients. Occasionally, xanthomas are seen on the patellar tendon. Because xanthomas are subtle, careful examination of the dorsal hand tendons and Achilles tendon is required for their detection. Xanthelasma (cutaneous xanthomas on the palpebra) and corneal arcus are common in patients with FH after 30 years of age; however, they also occur in normocholesterolemic persons. Early corneal arcus is seen superiorly and inferiorly in the eyes and later becomes totally circumferential.

CAD develops early, with symptoms often manifesting in men in the fourth or fifth decade. Approximately 5% of all cases of premature MI occur in patients with heterozygous FH.[8] Before the development of statin therapy, at least 50% of men with heterozygous FH experienced MI by 60 years of age; in women, symptoms tend to develop about 10 years later. The total cholesterol level in heterozygous patients generally ranges from 350 to 550 mg/dl. The triglyceride level may be mildly elevated, and the HDL cholesterol level is reduced in about 10% of heterozygotes. LDL receptor function can be measured only in special laboratories.

Heterozygous FH should be suspected when severe hypercholesterolemia from elevated LDL is detected. If tendon xanthomas are present, the diagnosis is virtually certain. If tendon xanthomas are absent, secondary causes of hypercholesterolemia (e.g., hypothyroidism) should be sought, but the diagnosis of familial hypercholesterolemia is not excluded. A comprehensive family history should reveal a strong history of premature CAD and hypercholesterolemia without hypertriglyceridemia; the disorder affects approximately one half of first-degree relatives. The presence of hypercholesterolemia and tendon xanthomas in a parent or sibling is virtually diagnostic, as is hypercholesterolemia in a child in the family. Careful screening of family members is mandatory, because 50% of first-degree relatives will be affected and will require aggressive lipid-lowering therapy.[18,46]

Treatment

Management of FH requires both dietary intervention and drug therapy. The goal of therapy is to lower the LDL cholesterol level to less than 130 mg/dl, or even lower if the patient exhibits CAD. In patients with heterozygous FH, effective treatment is possible with combinations of statins, intestinally active drugs, and nicotinic acid. Because LDL cholesterol levels tend to be very high, combination therapy with two drugs is often required, and three drugs may be necessary [*see* Drug Therapy in Dyslipidemia, *below*]. Although diet therapy alone is not sufficient for patients with heterozygous FH, reducing saturated fatty acid and cholesterol intake will lower LDL levels and reduce the amount of medication required. This is particularly important in children and adolescents before initiation of drug therapy. Tendon xanthomas have been shown to regress when LDL levels are maintained in a desirable range. Aggressive reduction of LDL cholesterol in men and women who have heterozygous FH may cause a regression of coronary atherosclerosis.

FAMILIAL DEFECTIVE APOLIPOPROTEIN B-100

A mutation in apo B-100 that inhibits its binding to the LDL receptor is another genetic cause of elevations in the LDL level. The prevalence of this disorder is unknown but is estimated to be 5% to 10% that of FH. LDL receptor structure and function are normal. A full-length apo B-100 molecule is produced with a single amino acid substitution; this results in apo B that binds poorly to LDL receptors, leading to LDL accumulation in the plasma.

Affected individuals are clinically indistinguishable from patients with heterozygous FH: they may present with severe hypercholesterolemia, tendon xanthomas, and premature atherosclerosis. Treatment with statins appears to lower LDL cholesterol levels in patients with this disorder. Specialized tests available only in selected research laboratories are required to distinguish affected people with defective apo B from those with defective LDL receptors.

INCREASED LEVELS OF LIPOPROTEIN(A)

Lp(a) is a specific class of lipoprotein particles synthesized in the liver.[5] An important component of Lp(a) is apo(a), which has a structure homologous with plasminogen, a key protein in the coagulation cascade. Plasma concentrations of Lp(a) vary markedly among individuals, ranging from undetectable to 200 mg/dl. Lp(a) plasma concentration is strongly controlled by genetic factors.

Most epidemiologic studies suggest that Lp(a) is a risk factor for CAD and stroke. If Lp(a) is atherogenic, it may be because of its LDL-like properties: Lp(a) has been shown to undergo endothelial uptake and oxidative modification and to promote foam cell formation. Because Lp(a) has a high degree of homology with plasminogen, it may play a role in thrombosis by interfering with the binding of plasminogen to fibrin. Elevated Lp(a) levels appear to increase the atherogenicity of other cardiovascular risk factors, with earlier onset of cardiovascular events.

Data suggest that reducing LDL cholesterol levels in patients with high levels of Lp(a) may be an effective strategy to slow the progression of atherosclerosis and to prevent coronary events. The Lp(a) level itself can be reduced with high-dose niacin, estrogen, or tamoxifen, as well as with LDL apheresis. Insufficient data exist regarding the efficacy of lowering the Lp(a) level per se to inhibit atherosclerosis or to prevent coronary events.[5]

REMNANT REMOVAL DISEASE

Remnant removal disease, also called type III hyperlipoproteinemia, dysbetalipoproteinemia, and broad-beta disease, is defined as the presence of VLDL particles that migrate in the beta position on electrophoresis (normal VLDL particles migrate in

the pre-beta location). Beta-VLDL particles are chylomicron and VLDL remnants.

Remnant removal disease is caused in part by a mutation in the *APOE* gene[7] [*see* Regulation of Lipoprotein Catabolism, *above*]; this mutation leads to an impairment in the hepatic uptake of apo E–containing lipoproteins and stops the conversion of VLDL and IDL to LDL. Without the presence of additional genetic, hormonal, or environmental factors, remnants do not accumulate to a degree sufficient to cause hyperlipidemia, because they are cleared by hepatic receptors that also bind, with less avidity, to apo B-48 and apo B-100. Remnant removal disease results when an apo E defect (almost always the E2/E2 genotype) occurs in conjunction with a second genetic or acquired defect that causes either overproduction of VLDL (such as occurs with FCHL) or a reduction in LDL receptor activity (such as occurs in heterozygous FH or hypothyroidism). The E2/E2 genotype is found in 1% of the white population and in virtually all persons with remnant removal disease.

Diagnosis

Persons with remnant removal disease have elevations in both cholesterol and triglyceride levels and are likely to develop premature CAD. For reasons that are not understood, these patients are at particularly increased risk for peripheral vascular disease. Hyperlipidemia usually does not develop before adulthood. Palmar xanthomas (xanthoma striata palmaris)—orange-yellow discolorations of the palmar creases—are pathognomonic for genetic remnant removal disease, but they are not always present. Palmar xanthomas may be difficult to see and should be carefully sought using good lighting. Tuboeruptive xanthomas are occasionally found at pressure sites, particularly the elbows, buttocks, and knees.

The diagnosis of remnant removal disease should be suspected in a person with elevated total cholesterol and triglyceride levels, elevated VLDL and IDL cholesterol levels, and reduced LDL and HDL cholesterol levels. Cholesterol and triglyceride levels range from 300 to 1,000 mg/dl and are roughly equal, except during an acute exacerbation, at which time hypertriglyceridemia tends to predominate. Beta-migrating VLDL is present on electrophoresis, although this test is seldom used today. Ultracentrifugation demonstrates that the ratio of VLDL cholesterol to total plasma triglyceride is greater than 0.3. Definitive diagnosis is made by detecting the E2/E2 phenotype by isoelectric focusing of plasma lipoproteins or the genotype by gene analysis.

Treatment

Generally, therapy for remnant removal disease is the same as that for other forms of hypertriglyceridemia. A low-fat diet, weight loss, and exercise can have a major effect on lipid levels. Fibrates, statins, and nicotinic acid have been used successfully in this disorder. However, drugs that increase triglyceride levels, such as bile acid-binding resins, must be avoided.

RARE DISORDERS

Severe hypertriglyceridemia can present in childhood as a result of LPL deficiency or, extremely rarely, as apo C-II deficiency. These patients are at risk for acute pancreatitis with severe hypertriglyceridemia and must be treated with moderate to severe dietary-fat restriction until plasma triglyceride levels are below 1,000 to 2,000 mg/dl.

Homozygous FH is extremely rare and leads to severe hypercholesterolemia, atherosclerosis, and death, often in the first two decades of life. Patients with homozygous FH may benefit from LDL apheresis. At the other extreme, the absence of apo B-containing lipoproteins can result from defects in the synthesis of apo B (e.g., homozygous hypobetalipoproteinemia) or from defects in the transport of apo B into the hepatic endoplasmic reticulum. Individuals with very low apo B levels are not at risk for atherosclerosis.

The absence of HDL can occur in persons with homozygosity for defects in the cholesterol and phospholipid transporter ABCA-1. The heterozygous state is an uncommon cause of isolated low-HDL cholesterolemia[11] (i.e., hypoalphalipoproteinemia).

MISCELLANEOUS COMMON DYSLIPIDEMIAS

Polygenic hypercholesterolemia was once thought to be common. Polygenic hypercholesterolemia is a term used to refer to the occurrence of mild elevations in LDL cholesterol in the apparent absence of a familial form of dyslipidemia or of dyslipidemia of secondary cause. This category of dyslipidemia continues to shrink as LDL variants such as Lp(a) and small, dense LDL particles are discovered.

Mild to moderate hypertriglyceridemia may occur in the presence of modest defects in LPL. Typically, it presents as an increase in VLDL levels in conjunction with a decrease in HDL cholesterol levels. It is seen in the obligate heterozygote parents of children with LPL deficiency. This defect may predispose to premature CAD.

Secondary Disorders of Lipoprotein Metabolism

Secondary dyslipoproteinemias are caused by acquired defects in lipoprotein metabolism that result in hypercholesterolemia, hypertriglyceridemia, or combined hyperlipidemia; the HDL level may or may not be low. Secondary hypertriglyceridemia in conjunction with a common genetic form of hypertriglyceridemia may be severe enough to cause chylomicronemia with pancreatitits. Dyslipoproteinemia may also be caused by selected medications.

ENDOCRINE DISORDERS THAT CAUSE DYSLIPIDEMIA

Untreated Hyperglycemia

Untreated hyperglycemia in patients with diabetes mellitus causes an increase in VLDL synthesis, a reduction in VLDL catabolism with an accompanying reduction in LPL activity, or both. These abnormalities result in hypertriglyceridemia and a reduction in the level of HDL. The LDL level usually is normal. Fasting chylomicronemia occurs when there is a coexisting primary form of hypertriglyceridemia. VLDL and chylomicrons compete to interact with LPL, and both lipoproteins may accumulate. A low HDL level results from impaired lipolysis of triglyceride-rich lipoproteins, which supply lipid components for HDL development. These defects occur in both untreated type 1 and untreated type 2 diabetes mellitus. Lipid levels should approach normal with comprehensive treatment of diabetes; if they fail to do so, additional causes should be sought [*see* Genetic Disorders of Lipoprotein Metabolism, *above*]. In diabetic patients with persistent moderate to severe hypertriglyceridemia, a fibric acid is suitable because it reduces the secretion of VLDL and enhances the activity of LPL. Nicotinic acid may be used, but with care, particularly in patients with type 2 diabetes mellitus, because it may exacerbate hyperglycemia.[47] Statins are effective in reducing coronary events in diabetic patients.[45]

Hypothyroidism

Hypothyroidism may cause a severe elevation of LDL levels because of reduced LDL receptor activity; in addition, it frequently causes hypertriglyceridemia and an associated reduction in the HDL level as a result of reduced LPL activity. Remnants of chylomicrons and VLDL may also accumulate and unmask remnant removal disease. The dyslipoproteinemia that occurs with hypothyroidism is corrected by thyroid hormone replacement.

Dyslipidemia Secondary to Estrogen and Progestin Therapy

Oral contraceptives that contain a combination of estrogen and progestin can have variable effects on lipoproteins, depending on the specific combination used. Estrogen tends to raise VLDL and HDL levels and lower LDL levels. Progestins tend to lower VLDL and HDL levels and raise LDL levels, but the effect varies considerably. Postmenopausal estrogen replacement therapy lowers LDL levels and raises HDL levels; the addition of progesterone to protect the uterus lessens these effects but does not eliminate them.[48] Estrogen may increase triglycerides to severe levels in women who have an underlying primary triglyceride disorder, leading to pancreatitis; therefore, triglyceride levels should be closely monitored in these patients.[6] Oral combination therapy with estrogen and progesterone was associated with a mild increase in CAD[43] in the Women's Health Initiative Study. In this randomized study of 16,608 women, use of oral hormone replacement therapy also was associated with an excess rate of breast cancer. In women who have undergone hysterectomies, estrogen therapy has been shown to increase the risk of stroke [*see* Managing Dysplipidemia in Women, *below*].[49] These studies have led to a decrease in the use of postmenopausal hormone replacement therapy.

RENAL DISORDERS THAT CAUSE DYSLIPIDEMIA

Nephrotic Syndrome

The nephrotic syndrome causes enhanced hepatic secretion of apo B-100–containing lipoproteins (i.e., VLDL) in response to the loss of albumin and other proteins in the urine. Hepatic synthesis of cholesterol is also increased. The LDL level is typically elevated, and it may be severely elevated. The VLDL level elevation may be associated with a reduction in the HDL level as lipolysis becomes impaired.[50] Patients with the nephrotic syndrome are at increased risk for CAD, and the lipid disorder should be treated aggressively. Dietary change, weight loss, and exercise may improve lipoprotein levels, but pharmacologic therapy is necessary to achieve desirable lipoprotein levels. Nicotinic acid should be effective in the treatment of this disorder because it inhibits hepatic secretion of apo B-100–containing lipoproteins; however, it has not been studied extensively for this use. The statins are useful in lowering LDL cholesterol levels in patients with the nephrotic syndrome. Combination drug therapy with statins, nicotinic acid, fibrates, or ezetimibe may be necessary for the reduction of LDL cholesterol and triglyceride levels [*see* Drug Therapy in Dyslipidemia, *below*]. Studies are needed to evaluate the effects of various drug combinations on cardiovascular outcomes.

Chronic Renal Failure

Chronic renal failure produces hypertriglyceridemia as a result of a decrease in LPL and hepatic triglyceride lipase.[50] Triglyceride levels typically range from 150 to 750 mg/dl, and the HDL level is usually low; the risk of CAD is increased. Dietary measures should be initiated while drug treatment is being considered. Gemfibrozil, a drug that enhances LPL activity, has been shown to be effective in lowering triglyceride levels in patients with renal insufficiency.[51] Gemfibrozil is preferred over other fibrates (e.g., fenofibrate and clofibrate) in this setting because gemfibrozil is partly cleared by the liver; as such, it carries a lower risk of drug-induced myopathy than do fibrates that are cleared by the kidneys. Nonetheless, because gemfibrozil is partially excreted renally, the drug should be administered in the lowest effective dose. Nicotinic acid and statins have been less well studied in this condition. Combination therapy with nicotinic acid, statins, or gemfibrozil may be necessary to attain the therapeutic goal.

GASTROINTESTINAL DISORDERS THAT CAUSE DYSLIPIDEMIA

Primary biliary cirrhosis is the most significant gastrointestinal cause of dyslipidemia. In the early stages of primary biliary cirrhosis, when some hepatocellular function remains, mild elevations of VLDL and LDL levels occur because of elevations in the levels of remnant lipoproteins and HDL. Terminal liver disease with cirrhosis results in severe elevation in cholesterol levels because of increased production of lipoprotein X—an abnormal lipoprotein particle containing albumin and other plasma components that is rich in free cholesterol and phospholipid. Treatment of this terminal disorder requires liver transplantation.

OTHER CAUSES OF SECONDARY DYSLIPIDEMIA

Many commonly used drugs have adverse effects on lipoproteins [*see Table 2*]. Discontinuance of the drug often will improve lipid levels. An increase in VLDL, LDL, and HDL cholesterol levels can result from the use of drugs for the prevention of rejection after organ transplantation. Pravastatin is the drug of choice for lowering LDL levels because of its unique catabolic pathways. Immunosuppressive agents such as cyclosporine compete with atorvastatin and simvastatin for the cytochrome P-450 3A4 system. The use of antifungal agents also can interfere with the metabolism of these statins. The predominant dyslipidemia that is seen in patients with AIDS is similar to the dyslipidemia that occurs in patients with the metabolic syndrome; mild hypertriglyceridemia is common, and low HDL cholesterol is seen in some patients.[52] In others, extreme hypertriglyceridemia can result from the use of HIV drugs, and the resultant hypertriglyceridemia may be associated with pancreatitis. The etiology of dyslipidemia in AIDS is complex: excessive free fatty acid mobilization is seen, along with the development of lipodystrophy and insulin resistance. In addition, AIDS patients typically use dyslipidemia-causing drugs. The specific therapy in each patient needs to be individualized.

Prevention and Treatment of Coronary Artery Disease

PRIMARY PREVENTION

The treatment of lipid disorders in individuals who do not have clinical evidence of CAD is considered primary prevention. Primary prevention is based on the assumption that modification of lipid risk factors will alter the natural history of the untreated condition—the so-called lipid hypothesis. An association between cholesterol and CAD has been known since the early 1950s; however, it was not until the publication of the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT) in 1984 that there were data to support the lipid hypothesis.

The LRC-CPPT enrolled almost 4,000 men with moderate hypercholesterolemia; patients were followed for 7 years. The treat-

ment group was prescribed cholestyramine, which resulted in LDL cholesterol levels being 12.6% lower than those of the control subjects, who were given placebo. The cholestyramine group had a 19% reduction in CAD deaths and nonfatal myocardial infarcts ($P < 0.05$), although no decrease in total mortality was observed.[53] Further analysis demonstrated that the extent of benefit depended upon the achieved reduction in serum cholesterol (reflecting drug compliance). Use of a proportional hazards model indicated that a 25% decrease in total cholesterol or a 35% decrease in LDL cholesterol would be expected to decrease the risk of a CAD event by 50%.[54]

The Helsinki Heart Study used the fibrate gemfibrozil to treat dyslipidemic men without CAD. After 6 years of follow-up, a 34% reduction in CAD events was seen in the treatment group, compared with the group receiving placebo.[55] Again, no decrease in CAD mortality was demonstrated.

In both the Helsinki Heart Study and the LRC-CPPT, the sample size was calculated on the power to detect CAD events, not on fatal outcomes alone. As such, the lack of an effect on mortality was not surprising, but an increase (not statistically significant) in noncoronary death in the treatment groups of both these studies was troublesome[53-55] and confounded the recommendations for primary preventive therapy in hypercholesterolemic patients. These concerns were not completely addressed until 1995, when results of the West of Scotland Coronary Prevention Study (WOSCOPS) were published.[56]

The WOSCOPS trial evaluated the effect of 5 years of treatment with pravastatin on the incidence of nonfatal myocardial infarction (MI) and CAD deaths in 6,595 men. The men were middle-aged (45 to 64 years of age) and moderately hypercholesterolemic (LDL cholesterol level above 155 mg/dl). The treatment group manifested a 20% reduction in total cholesterol, a 26% reduction in LDL cholesterol, a 12% decrease in triglycerides, and a 5% increase in HDL cholesterol, as compared with the control group. On the basis of intention-to-treat principles, these changes were associated with a 31% risk reduction in nonfatal MI or CAD deaths ($P < 0.001$), a 32% risk reduction in all cardiovascular deaths ($P = 0.033$), and a 22% risk reduction in total mortality ($P = 0.051$). In addition, coronary interventions (i.e., angiography, angioplasty, and coronary artery bypass surgery) were reduced 31% to 37% ($P < 0.01$).

The reduction in clinical events began within 6 months of randomization and were independent of other risk factors, such as diabetes, smoking, blood pressure, family history of CAD, and the ratio of total cholesterol to HDL cholesterol.[57] Although there was no risk reduction without a decrease in LDL cholesterol, a decrease in LDL cholesterol of approximately 24% was adequate to see the full benefit of treatment. The treatment effect was proportionately the same regardless of baseline lipid levels and the reduction in LDL cholesterol. As such, LDL reduction alone did not account for all the benefits of treatment with pravastatin.[58] Importantly, there was no increase in noncoronary deaths, which was reported in earlier primary preventive trials.

The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) was the first large primary intervention trial to study the effects of cholesterol lowering in individuals with average cholesterol levels.[59] That is, the mean total and LDL cholesterol levels were nearer the average value for the general population (221 mg/dl and 150 mg/dl, respectively). In addition, it was the first large study to include women (997 of a total of 6,605 patients). Lovastatin was the treatment agent in this randomized, placebo-controlled trial. LDL cholesterol reduction was 25%, and follow-up was 5 years. The total absolute benefit was 2%, meaning that 50 patients had to be treated for 5 years to prevent one event. The treatment group had a 28% reduction in cardiovascular hospitalizations, a 23% decrease in angioplasty, and a 32% reduction in coronary bypass surgery. An analysis of the cost-effectiveness of lovastatin treatment demonstrated a 27% (or $524 per patient) reduction in cardiovascular health care costs for the lovastatin group, as compared with the group that received placebo.[60]

Persons with average cholesterol levels were also evaluated in the Anglo-Scandinavian Cardiac Outcomes Trial–Lipid Lowering Arm (ASCOT-LLA).[61] Nearly 20,000 hypertensive patients were randomized to one of two antihypertensive regimens. The lipid-lowering arm of this study randomized 10,305 patients with total cholesterol levels of 251 mg/dl or lower to treatment with atorvastatin or placebo. The study was halted early because a significant benefit was observed in the treatment group. Median follow-up was 3.3 years. The study did not demonstrate statistically significant reductions in cardiovascular or all-cause mortality; however, significant reductions were seen in total coronary events, total cardiovascular events and procedures, and stroke.[61]

The effect of atorvastatin (10 mg/day) on primary prevention of cardiovascular disease in diabetic patients was examined in the Collaborative Atorvastatin Diabetes Study (CARDS).[45] CARDS randomized almost 3,000 diabetic patients with LDL levels of 160 mg/dl or lower, triglyceride levels of 600 mg/dl or lower, and at least one of the following: retinopathy, albuminuria, smoking habit, or hypertension. The trial was stopped 2 years early because predetermined criteria had been met. The atorvastatin group demonstrated a 36% reduction in coronary events, a 31% reduction in coronary revascularization procedures, a 48% decrease in stroke, and a 27% reduction in all-cause deaths, as compared with the placebo group.

These studies support lipid-lowering therapy as primary prevention for patients with high LDL and average LDL values. There are virtually no data on primary prevention in patients with other lipid abnormalities, such as isolated low HDL cholesterol levels or elevated triglyceride levels.

SECONDARY PREVENTION

Lipid-lowering therapy in patients with documented CAD is considered secondary prevention. Lipid levels have a significant influence on CAD death rates in those with and without CAD; however, the impact is significantly greater in patients with established CAD.[62]

Several trials have investigated the effect of aggressive lifestyle intervention in patients with CAD. The Saint Thomas Atherosclerosis Regression Study (STARS) randomized men with CAD and total cholesterol levels above 232 mg/dl to conventional care or a low-fat, low-cholesterol diet. Despite relatively modest changes in lipid levels (the intervention group had an LDL cholesterol average of 162 mg/dl), the progression of CAD decreased and the rate of regression increased in the intervention group. Angina symptoms also improved.[63]

The effects of a Mediterranean diet (increased α-linoleic acid) were compared with those of a prudent Western diet in the Lyon Diet Heart Study.[64] All study participants had had a first MI. Those consuming the Mediterranean diet had lower rates of primary (death and MI) and secondary (unstable angina, stroke, heart failure) end points than those on the prudent Western diet at 27 months. This effect persisted after 4 years of follow-up. The group on the Mediterranean diet had a rate of combined prima-

ry and secondary end points of 2.59 events per 100 patients per year, compared with 9.03 events per 100 patients per year in the group on the prudent diet.[65]

A variety of pharmacologic agents have been used alone and in combination in secondary prevention trials. Some trials have used angiographic end points in assessing progression or regression of CAD, whereas others have used clinical end points. The Familial Atherosclerosis Treatment Study (FATS) examined the effect of several lipid-reducing regimens in men with elevated apo B levels. The two most aggressive regimens (nicotinic acid–colestipol and lovastatin-colestipol) were equally effective; both regimens were associated with delayed progression (21% and 25%, respectively, versus 46% in the placebo-colestipol group) and an increased likelihood of regression of coronary artery stenoses (32% and 39%, respectively, versus 11% in the placebo-colestipol group). Clinical end points (death, MI, worsening angina, and revascularization) were also reduced in the more aggressively treated groups (4.2% and 6.5%, respectively, versus 19% in the placebo-colestipol group).[44] This was the first major study to document the regression of CAD with aggressive lipid-lowering therapy. A subsequent analysis of these patients correlated the change in CAD severity with therapy-induced changes in LDL buoyancy and hepatic lipase activity.[66]

The Scandinavian Simvastatin Survival Study (4S) evaluated 4,444 patients with known CAD and moderate to severe hypercholesterolemia at baseline (total cholesterol concentration ranging from 212 to 309 mg/dl).[67] Patients were randomized to a regimen of diet plus simvastatin or diet plus placebo. At 5.4 years, there was a significant reduction in total mortality (8% on simvastatin versus 12% on placebo), major coronary events (19% versus 28%), CAD deaths (42% reduction), and cerebrovascular events (2.7% versus 4.3%). The reduction in cardiovascular events correlated with total cholesterol and LDL cholesterol levels and with changes from baseline.[68]

The Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) trial randomized approximately 9,000 men and women with a history of recent MI or unstable angina to receive either placebo or pravastatin.[69] The study was stopped prematurely at 60 months because of a significant benefit associated with pravastatin therapy. CAD death was reduced in the treatment arm of the study (6.4% versus 8.3%), as were total mortality (11% versus 14%), stroke (20% relative decrease), need for bypass surgery (8.9% versus 11.3%), and MI (7.4% versus 10.1%). The benefit was primarily related to changes in lipid levels and was seen in all predefined subgroups. The greatest reduction in coronary events was seen in those patients thought to be at highest risk, as assessed by concomitant risk factors.[70]

The Cholesterol and Recurrent Events (CARE) trial evaluated 4,159 patients with relatively low lipid levels. The average total cholesterol level was 209 mg/dl, and the average LDL cholesterol level was 139 mg/dl. Treatment with pravastatin over 5 years resulted in significant reductions in coronary death or nonfatal myocardial infarction (10.2% versus 13.2% for placebo), need for revascularization (14.1% versus 18.8%), and frequency of stroke (2.6% versus 3.8%).[71] However, in contrast to the results seen with 4S and LIPID, the absolute or percentage reductions in LDL had little relationship to coronary events.[72] The benefits were seen only in patients with LDL levels above 125 mg/dl.[72]

The Heart Protection Study enrolled over 20,000 persons with a history of cardiovascular disease (coronary, cerebrovascular, or peripheral vascular disease), diabetes, or treated hypertension.[73] As such, it was a mixture of primary and secondary intervention. One third of the individuals had baseline LDL cholesterol levels below 116 mg/dl, and 25% had initial LDL levels ranging from 116 to 135 mg/dl. Participants were randomized to receive simvastatin or placebo. After an average follow-up of 5.5 years, the lipid-lowering group showed a 24% reduction in major cardiovascular events, an 18% reduction in cardiovascular deaths, and a 13% reduction in all-cause mortality, as compared with the placebo group. The percentage reductions in events were similar in all three tertiles of baseline LDL cholesterol levels and in patients with LDL cholesterol levels below 100 mg/dl at baseline. These results differ from those reported in the CARE study, but they are consistent with results from the 4S and LIPID trials. The results of the Heart Protection Study also suggest that there may not be a threshold beyond which increased LDL-lowering therapy ceases to improve outcome, at least in patients at high risk for recurrent coronary events.

Aggressive LDL-lowering therapy appears to be more effective than standard lipid-lowering treatment. The Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) trial compared standard LDL-lowering treatment (pravastatin, 40 mg daily) with intensive LDL-lowering treatment (atorvastatin, 80 mg daily) in more than 4,000 patients recently hospitalized with an acute coronary syndrome.[74] The average follow-up was 24 months. The median LDL cholesterol level achieved with atorvastatin was 62 mg/dl, compared with 96 mg/dl in the group treated with pravastatin. The primary composite end point was death from any cause, MI, unstable angina not requiring hospitalization, coronary revascularization, and stroke. The rate of reaching the primary end point was 22.4% in the atorvastatin group and 26.3% in the pravastatin group. The benefit of aggressive therapy with atorvastatin was apparent as early as 30 days after initiating therapy and was consistent over time.

The Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL) trial also compared moderate LDL-lowering therapy (pravastatin, 40 mg daily) with more intensive LDL-lowering therapy (atorvastatin, 80 mg daily).[75] The study used coronary intravascular ultrasound, a sensitive means of measuring plaque volume, as a baseline measurement and primary end point. The median percentage change in atheroma volume was –0.4% in the atorvastatin group, compared with +2.7% in the pravastatin group. This finding correlated with mean LDL cholesterol levels of 79 mg/dl in the atorvastatin group and 110 mg/dl in the pravastatin group. These results gave further support to the view that aggressive LDL-lowering therapy is superior to standard LDL-lowering therapy.

Few studies have examined the benefit of raising HDL cholesterol levels in the secondary prevention of CAD. The VA-HIT trial enrolled 2,531 patients with known CAD and with LDL cholesterol levels below 140 mg/dl, HDL choleserol levels of 40 mg/dl or above, and triglyceride levels of 300 mg/dl or below.[19] The patients were randomized to receive gemfibrozil or placebo. The subsequent mean HDL cholesterol level in the gemfibrozil group was 6% higher than that in the placebo group, and the mean triglyceride level in the gemfibrozil group was 31% lower. The mean LDL cholesterol levels were 113 mg/dl in both groups. The combined primary end point of cardiac death and nonfatal myocardial infarction was 17% in the gemfibrozil group and 22% in the placebo group (relative risk reduction, 22%). The beneficial effect of gemfibrozil did not become apparent until 2 years after randomization.

Combination therapy using a statin to lower LDL cholesterol levels and niacin to raise HDL cholesterol levels has been shown to provide increased cardioprotection. In one study, patients

were randomized to one of four groups: simvastatin plus niacin, vitamins, simvastatin-niacin plus antioxidants, or placebos. At entry, the HDL choleseterol level was below 35 mg/dl, and the LDL cholesterol level was below 145 mg/dl. The mean LDL and HDL cholesterol levels were unaltered in the antioxidant and placebo groups but were changed significantly in the simvastatin plus niacin groups (mean LDL cholesterol level reduced by 42% and mean HDL cholesterol level raised by 26%). At 3 years, the reduction of clinical events in the simvastatin and niacin groups was greater than that which is usually reported in studies of statins alone (relative risk, 0.1 to 0.4 compared with placebo), suggesting that a benefit may be associated with the elevation of HDL cholesterol levels. The antioxidants provided no additional benefit and may even have attenuated the benefits of combination therapy.[76]

RISK STRATIFICATION

CAD risk factors seldom occur in isolation, and the risk associated with each varies widely in combination with other risk factors. The variability in risk prompted the NCEP ATPIII to standardize guidelines for risk assessment of CAD. Over time, the guidelines were revised to recommend more aggressive lipid-lowering targets as a means of reducing CAD risk. This evolution in guidelines is the result of consistently emerging data that extend our understanding of dyslipidemia, associated risk factors and their relationship to CAD, and the utility of new therapeutic options.

The ATP guidelines focus primarily on LDL cholesterol levels as the major lipid risk factor. More recently, low HDL levels have become a factor in risk assessment. In ATPIII, the metabolic syndrome was added as a risk factor in an attempt to assess risk for CAD in centrally obese patients who have modest elevations in triglyceride levels, low HDL cholesterol levels, and small, dense LDL particles, as well as type 2 diabetes mellitus or FCHL. In an effort to better identify those at highest risk for CAD events, the NCEP recognizes several CAD equivalents. They include diabetes mellitus, peripheral arterial disease, abdominal aortic aneurysm, symptomatic carotid artery disease, and multiple risk factors that confer a 10-year risk of CAD greater than 20%.[15] The presence of these CAD equivalents requires a level of therapeutic aggressiveness equal to that recommended for patients with established CAD.

The American College of Physicians (ACP) has adopted a somewhat less aggressive recommendation for treatment of individuals with type 1 diabetes mellitus. The ACP reserves the use of statins for patients with type 2 diabetes and other CAD risk factors.[77] The ATPIII guidelines do not differentiate between the risk of CAD in patients with type 1 diabetes and that in patients with type 2 diabetes. An argument can be made that the CAD risk is greater in type 2 diabetes and that treatment guidelines should differentiate between these entities.

The ATPIII guidelines use the Framingham scoring system for estimating the 10-year risk of CAD. Some studies indicate that the Framingham score overestimates risk in Japanese-American and Hispanic men, Native-American women, and some European and Asian populations.[78-80] It also has been suggested that the Framingham score weights age too heavily as a risk factor. The Pravastatin in Elderly Individuals at Risk of Vascular Disease (PROSPER) study, which is the only prospective study to assess statin therapy in men and women older than 70 years, demonstrated that statin therapy was of no benefit in those without preexisting atherosclerosis.[81] Any age bias present in the Framingham scoring system is eliminated when the system is used to predict risk in nonelderly patients.

A multicenter, international study confirmed the validity of risk stratification. In this study of over 15,000 patients with acute MI from 52 countries, over 90% of the population-attributable risk could be accounted for by nine potentially modifiable risk factors.[82] Most of the risk is accounted for by an elevated apo B to apo A1 ratio, smoking, hypertension, and diabetes. These risk factors were more important in younger than in older individuals. As such, principles of cardiovascular disease prevention are similar worldwide and have the potential to have a major impact.

DRUG THERAPY IN DYSLIPIDEMIA

Drugs Used to Lower LDL Cholesterol Levels

Several classes of drugs lead to a reduction in LDL cholesterol levels [*see Table 4*].[16] Before the introduction of statins in the mid-1980s, the major drugs used for this purpose were the bile-acid sequestrants and niacin. The introduction of statins, with their powerful effects on LDL cholesterol, their tolerability, and their relative lack of toxicity, provided a significant advance in the management of patients with hypercholesterolemia. The introduction of intestinally active drugs has provided additional approaches both for monotherapy—especially for individuals who are unable to tolerate statins—and, more particularly, for combination therapy.

Statins Several statins are now available, and new ones continue to be introduced. To date, statins have been highly effective in clinical trials in reducing clinical events, including stroke. Although some of the benefits of statins have been attributed to the so-called pleotropic effects of this class of drugs, the extent of reduction in LDL cholesterol levels nonetheless appears to be the major determinant of risk reduction.

Intestinally active compounds Bile-acid sequestrants were among the earliest drugs to become available for the treatment of hypercholesterolemia, and they were the first class of drugs to demonstrate that the reduction of LDL cholesterol was associated with reduced risk of CAD; however, their use was limited by their very poor tolerability and their modest effect in reducing LDL cholesterol. Moreover, triglyceride levels tend to increase with their use in patients with high baseline plasma triglyceride levels. The introduction of a more tolerable bile-acid sequestrant, colesevelam, resulted in improved compliance with this class of drugs, especially when used in combination therapy in patients with very high LDL cholesterol levels (e.g., for patients with FH).

Unlike bile-acid sequestrants, the intestinally active drug ezetimibe directly inhibits cholesterol absorption. Although clinical data are limited, it appears ezetimibe is able to reduce LDL cholesterol by approximately 20%, whether used as monotherapy or in combination with other lipid-lowering agents.[83] In addition, ezetimibe does not cause an increase in plasma triglyceride levels, as occurs with bile-acid sequestrants. Ezetimibe has not yet been reported in clinical trials with cardiovascular end points.

Drugs Used Primarily to Lower Triglyceride Levels

The preferred drugs for treatment of hypertriglyceridemia are the fibrates and niacin. Niacin is the best drug currently available for raising HDL cholesterol levels. It also produces modest re-

Table 4 Drug Treatment of Lipid Disorders

Drug	*Dosage*	*Cost per Month*	*Comment*
Bile acid–binding resins	Start with one packet (2 g for colestipol tabs) b.i.d., increase over 1–2 wk to desired dose		For elevated LDL, normal triglycerides; take other drugs 1 hr before or 4 hr after; may be used with nicotinic acid, statins, or fibrates
Cholestyramine	Maximum 24 g/day b.i.d. or t.i.d.	$69	
Colestipol	Maximum 30 g/day b.i.d. or t.i.d.	$305	t.i.d. more effective
Colestipol tablets	Maximum 16 g/day	$267	
Colesevelam	Three 625 mg tablets b.i.d. with meals or six tablets/day with a meal; maximum seven tablets/day	$142	Better tolerated than other resins
Ezetimibe	10 mg/day	$72	Can reduce LDL cholesterol by ~20% without increasing plasma triglyceride levels
Fenofibrate	200 mg/day	$73	For elevated triglycerides and patients in whom both LDL and triglycerides are elevated; may be used with bile acid–binding resins or nicotinic acid; decrease dose with severe renal disease
Gemfibrozil	600 mg b.i.d. before meals	$17	
Niacin	Start with 250 mg q.d. with meals; increase to 1.5–2.0 g/day; maximum 6 g/day	$28	For elevated LDL, triglycerides, or both; may be used with bile acid–binding resins or fibrates
Statins			For elevated LDL; possibly useful for patients in whom both LDL and triglycerides are elevated; may be used with bile acid–binding resins
Atorvastatin	Start with 10 mg/day; maximum 80 mg/day	$95	
Fluvastatin	Start with 20 mg b.i.d. or at bedtime; maximum 80 mg/day	$68	
Lovastatin	Start with 20 mg b.i.d. or with dinner; maximum 80 mg/day	$126	
Pravastatin	Start with 10 mg at bedtime; maximum 40 mg/day	$120	May be used with drugs that are cleared by hepatic enzymes CYP450, CYP3A4
Simvastatin	Start with 10 mg at bedtime; maximum 40 mg/day	$124	

ductions in LDL and reduces apo B levels, but because it worsens insulin sensitivity, its use in patients with type 2 diabetes mellitus is limited. Fibrates are the drugs of choice for patients with marked hypertriglyceridemia, for whom the primary goal of therapy is the prevention of pancreatitis and other features of the chylomicronemia syndrome. They also are of use in hypertriglyceridemic states (e.g., the familial forms of hypertriglyceridemia and in some patients with diabetic dyslipidemia), especially when triglyceride levels are more than mildly elevated. Fibrates also have a modestly beneficial effect on HDL cholesterol levels. Both fibrates and niacin are useful in combination therapy, primarily with statins.

Omega-3 fatty acids (e.g., those found in marine oils) have been used for the treatment of hypertriglyceridemia, especially when other modalities of therapy have failed to reduce markedly elevated levels of triglycerides.

Combination Therapy

Combinations of drugs often need to be used when both LDL cholesterol and triglyceride levels are elevated. Combination therapy also is of use when monotherapy, especially with statins, fails in achieving target lipid and lipoprotein levels, especially LDL cholesterol levels. Commonly used combinations include statins and fibrates—although little is known of their additive benefit in reducing clinical events—and statins and niacin. Statins and bile-acid sequestrants also are a useful combination, and the use of the new cholesterol absorption inhibitors with other classes of drugs, particularly statins, is likely to be of value. In some cases, triple therapy (e.g., statins, niacin, and an intestinally active agent) is required.

Special Issues in the Management of Dyslipidemia

SCREENING FOR HYPERCHOLESTEROLEMIA IN CHILDREN

Numerous autopsy studies demonstrate that coronary atherosclerosis begins in childhood and adolescence and that lipoprotein levels are consistently associated with the extent of such atherosclerosis. Children in families with FH and early CAD have higher cholesterol levels, and childhood cholesterol levels are significant predictors of adult levels. However, a significant proportion of children and adolescents who have mildly elevated cholesterol level will not as adults develop cholesterol levels high enough to warrant intervention; screening all children for high cholesterol would risk labeling many young people as diseased. All children older than 2 years would benefit from a diet that is low in saturated fat; this goal should be a part of any population strategy for controlling epidemic atherosclerosis. However, the safety and efficacy of long-term drug therapy have not been established in this age group, and treatment must be approached cautiously.

Considering these and other issues, the recommendations of the NCEP's Expert Panel on Blood Cholesterol Levels in Children and Adolescents seem appropriate.[84] Physicians should advise patients younger than 55 years who have a known CAD or a lipid disorder that their children or grandchildren should undergo regular cholesterol testing, and patients with a genetically well-defined lipid disorder should obtain appropriate genetic counseling. Physicians who care for patients younger than 20 years who have markedly elevated LDL levels should exhaust all lifestyle interventions before considering medications. If such measures are ineffective, resins should be used, and referral to a specialty clinic should be considered.

Treatment of young adults with elevated cholesterol levels is controversial. The strategy of matching the intensity of intervention with the level of risk of atherosclerosis has been proposed, but for young adults, a short-term (e.g., 10-year) risk assessment may be inadequate for estimating the potential benefit of cholesterol lowering. It is incorrect to argue that all treatment can be safely deferred to later life or until the occurrence of an atherosclerotic event. Population-level prevention and lifestyle interventions should still be favored for young adults, but advances in technology that better enable the identification of asymptomatic patients (of any age) who should take steps to reduce risk are greatly needed. Such advances may make it possible to reliably identify or quantify vulnerable plaques; markers of inflammation; or noninvasive measurements of endothelial dysfunction.

MANAGING DYSLIPIDEMIA IN WOMEN

Before menopause, women have a lower incidence of CAD than men of the same age. Although rare, CAD does occur in premenopausal women, usually in association with multiple genetic and environmental risk factors, such as in patients with familial forms of dyslipidemia or in diabetic patients who smoke cigarettes.

After menopause, some women develop the metabolic syndrome, characterized by visceral obesity, insulin resistance, hypertension, and dyslipidemia.[21] There is some evidence that estrogen replacement therapy can reverse these findings. However, the Women's Health Initiative Study demonstrated that combined oral estrogen and progesterone did not protect women from CAD and that it in fact had adverse effects.[85] The estrogen-alone component of the Women's Health Initiative Study indicated that estrogen therapy carried modest risk of CAD (i.e., MI or CAD death); the study was halted prematurely because of increased risk of stroke.[49]

MANAGING DYSLIPIDEMIA IN OLDER PATIENTS

Age is the most significant risk factor for the development of atherosclerosis. CAD is currently a major cause of disability and mortality in older populations; however, the relative risk associated with any single coronary risk factor decreases with age because of the comordid conditions and noncardiovascular mortality that affect an aging population. One implication of the complex relationships between risk factors and comorbid conditions in the pathogenesis of coronary-related events in the elderly is represented by the multiple effects of treatment of single risk factors, such as the decrease in LDL cholesterol levels and inflammation markers yielded by statins. A growing body of evidence from clinical trials indicates that statin therapy is effective in the elderly; lipid-lowering therapy is probably indicated in this population in persons who are at high risk for atherosclerosis or who have preexisting atherosclerosis.[73,81] Primary intervention with drug therapy in persons not at high atherosclerotic risk is controversial. In the PROSPER trial of persons older than 70 years, no benefit was seen with statin therapy in those who did not have preexisting clinical atherosclerosis. Indeed, there was a suggestion of increased gastrointestinal cancer with statin therapy in these elderly patients.[81] Attention to other concomitant diseases and the nutritional state, as well as to capabilities of the elderly, are important considerations in the management of older patients with dyslipidemia.[86]

V THE PORPHYRIAS

Shigeru Sassa, m.d., ph.d.
Attallah Kappas, m.d.

The porphyrias are uncommon disorders caused by deficiencies in the activities of the enzymes of the heme biosynthetic pathway. The enzymatic defects that cause porphyrias may be either inherited or acquired, and there is significant interplay between the gene defect and acquired or environmental factors in the expression of clinical symptoms.

Acute forms of the porphyrias may be life threatening and may be misdiagnosed because of the nonspecific nature of the clinical presentations (e.g., acute abdominal pain, psychiatric disturbances, and polyneuropathies). The course of the acute forms of disease is characterized by long latent periods interrupted by acute attacks, which are associated with substantial morbidity and mortality.

Classification

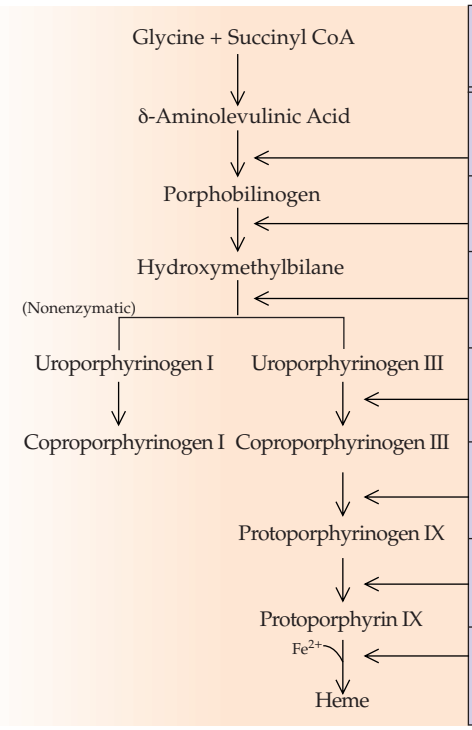
Porphyrias may be classified as neurovisceral or photosensitive, depending on their prominent clinical characteristic, but some porphyrias have both symptoms [*see Figure 1*]. Alternatively, the porphyrias can be classified as hepatic or erythropoietic, depending on the principal site of expression of the specific enzymatic defect involved, but in some porphyrias the expressions overlap.

Pathophysiology

The porphyrias are best understood by the examination of the basic scheme of heme synthesis [*see Figure 2*]. The rate of synthesis is controlled by the mitochondrial enzyme δ-aminolevulinic acid (ALA) synthase. Subsequently, in the cytoplasm, the tetrapyrrole rings remain in the reduced state (porphyrinogens), but the number of carboxyl residues progressively decreases. The last three enzymatic reactions take place in the mitochondrion, resulting in heme, which represses the production of ALA in the liver, the initial and rate-limiting enzyme in this metabolic pathway. The loss of carboxyl groups makes each successive compound less water soluble.

The oxidation of porphyrinogen by the removal of hydrogen atoms results in a series of porphyrins that absorbs light with a wavelength of approximately 400 nm (the Soret band), accounting for the fluorescence characteristic of all porphyrins. Porphyrinogen intermediates oxidize spontaneously, especially in the presence of light. The resulting porphyrins are excreted in the urine, the stool, or both, depending on their relative water solubility.

Each specific abnormality in the pattern of excretion of porphyrins and porphyrin precursors is caused by a reduction in the activity of one of the enzymes from ALA dehydratase (ALAD) to ferrochelatase. The two major organs that are active in heme synthesis are the liver and the erythroid bone marrow, and the consequences of inherited enzymatic defects in the por-



Enzyme	Disease	Major Symptoms	Accumulation Products
δ -Aminolevulinate Dehydratase	ALAD Deficiency Porphyria	Neurovisceral	Urinary ALA
Porphobilinogen Deaminase	Acute Intermittent Porphyria	Neurovisceral	Urinary ALA and PBG
Uroporphyrinogen III Cosynthase	Congenital Erythropoietic Porphyria	Photosensitivity	Erythrocyte and Urinary Uroporphyrin I and Coproporphyrin I
Uroporphyrinogen Decarboxylase	Porphyria Cutanea Tarda; Hepatoerythropoietic Porphyria	Photosensitivity	Urinary 7-Carboxylate Porphyrin; Fecal Isocoproporphyrin
Coproporphyrinogen Oxidase	Hereditary Coproporphyria	Neurovisceral and Photosensitivity	Urinary ALA, PBG, and Coproporphyrin; Fecal Coproporphyrin
Protoporphyrinogen Oxidase	Variegate Porphyria	Neurovisceral and Photosensitivity	Urinary ALA and PBG; Fecal Protoporphyrin
Ferrochelatase	Erythropoietic Protoporphyria	Photosensitivity	Erythrocyte, Plasma, and Fecal Protoporphyrin

Figure 1 **Classification and major symptoms of the porphyrias. δ-Aminolevulinate dehydratase deficiency and porphobilinogen deaminase deficiency are accompanied by acute hepatic porphyria, but not by photocutaneous porphyria, because their enzymatic blocks result in a decrease in porphyrin precursor synthesis. Enzymatic defects beyond uroporphyrinogen III cosynthase are all associated with photocutaneous porphyrias, because they produce excessive amounts of various porphyrins. Both hereditary coproporphyria and variegate porphyria are additionally associated with acute hepatic porphyria.**

phyrias are mainly expressed in these tissues. There is significant tissue-specific regulation for some enzymes in the heme biosynthetic pathway.[1] For example, there are two genes for ALA synthase (ALAS)—namely, the erythroid-specific ALAS gene (*ALAS2*, also called *ALAS-E*) and the housekeeping ALAS gene (*ALAS1*, also called *ALAS-N*). Heme-mediated regulation of ALAS is also tissue specific—namely, *ALAS1* expression in the liver is suppressed by heme, whereas *ALAS2* in the erythroid bone marrow is not. Although deficiency of ALAS does not cause porphyria, *ALAS2* gene defects are associated with X-linked sideroblastic anemia. Genetic deficiency of *ALAS1* has not been described, suggesting that it may not be compatible with life. In addition, there are the erythroid-specific and housekeeping messenger RNAs (mRNAs) for ALAD, porphobilinogen deaminase (PBGD), and uroporphyrinogen cosynthase (UCS), as well as the erythroid-specific and housekeeping enzymes for ALAS and PBGD.

The presence of functional or nonfunctional enzyme proteins can be verified by cross-reaction with specific antibodies to the normal enzymatic protein (called cross-reacting immunologic material [CRIM]). Because individual mutations define differing protein structures, gradations of enzyme activities are encountered and can account for some of the differences in clinical severity.

Clinical Presentation of the Porphyrias

PORPHYRIAS ASSOCIATED WITH NEUROVISCERAL ATTACKS

Porphyrias associated with neurovisceral attacks are also called acute hepatic porphyrias; they include acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and ALAD-deficiency porphyria (ADP). Along with having neurovisceral attacks, patients with HCP and VP may also present with photosensitivity [*see Figure 1*].

Acute Intermittent Porphyria

AIP is an autosomal dominant disorder resulting from a partial deficiency of PBGD.[2] In most patients, the deficient enzyme activity (i.e., approximately 50% of normal) is found in all tissues, including erythrocytes, whereas in 5% of patients, it is found in nonerythroid cells but not in erythrocytes. The cardinal pathobiologic defect of the disease is a neurologic dysfunction that may affect the peripheral, autonomic, and central nervous systems. The majority of persons with this inherited enzyme deficiency remain clinically normal throughout life. Clinical expression of the disease is usually linked to environmental or acquired factors (e.g., nutritional status, drugs, sex steroids, and other chemicals of endogenous or exogenous origin), indicating that there is a significant environmental effect on the clinical expression of the primary gene defect.

Epidemiology AIP is the severest form of the acute hepatic porphyrias and probably the most common of the genetic porphyrias. The highest incidence of AIP occurs in Lapland, Scandinavia, and the United Kingdom, although it has been reported in many population groups. The disorder is expressed clinically almost invariably after puberty and more often in women than in men.

Molecular defects and pathophysiology PBGD catalyzes the condensation of four molecules of PBG to yield hydroxymethylbilane [*see Figure 2*]. In the presence of the next enzyme, uroporphyrinogen III cosynthase, hydroxymethylbilane is converted to uroporphyrinogen III, which involves an intramolecular rearrangement of the D-ring pyrrole.[3] Both the hepatocyte and erythrocyte PBGD are derived from a gene containing 15 exons, but the mRNA is spliced differently in the two tissues, allowing heme synthesis to be regulated differently.[4] In the hepatocyte, transcription starts from exon 1 and encodes an enzyme slightly larger (i.e., 17 additional amino acids at the amino-terminal of the enzyme but otherwise identical) than the enzyme in the erythrocyte. In the erythrocyte, transcription starts at exon 2 rather than at exon 1.

More than 170 different point mutations of the human *PBGD* gene have been described in AIP. Patients with AIP can be classified into three subsets: type I, type II, and type III.

Patients with type I mutations are characterized by PBGD mutations that are negative for CRIM, and they exhibit 50% reduction in enzyme activity and PBGD protein. Mutations found in type I AIP are mostly single-base substitutions or deletions that lead to a single amino acid change or to truncated proteins, which result in the loss of expression of the enzyme protein.

Type II mutations are observed in fewer than 5% of AIP patients and are characterized by decreased PBGD activity in nonerythroid cells (e.g., liver cells) but normal erythroid PBGD activity. The mutations found in type II AIP are single-base substitutions that occur in the exon-intron boundary of exon 1, resulting in a splicing defect that affects the nonspecific form of PBGD but not the erythroid-specific PBGD.[5]

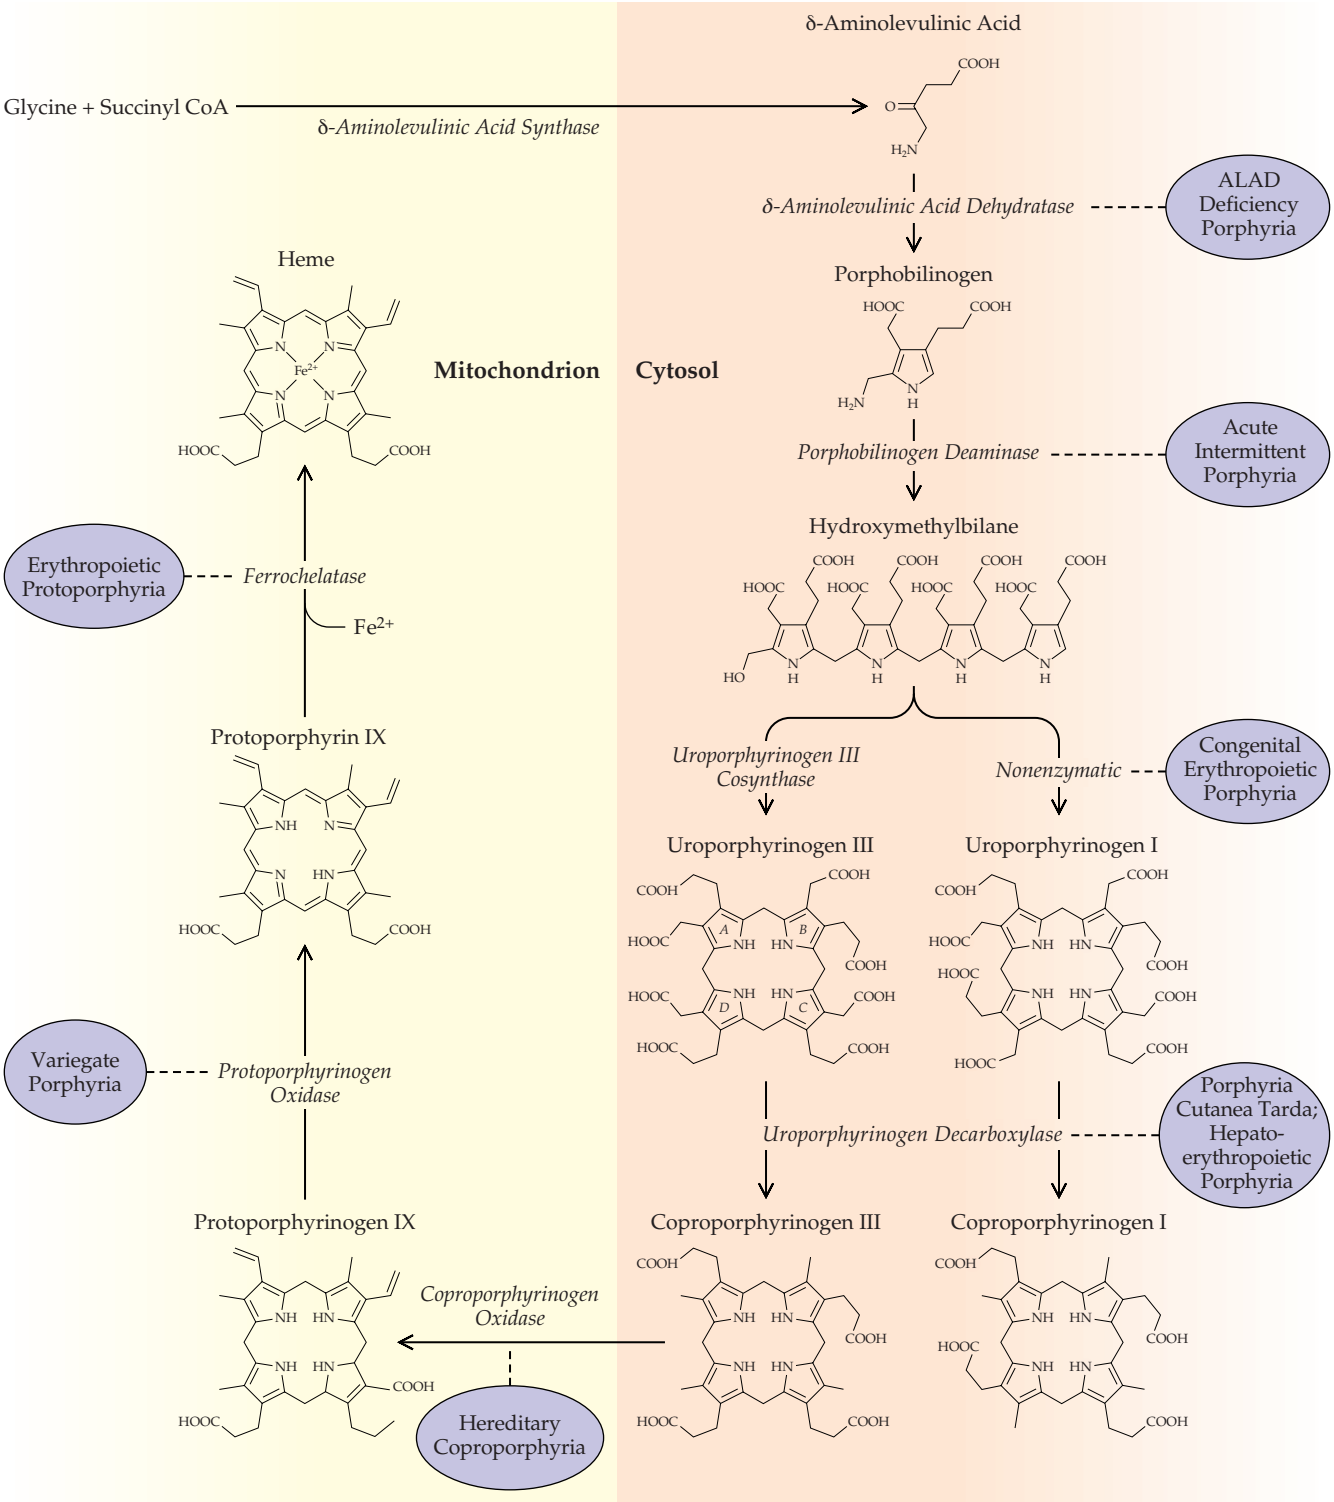
Patients with type III mutations are characterized by CRIM-positive mutations—that is, decreased enzyme activity and the

Figure 2 **The initial rate-limiting step in the synthesis of heme is the synthesis of δ-aminolevulinic acid (ALA) from glycine and succinyl–coenzyme A (succinyl-CoA). This step is catalyzed by the intramitochondrial enzyme ALA synthase. The next step, which takes place in the cytosol, consists of the condensation of two molecules of ALA by the enzyme ALA dehydratase (ALAD) to form the ring pyrrole, porphobilinogen. Porphobilinogen contains two carboxyl residues, acetate (– CH_2COOH) and propionate (– CH_2CH_2COOH) and is water soluble. Porphobilinogen deaminase catalyzes the third step in the biosynthesis of heme, involving the sequential condensation of four molecules of porphobilinogen, yielding the first tetrapyrrole in the biosynthetic pathway, hydroxymethylbilane. In the presence of uroporphyrinogen III cosynthase, hydroxymethylbilane is rapidly converted to uroporphyrinogen III, the vital substrate for subsequent porphyrin and heme formation. In the absence of uroporphyrinogen III cosynthase, hydroxymethylbilane is converted nonenzymatically to the nonphysiologic porphyrin isomer, uroporphyrinogen I. Only uroporphyrinogen III is a precursor of heme. Partial decarboxylation of uroporphyrinogen III yields coproporphyrinogen III, which contains four carboxyl groups. Coproporphyrinogen III reenters the mitochondrion and is oxidized by coproporphyrinogen oxidase to form protoporphyrinogen IX, with a loss of two more propionate residues. The enzyme protoporphyrinogen oxidase catalyzes futher oxidation of the molecule, with a loss of six hydrogen atoms, to form protoporphyrin IX. Finally, the insertion of Fe^{2+} by the mitochondrial enzyme ferrochelatase completes the synthesis of heme. Heme may inhibit ALA-synthase activity directly but also acts to repress synthesis of the enzyme. The porphyrias are caused by inherited defects in specific enzymes in the heme synthetic pathway. A partial blockage at any step in the pathway, when combined with certain endogenous or exogenous factors, results in an overproduction of intermediates or of products normally produced only in small amounts and is associated with overt clinical disease.**

presence of structurally abnormal enzyme protein.[6] Mutations characterizing type III AIP, which mostly occur in exons 10 and 12, are observed in the region that is essential for catalytic activity.

Diagnosis Abdominal pain is the most common symptom of AIP and is often the initial symptom of an acute attack. Other gastroenterologic features may include nausea, vomiting, constipation or diarrhea, abdominal distention, and ileus. Urinary retention, incontinence, and dysuria are frequently observed. Tachycardia, hypertension, and, less commonly, fever, sweating, restlessness, and tremor are also observed. Peripheral neuropathy and muscle weakness are common features of AIP. Muscular weakness can progress to quadriparesis and respiratory paralysis and arrest, which may resemble the Guillain-Barré syndrome.[7]

Acute attacks of AIP may be accompanied by seizures, espe-



cially in patients with hyponatremia caused by vomiting, inappropriate fluid therapy, or the syndrome of inappropriate antidiuretic hormone. No cutaneous manifestations are associated with this enzyme deficiency. Patients with clinically expressed AIP excrete increased amounts of ALA and PBG in the urine during attacks and sometimes between attacks. In severe cases, the urine develops a port-wine color from a high content of porphobilin, an auto-oxidation product of PBG.

In persons with latent disease, an acute attack may be precipitated by endogenous or exogenous environmental factors. Precipitating factors of AIP fall into five categories: (1) drugs that induce ALAS1 in the liver; (2) endocrine factors that facilitate ALAS1 induction; (3) reduced caloric intake that derepresses the synthesis of ALAS1; (4) drugs that induce hepatic cytochrome P-450, thereby driving heme synthesis; and (5) various oxidative stresses (e.g., infections and surgery) that induce heme oxygenase–1, which results in excessive heme catabolism and leads to the derepression of ALAS1. In women, relapses occur, particularly premenstrually. One study showed oral contraceptives precipitated acute attacks in 24% of the persons studied, whereas menopausal hormone replacement therapy only rarely affected the disorder.[8] Nevertheless, as a precaution, it is practical to restrict use of exogenous sex hormones in all women who have AIP.

The diagnosis of clinically expressed AIP requires demonstration of increased urinary excretion of PBG and ALA. A urine sample can be rapidly screened for PBG by the Watson-Schwartz or the Hoesch test, both of which utilize the Ehrlich reagent to detect a chromogen. Twenty-four-hour urine samples should be collected, placed in opaque containers, refrigerated, and delivered to a qualified laboratory for quantitative analysis of ALA, PBG, and porphyrins. Because the other hepatic porphyrias (i.e., VP, HCP, and ALAD deficiency) may produce identical neuropathic syndromes and may be marked by excess excretion of PBG, ALA, or both, definitive diagnosis should be sought by the erythrocyte PBGD assay. The diagnosis of AIP types I and III can be made by demonstrating decreased PBGD activity using an erythrocyte PBGD assay.

Treatment The same treatment is applied to all acute hepatic porphyrias, including AIP. During latent periods, when clinical manifestations are absent, management of AIP comprises adequate nutritional intake, avoidance of drugs and chemicals known to exacerbate porphyria, and prompt treatment of concurrent diseases or infections. Drug treatment should be prescribed only after reviewing a drug list. Some drugs are generally agreed to be safe in acute porphyria; some are considered unsafe [*see Table 1*]. Reactions to a drug, however, may be variable depending on the individual patient.

Severe cases of AIP should be treated with I.V. administration of carbohydrate (dextrose) to provide a minimum of 300 g of carbohydrate a day.[9] Intravenous hematin (4 mg/kg every 12 hours) is probably most effective in reducing ALA and PBG excretion, as well as in curtailing acute attacks.[10]

Variegate Porphyria

VP, also known as South African genetic porphyria, is caused by a heterozygous deficiency in protoporphyrinogen oxidase (PPO) activity and is inherited as an autosomal dominant trait.[2] The disease is called variegate because patients with this disorder can present with neurovisceral symptoms, photosensitivity, or both.

Epidemiology VP is rarer than AIP but has a substantially higher incidence in South Africa (three per 1,000 population) than elsewhere.[11] In 1980, it was estimated that there were 10,000 affected individuals in South Africa, and good evidence suggests that they were all descendants of a single union between two Dutch settlers in 1688.[12,13] With the exception of the incidence of disease in South Africa, VP probably has no racial or geographic predilection. Very rare forms of VP are seen with homozygous deficiency in PPO activity.[14]

Molecular defects and pathophysiology VP is attributed to a 50% reduction of PPO activity. PPO catalyzes the oxidation of protoporphyrinogen to yield protoporphyrin [*see Figure 2*]. In homozygous VP patients, which are rare, PPO mutations are found that are usually not found in heterozygous VP patients, suggesting that the PPO mutations in homozygotes are associated with residual activity.[15]

Diagnosis Patients with VP can have neurovisceral symptoms, photosensitivity, or both. The neurovisceral findings in VP are identical to those observed in the other acute hepatic porphyrias (e.g, abdominal pain, gastroenterologic symptoms, peripheral neuropathy, and muscle weakness). Photosensitivity and the resulting lesions tend to be more chronic in VP than in hereditary coproporphyria. Typically, lesions appear in sun-exposed areas. Blisters, as well as superficial ulcers, are present in various stages of healing and scarring. Mechanical fragility is common, especially at sites of bony protuberances such as knuckles and ankles. Skin lesions and neuropathic lesions may occur separately or together. Because the skin lesions are identical to those seen in hereditary coproporphyria and porphyria cutanea tarda, VP must be differentiated from these two conditions. The presence of neuropathic lesions without cutaneous manifestations in VP necessitates differentiation from AIP. When both cutaneous and neuropathic lesions occur in a person or kindred, hereditary coproporphyria should be considered in the differential diagnosis.

PPO activity in most patients with VP is decreased by 50%. In very rare cases of homozygous VP, however, a virtual absence of PPO activity has been documented.[16] Symptoms in homozygous VP patients are severe photosensitivity, growth and mental retardation, and marked neurologic abnormalities. Onset of the homozygous disease is in childhood. Protoporphyrin is excreted by the liver and partially reabsorbed in the gut. It must be sought in plasma and feces, where increased levels of protoporphyrin are found in 95% of VP cases. Thus, the biochemical hallmark of VP is an elevated concentration of plasma and fecal protoporphyrin IX. Plasma invariably shows a fluorescence emission when excited by longwave ultraviolet light (maximum, ~ 400 nm), which is caused by the presence of a protoporphyrin-peptide conjugate.

Treatment The treatment of neurovisceral symptoms in VP is the same as that in AIP. Cutaneous lesions are limited to sun-exposed areas, but management of VP skin lesions remains inadequate. Protection from sunlight, therefore, is an important management consideration and may include wide-brimmed hats, protective clothing, and sunscreen.[17]

Hereditary Coproporphyria

HCP is a disease caused by a heterozygous deficiency of coproporphyrinogen oxidase (CPO) activity that is inherited as an

Table 1 Safe and Unsafe Drugs for Patients with Acute Intermittent Porphyria, Variegate Porphyria, Hereditary Coproporphyria, or ALA Dehydratase Deficiency Porphyria

Safe Drugs	**Unsafe Drugs**

*Has produced conflicting results (occasionally positive but mainly negative) in experiments on porphyrinogenicity. None of the safe drugs listed has been associated with human porphyric attacks.

†Has been associated with acute attacks of porphyria.

‡Has produced conflicting results (some positive, some negative) in experiments on porphyrinogenicity.

autosomal dominant trait.[2] Clinically, the disease is similar to AIP, although it is often milder; additionally, HCP may be associated with cutaneous photosensitivity. Very rarely, homozygous deficiency of CPO occurs and is associated with a more severe form of HCP.[18]

Molecular defects and pathophysiology CPO is a mitochondrial enzyme that catalyzes the removal of the carboxyl group and two hydrogens from the propionic groups of pyrrole rings A and B of coproporphyrinogen to form vinyl groups at these positions [*see Figure 2*]. Molecular analysis of several families with HCP revealed a variety of mutations in the *CPO* gene. These include missense, nonsense, and splicing mutations, as well as insertions and deletions. CPO activity in HCP is typically reduced by about 50% in heterozygotes and by 90% to 98% in homozygotes, who are rare.[18]

Diagnosis Neurovisceral symptoms predominate in HCP and are essentially indistinguishable from those seen in other acute hepatic porphyrias. Abdominal pain, vomiting, constipation, neuropathies, and psychiatric manifestations are common. Cutaneous photosensitivity is a feature in about 30% of cases. Attacks can be precipitated by the same factors as those that are known to aggravate AIP.

The biochemical hallmark of HCP is hyperexcretion of coproporphyrin (predominantly type III) in urine and feces. Hyperexcretion of ALA, PBG, and coproporphyrin into the urine may accompany exacerbation of the disease; however, in contrast to such findings in AIP, these findings in HCP generally return to normal between attacks.

HCP should be suspected in patients with the signs, symptoms, and clinical course characteristic of the acute hepatic porphyrias but in whom PBGD activity is normal. Urinary excretion of heme precursors in HCP is similar to that in VP, but the predominant or exclusive presence of fecal coproporphyrin is highly suggestive of HCP. Fecal or urinary predominance of harderoporphyrin, with greatly reduced CPO activity, was reported in a case of harderoporphyria,[19] a variant form of HCP.

Treatment Treatment of and prophylaxis for HCP are the same as those for VP and AIP. The use of drugs in patients with HCP should be the same as that in patients with AIP [*see Table 1*].

ALAD-Deficiency Porphyria

ADP is the rarest of the porphyrias; only four cases have been reported as confirmed by molecular diagnosis. The symptomatology is similar to that seen in AIP, but ADP can be differentiated from AIP by the lack of PBG overproduction. Urinary ALA excretion is greatly increased, whereas urinary PBG excretion is within the normal range. Patients with ADP display markedly

decreased activity of ALAD in erythrocytes, as well as in nonerythroid cells (less than 2% of normal), and their parents typically show 50% decreases in enzyme activity.

ADP results from a marked reduction in ALAD activity caused by a homozygous enzyme deficiency [*see Figure 2*].[2] ALAD catalyzes the reaction that converts two molecules of ALA to form a monopyrrole, PBG, by the removal of two molecules of water. The enzyme is a homo-octamer, with a subunit size of 36,274 daltons,[20] and requires an intact sulfhydryl group and one zinc atom per subunit for full activity.[21] The human *ALAD* genomic structure is 16 kb in length, with two promoter regions and two alternative noncoding exons, 1A and 1B, that generate housekeeping and erythroid-keeping transcripts, respectively.[22] The two transcripts encode the same amino acid sequence, because translation begins in exon 2. Lead displaces zinc from the enzyme, resulting in an inactive enzyme and neurologic disturbances, some of which resemble those of ADP.[23] The most potent inhibitor of the enzyme is succinylacetone, a structural analogue of ALA, which is found in urine and blood of patients with hereditary tyrosinemia, who frequently develop symptoms similar to those of ADP.[24,25]

All ALAD point mutations have been studied by bacterial expression. The studies have revealed that eight of nine different mutations are unique and have markedly decreased enzyme activity, indicating the highly heterogeneous nature of the enzyme phenotypes.[26]

The clinical management of ADP is essentially identical to that of AIP.

PORPHYRIAS ASSOCIATED WITH CUTANEOUS PHOTOSENSITIVITY

The porphyrias associated with cutaneous photosensitivity are porphyria cutanea tarda (PCT), hepatoerythropoietic porphyria (HEP), erythropoietic protoporphyria (EPP), and congenital erythropoietic porphyria (CEP) [*see Figure 1*]. CEP, HEP, and EPP are also called erythropoietic porphyrias.

Porphyria Cutanea Tarda

PCT refers to a heterogeneous group of cutaneous porphyric diseases caused by uroporphyrinogen decarboxylase (UROD) deficiency, which may be either inherited or, more commonly, acquired.[2,27]

Epidemiology PCT is probably the most common of all forms of the porphyrias, but its exact incidence is not clear. The disease is recognized worldwide, and there is no racial predilection except for the high incidence of hemochromatosis found in the Bantus in South Africa. PCT was once considered more common in men, possibly because of greater alcohol intake; however, the incidence in women has recently matched that of men, which may be explained by women's use of contraceptive steroids and postmenopausal estrogens and increased alcohol intake .

Molecular defects and pathophysiology UROD is a cytosolic enzyme that catalyzes the removal of the four carboxyl groups of the carboxymethyl side chains from uroporphyrinogen to yield coproporphyrinogen [*see Figure 2*]. In contrast to the unique erythroid-expression mechanism for the first four enzymes of the heme biosynthetic pathway, the *UROD* gene has only a single promoter, and the gene is transcribed as a single mRNA.[28] Both PCT and the much rarer HEP [*see* Hepatoerythropoietic Porphyria, *below*] are characterized by a partial and a nearly complete UROD deficiency, respectively. Inherited PCT is caused by heterozygous UROD deficiency, whereas HEP is caused by homozygous UROD deficiency. Both inherited and noninherited forms of PCT display reductions in hepatic UROD activity, but erythrocyte UROD activity may or may not be decreased, depending on the clinical subtype. There are three types of PCT. Type I PCT, which accounts for 80% to 90% of all cases, is an acquired disease that typically presents in adults as decreased hepatic UROD activity but not decreased erythroid UROD activity. The disease may occur spontaneously, but it more commonly occurs in conjunction with precipitating environmental factors, such as use of alcohol, estrogen, or drugs. Type II PCT is inherited as an autosomal dominant trait and is associated with decreased UROD activity in all tissues. Type III PCT is also inherited, but the defect is confined to the UROD activity in the liver and in erythrocytes, and its protein concentrations are normal.

A variety of UROD mutations causing type II familial PCT have been identified, including missense, nonsense, and splice-site mutations; several small and large deletions; and a small insertion. In contrast to genetic defects in type II PCT, UROD mutations are not found in type I PCT.[29]

The pathogenetic processes of PCT are not fully understood. Porphyrin-mediated activation of the complement system after irradiation is implicated as one of the possible mechanisms and has been demonstrated in patients with PCT; activation of the complement system is presumed to result from the generation of reactive oxygen species, most likely singlet oxygen.[30]

Diagnosis The pathognomonic clinical feature of PCT is the formation of vesicles on sun-exposed areas of the skin, particularly the dorsal aspects of the hands, as well as on the face, forearms, and legs. The vesicles are superseded by crusting, superficial scarring, or milia formation and by residual pigmentation. Facial hypertrichosis may be present and is conspicuous in women. Iron, estrogens, alcohol, viral hepatitis, and chlorinated hydrocarbons can aggravate PCT.[31] Mild iron overload is nearly always present in patients with PCT. Iron plays a particularly important role in the symptomatology of PCT, in that phlebotomy to decrease hepatic iron overload is effective in treating PCT [*see* Treatment, *below*], whereas iron supplementation results in relapse of PCT. A significant number of PCT patients have associated hemochromatosis gene (*HFE*) mutations.[32] Isocoproporphyrin, unique to PCT and HEP, may be detected in serum or in stool and is diagnostic of PCT. Plasma porphyrin levels are increased in PCT, HEP, and other photosensitizing porphyrias. In PCT, serum ferritin levels are also typically elevated, which is not the case in other cutaneous porphyrias.

Although many PCT patients have moderately excessive alcohol intake or hepatitis C infection, few have advanced liver disease at the time of initial presentation. However, liver abnormalities are seen even in patients without heavy alcohol intake or hepatitis C, indicating PCT itself is associated with liver damage. PCT appears to increase the risk for hepatocellular carcinoma in patients with chronic liver disease.[33]

Treatment In type I PCT, the identification and avoidance of precipitating factors represent the first line of treatment. Abstinence from alcohol ingestion should be recommended to the patient.

The cornerstone of therapy for all types of PCT is depletion of

iron, even in patients lacking biochemical evidence of iron overload. Repeated phlebotomy of one unit of blood twice monthly for a total of 5 to 10 L, with treatment guided by the patient's hematocrit and ferritin levels, decreases both uroporphyrin excretion and photosensitivity. Improvement occurs within several months to a year. Patients who are on hemodialysis, who are anemic, or who cannot tolerate phlebotomy should receive erythropoietin. Subcutaneous infusion of desferrioxamine by portable syringe pump (1.0 to 1.5 g in 8 to 10 ml of sterile water for 8 to 10 hours 5 nights a week for 2 to 5 months) is also effective.[34]

If phlebotomy is ineffective or contraindicated, low-dose chloroquine therapy may also be considered. Chloroquine, which forms complexes with uroporphyrin, has produced improvement over 3 to 6 months; however, hepatotoxicity may occur. Resolution of type 1 PCT has followed successful interferon therapy for HCV infection.[35]

Hepatoerythropoietic Porphyria

HEP is a rare form of porphyria resulting from a homozygous deficiency of UROD.[36] Individuals in HEP families who have heterozygous UROD deficiency usually do not have clinical symptoms. HEP is characterized clinically by the childhood onset of severe photosensitivity and skin fragility and is indistinguishable from CEP. Some 20 cases have been reported worldwide.

Molecular defects and pathophysiology As in PCT, HEP is caused by a UROD deficiency [*see Figure 2*]. A variety of UROD mutations have been identified in HEP patients, indicating the molecular heterogeneity of the disease. Most UROD mutations in HEP have not been found in familial PCT and are associated with residual UROD activity.[29]

Diagnosis Clinical findings of HEP are very similar to those of CEP. Pink urine, severe photosensitivity leading to scarring and mutilation of sun-exposed areas of skin, sclerodermoid changes, hypertrichosis, erythrodontia, anemia (often hemolytic), and hepatosplenomegaly are characteristic features of HEP. In contrast to PCT, serum iron concentrations are usually normal, and phlebotomy has no beneficial effects in patients with HEP. Isocoproporphyrin concentrations are equal to or greater than concentrations of coproporphyrin found in urine and feces, and although the reasons are unclear, an elevated erythrocyte zinc protoporphyrin concentration is commonly observed.

Urinary fluorescence under ultraviolet light and quantitation and identification of isocoproporphyrin by thin-layer or high-performance liquid chromatography establish the diagnosis of HEP.

As in other photosensitizing porphyrias, plasma porphyrin levels are elevated in HEP. Fecal porphyrin levels are often elevated. The detection of isocoproporphyrin in feces is diagnostic of HEP and PCT. The diagnosis of HEP should be suspected in patients with severe photosensitivity and should especially be included in the differential diagnosis of CEP.

Treatment The identification and avoidance of precipitating factors represent the first line of treatment for PCT. In contrast to treatment for PCT, avoidance of the sun and the use of topical sunscreens are essentially all that can be recommended to patients with HEP; phlebotomy, which is most useful for treatment of PCT, provides no beneficial response in patients with this disorder.

Erythropoietic Protoporphyria

EPP is due to a partial deficiency of ferrochelatase and is inherited as an autosomal dominant trait.[2] Biochemically, this defect results in massive accumulations of protoporphyrin in erythrocytes, plasma, and feces. Clinically, the disease is characterized by the childhood onset of cutaneous photosensitivity in light-exposed areas, but skin lesions are milder and less disfiguring than those in CEP. EPP is the most common form of the erythropoietic porphyrias. There is no racial or sexual predilection, and onset is typically in childhood.

Molecular defects and pathophysiology Ferrochelatase catalyzes the final reaction in heme biosynthesis—that is, the insertion of iron into protoporphyrin IX. Unlike other steps in the heme biosynthetic pathway, this mitochondrial enzyme utilizes protoporphyrin IX, rather than its reduced form (i.e., protoporphyrinogen IX), as substrate. However, the enzyme specifically requires the reduced form of iron (i.e., ferrous, not ferric, iron) [*see Figure 2*]. The gene for human ferrochelatase has been assigned to chromosome 18q21.3.

Molecular analysis of ferrochelatase mutations causing EPP has revealed a variety of alterations, including missense, nonsense, and splice-site mutations, as well as insertions and deletions. Of these alterations, splice-site mutations are the most frequent. EPP patients have only 10% to 25% of normal ferrochelatase activity, whereas their asymptomatic family members typically have 50% ferrochelatase activity. A normal coding ferrochelatase sequence allele, expressed at a lower than normal level,[37] is present in about 10% of the white population. Inheritance of a ferrochelatase mutation in *cis* and the low expression allele in *trans* appears to account for the markedly low ferrochelatase activity and clinical expression of the disease.[37]

Light-excited porphyrins generate free radicals and singlet oxygen.[38] Such radicals, notably singlet oxygen, can lead to peroxidation of lipids and cross-linking of membrane proteins, which, in erythrocytes, can result in reduced deformability and thus hemolysis. Protoporphyrin IX, but not zinc protoporphyrin IX, can be released from erythrocytes after irradiation.[39] This finding explains why patients with EPP exhibit elevated levels of free protoporphyrin in plasma and manifest photosensitivity, whereas patients with lead intoxication and iron deficiency, who have elevated zinc protoporphyrin levels in erythrocytes, do not exhibit photosensitivity.[40]

Diagnosis Cutaneous photosensitivity of EPP is quite different from that of CEP or PCT. Stinging or painful burning sensations of the skin occur within 1 hour after exposure to the sun and are followed several hours later by erythema and edema. Petechiae or, more rarely, purpura, vesicles, and crusting may develop and may persist for several days after sun exposure. Symptoms are usually worse during spring and summer and occur in light-exposed skin. Excoriations secondary to scratching may be present. Recurrence of the lesions as a result of chronic sun exposure may result in onycholysis, scarring, altered pigmentation, lichenification, and premature aging of the skin. Gallstones, sometimes presenting at an early age, are fairly common in patients with EPP, and hepatic disease, although unusual, may be severe and associated with significant morbidity.

The biochemical hallmark of EPP is excessive concentrations of protoporphyrin in erythrocytes, plasma, bile, and feces—but not in urine, because of the poor solubility of protoporphyrin in water.

Photosensitivity should suggest the diagnosis of EPP, which can be confirmed by the demonstration of increased concentrations of free protoporphyrin in erythrocytes, plasma, and stool and normal levels of urinary porphyrins. The presence of protoporphyrin in both plasma and erythrocytes is a finding specific for EPP. Fluorescent reticulocytes on examination of peripheral blood smear also suggest the diagnosis.

Treatment Avoidance of the sun and use of topical sunscreen agents are helpful in the management of EPP. Oral administration of β-carotene can afford systemic photoprotection, resulting in improved, although highly variable, tolerance to the sun. The recommended serum β-carotene level of 600 to 800 μg/dl is usually achieved with oral dosages of 120 to 180 mg daily, and beneficial effects are typically seen 1 to 3 months after the therapy is begun. The mechanism of this beneficial effect of β-carotene probably involves quenching of activated oxygen radicals.[41]

Congenital Erythropoietic Porphyria

CEP, which is also referred to as Günther disease, is an autosomal recessive disorder caused by a homozygous deficiency of the cytosolic enzyme, uroporphyrinogen cosynthase (UCS). The enzymatic defect results in accumulation and hyperexcretion of predominantly type I porphyrins.[2] Fewer than 200 cases have been reported, and some of these cases may have been PCT or HEP. No clear racial or sexual predilection is apparent.[2]

Molecular defects and pathophysiology UCS catalyzes the formation of uroporphyrinogen III (UROIII) from hydroxymethylbilane (HMB). In the absence of UCS, HMB is converted nonenzymatically to uroporphyrin I, which is then enzymatically converted to coproporphyrin I [*see Figure 2*]. Excess porphyrin causes the staining of bones and teeth (erythrodontia), hemolysis, dark urine, and photosensitivity, all of which are usually identified early in infancy.

Similar to the *ALAD* and *PBGD* genes, the *UCS* gene has alternative promoters that generate housekeeping and erythroid transcripts.[39] A heterogeneity of mutations in the *UCS* gene is found in patients with CEP. A $Cys^{73} \rightarrow$ Arg point mutation appears to occur more frequently than others, because it has been found in eight of 21 unrelated patients with CEP (about 21% of CEP alleles).[42]

Diagnosis The first clue suggesting the diagnosis of CEP at birth is pink to dark-brown staining of diapers, which is caused by large amounts of porphyrins in the urine. Early onset of cutaneous photosensitivity is characteristic and is exacerbated by exposure to sunlight. Subepidermal bullous lesions progress to crusted erosions that heal with scarring and either hyperpigmentation or, less commonly, hypopigmentation. Hypertrichosis and alopecia are frequent and erythrodontia (appearing as red fluorescence under ultraviolet light) is pathognomonic of CEP. Patients may display symptoms and signs of hemolytic anemia with splenomegaly and porphyrin-rich gallstones. Bone marrow shows erythroid hyperplasia, which may result in pathologic fractures or vertebral compression-collapse and shortness of stature. Urinary levels of uroporphyrins and coproporphyrins are always elevated (20- to 60-fold), with predominant elevations of type I isomers.

Pink urine or the onset of severe cutaneous photosensitivity in infancy (and rarely in adults) suggests the diagnosis of CEP. Demonstration of increased levels of urinary, fecal, and erythrocyte porphyrins, together with elevated type I isomers of uroporphyrin and coproporphyrin, establish the diagnosis of CEP.

Treatment The avoidance of sunlight, trauma to the skin, and infections is the most important preventive measure. Topical sunscreens may be of some help, as may oral administration of β-carotene. Transfusions with packed erythrocytes transiently decrease hemolysis and its attendant drive to increased erythropoiesis and also decrease porphyrin excretion by suppressing erythropoiesis in the bone marrow. Bone marrow transplantation is curative.[43]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VI DIABETES MELLITUS

Saul Genuth, m.d.

Definition and Overview

Diabetes mellitus is a metabolic disease characterized by hyperglycemia that results from defects in insulin secretion, insulin action, or both. Important abnormalities in fat and protein metabolism are also present. Nonetheless, the diagnosis still rests upon demonstrating elevated plasma glucose levels. The chronic hyperglycemia of diabetes mellitus is specifically associated with long-term damage, dysfunction, and failure of various organs, especially the retina and lens of the eye, the kidneys, and both somatic and autonomic nervous systems. The heart, arterial system, and microcirculation are also adversely affected.

A variety of pathogenic processes are involved in the development of different forms of diabetes. These processes range from autoimmune destruction of the beta cells of the pancreatic islets with consequent insulin deficiency to mutations in the insulin receptor gene with consequent resistance to insulin action. The basis for the metabolic abnormalities of diabetes mellitus is deficient action of insulin on its major target tissues, including skeletal muscle, cardiac muscle, adipose tissue, and liver. Loss of proper insulin regulation of metabolism results from inadequate secretion of insulin, from diminished tissue responses to insulin at one or more points in the complex pathways of insulin action, or from both processes. Impairment of insulin secretion and defects in insulin action coexist in many patients, and in these patients, it is often unclear which abnormality is the primary cause of the hyperglycemia.

Acute life-threatening consequences of diabetes mellitus are ketoacidosis and nonketotic hyperglycemic hyperosmolar coma. Overtreatment of hyperglycemia can lead to hypoglycemia, which may be severe enough to cause seizures and loss of consciousness. Symptoms of poorly controlled hyperglycemia include polyuria, polydipsia, blurred vision, weight loss, polyphagia, stunting of growth, and vulnerability to infections or susceptibility to a more virulent or chronic course when infected.

Specific long-term complications of diabetes include (l) retinopathy with potential loss of vision, (2) nephropathy leading to end stage renal disease (ESRD), and (3) neuropathy with risk of foot ulcers, amputation, Charcot joints, sexual dysfunction, and potentially disabling dysfunction of the stomach, bowel, and bladder. Numerous mechanisms have been discovered that may mediate the specific tissue damage caused by hyperglycemia. Diabetic patients are also at increased risk for atherosclerotic cardiovascular, peripheral vascular, and cerebrovascular disease. These conditions may be related to hyperglycemia as well as to hypertension and abnormal lipoprotein profiles that are often found in diabetic patients.

Sufficient hyperglycemia to cause pathologic and functional changes in target tissues may be present for some time before clinical symptoms lead to a diagnosis of diabetes in many patients. At an even earlier stage, an incipient abnormality in glucose metabolism can be identified on plasma glucose testing, which indicates that the patient is at considerably increased risk for the full clinical disorder.

Classification

The classification of diabetes mellitus has recently been revised by a task force of the American Diabetes Association that included representation from Europe.[1] Major etiologic classes of the disease, along with more esoteric examples, have been categorized [*see Table 1*]. The vast majority of cases of diabetes mellitus are either type 1 (insulin-dependent) or type 2 (non–insulin-dependent) in an approximate ratio of 1:9.

type 1 and type 2 diabetes mellitus

Type 1 and type 2 diabetes were formerly known as insulin-dependent diabetes mellitus (IDDM) and non–insulin-dependent diabetes mellitus (NIDDM), respectively. This classification was abandoned largely because it was difficult to distinguish patients with IDDM from those patients with NIDDM who eventually required insulin treatment to mitigate hyperglycemia. Physicians, nurses, hospital-record-room personnel, health insurers, and even sometimes researchers were hard put to distinguish between these two forms of diabetes using the old terminology. The new classification, dependent on etiology rather than mode of treatment, puts a greater emphasis on the history and characteristics of the patients to determine the probable etiology and type. Two categories of blood glucose elevation, impaired glucose tolerance (IGT) and impaired fasting glucose (IFG), that lie between normal glucose levels and overt diabetes have also been established [*see Impaired Glucose Tolerance, below*].[2]

gestational diabetes mellitus

Gestational diabetes mellitus (GDM) constitutes a separate category for cases of diabetes first detected during pregnancy.[3] When diabetes is detected early in pregnancy, it is likely to be type 1 or type 2 diabetes mellitus that is presenting symptomatically and was probably precipitated or worsened by the pregnant state. Diabetes is commonly detected in the second and third trimester (i.e., in 4% of pregnant women) and is likely to be specific for the pregnant state, to be transient, and to reverse to normal glucose tolerance or to IGT on follow-up oral glucose tolerance testing 6 weeks after delivery. However, GDM is associated with a high risk of future diabetes, especially in women who have IGT post partum or who remain obese.[3] Permanent diabetes will develop in approximately 50% of patients within 10 years of GDM. The greatest importance of any single episode of GDM lies in the risks it poses to the fetus. These risks include intrauterine mortality, neonatal mortality, respiratory distress syndrome, hypoglycemia, hypocalcemia, jaundice, and macrosomia, which can cause trauma such as shoulder dystocia during passage through the birth canal.

secondary forms of diabetes mellitus

Of the categories of secondary diabetes [*see Table 1*], endocrinopathies and drug- or chemical-induced diabetes are noteworthy because they represent instances of diabetes that are potentially reversible if they are recognized and the physician can cure the endocrinopathy or discontinue the offending drug. The category of genetic defects in beta cell function illustrates how the classification will grow ever more detailed as knowledge increases. For example, the single diabetes mellitus phenotype formerly called maturity-onset diabetes of the young (MODY) can now be

more precisely classified into at least four genetic varieties, each of which arises from mutation of a different gene.

Diabetes caused by chronic pancreatitis, pancreatectomy, or occasionally carcinoma of the pancreas is usually type 1 in character. Because patients with this disease have glucagon as well as insulin deficiency, they are somewhat less likely to go into ketoacidosis[4] but are quite vulnerable to hypoglycemia. Because they are deficient in pancreatic enzymes, their digestion and subsequent absorption of nutrients is somewhat erratic, even though replacement enzymes are ingested with meals. If alcoholism, often the cause of chronic pancreatitis, is irremediable, it also contributes to blood glucose instability, as does the often accompanying irregular lifestyle. Small frequent doses of lispro insulin should be helpful, but safety may require less stringent blood glucose goals in such patients.

Although many individual drugs have been incriminated as a cause of hyperglycemia, the continued use of pharmacologic anti-inflammatory or immunosuppressive doses of synthetic glucocorticoids is an especially important continuing problem. Up to 25% of renal transplant patients develop so-called steroid diabetes.[5] In a case-control study, use of glucocorticoids for up to 45 days was a risk factor for diabetes that required pharmacologic treatment.[6] The odds ratio rose from 1.77 at a prednisone equivalent of 10 mg/day to an odds ratio of 10.3 at 30 mg/day. Obesity and family history of diabetes increased the risk of steroid diabetes. Although insulin resistance in the liver and muscle is a well-recognized effect of glucocorticoids, an action on the beta cells to limit the compensatory response to hyperglycemia[7] adds to the diabetogenic effect at higher steroid doses. Patients treated with glucocorticoids for more than a few days need to be warned to watch for and report clinical symptoms of hyperglycemia promptly. Ketoacidosis is rare, but hyperglycemic hyperosmolar nonketotic coma can occur. Insulin treatment is usually necessary for symptomatic patients and for those with a fasting plasma glucose (FPG) level greater than 200 mg/dl, but sulfonylurea drugs are sometimes effective. There is little systematic information on the efficacy of the other oral agents. In most instances, steroid diabetes is transient, but in a minority of cases, diabetes persists even after withdrawal of the glucocorticoids.

Table 1 Etiologic Classification of Diabetes

- Type 1 diabetes mellitus* (β cell destruction, usually leading to absolute insulin deficiency)
  - Immune mediated
  - Idiopathic
- Type 2 diabetes mellitus* (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)
- Other specific types of diabetes
  - Genetic defects of β cell function
    - Chromosome 12, HNF-1α (formerly MODY3)
    - Chromosome 7, glucokinase (formerly MODY2)
    - Chromosome 20, HNF-4α (formerly MODY2)
  - Genetic defects in insulin action
    - Type A insulin resistance
  - Disease of the exocrine pancreas
    - Pancreatitis
    - Trauma/pancreatectomy
    - Neoplasia
  - Endocrinopathies
    - Acromegaly
    - Cushing syndrome
    - Glucagonoma
  - Drug- or chemical-induced
    - Nicotinic acid
    - Glucocorticoids
    - Thiazides
  - Infections
    - Congenital rubella
    - Cytomegalovirus
  - Uncommon forms of immune-mediated diabetes
    - Stiff-man syndrome
    - Anti-insulin receptor antibodies
  - Other genetic syndromes associated with diabetes
    - Down syndrome
    - Turner syndrome
    - Friedreich ataxia
    - Myotonic dystrophy
- Gestational diabetes mellitus (GDM)

Note: The list of other specific types of diabetes is not comprehensive. There are many other such syndromes.
*Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient.

Screening for Diabetes

Screening for type 1 diabetes mellitus by office glucose testing is currently indicated in high-risk patients. Current American Diabetes Association criteria for office screening of asymptomatic individuals for type 2 diabetes mellitus employ FPG levels.[1] Screening is recommended in all individuals 45 years of age and older at 3-year intervals. Younger individuals should be screened if they are obese (> 120% desirable body weight or a body mass index ≥ 27), have a first-degree relative with diabetes, are members of a high-risk ethnic population (African American, Hispanic American, Native American, Asian American), have delivered a baby weighing more than 9 lb, have previously had GDM, are hypertensive (blood pressure ≥ 140/90 mm Hg), have atherogenic dyslipidemia (high-density lipoprotein [HDL] cholesterol levels ≤ 35 mg/dl or triglyceride levels ≥ 250 mg/dl) or had IFG or IGT on previous testing.[1] Mass indiscriminate public screening is not justified, because there is as yet no proof of population benefit.

Epidemiology

TYPE 1 DIABETES MELLITUS

Available, but not up-to-date, studies suggest the prevalence of type 1 diabetes mellitus in the United States is 1.7 per 1,000 in individuals younger than 19 years and 2.1 per 1,000 in adults.[8] A total prevalence of approximately 500,000 is estimated. Current estimates of annual incidence are 18 per 100,000 population in the 0- to 19-year age range and 9 per 100,000 population in those older than 20 years.[8] Approximately 30,000 cases of type 1 diabetes mellitus are estimated to occur yearly in the United States, and it is more common in whites than in African Americans. Worldwide, the highest annual incidence of type 1 diabetes mellitus is found in Finland (35 cases per 100,000) and the lowest is found in Korea (< 1 per 100,000).

TYPE 2 DIABETES MELLITUS

Analysis of data from the third National Health and Nutrition Examination Survey (NHANES III), conducted from 1988 to 1994,[9] indicates a prevalence of 5.1% for adults at least 20 years of

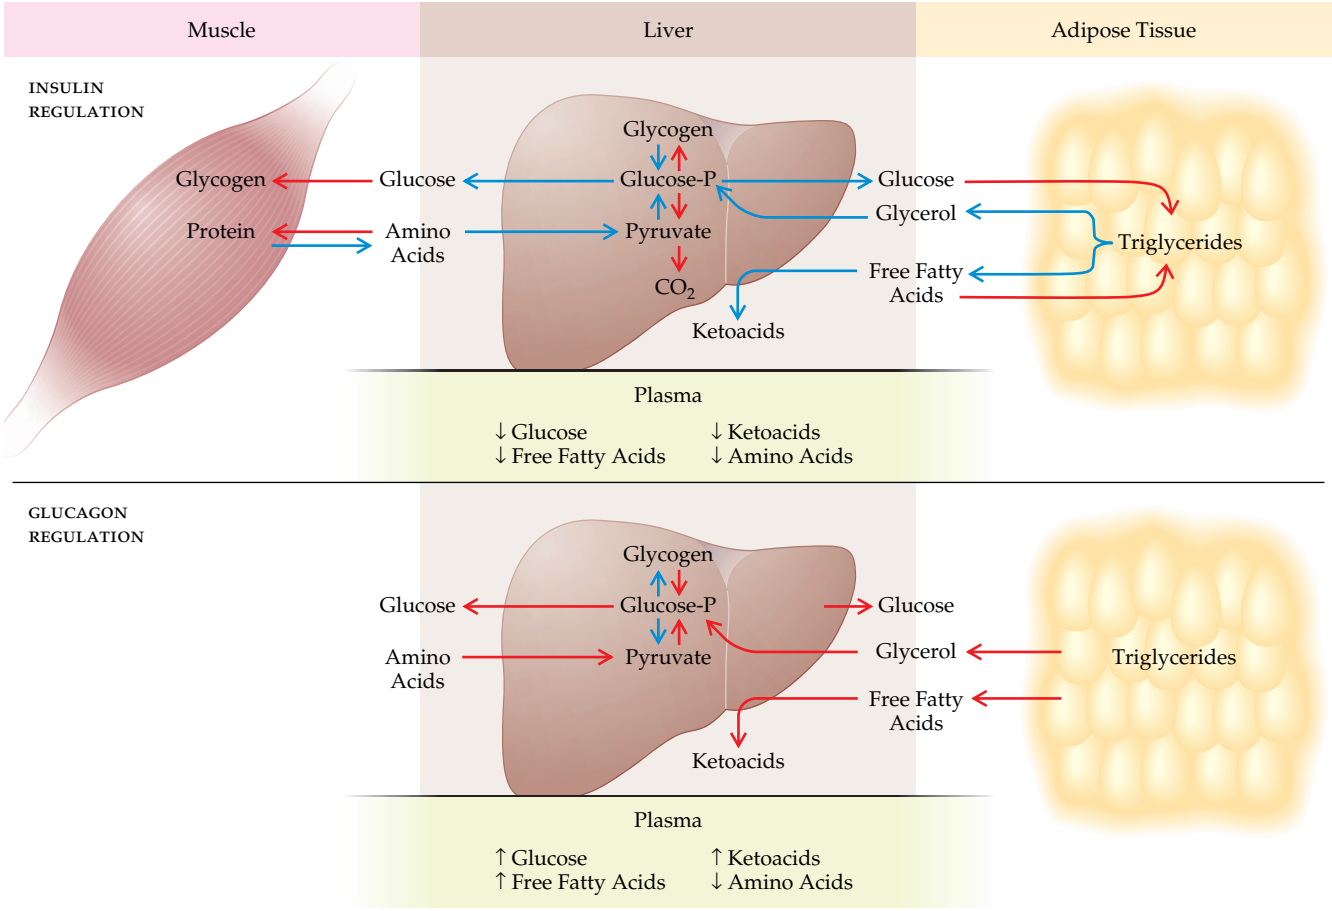

Figure 1 **The opposing actions of insulin and glucagon, particularly within the liver, on substrate flow and plasma levels are seen here. The two hormones have directly opposite effects on key enzymes, such as glycogen synthase and phosphorylase. Thus, stimulatory effects of glucagons on glucose and ketoacid production are magnified when insulin is deficient, as in type 1 diabetes mellitus. Red arrows indicate stimulation. Blue arrows indicate inhibition.**

age in the United States and a prevalence of 2.7% of undiagnosed diabetes (FPG ≥ 126 mg/dl). A prevalence of 12.3% (diagnosed plus undiagnosed) was estimated for individuals 40 to 74 years of age. There are an estimated 10.2 million diagnosed and 5.4 million undiagnosed cases of diabetes in the United States. The estimated number of persons with IGT approximately equals the number with diabetes. Non-Hispanic African-American and Mexican-American women have nearly twice the prevalence of diabetes as non-Hispanic white women. Non-Hispanic African-American men have a slightly higher risk than non-Hispanic white men, but Mexican-American men have about a 50% greater risk than non-Hispanic white men.[9]

Annual incidence of type 2 diabetes mellitus per 100,000 population ranges from 180 in 25 to 44 year olds to a peak of 860 in 65 to 74 year olds. Approximately 625,000 cases of type 2 diabetes mellitus develop yearly in the United States.[10] The prevalence is expected to rise from 15 million in the year 2000 to 21 million in 2025. Worldwide, the prevalence of type 2 diabetes mellitus will likely increase from 150 million to 300 million during that time.[11] The increase[12] reflects aging of the population, strikingly increased obesity,[13] and a sedentary lifestyle. This rise in the number of cases is especially troubling in regard to high-risk ethnic minorities whose access to medical care may be limited.[14,15]

Obesity is a major risk factor for type 2 diabetes mellitus.[16] The current definition of obesity employs the body mass index (BMI) (body weight in kilograms divided by height in meters squared). A person with a BMI of at least 25 but less than 30 is defined as overweight.[17] A BMI of 30 or more is defined as obesity,[16] and a BMI of 40 and above is associated with a 15-fold increased risk of type 2 diabetes mellitus.[15] Abdominal obesity, defined as a waist circumference greater than 100 cm in men and greater than 88 cm in women or a waist-to-hip ratio greater than 0.9, is an especially strong risk factor for type 2 diabetes mellitus. A large preponderance of patients with type 2 diabetes mellitus are obese; even those with normal BMI may have an increased percentage of their body weight accounted for by fat.[18] Longer duration of obesity further increases the risk of diabetes, emphasizing the importance of early efforts to control weight. Many patients with type 2 diabetes mellitus have a strong family history of that disease in first-degree relatives. An extraordinary example is found among the Arizona Pima Indians on the Gila River reservation, where 50% of the adult population has type 2 diabetes mellitus. Other risk factors for the disease include physical inactivity, hypertension, dyslipidemia, gestational diabetes, low birth weight, low income, low level of education, and low socioeconomic status.[1,19]

Hormonal Regulation of Metabolism

Diabetes involves the most fundamental aspects of human metabolism. The following are all affected by the hormonal abnormalities of diabetes: energy production and expenditure; the proportioning of carbohydrate, fat, and protein as energy sourc-

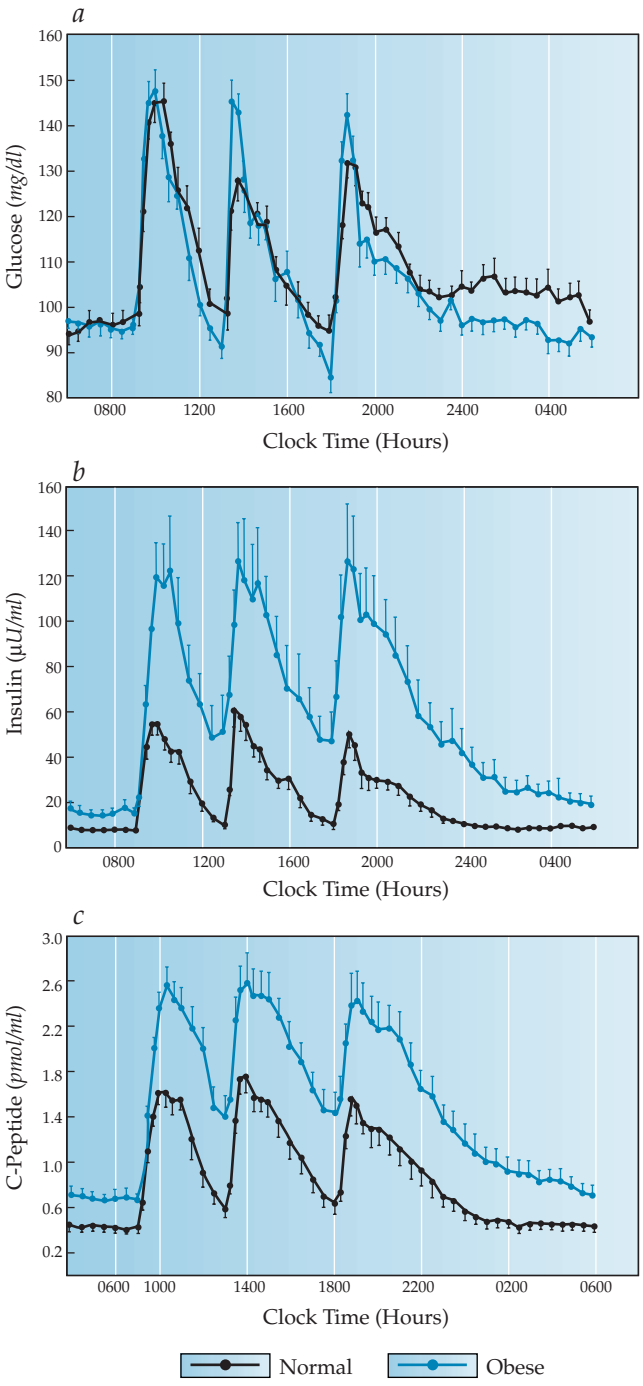

Figure 2 **Plasma glucose (*a*) is normally kept within a narrow range throughout the day, largely because of beta cell function. Plasma insulin (*b*) and plasma C-peptide (*c*) rise sharply from their basal levels with each meal and, after reaching peaks, return promptly to basal levels, which are maintained throughout the night. Note also that plasma insulin and C-peptide levels are elevated in obese individuals who are insulin resistant.**

es; the storage of energy as carbohydrate and fat; and the balance between protein synthesis (anabolism) and degradation (catabolism). To understand the pathogenesis of diabetes, it is useful to start with a brief review of normal metabolism.[20]

A proper balance between insulin and glucagon is one crucial hormonal regulator of basal metabolic homeostasis.[20] Insulin primarily facilitates storage of glucose as glycogen, free fatty acids in triglycerides, and amino acids in protein, and it inhibits glycogenolysis, lipolysis, ketogenesis, proteolysis, and gluconeogenesis [*see Figure 1*]. Glucagon stimulates mobilization of glucose, free fatty acids, and glycerol and stimulates hepatic uptake of amino acids and the conversion of their carbon skeletons to glucose. Glucagon also stimulates ketogenesis from free fatty acids. The normal steady-state levels of insulin and glucagon help maintain the overnight FPG level at 60 to 110 mg/dl, free fatty acid levels at less than 0.7 mmol/L, ketoacids at less than 0.2 mmol/L, and each amino acid at its unique level. After a mixed meal, plasma insulin rises sharply [*see Figure 2*] and, with it, the insulin-glucagon ratio. This condition reverses all the previously described processes. Dietary carbohydrate is stored in muscle and liver glycogen, free fatty acids are reesterified and stored as triglycerides in adipose tissue, and protein metabolism shifts back toward anabolism. When all the nutrients have been assimilated and plasma glucose returns to its basal preprandial level, plasma insulin [*see Figure 2*] and the insulin-glucagon ratio promptly return to basal levels, preventing an overshoot of insulin action that would otherwise cause hypoglycemia. Thus, an immediate rise, an early peak, and a prompt fall in insulin secretion are requisite to normal postprandial metabolism [*see Figure 2*].

Insulin is synthesized in pancreatic islet beta cells from a larger molecule called proinsulin, which is then split to yield insulin and an intramolecular connecting peptide called C-peptide [*see Figure 3*]. The two molecules are stored in the same granules and secreted in an equimolar ratio when the beta cell is stimulated. Thus, plasma C-peptide levels are a faithful marker of beta cell function [*see Figure 3*].

Insulin acts via a plasma insulin receptor that leads to the generation of multiple mediators of insulin's numerous intracellular cytoplasmic and nuclear effects [*see Figure 4*]. Insulin regulates both the activities and syntheses of target enzymes. Sensitivity of target tissues to insulin is the other major determinant of insulin action. Insulin sensitivity is best measured in humans by infusing insulin to establish steady-state plasma insulin levels [*see Figure 5*]. Simultaneously, the baseline plasma glucose is maintained at a constant level by a variable glucose infusion. The amount of glucose required to prevent plasma glucose from decreasing under the effect of insulin is equal to the increased amount of glucose being used per unit time under insulin stimulation (assuming that insulin has completely suppressed hepatic glucose output by the liver). The quantity of glucose used per unit time divided by the plasma insulin level provides an index of whole body sensitivity to insulin in the sphere of glucose metabolism.

A feedback loop exists between insulin responsiveness in target tissues and insulin secretion by beta cells. This relation operates to increase insulin secretion in individuals relatively resistant to insulin action and to decrease insulin release in individuals very sensitive to insulin action. The result is one critical mechanism for maintaining fasting and postprandial plasma glucose levels within narrow normal ranges.

Pathogenesis of Microvascular Complications in Diabetes

A distinctive feature of diabetes—the microvascular complications—were only revealed or commonly appreciated after the introduction of insulin therapy in 1922 allowed patients with type 1 diabetes mellitus to live long enough to experience these complications. It should be borne in mind that the descriptions and pathogenetic sequences presented below reflect a former

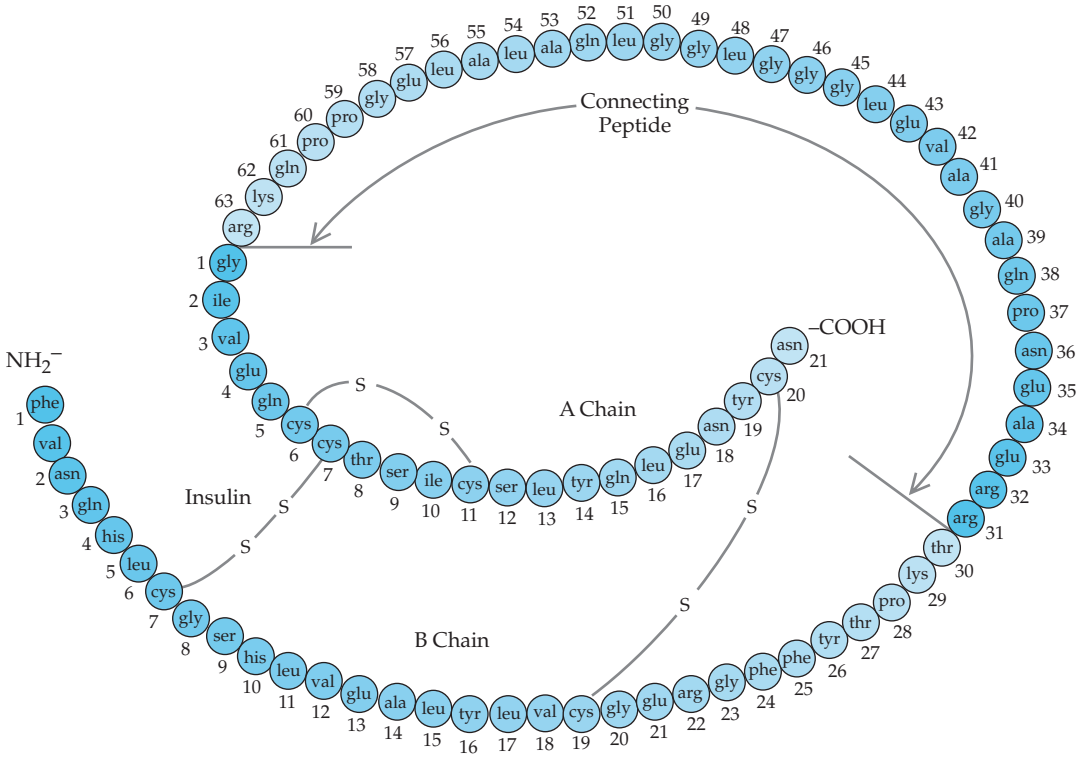

Figure 3 **The structure of human proinsulin, the precursor molecule to insulin. The peptide that connects the amino terminus (NH_2^-) of the A chain to the carboxyl terminus (–COOH) of the B chain is called connecting peptide (C-peptide). Proinsulin is converted to insulin and C-peptide, and these two molecules are packaged together in the secretory granule. On stimulation of the beta cell, C-peptide and insulin are secreted in equimolar proportions. Thus, C-peptide levels reflect beta cell functional capacity.**

commonly practiced degree of metabolic control no longer considered acceptable. Prevention of these complications is a major goal of current therapeutic policy and recommendations for all but transient forms of diabetes [*see* Prevention and Treatment of Microvascular Complications, *below*].

RETINOPATHY

Given a long enough duration, retinopathy occurs in almost all patients with type 1 diabetes mellitus and in most patients with type 2 diabetes mellitus who are on conventional treatment that does not come close to normalizing glycemic levels [*see Table 2*].[21] The most common form of retinopathy is nonproliferative retinopathy (also termed background retinopathy). It begins with loss of capillary pericytes, the supporting cells of the retinal vasculature, a loss leading to capillary dilatations that are seen on direct fundoscopy as microaneurysms [*see Figure 6a*]. Microaneurysms measure 50 to100 µm in diameter and can occur anywhere in the retina. However, they tend to cluster near the macula, the area responsible for central vision and visual acuity. Small dot hemorrhages form when microaneurysms leak blood. Hard lipid exudates form on leakage of serum [*see Figure 6a*]. These lesions are usually benign unless they occur quite close to the macula and in sufficient number to cause clinically significant macular edema. The latter is a feared complication that can decrease central vision and acuity. Capillary closure, which actually begins in the phase of background retinopathy, increases; and in the phase of preproliferative retinopathy, enough capillaries become obstructed to cause ischemia of the retina. Infarctions of the retinal nerve layer appear as soft (cotton wool) exudates. The retina responds to further ischemia with proliferation of new blood vessels from its surface [*see Figure 6b*]. In this phase of proliferative retinopathy, ischemic retina releases vascular endothelial growth factor (VEGF), which stimulates new vessel formation. These new vessels grow forward into the vitreous. They are extremely fragile and can bleed into the vitreous, causing temporary loss of vision until the blood is reabsorbed. If no reabsorption occurs, blindness can result unless successful vitrectomy is carried out. Proliferative vessels that cover more than one fourth of the disk diameter and that occur within 1 disk diameter of the disk [*see Figure 6b*] are especially likely to bleed. Even after reabsorption of the vitreous blood, fibrous scars form that can cause traction on the retina and can lead to retinal detachment, another cause of profound and often permanent loss of vision.

NEPHROPATHY

Diabetic nephropathy [*see Figure 7*] is the complication associated with the highest mortality. Between 35% and 45% of patients with type 1 diabetes mellitus and a somewhat smaller percentage of patients with type 2 diabetes mellitus experience significant nephropathy.[22-24] Histologically, the earliest change is thickening of the capillary basement membrane. Subsequently, mesangial material accumulates diffusely throughout the glomerulus [*see Figure 8*]. Ultimately, there is loss of podocytes and development of peritubular fibrosis. Excretion of low but abnormal levels of albumin in the urine is a marker of the incipient phase of nephropathy.[25] As glomeruli become increasingly filled with mesangial matrix products, albuminuria increases and eventually gross proteinuria appears. Microalbuminuria is defined as excretion of 30 to 300 mg of albumin a day or an albumin-creatinine ratio between 30 and 300 in a random urine spec-

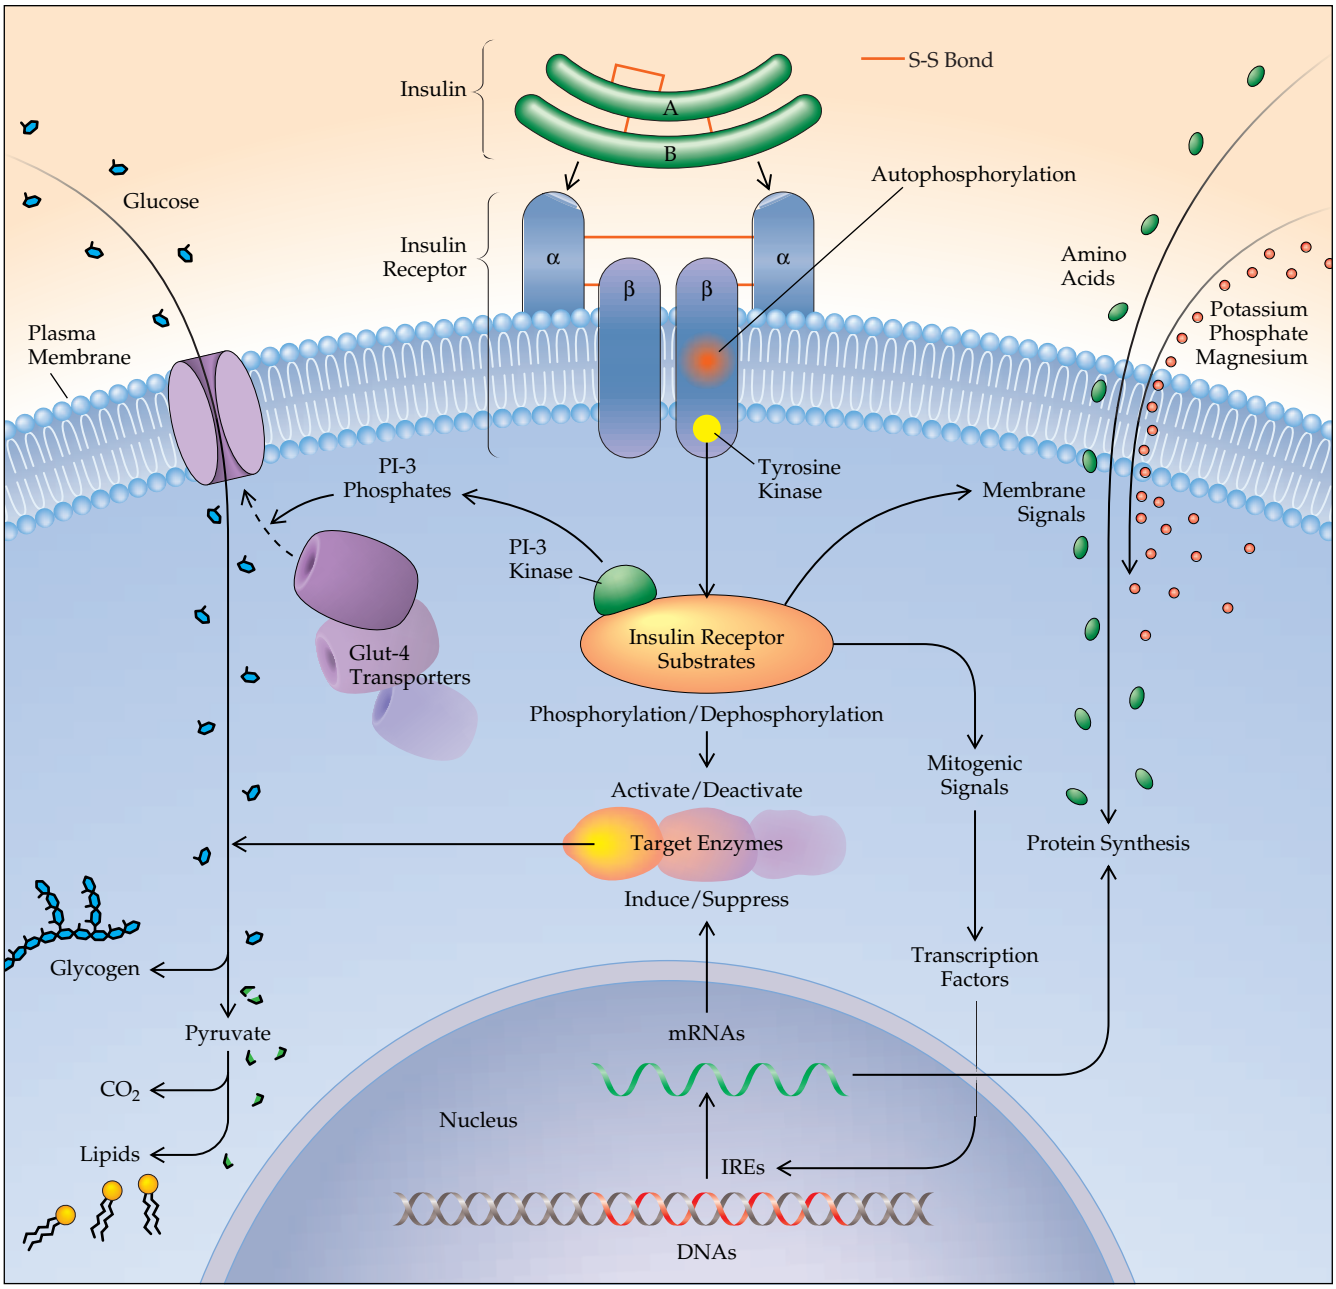

Figure 4 **The cellular actions of insulin begin with binding to its plasma membrane receptor. As a result, certain tyrosine molecules in the intracellular portion of the transmembrane receptor are autophosphorylated, creating tyrosine kinase activity in the receptor. Several intracellular insulin receptor substrates (IRS) are then tyrosine phosphorylated by the receptor. Phosphorylated IRS docks and either activates or inactivates numerous enzymes (e.g., phosphatidylinositol-3-kinase [PI-3 kinase]) and other mediating molecules. Among the chief effects of these insulin-stimulated cascades are translocation of glucose (Glut-4) transporters to the plasma membrane, where they facilitate glucose diffusion into the cell; shifting of intracellular glucose metabolism toward storage as glycogen by activating glycogen synthase; stimulation of cellular uptake of amino acids, phosphate, potassium, and magnesium; stimulation of protein synthesis and inhibition of proteolysis; and regulation of gene expression via insulin regulatory elements (IRE) in target DNA molecules. Numerous intermediates in these various pathways, along with the molecules mentioned above, are products of candidate genes whose mutation could produce the state of insulin resistance characteristic of type 2 diabetes mellitus. Red connectors between insulin chains A and B and among insulin receptor subunits α and β indicate S-S bonds. The A chain also has an intramolecular S-S bond.**

imen. Clinical proteinuria is defined as excretion of more than 0.5 g of total protein a day. This level of excretion can be detected by a positive dipstick urine test for protein. The nephrotic syndrome may also eventually occur.

Early in type 1 diabetes mellitus, kidney size and glomerular filtration rate (GFR) may actually be greater than normal. However, in both types of diabetes, GFR begins to decline, and after clinical proteinuria develops, GFR almost inexorably falls to the level of ESRD [*see Figure 7*]. Unlike the risk of retinopathy, the risk of nephropathy does not continue to rise with increasing duration. The incidence of nephropathy peaks at approximately 15 to 17 years and declines somewhat thereafter.[26] The prevalence of nephropathy remains approximately constant after that time. If the dipstick test has not revealed proteinuria by 25 to 30 years

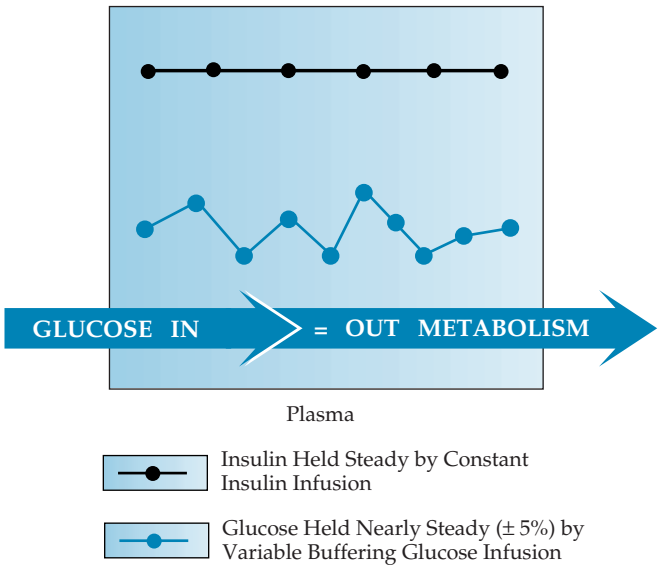

Figure 5 **The diagram represents the gold standard for measuring the sensitivity of glucose metabolism to insulin, utilizing a glucose insulin clamp. When steady state is reached, glucose metabolized/unit time = glucose infused/unit time. Assuming endogenous glucose production is suppressed to zero, insulin sensitivity = (glucose metabolized/unit time) ÷ plasma insulin. For each dose of insulin, the more exogenous glucose required to sustain plasma glucose at its basal levels, the greater the insulin sensitivity. Conversely, individuals who require lesser amounts of glucose than usual to maintain the basal plasma glucose level are insulin resistant. The latter is usually the case in type 2 diabetes mellitus.**

of diabetes duration, the risk of ESRD decreases. Coincident with or shortly after the development of microalbuminuria, hypertension often appears. Hypertension in turn further aggravates diabetic nephropathy and is an important component in the progression to renal failure.

NEUROPATHY

Neuropathy has protean manifestations in diabetes. The most common presentation is peripheral symmetrical sensorimotor neuropathy, which causes numbness or tingling in the toes and feet.[27] At this point, symptoms are only mildly disturbing and require no specific treatment. These symptoms may even abate over time as neuropathy becomes more severe and hypoesthesia or anesthesia takes the place of paresthesias and dysesthesias. Ultimately, insensate feet become very vulnerable to trauma, and neuropathic foot ulcers are frequent causes of hospitalization and even amputation. Testing sensation with a nylon monofilament providing a calibrated 10 g point pressure is an effective way to screen for high risk of foot ulcers. Patients who cannot detect the pressure of the nylon filament have a 30- to 40-fold increased risk of foot ulcer.[28] In some instances, neuropathy is manifested by severe pain that can interfere with sleep and normal daily activities. The distribution of pain can suggest mononeuropathy and radiculopathy. Abrupt onset of cranial neuropathies that most commonly give rise to extraocular muscle weakness and diplopia has been attributed to microinfarcts caused by thrombosis of nutrient blood vessels. Carpal tunnel syndrome and other entrapment syndromes are more frequent in diabetic patients than in nondiabetic patients.

Involvement of the autonomic nervous system is also common and can become debilitating. Manifestations include male impotence and female anorgasmia, difficulty voiding and urinary retention, impaired gastric emptying with early satiety and emesis, diarrhea, orthostatic hypotension, and decreased sweating and vasomotor tone in the lower extremities. The combination of decreased sympathetic tone and loss of vagal control of the heart rate can produce persistent resting sinus tachycardia; sudden death can result.

A form of diabetic neuropathy called amyotrophy occurs most commonly in elderly men with diabetes. It is manifested by severe, unremitting pain and weakness in the thigh muscles. Severe depression, cachexia, and weight loss may mark the 1- to 2-year course of this form of neuropathy. Sometimes confused with painful neuropathy are rare muscle infarcts, usually occurring in the thigh muscles. These infarcts are marked by abrupt onset of severe pain lasting several months. Magnetic resonance imaging of the affected area can demonstrate the presence of necrosis.

Diabetic neuropathy may be another microvascular complication, but the pathogenesis is still not completely understood.[29] Demyelinization of nerves is manifested by decreases in motor and sensory nerve conduction velocities. Axonal degeneration is reflected in decreased amplitudes of action potentials. Histologically, swelling is seen at the axonal nodes. An inflammatory component to diabetic neuropathy has also been suggested.[30]

RELATION OF MICROVASCULAR COMPLICATIONS TO GLYCEMIA

The appearance of microvascular complications in the 1930s generated a 50-year debate about whether diabetic retinopathy, nephropathy, and neuropathy were the direct result of the metabolic abnormalities, most notably hyperglycemia, or whether they were a parallel independent consequence of diabetes that had formerly been usually preempted by death from extreme metabolic disequilibrium (i.e., diabetic coma). This debate ultimately came to encompass type 2 diabetes mellitus as well. The debate was not merely academic, because it was reflected in quite different approaches to treatment. A belief in the metabolic hyperglycemic cause of retinopathy, nephropathy, and neuropathy impelled the physician to work with inadequate means to help the patient achieve as close to normal blood glucose levels as possible. Conversely, a belief in the metabolically independent nature

Table 2 Diabetic Retinopathy

*Stage**	*Pathologic Process*	*Manifestations*
Background	Loss of capillary integrity Leakage, exudation, diapedesis Early capillary closure	Microaneurysms Dot hemorrhages Hard exudates Macular edema
Preproliferative	Capillary closure Microinfarcts Ischemia	Blot hemorrhages Soft exudates Intraretinal microvascular abnormalities Venous beading Macular edema
Proliferative	Forward growth of new large vessels Fibrosis Traction on retina or vitreous	Preretinal hemorrhage Vitreous hemorrhage Retinal detachment Macular edema

*Loss of visual acuity may occur from macular edema at any stage. Blindness may occur from severe macular edema, vitreous hemorrhage, or retinal detachment.

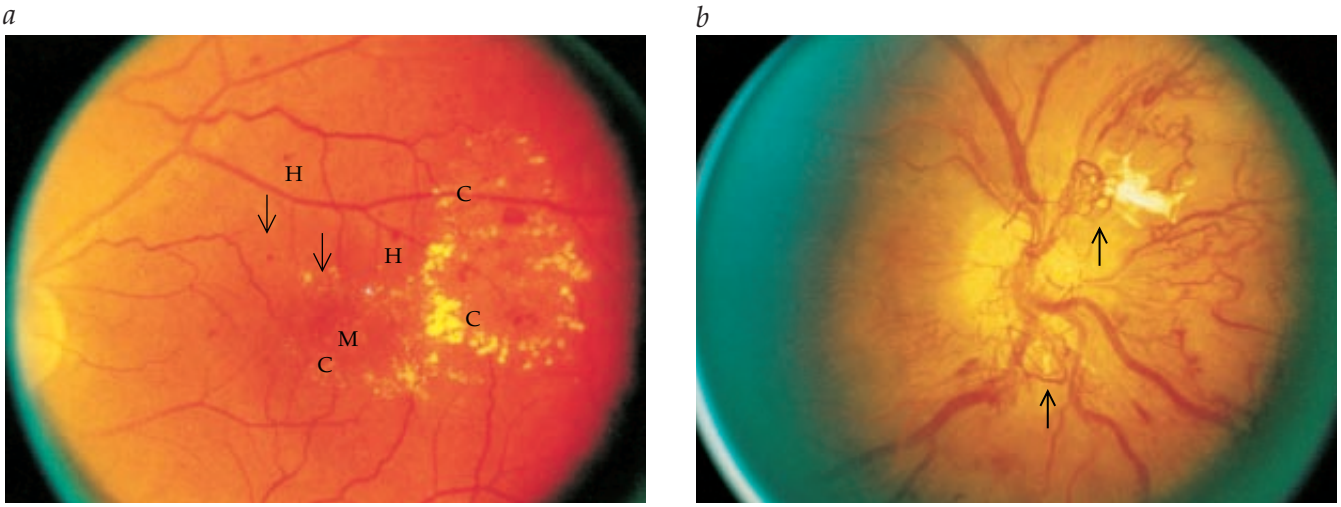

Figure 6 **(*a*) This fundus photograph reveals nonproliferative (or background) retinopathy in a diabetic patient. Microaneurysms (arrows) occur at end capillaries. Punctate (or dot-and-blot) hemorrhages (H) and hard exudates (C) can also be seen. The hard exudates form three distinct circles (termed circinate retinopathy), which indicate leakage of plasma proteins from abnormal vessels located in the centers of the three circles. Lesions in the area of the macula (M) are potentially more dangerous, as they may lead to macular edema requiring laser therapy. (*b*) In proliferative retinopathy, new vessels grow from the retina into the vitreous. This fundus photograph reveals fine, tangled, new vessels originating from several areas of the disk (arrows). The vessels often form arcades and characteristically have thin walls and are fragile. They tend to bleed into the vitreous; the scars that form can cause retinal detachment and loss of vision. Proliferation within one disk diameter of the disk (termed neovascularization of the disk) is particularly dangerous, as these vessels are especially prone to bleed and form traction scars.**

of these complications encouraged a somewhat more laissez-faire approach, which attempted primarily to eliminate the immediate symptoms, such as polyuria, that were produced by plasma glucose levels exceeding the renal threshold (> 180 mg/dl). Furthermore, the risks associated with the more aggressive approach to hyperglycemia reinforced the arguments of the conservative practitioners. A large body of evidence was eventually built up that supported but did not prove the so-called glucose hypothesis.[31] The Diabetes Control and Complications Trial (DCCT) and United Kingdom Prospective Diabetes Study (UKPDS) ended this debate for type 1 and type 2 diabetes mellitus, respectively.

The DCCT[32] was a randomized clinical trial that enrolled 1,441 nonobese patients, aged 13 to 39 years, with type 1 diabetes mellitus. Half of the patients with diabetes of 1 to 5 years' duration participated in a primary prevention trial that excluded all patients with retinopathy or microalbuminuria, and half of the patients with diabetes of 1 to 15 years' duration participated in a secondary intervention trial that included only patients who already had mild to moderate nonproliferative diabetic retinopathy but less than 200 mg/day of urinary albumin excretion. In both of these DCCT trials, patients were randomly assigned either to receive conventional treatment (no more than two insulin injections a day) or to receive intensive treatment (three to four insulin injections a day or use of a continuous subcutaneous insulin infusion [CSII] pump; self-monitoring of blood glucose at least four times a day; premeal target blood glucose levels of 70 to 120 mg/dl; glycated hemoglobin [HbA_{1c}] goal of less than 6.05%; and very frequent contacts between patient and treatment team). An HbA_{1c} difference of 1.8% (8.9% versus 7.1%) was maintained between the two treatment groups for up to 9 years.[33]

Over a mean follow-up of 6.5 years, intensive treatment produced substantial benefits. The risks of de novo development (primary prevention trial) or of progression (secondary intervention trial) of retinopathy were reduced by 27% to 76%; the development of microalbuminuria was reduced by 35%; macroalbu-

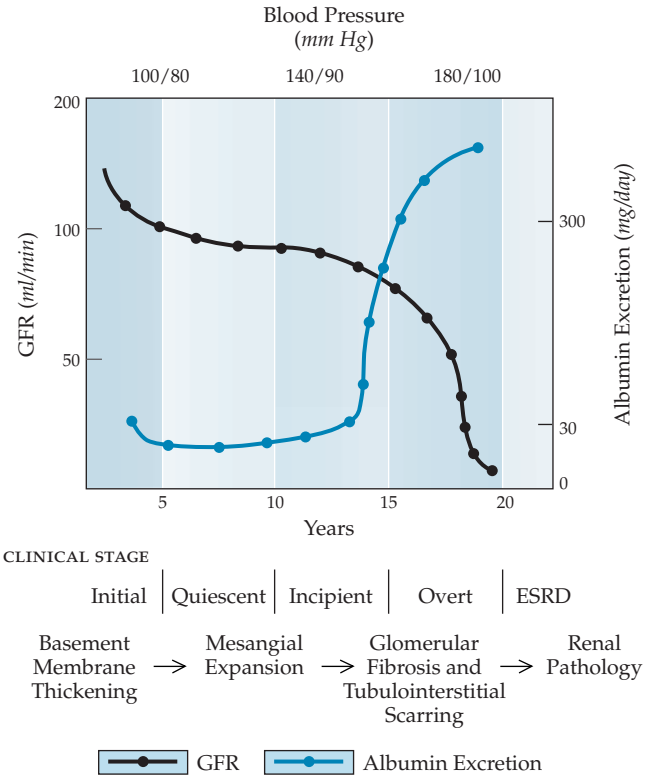

Figure 7 **Relation of the developing histopathologic changes in the kidney to the development of renal functional abnormalities. Note that GFR is actually elevated early, corresponding to early renal hypertrophy. The appearance of microalbuminuria (albumin excretion > 30 mg/day) indicates that the patient is at considerable risk for overt nephropathy and end-stage renal disease (ESRD), but not all such individuals suffer this fate. Blood pressure begins to rise at about the time that microalbuminuria appears, and hypertension further damages the kidney.**

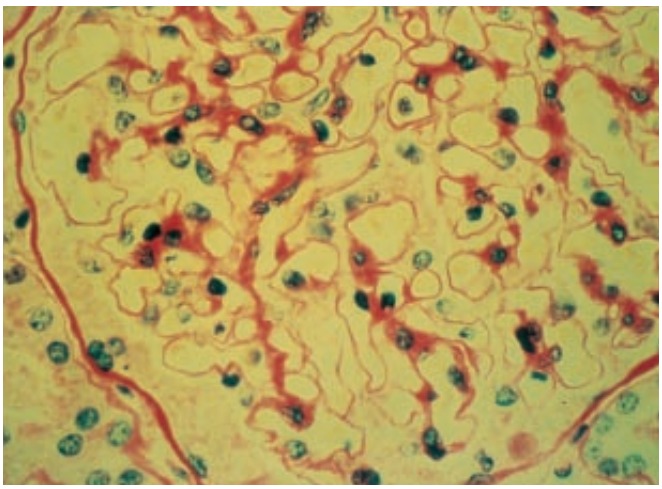
a



b

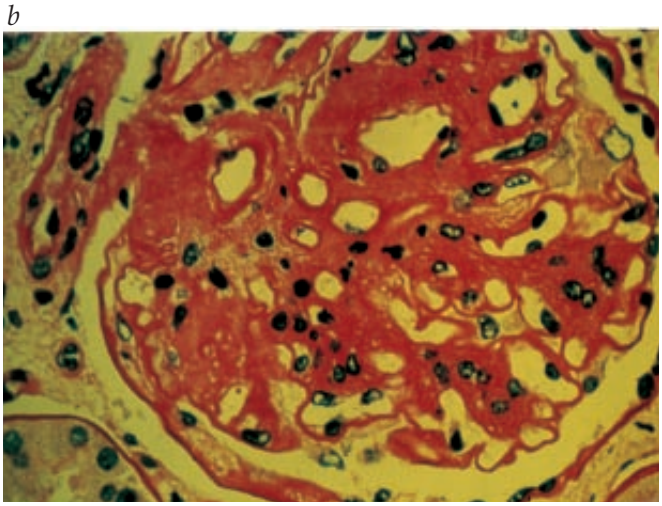


Figure 8 **(*a*) The normal glomerulus with a large filtration surface has a lacy appearance. (*b*) There is diffuse deposition of extramesangial material throughout, as well as thickening of capillary basement membranes in a diabetic glomerulus. The GFR through such a glomerulus is reduced.**

minuria (i.e., proteinuria) was reduced by 56%; and development of clinical neuropathy, confirmed by abnormal nerve conduction velocities or autonomic nervous system function tests, was reduced by 60%.[32] Patients in the primary prevention cohort, with a mean diabetes duration of 2.5 years, had a greater response to intensive treatment than did patients in the secondary prevention cohort, with a mean diabetes duration of 8.5 years.

The main adverse effect of intensive treatment was a threefold increase in the risk of severe hypoglycemic episodes characterized by coma, convulsions, or the required assistance of others to treat and reverse the episode.[32,34] At least one such event per year was experienced by 25% of intensively treated patients, and 50% had experienced more than one such episode by the end of the study[34];14% experienced 10 or more episodes. The overall rate of severe hypoglycemia was 62 events per 100 patient-years for intensive treatment, compared with 19 events per 100 patient-years for conventional treatment. In addition, intensive treatment caused greater weight gain; one third of the patients exceeded 120% of ideal body weight (approximate BMI, 27) by the end of the study.[32] Intensive treatment was also more expensive than conventional treatment.[35] However, the cost was partly offset by projected decreased costs of a lower rate of complications,[36] and the estimated cost per year of quality life gained was $28,661, a figure thought to represent a good value.

The UKPDS[37,38] enrolled 5,102 patients with newly diagnosed type 2 diabetes mellitus, a mean age of 53 years, and a mean BMI of 28. After a 3-month dietary run-in, 1,138 patients were randomly assigned to a continuation of diet treatment only as long as their FPG remained below 270 mg/dl and they had no hyperglycemic symptoms. In the study, 2,729 patients were randomly assigned to intensive treatment, 1,573 to receive one of three sulfonylurea (SU) drugs, and 1,156 to receive insulin. In two thirds of the clinical sites, 342 patients were also randomized to intensive treatment with metformin. The goal of intensive treatment was an FPG of less than 108 mg/dl. Of the conventional-treatment patients, 80% ultimately required drugs to maintain their treatment goals of an FPG of less than 270 mg/dl and freedom from symptoms, although nearly 60% of their total treatment time was spent on diet therapy alone. Likewise, in the intensive-treatment groups, metformin therapy had to be added to the SU therapy, and insulin had to be substituted for or added to oral-drug therapy to maintain the stringent treatment goal.

Despite these drug crossovers, after 10 years of follow-up, patients who received intensive treatment showed a 25% decrease in the risk of serious microvascular complications (vitreous hemorrhage, need for laser treatment, and renal failure), compared with patients given conventional treatment.[37] This important benefit was associated with an HbA_{1c} difference of 0.9% (7.9% for conventional therapy; 7.0% for intensive therapy). Serious hypoglycemia occurred in 3% of insulin-treated patients each year and in 1% to 2% of SU-treated patients. These rates were much lower than that experienced with intensive treatment in patients with type 1 diabetes mellitus in the DCCT.

These two trials provided experimental proof that microvascular and neuropathic complications could be prevented or at least substantially delayed by maintaining blood glucose levels as near to normal as treatment techniques would safely allow. Although these two experimental trials did not prove that hyperglycemia caused microvascular complications, both trials provided additional strong evidence supporting that hypothesis. In the DCCT, the risk of retinopathy was directly related to the preceding mean HbA_{1c} difference in a similar exponential fashion in each of the two treatment groups.[39] The risk of retinopathy was decreased by about 44% for each proportional 10% decrease in HbA_{1c} (e.g., a decrease in HbA_{1c} from 10% to 9.0%). Microalbuminuria and neuropathy showed similar risk relations with glycemia. In the UKPDS, the risk of microvascular complications was also directly related to the mean HbA_{1c} in an exponential fashion.[40] The risk of these complications was decreased by about 37% for every absolute decrease of 1% in HbA_{1c}. These similarities suggest that similar biologic processes are at work. Neither the UKPDS nor the DCCT analyses indicated any glycemic threshold in the diabetic range of HbA_{1c}, below which there was no further risk of microvascular complications.[40,41] This observation sets normoglycemia as the ultimate goal of treating type 1 and type 2 diabetes mellitus. Furthermore, the benefits of previous intensive treatment (or the adverse effects of previous conventional treatment) are still demonstrable 7 years after the DCCT was completed, during which time interval the mean HbA_{1c} concentrations in both groups were nearly identical (approximately 8.0%).[42] Thus, sustained periods of glycemic exposure are associated with pro-

longed consequences. An unacceptable level of hyperglycemia continues to have adverse effects even after some improvement in metabolic control, and a marked reduction in hyperglycemia with intensive treatment continues to have beneficial effects even after some worsening in metabolic control.

Multiple mechanisms by which increased glucose concentrations may cause damage to the retina, kidney, and nerves have been discovered [*see Figure 9*]. (1) Glucose itself can react nonenzymatically with free amino groups in N-terminal amino acids and lysine residues of proteins. $HbA_{1c}$is one such molecule. This reaction sets into motion cross-linking of proteins that ultimately generate harmful advanced glycation end products (AGEs).[43,44] Such products include carboxymethyllysine and pentosidine. Concentrations of long-lived AGEs were higher in tissues of conventionally treated patients in the DCCT than in tissues of intensively treated patients in the DCCT.[45] AGEs correlated with HbA_{1c} and, independent of HbA_{1c}, with the presence of retinopathy, nephropathy, and neuropathy.[45] (2) Three-carbon dicarbonyl products of glucose and lipid metabolism, glyoxal and methylglyoxal, also react readily with amino groups in proteins and produce other AGEs, one of which is argpyrimidine. AGEs react with specific cellular receptors and can stimulate numerous potentially dangerous processes.[43,44] (3) Hyperglycemia can also secondarily produce oxidative stress in tissues, with depletion of glutathione and formation of reactive oxygen species and damaging free radicals.[46] (4) When glucose is insufficiently metabolized by insulin-stimulated routes [*see Figure 1*], it can overflow into the sorbitol (polyol) pathway via the enzymes aldose reductase and sorbitol dehydrogenase.[47] Accumulation of sorbitol and fructose in vulnerable tissues such as nerves produces osmotic damage, loss of myoinositol essential to nerve membrane integrity, and reduction of Na^+, K^+–ATPase activity.[47] (5) Elevated glucose levels increase protein kinase C, an enzyme whose activity influences numerous cellular processes with damaging potential,[48] such as stimulating neovascularization and epithelial cell proliferation, increasing collagen synthesis, increasing vascular permeability, increasing apoptosis (programmed cell death), increasing oxidative stress, and mediating the actions of VEGF and transforming growth factor–β. (6) Elevated glucose levels also increase the production of VEGF, a molecule that stimulates angiogenesis. VEGF is present in high concentrations in human diabetic ocular tissues and in kidneys of animals with experimentally produced diabetes. It is a logical candidate to mediate development of proliferative retinopathy. (7) Hyperglycemia stimulates nitric oxide synthase to produce nitric oxide, a molecule that itself generates damaging free radicals.[46] (8) Excess blood glucose also overflows into the hexosamine pathway, resulting in deleterious products.[49] A single mitochondrial defect that leads to overproduction of reactive oxygen species can result in at least three of the above pathways and has been proposed as the primary culprit.[50] A number of these pathways are also mutually reinforcing, setting up vicious circles that can accelerate tissue damage.

The therapeutic importance of elucidating the mechanistic links between hyperglycemia and microvascular/neuropathic complications lies in our current inability to normalize blood glucose consistently. Therefore, drug therapies that intercept pathogenetic processes downstream from glucose hold promise for preventing these complications, even in the presence of hyperglycemia. An inhibitor of AGE formation, aminoguanidine, has been successful in animal experiments, but human trials

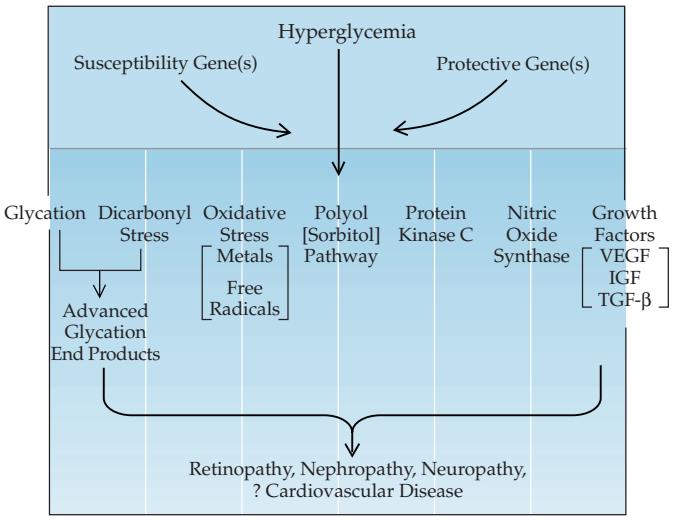

Figure 9 **Multiple pathways have been described that may link high blood glucose levels to the microvascular and neuropathic complications of diabetes (see text). There are good reasons to believe that genetic factors, possibly operating through such pathways, may explain the observation that some individuals with consistently high blood glucose levels do not experience complications, whereas other individuals with near-normal blood glucose levels do experience complications.**

have revealed unacceptable toxicity. Several inhibitors of aldose reductase, catalyzing the first step in the polyol pathway, have been studied in clinical trials, but none have shown sufficient clinical benefit or an acceptable adverse-effect profile to warrant approval in the United States. Nonetheless, such drugs have been effective in animal models. Current clinical trials are testing the effects of antioxidants such as vitamin E and a relatively nontoxic oral inhibitor of protein kinase C. Antagonists to VEGF and other growth factors to be administered by systemic or local injection are also in development.

GENETICS OF MICROVASCULAR COMPLICATIONS

There is considerable evidence from several studies that diabetic nephropathy clusters in families.[51] Thus, either genetic susceptibility or genetic protection is likely to explain the fact that nephropathy develops in only 35% to 40% of patients with diabetes. One likely influence on the development of nephropathy is the family of genes that code for the components of the renin-angiotensin system. Both positive and negative findings have been reported concerning involvement of the gene for angiotensin-converting enzyme (ACE) and the gene for angiotensinogen in the risks for nephropathy and retinopathy. A family study conducted in the DCCT showed no evidence for familial clustering of diabetic retinopathy per se. In view of the nearly 100% prevalence of retinopathy in patients with type 1 diabetes mellitus of many years' duration, it is not likely that a genetic factor is involved in the initiation of retinopathy. The DCCT analyses did, however, show evidence of familial clustering of severe diabetic retinopathy and confirmed familial clustering of nephropathy.[52]

Type 1 Diabetes Mellitus

PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes mellitus is characterized by absolute insulin deficiency, making patients dependent on exogenous insulin re-

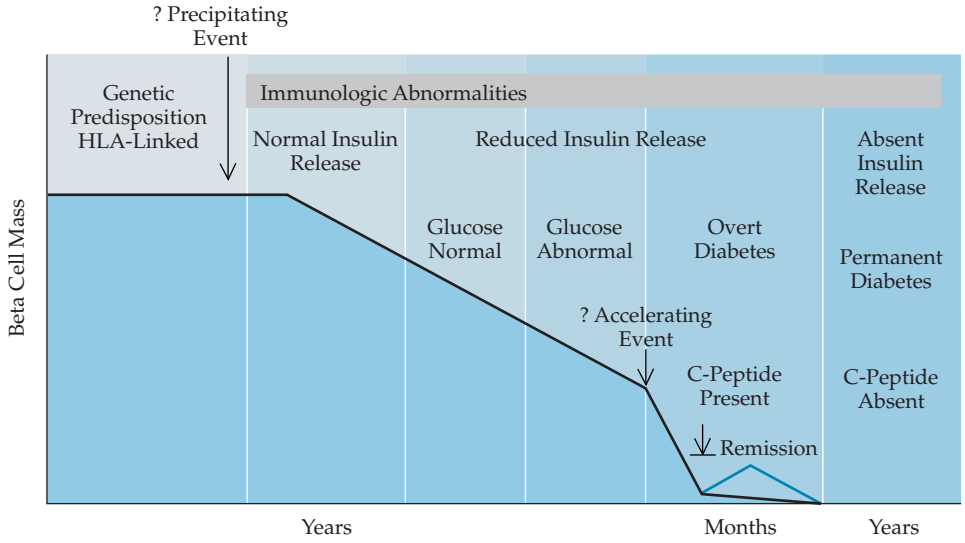

Figure 10 **Current view of the pathogenesis of type 1 autoimmune diabetes mellitus. In some individuals, HLA-linked genes set in motion an autoimmune attack on islet cells, predominantly beta cells. In other individuals, HLA-linked genes protect against the autoimmune destructive response. An initiating event, such as exposure to a virus with an antigenic epitope that resembles a beta cell antigen or to a toxin, may start the process of self-destruction. Disappearance of the beta cells may occur because the viral antigen accelerates the normal rate of apoptosis (programmed cell death). As time passes, insulin production and secretion diminish, despite increasing hyperglycemia. When insulin release falls to trivial amounts or none, diabetic ketoacidosis results. Another external event may trigger this final beta cell catastrophe. A few beta cells may survive, because after this, a brief period of remission marked by reappearance of C-peptide in plasma may ensue if plasma glucose levels are controlled very tightly with exogenous insulin. Eventually, all beta cell function ceases, leading to metabolic instability.**

placement for survival.[53] Insulin deficiency results from destruction or disappearance of the insulin-producing beta cells[54] that constitute 80% of the pancreatic islets of Langerhans. When 90% of the beta cells have been eliminated, clinical diabetes occurs [*see Figure 10*].

Autoimmune Factors

There is strong evidence for a cell-mediated autoimmune process being involved in the destruction of beta cells in the majority of cases of type 1 diabetes mellitus.[55-57] In a number of cases in which death occurred from an accident or from an illness other than diabetes shortly after diagnosis of type 1 diabetes mellitus, a mononuclear lymphocytic infiltrate was found in the islets. In this form of insulinitis, T cell distribution shows an increase in CD8 suppressor-inducer T cells and a decrease in CD4 helper-inducer T cells.[55] A similar immunocellular response has been found in animal models of spontaneous insulin-deficient diabetes.[57] In some instances, experimental manipulations that prevent T cell lymphocytic responses also prevent the development of diabetes. Furthermore, transfer of diabetes from affected animals to nonaffected animals by lymphocytes has also been described. Interleukins and other cytokines have been shown to exhibit toxic effects on the beta cells and to inhibit insulin secretion.

Autoantibodies to a variety of beta cell and islet autoantigens are present in the sera of patients with type 1 diabetes mellitus at the time of diagnosis.[58] The autoantigens include the enzymes glutamic acid decarboxylase (GAD), carboxypeptidase H, a protein tyrosine phosphatase labeled ICA512 or IA-2, and insulin itself.[58-60] Some, but not all, studies have shown that islet autoantibodies are capable of inhibiting insulin secretion in vitro or even causing lysis of beta cells. Other evidence supports the importance of autoimmune phenomena in the pathogenesis of type 1 diabetes mellitus. In cases of transplantation of pancreases from nondiabetic identical twins to patients with type 1 diabetes mellitus who were not given immunosuppressive therapy, the pancreas was rejected by the diabetic host's immune system, which apparently recognized as self, identical antigens in the normal twin's pancreatic islets. If treatment of type 1 diabetes mellitus with the immunosuppressive agent cyclosporine is initiated within 2 to 6 weeks after clinical onset of diabetes, dependency upon insulin can be eliminated or insulin doses markedly reduced, but only as long as immunosuppression is maintained.[61,62] The toxicity associated with cyclosporine and other immunosuppressive agents has precluded use of this form of therapy in clinical practice.

It is now clear that the autoimmune phenomena begin long before clinical onset of the disease. Islet or beta cell autoantibodies can be found in 2% to 4% of first-degree relatives of patients with type 1 diabetes mellitus, which is 10 to 20 times the prevalence of control subjects. Longitudinal studies have shown that type 1 diabetes mellitus is much more likely to develop in clinically unaffected relatives with high autoantibody titers than in relatives without such antibodies, and that the disease will develop in such patients within a few years.[63-65] Longitudinal serial testing of plasma insulin responses to intravenous glucose injection demonstrates progressively declining beta cell function in autoantibody-positive relatives before the clinical onset of diabetes.[66]

Environmental Factors

Because only 30% to 50% of unaffected monozygotic identical twins of patients with type 1 diabetes melllitus will eventually develop the disease, it is likely that an environmental factor may be required to trigger the autoimmune destructive process.[67] A

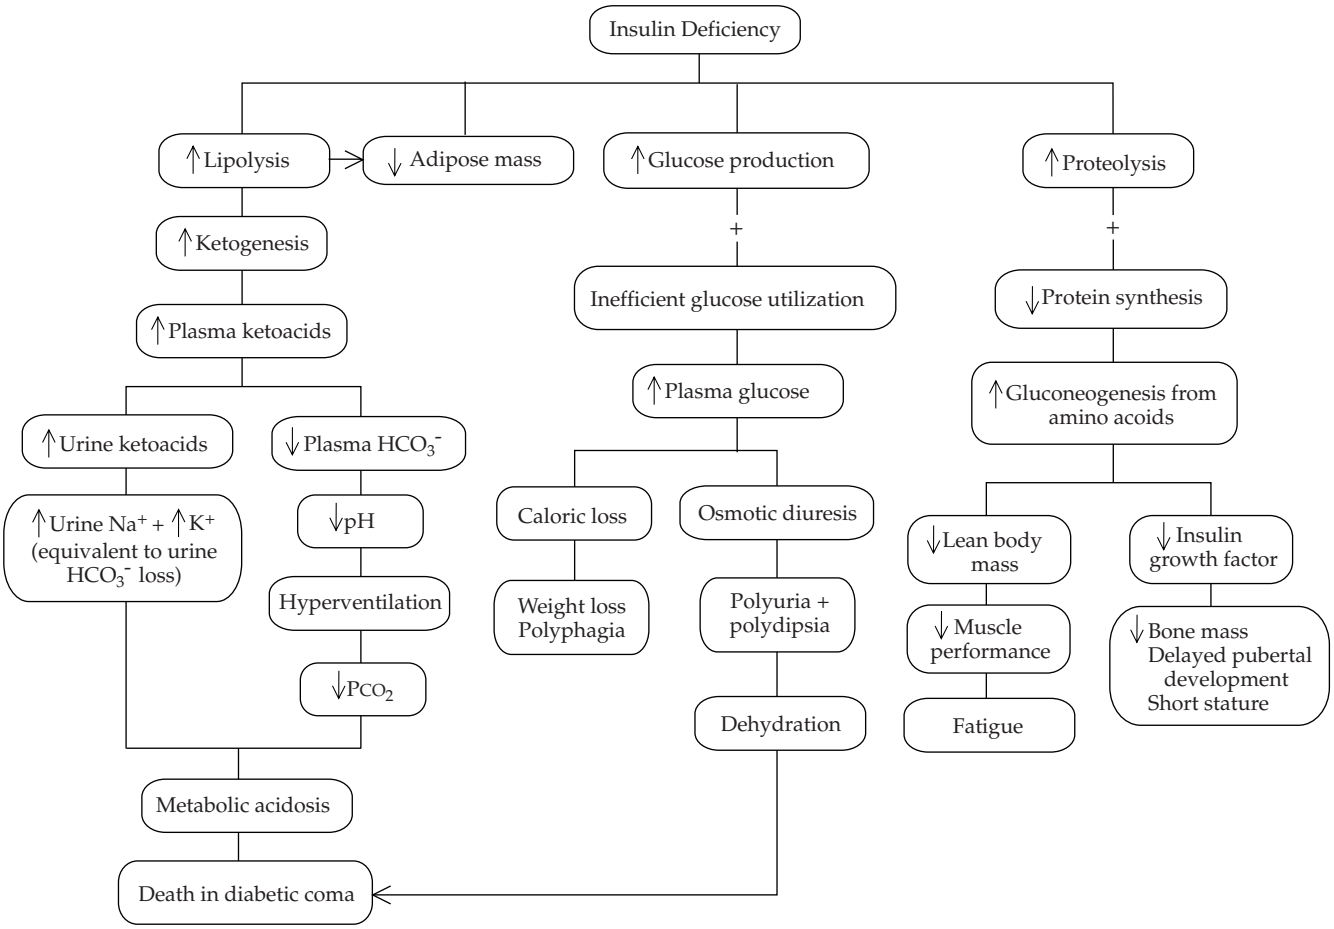

Figure 11 **Shown are the pathways that lead from insulin deficiency to the major clinical manifestations of type 1 diabetes mellitus. Note that a decrease in insulin growth factor also results from insulin deficiency and decreases growth rate.**

number of viral candidates have been proposed.[67] The only certain association is that offspring of women who are infected with rubella during pregnancy are at increased risk for type 1 diabetes mellitus. A small amount of indirect evidence also associates coxsackievirus B with type 1 diabetes mellitus.[68] Toxins in the environment or diet might also initiate the destruction of genetically vulnerable beta cells.

Temporal Sequence of Beta Cell Destruction

At the time of clinical onset of type 1 diabetes mellitus, at least a small number of beta cells are still potentially capable of function.[69,70] After several weeks of exogenous insulin treatment, particularly if exemplary metabolic control has been established,[71] dependency on exogenous insulin decreases or ceases entirely for weeks to months in some patients. This temporary so-called honeymoon remission phase is marked by an increase in serum C-peptide levels, which indicates an increase in endogenous insulin secretion [*see Figure 10*].[70] However, within 5 years after diagnosis of childhood type 1 diabetes mellitus, C-peptide virtually disappears from the serum.[72]

Type 1 diabetes mellitus does not develop in all autoantibody-positive individuals. Moreover, the latency period between initiation of beta cell destruction and appearance of the clinical disorder may be many years,[73] as the disease does not appear in some patients until considerably later in life. The gradual, indolent nature of the disease in these autoantibody-positive individuals is also suggested by the fact that some can be treated with beta cell–stimulating drugs before absolutely requiring insulin.[74] A trial sponsored by the National Institute of Diabetes and Digestive and Kidney Diseases unfortunately found no evidence that type 1 diabetes mellitus can be prevented by inducing immune tolerance to exogenous human insulin given subcutaneously or orally to relatives of patients with high islet autoantibody titers.

Genetic Factors

Although a family history of type 1 diabetes mellitus is more likely to be absent than present in index cases, it is nonetheless true that offspring and siblings of patients with type 1 diabetes mellitus are at increased risk for the disease. There is a genetic basis for susceptibility to type 1 diabetes mellitus but not for inevitable development of the disease.[75] The disease will develop in 5% to 10% of first-degree relatives of patients with type 1 diabetes mellitus and in 20% of persons who have two first-degree relatives (e.g., both parents) with the disease. Association and linkage studies have incriminated a number of genes involved in the risk of type 1 diabetes mellitus. Polymorphism of HLA genes in the MHC locus on chromosome 6 account for 50% of the genetic risk.[75] DR3 and DR4 are susceptibility alleles that appear to operate synergistically. Individuals heterozygous for DR3 and DR4 are at greater risk than either homozygous DR3 or homozygous DR4 individuals. The DR2 allele decreases the risk and dominates the susceptibility effect of DR3 or DR4 when either is accompanied by DR2. The HLA-DQ locus also is associated with increased risk of diabetes.[76] Substitution of alanine, valine, or ser-

ine for the more usual aspartic acid at position 57 of DQ β chain or the presence of arginine at position 52 of DQ α chain increases the risk of type 1 diabetes mellitus. A number of mechanisms have been suggested to explain how HLA class II molecules might predispose to or protect against the disease.[77] Despite the accumulation of considerable knowledge, type 1 diabetes mellitus still cannot be predicted with complete certainty.[78]

Type 1 diabetes mellitus is associated with at least 15 additional loci on nine other chromosomes.[78] Of particular interest is that a variable number of tandem repeats in the promoter region of the insulin gene has been associated with the disease. However, the insulin molecule itself is apparently normal in structure in patients with type 1 diabetes mellitus. With the human genome soon to be fully known and advanced genetic technology becoming cost-effective, it is likely that the genetic components of type 1 diabetes mellitus will be sorted out in a way that will make it possible to identify susceptible individuals who might benefit from preventive therapies.

The clinical and biochemical manifestations of type 1 diabetes mellitus can all be accounted for as consequences of insulin deficiency [*see Figures 1 and 11*].[79] Loss of the stimulating effect of insulin on glucose uptake by muscle and adipose tissue coupled with loss of the suppressive effect of insulin on hepatic glucose output lead to severe hyperglycemia. FPG rises typically to 300 to 400 mg/dl, and postprandial glucose levels rise to 500 to 600 mg/dl in patients before treatment.[79] This increase presents a high filtered load of glucose to the renal tubules, causing a severe osmotic diuresis, manifested by polyuria and compensatory polydipsia. Loss of the lipogenic and antilipolytic effects of insulin on adipose tissue leads to high plasma levels and increased hepatic uptake of free fatty acids. This condition enhances ketogenesis, and ultimately, high plasma ketoacid levels cause metabolic acidosis. Protein breakdown is favored in the absence of the anticatabolic and anabolic actions of insulin. The proteolysis of muscle protein provides amino acids that sustain high rates of gluconeogenesis. Body-weight loss thus includes fat and lean body mass, and it is further aggravated by an increase in basal energy expenditure.[80] The negative nitrogen balance, accompanied by losses of potassium, magnesium, and phosphate in the urine, impairs growth and development in children.

DIAGNOSIS OF TYPE 1 DIABETES MELLITUS

The diagnosis of type 1 diabetes mellitus is still almost always made on the basis of symptom history confirmed by a blood or plasma glucose level greater than 200 mg/dl, with the presence of glucosuria and often ketonuria. The classic symptoms are polyuria, polydipsia, weight loss with normal or even increased food intake, fatigue, and blurred vision, commonly present 4 to 12 weeks before the symptoms are noticed. In the future, however, before clinical onset of type 1 diabetes mellitus, diagnosis may be possible with serologic methods, complemented by beta cell function tests.

MANAGEMENT OF TYPE 1 DIABETES MELLITUS

Of all chronic diseases, diabetes is unique because its therapy involves daily self-management by the patient and a host of lifestyle adaptations. For optimal metabolic control, patients must prick their fingers to test blood glucose at least four times daily, inject insulin at least three times daily, pay regular attention to the timing and content of their meals, and try to follow a scheduled exercise program. The patient is truly at the center of his or her care. Patient self-management requires intensive education with regard to the skills of injection and blood glucose monitoring, urine ketone testing on sick days, meal planning, detection and treatment of hypoglycemia, and management of intercurrent illness. Family members and close associates of the patient need to be included as is appropriate, particularly with regard to recognition and treatment of hypoglycemia. Ideally, the patient should understand the pathophysiology of diabetes and its long-term complications almost as well as health care professionals. Some aspects of care require periodic educational reinforcement, which is often stimulated by some therapeutic mishap, such as a preventable episode of severe hypoglycemia.

The clinical goals of treatment include (1) decreasing plasma glucose levels and urine glucose excretion to eliminate polyuria, polydipsia, polyphagia, caloric loss, and adverse effects such as blurred vision from lens swelling and susceptibility to infection, particularly vaginitis in women, (2) abolishing ketosis, (3) inducing positive nitrogen balance to restore lean body mass and physical capability and to maintain normal growth, development, and life functioning, (4) preventing or greatly minimizing the late complications of diabetes previously discussed. After publication of the DCCT results, The American Diabetes Association revised their standards of care accordingly [*see Table 3*] to include firm biochemical goals[81]: (1) maintaining preprandial capillary whole blood glucose levels at 80 to 120 mg/dl, bedtime blood glucose levels at 100 to 140 mg/dl, and postprandial peak blood glucose levels at less than 180 mg/dl, and (2) maintaining

Table 3 American Diabetes Association Standards* for Glycemic Control in Diabetes Mellitus[288]

Biochemical Index	*Normal*	*Goal*	*Additional Action Suggested*
Capillary whole blood values† (mg/dl)			
Average preprandial glucose level	< 110	80–120	< 80 > 140
Average bedtime glucose level	< 120	100–140	< 100 < 160
HbA_{1c} (%)	< 6	< 7	> 8

*The values shown in this table are by necessity generalized to the entire population of individuals with diabetes. Patients with comorbid diseases, the very young, older adults, and patients with unusual conditions or circumstances may warrant different treatment goals. These values are for nonpregnant adults. Additional action suggested depends on individual patient circumstances. Such actions may include enhanced diabetes self-management education, comanagement with a diabetes team, referral to an endocrinologist, change in pharmacologic therapy, initiation of or increase in self-monitored blood glucose testing, or more frequent contact with the patient. HbA_{1c} is referenced to a nondiabetic range of 4.0% to 6.0% (mean, 5.0%; SD, 0.5%).
†To convert to plasma glucose values, add 10 mg/dl to whole blood values, except for 160 mg/dl, which becomes 180 mg/dl.

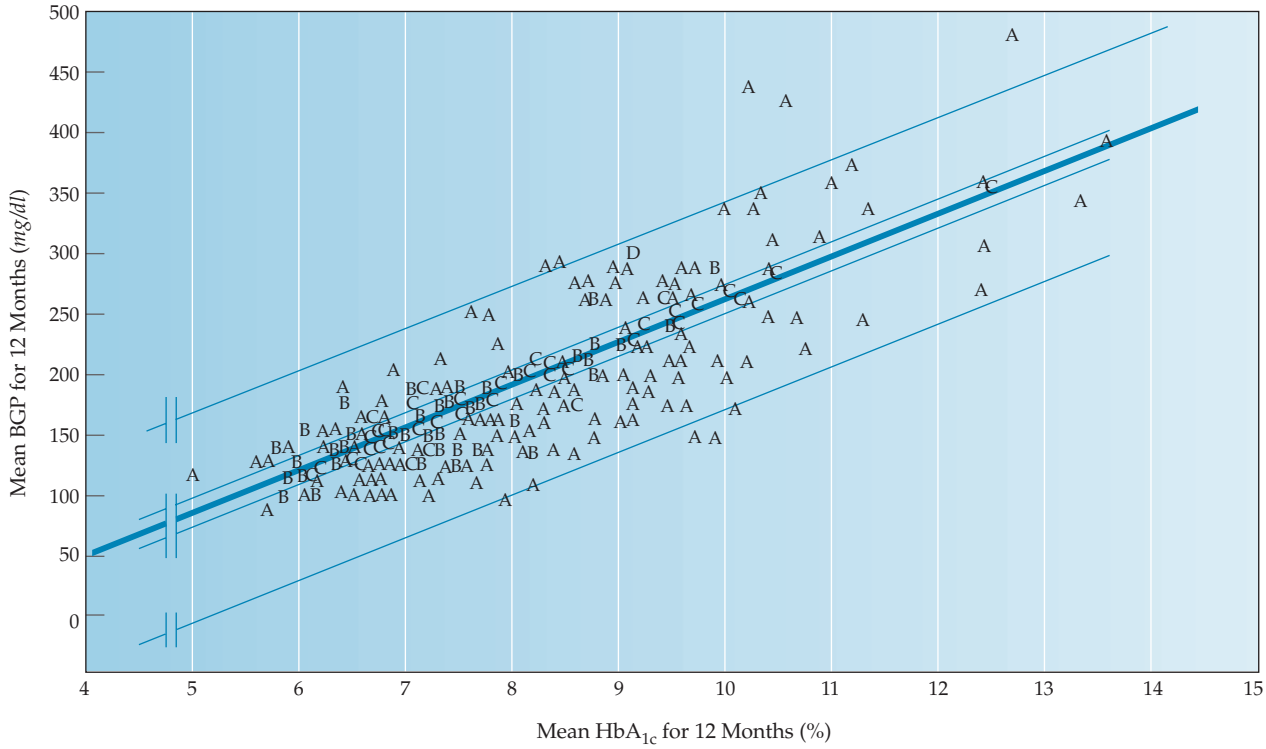

Figure 12 **The 12-month mean value of all seven-sample-a-day blood glucose profile values measured quarterly in the Diabetes Control and Complications Trial central biochemistry laboratory is plotted against the 12-month mean of quarterly HbA_{1c} values in the same patients. (A = 1 point, B = 2 points, C = 3 or more points; r = 0.80, $P < 0.001$)**

an HbA_{1c} of less than 7.0% (relative to a nondiabetic DCCT range of approximately 4.0% to 6.0%). Realistically, current therapeutic tools make it difficult to achieve these stringent goals in many patients with type 1 diabetes mellitus, particularly those with absolutely no endogenous insulin secretion. The exponential relation between the risk of microvascular complications and HbA_{1c} predicts that only normal HbA_{1c} levels would completely prevent the complications. However, maintaining an HbA_{1c} below 7.0% will remove much of the absolute risk from most patients. Efforts to achieve an HbA_{1c} of less than 7.0% should continue as long as hypoglycemia can be minimized.

Monitoring of Glycemic Control

In the past 5 to 10 years, blood glucose meters have undergone continuous development and improvement. They are now smaller, use less blood and more sites for puncture, are less vulnerable to inaccuracy because of patient errors, and have memory programs that allow the patient or caregiver to assess the pattern of blood glucose control over the previous 2 months, largely eliminating the problem of incorrect or fabricated written transcription of results. Devices that can accurately estimate blood glucose without a blood sample have been in development for a number of years but have not reached a state of reliability suitable for clinical practice. An indwelling subcutaneous catheter for blood glucose monitoring that can be used for 3 days and provide frequent readings is now available. Although the recorded profile can provide only a brief window into a lifetime of blood glucose fluctuation, such a profile can guide periodic adjustments of the regimen.

Currently, even with its imperfections, blood glucose testing before each meal or large snack is essential if the patient is to adjust each dose of rapid-acting insulin to the level of blood glucose before the meal and to the amount of carbohydrate about to be ingested. Blood glucose levels also need to be periodically checked after meals to ensure that undue postprandial hyperglycemia is not occurring. Patients should also check blood glucose levels before or after intensive exercise to prevent or abort hypoglycemia. It is very important to check blood glucose levels before driving to prevent motor vehicle accidents brought on by severe hypoglycemia, which can have adverse effects on drivers' judgment and reaction times. Occasional 3:00 A.M. blood glucose readings are useful in monitoring for otherwise unrecognized frequent nocturnal hypoglycemia. Most important, during intercurrent illnesses, especially those accompanied by nausea, vomiting, and limitation of fluid and caloric intake, patients must test blood frequently to guide insulin treatment. In addition, under these circumstances, the risk of ketoacidosis mandates testing of urine or blood for ketoacids. The presence of significant levels of ketoacids is a signal to call the caregiver immediately and establish frequent contact for instructions regarding insulin doses and carbohydrate intake.

A critical supplement to home blood glucose testing is monitoring of HbA_{1c} in the physician's office. It is now well established that this product of nonenzymatic glycation provides an excellent index of average blood glucose levels [*see Figure 12*] for approximately the preceding 2 months.[82,83] In at least one study, patients whose HbA_{1c} was measured periodically had a better health status, lower glycemic levels, and fewer hospitalizations than a randomly selected group of patients whose HbA_{1c} level remained unknown to both the patient and the physician.[84] Quarterly HbA_{1c} measurements are satisfactory except during pregnancy, when monthly levels should be obtained. Because methods and results vary among laboratories, a national glycohemoglobin standardization program is under way, and HbA_{1c} should be measured in laboratories certified to provide DCCT-equivalent results.[85] Use of rapid-turnaround, point-of-service

HbA_{1c} assays improves the efficiency with which diabetes caregivers can modify patients' regimens on office visits and improves treatment results.[86] Assays of other products of nonenzymatic glycation, such as fructosamine and glycated albumin, that reflect shorter periods of chronic glycemia are less useful in routine diabetes management.[85]

Insulin Types and Delivery

Correction of insulin deficiency is the most critical component in managing type 1 diabetes mellitus. Before the availability of insulin, patients with type 1 diabetes mellitus and complete insulin deficiency inevitably followed a predictable downhill course [*see Figure 11*] and died either in diabetic coma or essentially of starvation and inanition. Insulin extracted from beef and pork pancreas and purified to increasingly high levels was the mainstay of therapy until recombinant DNA technology made it possible to produce authentic human insulin in large quantities. Although animal insulins are therapeutically bioequivalent to human insulin, they disappeared from the market as manufacturers switched over to making only human insulin. In rare instances of local allergy to human insulin, lispro insulin (see below) can be substituted. In emergency situations, patients with systemic allergy to human insulin can be desensitized by administering extremely small amounts and gradually increasing the dose over 6 to 24 hours until the patient is tolerant and responsive to human insulin.

The basic principle of insulin replacement[87,88] is to provide a slow, long acting, continuous supply that mimics the nighttime and interprandial basal secretion by normal beta cells. In addition, a rapid and relatively short-acting form of insulin delivered before meals mimics the normal meal-stimulated burst of insulin secretion [*see Figure 2*]. A number of insulin preparations for subcutaneous administration are currently available [*see Table 4*]. It is important to recognize that there is considerable variability in the pharmacokinetic characteristics of these insulins both from individual to individual and within the same individual from day to day. Rates of insulin absorption from the skin vary with the injection site, the depth and angle of injection, ambient temperature, and exercise of an injected limb. Injection into the subcutaneous tissue of the abdomen produces the least variable results. The expected therapeutic action can also be affected by fluctuations in sensitivity to insulin from time to time in patients. Despite the variability of results, certain average patterns can be expected from the multiple daily injection regimens in common use [*see Figure 13*]. CSII by use of an external pump provides smooth basal delivery and somewhat more predictable acute increases in plasma insulin for meals. Only crystalline zinc insulin (regular insulin) and lispro insulin are used in such pumps, which is one reason for their greater consistency of effect.

Synthetic Insulin Analogues

Lispro was the first of what undoubtedly will be many new insulin analogues with structures designed to provide pharmacokinetics that more closely mimic physiologic insulin secretion and needs.[89] One of the features of natural (or synthetic) human insulin is that six molecules associate with a zinc molecule to form hexamers. Insulin hexamers must disassociate to monomers before they can be absorbed from subcutaneous injection sites. This requirement is the main reason that crystalline zinc insulin (regular insulin) has a peak action 2 to 4 hours after injection and must be taken 30 to 60 minutes before eating to have any chance of limiting postprandial hyperglycemia. By simply exchanging lysine and proline at positions 28 and 29 of the B chain of insulin [*see Figure 3*], hexamer formation is prevented and the monomer is rapidly absorbed from an injection site. Lispro insulin action begins within 15 minutes, the peak effect is reached at 1 to 2 hours, and the duration of action is only 4 to 6 hours. Thus, lispro insulin injected just before a meal provides a postprandial plasma insulin profile similar to that of normal human insulin secretion [*see Figure 2*]. The chief benefits of using lispro insulin are to reduce postprandial blood glucose peaks and to somewhat decrease the hypoglycemia that can result from the late tail of regular insulin action.[90,91] However, loss of that late action can lead to recurrent hyperglycemia before the next meal. Hence patients switched from regular insulin to lispro insulin may have no reduction in HbA_{1c} unless their doses of basal insulin (neutral protamine Hagedorn [NPH], Lente, or Ultralente or the basal rate in CSII) are increased.[92] It may even prove useful to combine lispro insulin with regular insulin in a single injection to optimize postprandial control.

Another synthetic rapid-acting analogue, insulin aspart, replaces proline with aspartic acid at position B28 [*see Figure 3*]. This substitution leads to a profile of action and therapeutic benefits that are very similar to those of lispro insulin.[93] A long-acting analogue, glargine, has also been synthesized as a basal insulin with no discernible peak and a longer duration of action than Ultralente insulin.[94,95] Glargine has two additional arginines at the carboxyl terminus of the B chain, B31 and 32, and has a glycine for arginine substitution at position A21 [*see Figure 3*]. Glargine is giv-

Table 4 Insulin Preparations

Insulin Type	*Onset (hr)*	*Duration (hr)*	*Peak (hr)*
Rapid acting (regular, crystalline zinc insulin [CZI])	0.5–1.0	6–8	2–3
Very rapid acting			
Lispro	0.25–0.5	4–6	1–2
Insulin aspart	0.25–0.5	4–6	1–2
Intermediate acting			
Lente, neutral protamine Hagedorn (NPH)	1	10–14	4–8
Long acting			
Ultralente	1	18–24	Minimal at 10–14
Glargine	1.5	30	None

en as a single bedtime injection to provide basal insulin for 24 hours with less nocturnal hypoglycemia.[96] For reasons that should now be clear, intensive treatment regimens are the preferred form of therapy and should be implemented early in as many patients as is safely possible. Different combinations of insulin preparations can be used to approximate (but never reliably reproduce) normal plasma insulin profiles [*see Figure 13*]. Type 1 diabetes mellitus can almost never be satisfactorily controlled on less than two injections a day of intermediate- or long-acting insulin combined with rapid-acting insulin. Only in patients experiencing a honeymoon remission or in patients with late-onset autoimmune type 1 diabetes mellitus in adults can satisfactory metabolic control be established with a single injection of insulin daily. Such success is made possible only by the presence of some normally regulated endogenous insulin secretion.

Insulin Regimens

As a rule of thumb, basal insulin and mealtime insulin pulses each constitute approximately 50% of the average total daily dose (0.6 to 0.7 U/kg) in intensive-therapy regimens. The dose of regular or lispro insulin or insulin aspart before each meal is chosen by the patient on the basis of the blood glucose level, the estimated amount of carbohydrate to be eaten, or both. A typical regimen would call for 1 to 2 extra units of insulin for each 50 mg/dl increment in blood glucose above the dose called for by the preprandial target of 80 to 120 mg/dl, or 1 U/10 to 15 g of extra carbohydrate to be ingested above the usual amount of carbohydrate prescribed by the nutrition plan. Very sophisticated patients can combine both guidelines. Glargine is rapidly achieving dominance as the basal insulin.

Fixed-dose mixtures of insulin are not physiologically very suitable for patients with type 1 diabetes mellitus. However, for patients who can or will implement only such conventional treatment, a typical regimen might be a total daily dose of 0.6 to 0.7 U/kg. Two thirds to three fourths of the dose would be given before breakfast and the remainder before supper; the ratio of intermediate-acting insulin to rapid-acting insulin might be 2:1 to 4:1 before breakfast and 1:1 before supper. Because giving NPH or Lente insulin before supper increases the risk of hypoglycemia between 2:00 and 4:00 A.M., patients on conventional treatment should be urged to switch to a three-injection regimen, taking the evening dose of intermediate-acting insulin at bedtime to avoid nocturnal hypoglycemia and to better control the prebreakfast blood glucose level. Glargine insulin may also be helpful in minimizing nocturnal hypoglycemia.[87,88]

Insulin requirements are increased by greater caloric and especially carbohydrate intake, by weight gain of both lean body mass and fat mass, by the onset of puberty, by infections and other medical or surgical stresses, by pregnancy, by glucocorticoid administration, and sometimes by the physiologic changes that pre-

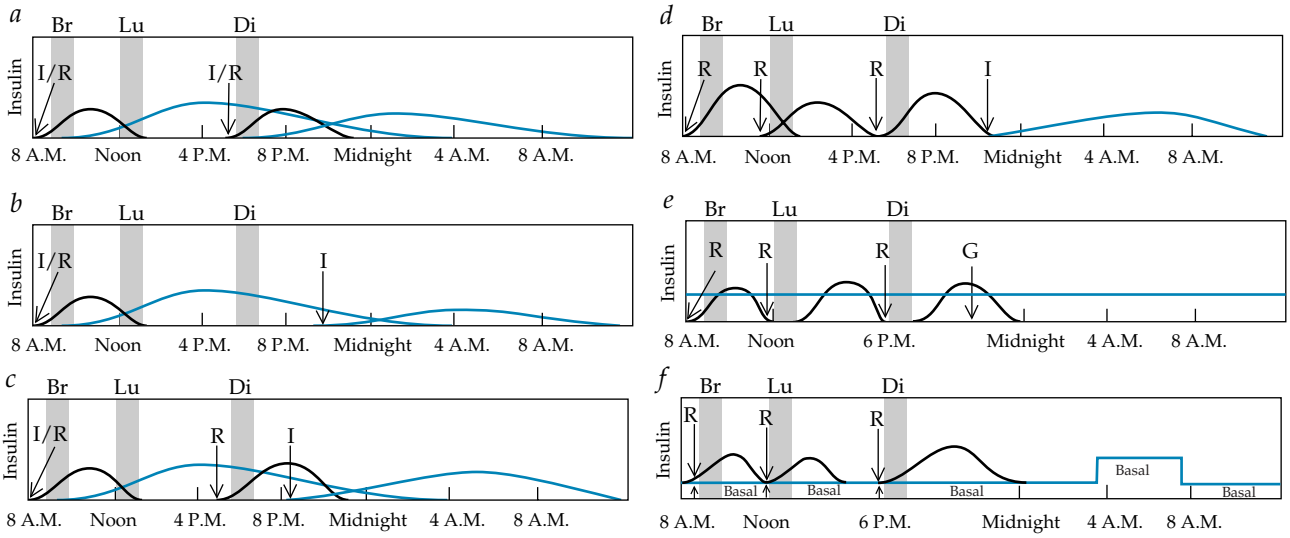

Figure 13 **Different combinations of various insulin preparations can be employed in establishing glycemic control in type 1 diabetes mellitus (and in those patients with type 2 diabetes mellitus who eventually reach an equivalent degree of insulin deficiency). Arrows indicate time of injection. Red curves represent rapid-acting (R) regular or lispro insulin. Blue curves represent intermediate-acting (I) NPH or Lente insulin. Gray curves represent long-acting insulin glargine (G). (*a*) A mixed injection of I and R insulin is administered before breakfast and dinner in this average regimen. In addition to the risk of hypoglycemia before lunch and in the late afternoon, the predinner administration of I insulin predisposes patients to hypoglycemia from 2:00 A.M. to 4:00 A.M. (*b*) This average regimen combines a mixed injection of I and R insulin given before breakfast with an injection of I insulin given before bed. The I insulin administered at bedtime provides safer, more effective overnight glucose control; without predinner insulin, however, glucose levels may rise to unacceptably high levels after dinner. (*c*) In this intensive regimen, the patient receives three injections: a mixed injection before breakfast, R insulin before dinner, and I insulin before bed. (*d*) This intensive regimen combines three preprandial injections of R insulin with one injection of I insulin before bed. Preprandial doses of R insulin are adjusted according to glucose levels and meal size. (*e*) This intensive regimen uses long-acting insulin glargine to replace basal insulin secretion. Preprandial doses of R insulin are adjusted according to blood glucose levels and anticipated meal carbohydrate content. (*f*) This intensive regimen provides only R insulin as regular or lispro insulin. A pump-driven continuous subcutaneous infusion of R insulin replaces basal insulin secretion. Basal rates can vary during different times of day or activities. For example, the basal rate can be lowered or even suspended during periods of intensive aerobic exercise. The nocturnal basal rate can be increased 1.5 to 2.0 times from 3:00 A.M. to 4:00 A.M. until breakfast to accommodate the rising early morning insulin requirement known as the dawn phenomenon. Preprandial bolus doses are individually dialed in and rapidly pumped in, adjusted according to blood glucose levels and anticipated meal carbohydrate content. (Br = breakfast, Lu = lunch, Di = dinner)**

cede the onset of menses. During acute illnesses, patients will require extra doses of rapid-acting insulin when hyperglycemia accelerates and especially if ketosis occurs. Frequent telephone contact with caregivers allows timely professional guidance of the extra insulin doses, nutrient intake to prevent hypoglycemia, and fluid intake to prevent dehydration. Lispro insulin or insulin aspart is especially useful in these circumstances because the effect of an overdose is short lived and hypoglycemia is less likely.

CSII has improved considerably since its introduction in the 1970s.[97] Modern insulin infusion pumps permit programming with multiple basal rates, allowing flexibility during the day as well as automatic adjustment of doses while sleeping at night. Frequently, the basal rate needs to be lower in the first half of the night and then increased to accommodate the so-called dawn phenomenon [*see Figure 13*]. The latter is a slow rise in the plasma glucose level before the patient awakens, demonstrable in normal individuals but exaggerated in individuals with type 1 diabetes mellitus who cannot limit it by increasing endogenous insulin secretion. On the other hand, interruption of insulin delivery from a pump for as little as 8 hours can result in extreme hyperglycemia, diabetic ketoacidosis (DKA), and hyperkalemia. In the DCCT, patients who used an insulin pump had a slightly but significantly higher DKA event rate (1.8 per 100 patient-years) than patients on multiple daily injection regimens (0.8 per 100 patient-years).[98] There was no difference in risk of severe hypoglycemia between patients treated with insulin pumps and patients treated with multiple daily injections, although episodes resulting in coma or seizure were more common in CSII-treated patients.[98] The rate of infection at catheter sites was kept very low by frequent change of catheters and preemptive use of antibiotics at the first visible signs of infection. Pump use has grown exponentially in the past 10 years; 200,000 patients now use pumps.

Avant-garde Therapy

Implantable pumps delivering insulin into the peritoneal cavity and resulting in a more physiologic first pass of insulin through the liver have provided acceptable HbA_{1c} levels with a lower frequency of severe hypoglycemia.[99] Difficulties with obstruction of insulin delivery and infection have occurred, and they are not yet approved for commercial use. Closed-loop insulin-delivery devices that would measure the patient's blood glucose level very frequently and would automatically adjust insulin delivery still await the development of a practical and long-lived indwelling continuous glucose sensor.

Insulin can be absorbed through the mucosa of the nose and also through the lungs. A nasal preparation of insulin has been effective in short-term clinical trials, but the disadvantages of high cost (10 times the subcutaneous insulin dose is needed to achieve the same blood glucose lowering) and failure to develop a vehicle that does not cause allergic nasal symptoms have prevented this preparation from being used in practice.[100] Inhaled insulin, with various delivery devices, is still undergoing clinical trials.[101,102] The pharmacokinetic properties of inhaled insulin resemble those of lispro insulin and insulin aspart, so inhaled insulin is suitable for preprandial use. Various attempts to package insulin for oral administration so as to prevent its degradation in the gastrointestinal tract have also been investigated, as has transdermal insulin.

Pancreas transplantation remains controversial as a routine form of insulin replacement therapy.[103] Over the period of 1994 to 1997, 1-year graft survival rates were 82% when a pancreas was transplanted with a needed kidney transplant and 62% when a pancreas was transplanted alone.[104] Successful pancreas transplants provide nondiabetic HbA_{1c} levels and free the patient from the rigors of diet, blood glucose testing, and insulin injection, and they virtually eliminate episodes of hypoglycemia.[104] Quality of life is usually improved. On the negative side, the patient incurs the risk of operative mortality and morbidity and must remain on immunosuppressive therapy with its attendant risks of infection and malignant disease.[103] Length of stay, readmission rates, morbidity, and the number of acute rejection episodes are higher for pancreas transplants than for kidney transplants. From 1994 to 1996, the 1-year pancreas transplant survival was 81%, compared with a kidney transplant survival of 88%.[103] The large majority of pancreas transplantations are still performed as an option in conjunction with a necessary kidney transplant.

Transplantation of isolated islets can be accomplished without major surgery. Furthermore, the ability to immunomodulate isolated islets in the laboratory (by masking or removing cell surface antigens) may someday allow transplantation with little or no immunosuppression. Alternatively, islets can be placed in semipermeable hollow tubes that allow glucose to enter and insulin to leave but shield the islets from inflammatory reactions to a foreign body. Islet transplantation with function lasting at least 1 year has been achieved in less than 10% of attempts worldwide. A Canadian group has reported on seven successive cases of islet injection into the liver, with persistent function and independence from insulin injections for up to 15 months, using a new immunosuppressive regimen.[105] This technique is undergoing a multicenter trial.

Nutritional Therapy and Exercise

Intensive and conventional insulin treatment will produce unsatisfactory results unless it is appropriate for the nutrient intake. To facilitate the matching of insulin doses to meals and to prevent hypoglycemia, patients with type 1 diabetes mellitus should eat consistent regular meals comprising about 50% carbohydrate calories, less than 30% total fat calories, and less than 300 mg cholesterol a day.[106] Various methods of teaching patients how to assess amounts of foods and their nutrient and caloric content have been utilized. These methods include exchange lists that place foods into six categories; each category has approximately the same quantity of carbohydrate, protein, and calories per serving. These exchange categories are bread, meat, milk, fruit, fat, and vegetable. Another approach is to focus only on the carbohydrate content of foods because carbohydrates cause most of the postprandial hyperglycemia. Because different carbohydrates are digested and absorbed at different rates and therefore have different effects on plasma glucose levels, glycemic indices have been developed for common foods that help adjust for their different effects.[107] It is noteworthy that numerous studies have disproved the myth that sucrose raises blood glucose more than equivalent amounts of other carbohydrates.[108] For optimal instruction and reinforcement of diet therapy, a dietitian should be part of the diabetes care team.

Exercise is another important component of diabetes care because it helps maintain cardiovascular conditioning, insulin sensitivity, and general well-being.[109] However, patients must be instructed how to adjust their meals, their insulin doses and timing, or both to prevent hypoglycemia during, immediately after, or even 6 to 12 hours after exercise as muscle glycogen stores are replenished from plasma glucose. High-impact sports are contraindicated for patients with advanced retinopathy who are at risk for vitreous hemorrhage or for patients with peripheral neuropathy or vascular disease who are at risk for foot trauma, because such sports can be hazardous.

Table 5 Typical Laboratory Findings and Monitoring in Diabetic Ketoacidosis

Test	*Average*	*Range*
Plasma glucose	600 mg/dl (33 mmol/L)	200–2,000 mg/dl (11– 110 mmol/L)
Plasma ketones (positive)	1:16	1:2–1:64
Blood betahydroxybutyrate (mmol/L)	—	3–25
Plasma HCO_3 (mEq/L)	10	4–15
Blood pH	7.15	6.80–7.30
Pco_2 (mm Hg)	20	14–30
Plasma anion gap (Na^+ – [CI + HCO_3]) (mEq/L)	23	16–30

Perform complete blood count, serum urea nitrogen measurement, serum creatinine measurement, urinalysis, appropriate cultures, and chest radiography.

1. Weigh on admission and every 12 hr.
2. Record cumulatively intake and output every 1 to 2 hr (Foley catheter if incontinent).
3. Check blood pressure, pulse, respiration, mental status every 1 to 2 hr and temperature every 8 hr.
4. Check blood (fingerstick) or plasma (laboratory) glucose every 1 to 2 hr.
5. Check serum potassium every 2 to 4 hr; check other electrolytes and serum ketones or betahydroxybutyrate every 4 hr.
6. Check arterial blood pH and gases on admission (in children, venous pH may be substituted; add 0.1 to result). If pH < 7.0 on admission, recheck as required until pH exceeds 7.1.
7. Check serum phosphate, magnesium, and calcium levels on admission. If low, repeat every 4 hr; otherwise, every 8 to 12 hr.
8. Spot-check voidings for ketones and glucose.
9. Perform ECG on admission; repeat if follow-up serum potassium level is abnormal or unavailable.

Note: 1–9 should be carried out until the patient is stable, glucose levels have reached and are maintained at 250 mg/dl, and acidosis is largely reversed (plasma HCO_3 > 15–18, plasma anion gap < 16). An intensive care setting is preferred.

DIABETIC EMERGENCIES IN TYPE 1 DIABETES MELLITUS

Diabetic Ketoacidosis

DKA is the ultimate result of insulin deficiency[110,111] [*see Figure 11*], which is aggravated by stress-induced elevations of glucagon, cortisol, growth hormone, epinephrine, and norepinephrine[110] that add a component of insulin resistance.[112] DKA occurs in 2% to 5% of patients with type 1 diabetes mellitus a year. In the closely followed DCCT patients, overall event rates were 2.0 per 100 patient-years in the intensively treated group and 1.8 per 100 patients-years in the conventionally treated group.[34] Reported mortality varies worldwide from as low as 0% to as high as 10%. Most cases occur in patients already diagnosed with type 1 diabetes mellitus, but DKA still can be the first manifestation of diabetes, especially in children. Self-monitoring of blood glucose and urine ketones and close contact with the diabetes care team should facilitate recognition and abortion of evolving DKA by early and aggressive treatment with extra insulin and fluids at home. Approximately half the cases of DKA are precipitated by infection. Sepsis, myocardial infarction, and other major intercurrent illnesses are more often the cause of death than the metabolic disequilibrium itself. In children, cerebral edema rarely occurs. It usually appears 6 to 12 hours after treatment is initiated when biochemical improvement is manifest; yet it is often fatal.

Presenting features DKA presents with signs and symptoms of dehydration secondary to osmotic diuresis and vomiting and, sometimes, to diarrhea caused by concurrent gastroenteritis; of compensatory hyperventilation to eliminate CO_2; and of various degrees of depressed mentation or decreased consciousness. Seizures are notably not a result of DKA. Complete coma almost certainly indicates a long period of DKA before medical attention. DKA yields a number of characteristic laboratory findings [*see Table 5*]. The anion gap metabolic acidosis is secondary to elevated levels of acetoacetate and betahydroxybutyrate with small contributions from lactate and free fatty acids. Although serum potassium and phosphate levels are usually normal or even high initially, this finding masks a profound total body depletion of these electrolytes, along with magnesium. Deviations from the customary pattern create pitfalls in diagnosis. Ketones, which current tests detect only as acetoacetate or acetone, may be missing from the serum if the redox potential of the patient is very high and the equilibrium of the ketoacids is shifted toward the reduced partner betahydroxybutyrate (as may occur in alcohol intoxication). Serum bicarbonate levels may be normal if there is coexisting respiratory acidosis. Arterial blood pH may be normal if there is coexistent metabolic alkalosis caused by diuretic ingestion or pernicious vomiting. Occasionally, plasma glucose levels are less than 250 mg/dl because of fasting,[113] high alcohol intake, profound inanition, or pregnancy.

Treatment Treatment of DKA[110,114,115] requires careful monitoring of the patient [*see Table 5*]. Volume repletion is as important as insulin therapy.[116] Intravenous 0.9% saline should be started even before the diagnosis is established. After an initial liter in 30 to 60 minutes, fluid therapy should continue aggressively until the circulating volume is replenished, as indicated by an increase in blood pressure to normal and a reduction in compensatory tachycardia. Subsequent total volume repletion is carried out more slowly at 150 to 500 ml/hr with 0.45% saline, switching to 5% glucose-containing solutions once plasma glucose has decreased to 250 mg/dl. Typical fluid deficits range from 50 to 100 mEq/kg. Average sodium deficits are 7 mEq/kg, and most important, potassium deficits may be as high as 7 mEq/kg. The effective depletion of total body bicarbonate through loss of the strong organic acids acetoacetate and betahydroxybutyrate in the urine is revealed later, when a hyperchloremic metabolic acidosis often ensues. Potassium repletion (10 to 40 mEq/hr) should begin promptly after insulin administration and as soon as hyperkalemia and oliguria or anuria have been ruled out [*see Table 5*]. Otherwise, serious hypokalemia will result as insulin stimulates potassium uptake by cells [*see Figure 4*]. If the serum potassium level is less than 40 mEq/L on admission, a very large deficit exists and repletion should be at a faster rate to maintain a level no lower than 3.5 to 4.0 mEq/L. Insulin should be withheld in such circumstances until serum potassium reaches 4.0 mEq/L. Hypokalemia is the most tragic cause of death resulting from therapeutic misjudgment.

Although DKA can be managed satisfactorily with insulin given intramuscularly or subcutaneously, intravenous administration is far more reliable and results in fewer instances of hypokalemia and hypoglycemia. A bolus of 10 U or 0.1 U/kg is followed by the same dose given hourly by intravenous infusion, preferably with a pump and through its own intravenous line. Routine addition of sodium bicarbonate or potassium phosphate has not been found to hasten recovery in ordinary cases of DKA.[115] Possible indications for administration of sodium bicarbonate (50 to 200 mEq)

include arterial pH less than 7.0, ECG changes of hyperkalemia, hypotension that does not respond to rapid infusion of 0.9% saline, and left ventricular failure. If bicarbonate therapy is given, serum potassium and arterial pH should be monitored hourly and extra potassium given to prevent hypokalemia. Rhabdomyolysis, hemolysis, and central nervous system deterioration can be caused by severe hypophosphatemia (<1.5 mg/dl) and call for intravenous administration of 60 mmol (approximately 2 g) of phosphate as the potassium salt over 6 hours. Once the anion gap has decreased to near normal and bicarbonate has risen to 15 to 18 mEq/L, the insulin infusion rate can be decreased to 2 U/hr. In general, it is best to maintain the insulin infusion at 1 to 2 U/hr with accompanying 5% glucose infusion, aimed at keeping the plasma glucose level at around 150 mg/dl until the following morning, when a subcutaneously mixed insulin regimen can be started or resumed along with a diet.

It is preferable to treat patients with DKA in an intensive care unit to ensure close monitoring. Persistent vomiting calls for gastric intubation, and the airway of an obtunded patient should be protected to prevent aspiration. Any suspicion of sepsis mandates treatment with broad-spectrum antibiotics.

Hypoglycemia

Hypoglycemia is a more common emergency than DKA and potentially as dangerous. Clinical hypoglycemia can range from annoying symptoms accompanying a biochemically low blood glucose level (< 50 to 60 mg/dl) to confusion, seizures, or coma. Any episode that requires intervention by another person to reverse is categorized as severe hypoglycemia. Severe hypoglycemia can have disastrous consequences, particularly if the patient is driving any sort of vehicle, working at heights, or operating potentially dangerous machinery.

The most common causes of hypoglycemia are missed meals and snacks,[117] insulin dosage errors, exercise, alcohol, and drugs such as beta-adrenergic blockers. During the DCCT, 55% of hypoglycemic episodes occurred during sleep.[117] Such episodes often go undetected.[118]

Glucagon and epinephrine are the major counterregulatory hormones that are secreted in response to hypoglycemia.[119] Both restore glucose levels by increasing hepatic glucose output, while epinephrine also decreases the sensitivity of muscles to insulin. Furthermore, catecholamine secretion alerts the patient to treat the episode because it produces the sympathoadrenal symptoms noted below. Cortisol and growth hormone are also secreted in response to hypoglycemia[119] and play a role in maintaining glucose levels but not in rapid recovery from hypoglycemia.

Presenting features The most common symptoms of early mild hypoglycemia are adrenergic and include tachycardia, tremulousness, anxiety, and sweating.[120] The last symptom requires sympathetic activation of cholinergic nerves innervating the sweat glands.

Factors affecting severity of hypoglycemic episodes The development of primary or secondary adrenal insufficiency, hypopituitarism, and hypothyroidism may increase the risk of hypoglycemia by increasing sensitivity to insulin, decreasing appetite, or both. Stress, exercise, or use of alcohol or illicit drugs may blunt or prevent recognition of hypoglycemia. Patients who do recognize incipient hypoglycemia but who consciously do not respond expeditiously (for example, they may wait for a meal in a restaurant or continue to drive after symptoms first appear) are also at increased risk for severe hypoglycemia. Moreover, some risk factors for hypoglycemia have multiple effects that can precipitate, prolong, or worsen the severity of hypoglycemia. Alcohol, for instance, impairs judgment and inhibits gluconeogenesis and hepatic glucose output, thereby delaying recovery. When hypoglycemia is inadequately treated, more severe hypoglycemia often ensues.

Finally, because glucagon and epinephrine are the major defense hormones against prolonged hypoglycemia, their absence promotes longer and more severe episodes by two mechanisms: (1) compensatory hepatic glucose output is decreased when not stimulated by glucagon or epinephrine and (2) the familiar adrenergic symptoms may cease in the absence of epinephrine, resulting in failure to recognize the episode.[119] The glucagon response to hypoglycemia often wanes in patients after they have had type 1 diabetes mellitus for a few years. In the absence of glucagon, epinephrine secretion still provides adequate counterregulatory defense; however, epinephrine response can also be lost eventually, sometimes in association with other autonomic neuropathies and sometimes selectively. Many patients lose the ability to counterregulate against hypoglycemia during the first 10 years that they have type 1 diabetes mellitus.

Given the importance of intensive regimens to prevent microvascular complications from hyperglycemia, it is most unfortunate that a lowered glucose threshold for release of glucagon and epinephrine in response to hypoglycemia has been observed, particularly in patients undergoing intensive insulin therapy.[121] The lowered glucose level needed to stimulate counterregulation narrows the safety margin of therapy. For instance, the first symptom of hypoglycemia may occur only at glucose levels as low as 35 mg/dl (as opposed to 55 to 60 mg/dl) and may consist of confusion or loss of judgment, which interferes with self-treatment. Some evidence suggests that unawareness of hypoglycemia is self-generating, because each episode may lower the threshold at which autonomic counterregulation begins in subsequent episodes.[119] The converse of this is that a period free of hypoglycemia, produced by daily therapeutic contact with caregivers, may restore hypoglycemia awareness,[122,123] though it may not restore normal counterregulatory responses.[122] Increased uptake of glucose by the brain in the presence of hypoglycemia[124,125] is a likely explanation for the relative infrequency of clinical hypoglycemic catastrophes.

Treatment Patients recognize most episodes of hypoglycemia quickly and can effectively treat themselves with a promptly absorbed oral carbohydrate. Approximately 15 g of carbohydrate is sufficient to restore blood glucose levels to normal. This amount is provided by approximately 6 oz of orange juice, 4 oz of a cola drink, 3 to 4 tsp of table sugar, five Life Savers, or three glucose tablets (each containing 5 g of glucose). The use of complex carbohydrates and foods with a high fat content, such as chocolate, may delay digestion and absorption of the glucose and are not first choices for treatment of hypoglycemia. If the patient cannot swallow or cooperate, a gel form of glucose and simple carbohydrates can be administered by mouth, applying it between the gums and cheeks, from where it slowly and generally safely trickles down into the stomach. Glucagon (1 mg administered subcutaneously or intramuscularly) will also usually raise blood glucose levels sufficiently within 15 to 30 minutes, when the patient can then take oral carbohydrates. Glucagon comes in emergency kits, and it should always be on hand for patients with a history of severe hypoglycemic episodes. Glucagon may

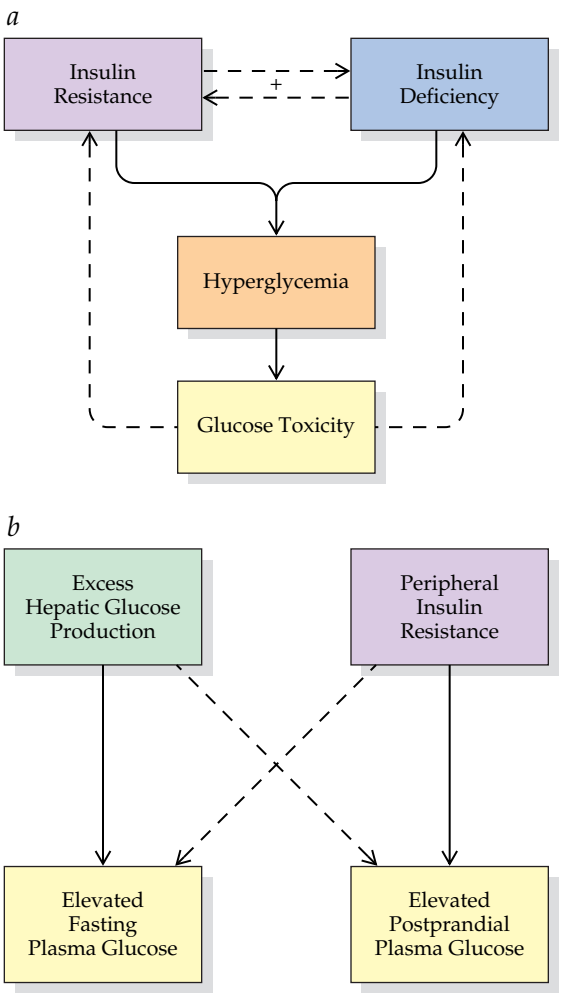

Figure 14 **(*a*) The interrelations of insulin resistance, insulin deficiency, and glucose toxicity that create overall hyperglycemia in type 2 diabetes mellitus are depicted. Insulin resistance and insulin deficiency are mutually reinforcing factors. Glucose toxicity refers to the secondary aggravating effects of hyperglycemia that both increase insulin resistance and reduce beta cell function. The glucose toxicity is diminished or eliminated by any therapy that lowers blood glucose. (*b*) Once fasting glucose levels are abnormal, they are correlated with and largely driven by the excess hepatic glucose production. Abnormal postprandial glucose levels are largely a consequence of peripheral insulin resistance that makes glucose utilization in muscle and adipose tissue inefficient. Insulin deficiency plays an increasingly important role in elevating both fasting and postprandial glucose levels as time goes on.**

cause nausea, vomiting, and headache, especially in children. When all else fails, intravenous glucose must be given by emergency medical service personnel or in an emergency room, whichever is quicker. When the timing of an episode suggests it was caused by intermediate- or long-acting insulin or by prior exercise, blood glucose may fall to hypoglycemic levels again and re-treatment may be necessary. Thus, a patient who has required assistance from others in reversing hypoglycemia should be kept under surveillance for some time thereafter.

Patients with severe hypoglycemia usually respond rapidly to treatment, although patients who are postictal or in a prolonged coma may require days to regain normal mental status and cognitive function. Quite often, there is amnesia for such extended episodes, including a period preceding the onset of hypoglycemia. In rare instances, neurologic deficits can be permanent. In general, however, long-term consequences of hypoglycemia have not been detected in adults.[126,127] In view of the potential consequences of prolonged episodes, hypoglycemia should always be treated immediately.

Prevention Patients should be instructed to treat themselves as though they have hypoglycemia whenever they suspect it, even if they are unable to do a confirmatory blood glucose test at the time. The threshold for symptoms of hypoglycemia varies from person to person and even varies in the same person on different occasions. Therefore, whenever possible, a confirmatory blood glucose test should be done to help the patient discriminate nonspecific symptoms from true hypoglycemia. Patients at increased risk for severe hypoglycemia should monitor their blood glucose levels more frequently.

Type 2 Diabetes Mellitus

PATHOGENESIS OF TYPE 2 DIABETES MELLITUS

Insulin Resistance and Insulin Deficiency

The pathogenesis of type 2 diabetes mellitus[128] is even more complex than that of type 1 diabetes mellitus. Insulin resistance, reported in 92% of one large group of people with type 2 diabetes mellitus,[129] plays a major role in generating hyperglycemia.[128] In addition, some degree of functional insulin deficiency exists [*see Figure 14*].[128] Certain studies suggest that insulin resistance is primary[128,130] and that impaired insulin secretion is only really evident when fasting hyperglycemia supervenes.[128, 131-133] Other investigators find evidence of early abnormal beta cell function in type 2 diabetes mellitus,[134-136] in IGT,[134,137] and in first-degree glucose-tolerant relatives of patients with type 2 diabetes mellitus.[138] Regardless of which comes first, the loss of compensatory beta cell hyperfunction to overcome insulin resistance is a key factor in the progression from genetic susceptibility to established type 2 diabetes mellitus.[139] Furthermore, insulin resistance may cause secondary insulin deficiency, and insulin deficiency tends to lead to insulin resistance; thus, they are mutually reinforcing defects, partly through an effect commonly referred to as glucose toxicity.[140] Some period of hyperglycemia has a secondary noxious effect that aggravates both insulin resistance and insulin deficiency; thus, hyperglycemia begets hyperglycemia. Therefore, any form of treatment of type 2 diabetes mellitus that lowers plasma glucose levels is self-reinforcing and may gain momentum with time by virtue of the added early benefit of eliminating the effects of glucose toxicity. For this reason, aggressive early treatment (e.g., with insulin) can sometimes be replaced with oral drugs or even diet.[141]

The exact locus of insulin resistance in type 2 diabetes mellitus remains unidentified. Indeed, there may be various sites because the disease is considered likely to be a heterogeneous disorder.[142,143] Numerous candidate genes for defective insulin action, including the insulin receptor, glucose transporter, insulin receptor substrate, and insulin target enzymes, such as glycogen synthase, have been largely excluded as common primary causes of insulin resistance[144,145] in type 2 diabetes mellitus.

As in type 1 diabetes mellitus, the loss of effective insulin action directly leads to unrestrained hepatic glucose production and inefficient peripheral glucose utilization [*see Figure 14*]. Exces-

Table 6 Definitions of the Metabolic Syndrome[155,156]

National Cholesterol Education Program Adult Treatment Panel III	*World Health Organization*
At least three of the following:	Diabetes, IGT, or IFG and/or insulin resistance*
Fasting plasma glucose ≥ 110 mg/dl	*plus at least two of the following:*
Abdominal obesity: waist circumference 35 in. in women or > 40 in. in men	Abdominal obesity: waist-to-hip ratio > 0.85 in women or > 0.9 in men and/or body mass index > 30 kg/m^2
Triglycerides > 150 mg/dl; HDL < 50 mg/dl in women or < 40 mg/dl in men	Triglycerides > 150 mg/dl and/or HDL < 40 mg/dl in women or < 35 mg/dl in men
Blood pressure ≥ 130/85 mm Hg	Blood pressure ≥ 140/90 mm Hg
	Microalbuminuria: urinary albumin excretion ≥ 20 µg/min or albumin-to-creatinine ratio ≥ 30 mg/g

*Insulin resistance assessed as fasting insulin ÷ (fasting glucose × 22.5).
HDL—high density lipoprotein IFG—impaired fasting glucose IGT—impaired glucose tolerance

sive hepatic glucose output largely accounts for elevation of FPG levels.[128] Resistance to the antilipolytic action of insulin in adipose tissue leads to elevated plasma free fatty acid (FFA) levels and increased FFA delivery to the liver. There, the oxidation of FFA generates energy (adenosine triphosphate [ATP]) needed to sustain gluconeogenesis; in addition, the latter process is stimulated by FFA metabolites such as acyl coenzyme A (acyl-CoA). In this indirect manner, insulin resistance also contributes to elevated glucose production in the liver.[146] Moreover, the elevation of FFA levels also contributes to insulin resistance in muscle.[147] The presence of some residual insulin secretion in type 2 diabetes mellitus, however, is ordinarily enough to restrain ketogenesis and prevent DKA. Elevated hepatic glucose output largely sustains an elevated FPG, whereas reduced peripheral glucose utilization especially causes elevation of postprandial glucose levels [*see Figure 14*].

The ratio of proinsulin to insulin in plasma is high and remains so even after glucose-lowering therapy,[148,149] suggesting an early abnormality in processing of proinsulin to insulin in the beta cell [*see Figure 3*]. Insulin is normally secreted in cyclic pulses that can be entrained by rapid changes in plasma glucose levels. Disruption of this close concordance between plasma glucose and plasma insulin fluctuations is a subtle lesion that is demonstrable early in patients with type 2 diabetes mellitus and, to a lesser extent, in some patients with only impaired glucose tolerance.[134,136] Finally, the plasma insulin response to abrupt elevation of plasma glucose levels normally shows a first sharp, spikelike phase.[150] Before the plasma insulin level returns to baseline, it slowly rises again to produce a second plateau phase of more prolonged insulin release. The immediate first-phase response to glucose decreases in type 2 diabetes mellitus, as it does in the preclinical phase of type 1 diabetes mellitus, and is completely lost when the FPG level exceeds the normal range.[151]

Other Beta Cell Abnormalities

Another, previously neglected abnormality in type 2 diabetes mellitus is the presence of amyloid in close proximity to the islet beta cells. The amyloid fibrils have been found to contain amylin, a peptide that is cosecreted with insulin.[152] Amylin deficiency parallels insulin deficiency in type 2 diabetes mellitus.[152] Whether the accumulation of amyloid impairs beta cell function or is an epiphenomenon resulting from beta cell hyperfunction with increased amylin secretion in the early phases of the disease remains unclear.

More than 10% of some patient populations presenting with the clinical phenotype of type 2 diabetes mellitus have serum islet cell autoantibodies typical of type 1 diabetes mellitus, such as antibodies to GAD.[153] This combination has been referred to as latent autoimmune diabetes in adults (LADA). These individuals exhibit a rapid decline in beta cell function, as shown by serum C-peptide levels, and they are likely to need insulin replacement therapy, even if their hyperglycemia is initially alleviated by oral beta cell stimulants.[154,155]

Metabolic Syndrome (Insulin-Resistance Syndrome)

The metabolic (insulin-resistance) syndrome is closely associated with, and often a forerunner of, type 2 diabetes mellitus. The metabolic syndrome has been defined both by the National Cholesterol Education Program and the World Health Organization (WHO) [*see Table 6*].[156,157] Only the WHO definition includes insulin resistance per se, assessed by determining the ratio of the fasting plasma insulin level to the glucose level. By either definition, the syndrome represents a collection of risk factors not only for diabetes regulation but also for cardiovascular disease, and it presages both diseases. One obvious link between the components of the metabolic syndrome is obesity, which is a cause of insulin resistance[158] and a contributor to the insulin resistance of type 2 diabetes mellitus.[159] Weight gain presages diabetes,[160] and weight loss in obese individuals prevents progression of IGT to full-blown diabetes.[161] Most patients with type 2 diabetes mellitus have abdominal obesity and many have dyslipidemia, hypertension, and other features of the metabolic syndrome.[129] Abdominal obesity is itself a risk factor for type 2 diabetes mellitus and cardiovascular disease.[162] The interrelationship of the metabolic syndrome, diabetes, and cardiovascular disease is exemplified in the NHANES III study. The overall prevalence of the metabolic syndrome in the United States is 23% in men and women older than 20 years and 44% in those older than 50 years.[163] This huge prevalence of the metabolic syndrome reflects the burgeoning of obesity in the population. In the over-50 age group, 87% of those with diabetes, 71% of those with IFG, and 33% of those with IGT also had the metabolic syndrome.[164] The prevalence of coronary heart disease (CHD) was 8.7% in those with neither diabetes nor the metabolic syndrome and 7.5% in those with only diabetes, but it increased to 13.9% in those with only the metabolic syndrome and to 19.2% in those with both the metabolic syndrome and diabetes. These cross-sectional data suggest that the metabolic syndrome is more potent than diabetes per se as a risk factor for CHD, but hyperglycemia (diabetes) aggravates the risk inherent in the metabolic syndrome. This relation explains much but not all of the vulnerability of patients with type 2 diabetes mellitus to cardiovascular complications resulting from accelerated atherosclerosis. On the other hand, not all patients with the metabolic syndrome and IGT go on to experience full-blown type 2 diabetes mellitus. A large randomized controlled trial is currently testing the ability of lifestyle changes (weight reduction and regular exercise) and the drug metformin to reduce the risk of progressing from IGT to type 2 diabetes mellitus.[165]

Genetic Factors

Type 2 diabetes mellitus has a strong hereditary component. In virtually all monozygotic twinships, the disease develops in both individuals, often within a few years of each other.[166] Offspring and siblings of diabetic patients are at great risk for the disease.

Table 7 American Diabetes Association Plasma Glucose Diagnostic Criteria for Diabetes Mellitus

Diagnosis	*Test Condition*	
	Plasma Glucose (mg/dl)	
	Fasting ≥ 8 hr	*2 hr after 75 g Oral Glucose*
Normal	< 110	< 140
Impaired glucose tolerance (IGT)	< 126	≥ 140–< 200
Impaired fasting glucose (IFG)	≥ 110–< 126	< 200
Diabetes mellitus	≥ 126	—
Diabetes mellitus	< 126	≥ 200
Diabetes mellitus (Classic symptoms + casual plasma glucose, ≥ 200 mg/dl)	—	—
	Plasma Glucose (mg/dl)	
	Fasting	*After 100 g Oral Glucose*
Gestational diabetes mellitus (GDM)	> 105*	1 hr ≥ 190*
		2 hr ≥ 165*
		3 hr ≥ 145*

Note: The Fourth International Workshop-Conference on Gestational Diabetes Mellitus has proposed lower criteria, which would increase the percentage of cases from 4% to 7% in white women. These criteria are fasting, 95; 1 hour, 180; 2 hours, 155; and 3 hours, 140, after 100 g oral glucose.
*Two of these four criteria must be met for diagnosis of GDM.

No HLA markers have been identified for type 2 diabetes mellitus, in contrast to type 1 diabetes mellitus. Most current thinking is that the common forms of type 2 diabetes mellitus represent a complex multigenic disorder. Examination of the mechanism of action of insulin [*see Figure 4*] suggests many logical candidate genes, mutations of which could lead to type 2 diabetes mellitus by causing primary insulin resistance. Thus far, genes for insulin, the insulin receptor, insulin receptor substrate, glucose transporter, protein tyrosine phosphatase (which inactivates the insulin receptor), muscle hexokinase, glycogen synthase, and other insulin target enzymes have all been excluded as the cause of so-called garden-variety type 2 diabetes mellitus.[167] Because of the association with obesity, genes that could cause obesity are also being investigated (e.g., leptin, uncoupling protein, and beta$_3$-adrenergic receptor). The positional cloning approach being used in populations with high diabetes prevalence, such as Pima Indians and Mexican Americans, has yielded hints of loci on certain chromosomes that require confirmation.

There is one form of diabetes, MODY [*see Table 1*], that does have genetic specificity. In this disorder, mutations of several different genes on different chromosomes lead to a common phenotype resembling type 2 diabetes mellitus, but the disorder begins at an early age.[168] One of the genes codes for glucokinase, an enzyme that plays a key role in stimulation of insulin secretion by glucose.[169] Another mutation occurs in a molecule known as insulin production factor–1, a transcription factor responsible for differentiation of precursor cells into beta cells capable of insulin secretion.[168] Two other genes responsible for MODY code for hepatic transcription factor–1 and hepatic transcription factor–4, which, despite their names, operate in beta cells to regulate the glucose responsive pathway of insulin secretion.[168] All of these genetic abnormalities more likely explain type 2 diabetes mellitus caused by beta cell dysfunction than that caused by peripheral insulin resistance. Their functional relation to the diabetic diathesis is still obscure. Even in a phenotypically well defined monogenic form of diabetes such as MODY, the existence of many alleles for hepatic transcription factor–1 indicates the genetic complexity of diabetes. Although the mutations responsible for MODY account for only a minute fraction of all cases of type 2 diabetes mellitus, they encourage the view that genes contributing to most or all cases of type 2 diabetes mellitus will eventually be found.

IMPAIRED GLUCOSE TOLERANCE

The state known as IGT [*see Table 7*] is associated with a future risk of development of diabetes of 1% to 10% a year, with different levels of risk for different ethnic groups. Equally important is the association of IGT with the metabolic syndrome [*see Table 6*], which includes hyperinsulinemia, glucose intolerance, dyslipidemia, hypertension, and impaired fibrinolysis. Presence of this syndrome constitutes a high risk for atherosclerosis, cardiovascular disease, thrombotic events, and mortality. The category of impaired fasting glucose was established by the American Diabetes Association as an intermediate zone between the upper limit of normal and the lower limit for diabetes.[1] IFG is also associated with increased risk of diabetes and cardiovascular disease. IFG and IGT are not identical states. About one third of people with IGT have IFG, one third of those with IFG have IGT, and one third of affected individuals have both.[2] The pathophysiologic bases and clinical significance of the differences between IFG and IGT remain to be determined. Both conditions can be thought of as early stages of type 2 diabetes mellitus and can be referred to as prediabetes.

PREVENTION OF TYPE 2 DIABETES

Five randomized clinical trials have recently demonstrated that the risk of progression from IGT to diabetes can be significantly reduced by lifestyle modifications or pharmacologic interventions. The Diabetes Prevention Program (DPP),[170] the Finnish Diabetes Prevention Study,[171] and the Da Qing IGT and Diabetes Study[172] showed that intensive diet and exercise therapy brought reductions ranging from 42% to 58% in the progression from IGT to diabetes over 3 to 6 years. The weight loss achieved and the amount of exercise performed were modest—5.6 kg and 150 minutes of brisk walking a week in the DPP. The DPP also had a placebo-controlled metformin (850 mg twice daily) treatment arm, which showed a 31% reduction in diabetes. Most of this effect persisted after a 1-week washout from metformin. In the STOP-NIDDM trial, 100 mg of acarbose three times daily, compared with placebo, reduced diabetes development by 25%.[173] Finally, in a group of Hispanic women with previous gestational diabetes, 400 mg of troglitazone daily, compared with placebo, reduced development of diabetes.[174] This benefit was still present after an 8-month drug washout.

The efficacy, safety, and consistency of lifestyle interventions are impressive, but long-term follow-up is needed to determine how long such patients will continue to implement this therapy and how durable the benefits will be from either lifestyle changes or drugs. Equally important is whether car-

diovascular disease events will be reduced eventually. A preliminary report from the first 3 years of the STOP-NIDDM trial suggests an encouraging significant reduction in myocardial infarction and total cardiovascular disease events.[175]

DIAGNOSIS OF TYPE 2 DIABETES MELLITUS

Although patients with type 2 diabetes mellitus may present with symptoms as florid as those of type 1 diabetes mellitus (but usually not exhibiting spontaneous ketonuria), most patients with type 2 disease have relatively mild polyuria and polydipsia, and many cases are diagnosed only by office screening or other health checks.

The preferred test for type 2 diabetes mellitus on the grounds of reproducibility, convenience, and cost is an FPG . Oral glucose tolerance testing (OGTT) is more sensitive than FPG but is not recommended for routine use, because it is less reproducible, more inconvenient, and more costly.[1] Moreover, the recommended treatment for almost all overweight or obese patients who would be candidates for OGTT would be the same regardless of OGTT results: a combined regimen of nutrition therapy, weight loss, and exercise. OGTT may be considered in unusually high risk patients and in those with IFG.

MANAGEMENT OF TYPE 2 DIABETES MELLITUS

The same glycemic goals discussed earlier [*see Table 5*] are appropriate for type 2 diabetes mellitus. However, these goals may sometimes have to be modified if severe cardiovascular disease, concurrent life-shortening malignancy, hypoglycemia unawareness, or inadequate family or social support make intensive treatment of diabetes dangerous or unlikely to benefit the patient in the long run. Self-monitoring of blood glucose when patients with type 2 diabetes mellitus are treated with diet plus exercise or with oral drugs is of less well established utility in patients with type 2 diabetes mellitus than in patients with type 1 diabetes mellitus. However, fasting and postprandial blood glucose levels both correlate with HbA_{1c} levels, and postprandial values can help reveal inadequate attention to diet and insufficient effectiveness of certain oral agents.

Nutritional Therapy and Exercise

An excellent short-term glycemic response to caloric reduction in patients with type 2 diabetes mellitus who are even modestly overweight can be expected.[175, 176] On the basis of the degree of obesity and with the help of a dietitian, the patient should be provided with individualized culturally appropriate instructions to reduce intake by at least 250 to 500 calories a day. Such a decrease generally leads to an overall weight loss of 0.5 to 1.0 lb a week. There should be periodic reinforcement by the dietitian and physician. In the absence of a dietitian, the patient's basal metabolic rate can be estimated at 10 cal/lb (20 cal/kg) of ideal body weight. A caloric prescription less than this amount will perforce decrease energy intake below the total daily energy expenditure. Consensus guidelines recommend that the calories should consist of less than 30% total fat, less than 10% saturated fat, less than 10% polyunsaturated fat, 10% to 15% monounsaturated fat, 10% to 20% protein, and 50% to 55% carbohydrate.[177] Table sugar and other concentrated forms of carbohydrates are allowable in small portions at any one time (e.g., 5 g or 1 tsp of table sugar). Adding high-fiber foods can also lower plasma glucose modestly.[178] Teaching patients to count the contemplated grams of carbohydrate before each meal helps them limit elevation of postprandial plasma glucose (PPG).

In massively obese individuals with BMI greater than 40 who are very symptomatic from hyperglycemia, a very low calorie diet (400 to 800 total calories a day using special high-protein supplements) can be very effective for the initial 2 to 3 months, but this strategy requires close medical monitoring.[179]

Weight losses of 5% to 10% (10 to 20 lb) produce significant decreases in FPG and HbA_{1c} over 1 to 3 months.[176] In the UKPDS, mean HbA_{1c} fell from 9% to 7% during the 3-month dietary run-in period before randomization of the study patients.[180,181] However, many patients are unable to maintain a calorie-restricted diet and even their initial weight loss. Pharmacologic aids for weight loss can be considered in such cases, but their efficacy is limited. These drugs include orlistat,[182] a gastrointestinal lipase inhibitor that causes malabsorption of fat calories, and sibutramine, an inhibitor of dopamine, norepinephrine, and serotonin reuptake. Even after the addition of a weight-loss drug to therapy, appropriate diet therapy is essential. The patient should not be blamed for recidivism, because inability to lower body weight to ideal and keep it there may well be a central nervous system manifestation of or contributor to type 2 diabetes mellitus and out of the patient's consistent control.[183] Surgical therapy for obesity by reduction of gastric volume[184,185] can effectively control type 2 diabetes mellitus and is gaining acceptance in very obese individuals who are unresponsive to other therapy. Of great interest, such treatment may work by altering the concentrations of humoral signals from the gastrointestinal tract that regulate appetite.

Additional benefits accrue from gradually increased aerobic exercise[186] aimed at achieving at least 60% of maximal heart rate (220 minus age), such as walking 45 minutes at a brisk pace (approximately 3 to 5 miles an hour) three to five times a week. Exercise decreases insulin resistance and glycemia, contributes modestly to weight loss, reduces the risk of future cardiovascular disease, improves prognosis should a myocardial infarction occur, and enhances the patient's sense of well-being and physical fitness. Conversely, physical inactivity predicts mortality in men with type 2 diabetes mellitus.[187] In the presence of known coronary artery disease (CAD), the exercise should be prescribed with input from the patient's cardiologist. If type 2 diabetes mellitus has existed for more than 5 to 10 years or if the patient already has peripheral vascular or cerebral vascular disease, autonomic neuropathy, microalbuminuria, dyslipidemia, or a history of smoking, an electrocardiogram is essential and an electrocardiographic exercise tolerance test is prudent before initiating a formal exercise program.

Pharmacologic Monotherapy

The array of pharmacologic agents available for treatment of type 2 diabetes mellitus is increasing steadily. Drugs can be specifically directed at the known pathophysiologic defects in type 2 diabetes mellitus [*see Figure 15*]. Although patient compliance favors initial use of monotherapy, none of the available agents can alone be expected to adequately control hyperglycemia indefinitely.[188] Therefore, diabetologists are beginning to consider using combinations of drugs from the outset of the need for any pharmacotherapy.[189] Clinical trial data have established the efficacy and safety of various drugs [*see Table 8*] . The degrees to which these drugs lower HbA_{1c} are fairly similar; the higher the initial dose of these agents, the greater the decrease in HbA_{1c}.

Sulfonylurea agents SU agents, the oldest oral hypoglycemic drugs, continue to have an important place in treat-

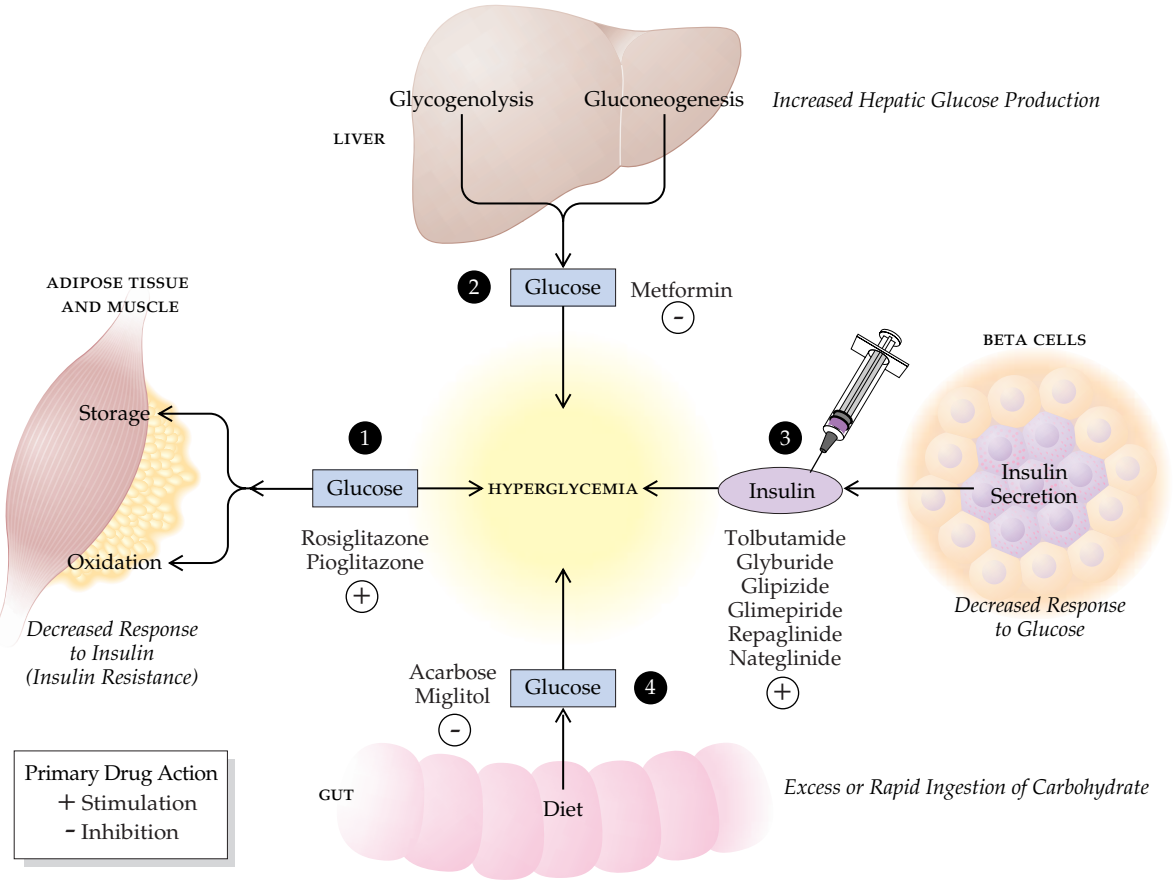

Figure 15 **Multiple drug classes with different predominant therapeutic effects are available for use singly or in numerous combinations. (1) Glitazones (thiazolidinediones) increase the sensitivity to insulin of glucose uptake by muscle and adipose tissue. (2) Metformin, the only approved biguanide drug, inhibits glucose production by the liver. (3) Sulfonylureas, repaglinide, and nateglinide stimulate insulin secretion, and insulin itself can be provided by injection. (4) α-Glucosidase inhibitors slow the digestion and absorption of carbohydrates from the diet. Plus signs indicate stimulation. Minus signs indicate inhibition.**

ment. Their primary mechanism of action is to close ATP-sensitive potassium channels in the beta cell (and other cell) membranes, which leads to an influx of calcium and stimulation of exocytosis of insulin storage granules. They are most effective in normal-weight or modestly obese individuals who have had diabetes for less than 5 years and who can still secrete considerable amounts of insulin. The SU drugs in common use stimulate the beta cells more or less continuously and secondarily decrease insulin resistance. These effects [*see Figure 14*] result in decreases in FPG of 50 to 70 mg/dl and HbA_{1c} of 1.0% to 2.0%.[190] Peak PPG levels fall approximately as much as FPG. For most patients, treatment is initiated with the lowest recommended dose, and the dose is increased every 1 to 2 weeks until target blood glucose levels are attained or a practical maximal dose is reached [*see Table 9*]. Modern SU drugs can be taken as a single daily dose but occasionally are more effective when split into twice-daily doses. In symptomatic patients with FPG greater than 250, the patient may begin with half the maximal recommended dose. Hypoglycemia, in particular, and weight gain are adverse effects of SU drugs. The highest prevalence of hypoglycemia occurs with glyburide and chlorpropamide,[191] drugs with long biologic half-lives. Elderly patients who live alone and lack concerned family, friends, or neighbors are at a special risk for severe, even fatal, hypoglycemia.[192] The shortest-acting SU drug, tolbutamide, may be the safest to use in such cases.

Patients who present to an emergency room in hypoglycemic coma from any SU drug should be given restorative treatment with intravenous boluses of glucose and then admitted to the hospital because SU drugs can have durations of biologic action for up to 7 days. A blood glucose should be maintained at 150 to 200 mg/dl on intravenous glucose, oral carbohydrate, or both until this level can be sustained by administration of only 5 g/hr of one of the therapeutic agents. In the UKPDS, SU drugs did not increase cardiovascular disease events or mortality.[37] This observation relieves much of the concern previously raised by the University Group Diabetes Program trial in 1970, which found that tolbutamide was associated with an excess of cardiovascular and total deaths.[193] However, interactions of even modern SU drugs with cardiac muscle are reported, particularly inhibition of ischemic preconditioning, a cardioprotective mechanism.[194] SU drugs are contraindicated in hepatic insufficiency and are dangerous when combined with alcohol ingestion. Glimepiride, the newest SU drug,[195] has been given safely to patients with renal insufficiency, although these patients are susceptible to hypoglycemia for other reasons. SU drugs are subject to interactions with other drugs that can either exaggerate or interfere with their effects.

Beta cell stimulants Repaglinide and the phenylalanine derivative nateglinide represent a new class of beta cell stimulants [*see Figure 15*] that differ in structure and timing of action

Table 8 Oral Drugs for Type 2 Diabetes Mellitus

Drugs	*Lowest Effective Single Dose (mg)*	*Practical Maximum Daily Dose (mg)*	*Hypoglycemia with Monotherapy*
Sulfonylureas*			
Glyburide	1.25	10	Yes
Micronized glyburide	1.5	6	Yes
Glipizide	5	20	Yes
Glipizide (gastrointestinal therapeutic system)	5	20	Yes
Glimepiride	0.5	8	Yes
Meglitinides†			
Repaglinide	0.5	4‡	Yes
Biguanides			
Metformin	500	2,000	No
Thiazolidinediones§			
Rosiglitazone	2	8	No
Pioglitazone	15	45	No
α-Glucosidase inhibitors			
Acarbose	25	100‡	No
Miglitol	25	100‡	No

*Tolbutamide, chlorpropamide, and acetohexamide are also still available.
†Nateglinide has a similar action to meglitinides but is technically phenylalanine derivative.
‡This maximal dose must be taken each time with meals.
§Troglitazone was the initial drug approved in this class but was later withdrawn because of serious liver toxicity.

from those of SU drugs.[196] Although they may act in part through SU drug mechanisms in the beta cells,[197] they do so rapidly, with a peak effect at about l hour, and transiently, with a duration of about 4 hours. Their major action is the decrease of PPG by 50 to 60 mg/dl, although FPG also declines somewhat as glucose toxicity is relieved. As monotherapy, these new beta cell stimulants are most logically used early in type 2 diabetes mellitus, when FPG is not greatly elevated. They lower HbA_{1c} by about 1.0%. Repaglinide and nateglinide must be taken 15 to 30 minutes before a meal and should never be taken without eating. Their short half-lives and the fact that, unlike SU drugs, they are active only in the presence of glucose are expected to reduce the likelihood of severe prolonged hypoglycemic episodes.[196] Weight gain may occur secondary to improved glycemic control.

Table 9 Combination Oral Drug Therapy for Type 2 Diabetes Mellitus

Combinations reported in the literature
- Sulfonylurea + metformin
- Sulfonylurea + thiazolidinedione
- Metformin + thiazolidinedione
- Metformin + repaglinide
- Repaglinide + thiazolidinedione
- Sulfonylurea + metformin + thiazolidinedione
- Acarbose + any other drug except repaglinide
- Miglitol + sulfonylurea
- Insulin + any other drug

Potentially useful combination
- Repaglinide + metformin + thiazolidinedione
- Nateglinide + metformin + thiazolidinedione

α-Glucosidase inhibitors α-Glucosidase inhibitors[197,198] are a class of drugs represented by acarbose and miglitol, which are poorly absorbed but act within the gut to inhibit the digestion of polysaccharides [*see Figure 15*]. This action results in a slow release of glucose from food and therefore slow absorption from the GI tract. PPG levels decrease by 60 to 70 mg/dl, but FPG decreases by only 15 to 20 mg/dl.[199] HbA_{1c} generally falls 0.5% to 0.8%.[198,199] These drugs are useful only as monotherapy when postprandial hyperglycemia is the main problem. They must be taken at the start of a meal. Flatulence, abdominal cramping, and diarrhea are frequent side effects that result from undigested carbohydrate reaching bacteria in the lower bowel. These side effects often limit patient acceptance of treatment with α-glucosidase inhibitors. Treatment should start with the smallest dose, and doses should be raised very gradually to enhance tolerance. With the exception of rare elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels, these agents are nontoxic. Although hypoglycemia does not occur with monotherapy, it can do so when α-glucosidase inhibitors are added to SU drugs or insulin. In those instances, patients must be warned to treat hypoglycemia only with pure glucose (e.g., glucose tablets) because the therapeutic benefits of complex carbohydrates and even sucrose will be delayed by slow digestion.

Biguanide agents Metformin,[200] the only drug approved in the biguanide class, acts primarily by decreasing excessive hepatic glucose production [*see Figure 15*],[201,202] most likely through inhibiting gluconeogenesis. Because insulin also inhibits gluconeogenesis [*see Figure 1*][20] and metformin requires the presence of insulin to be effective, metformin may be considered a hepatic insulin sensitizer. During metformin treatment, plasma insulin levels tend to decrease relative to glucose levels as a result of the decrease in insulin resistance. The chief action of this drug is to lower FPG by 50 to 70 mg/dl, with peak PPG levels following

suit.[203] Hypoglycemia almost never occurs with metformin monotherapy. Weight is not gained and may even be lost.[200] Metformin also decreases plasma triglyceride and low-density lipoprotein (LDL) cholesterol levels, and it increases HDL cholesterol levels to some degree. In addition, plasma plasminogen activator inhibitor–1 (PAI-1) activity declines.[204] The weight loss, the improvement in the dyslipidemia typical of type 2 diabetes mellitus, and the reduction in antifibrinolytic activity could explain one of the most interesting UKPDS observations. Compared with conventional diet treatment, metformin monotherapy substantially decreased the incidence of myocardial infarction, diabetes-related death, and all-cause mortality in an obese type 2 subcohort of the trial.[38]

The most common side effects of metformin therapy are diarrhea, which may be severe; abdominal cramps; and gastric upset. To reduce the likelihood of these symptoms, the starting dose should not exceed 500 mg twice a day, and the drug should be used with special caution, if at all, in patients who have inflammatory GI disease. The maximum effective dose is 2,000 mg/day.[205] The most feared, although rare, adverse effect is lactic acidosis.[206] This often fatal complication occurs in 30 per million patients a year, and it usually occurs when the drug is used inappropriately, such as when the serum creatinine level is elevated or the patient is dehydrated. Hemodialysis along with bicarbonate administration can be effective therapy for metformin-induced lactic acidosis.[207] The following are contraindications to use of metformin: serum creatinine level greater than 1.4 mg/dl in women and greater than 1.5 mg/dl in men; intravenous administration of radiographic iodinated contrast media; acute myocardial infarction; congestive heart failure; and any ischemic condition. Nausea, vomiting, tachypnea, and change in mental status call for measurements of serum electrolytes and lactate to rule out lactic acid metabolic acidosis. Although metformin monotherapy can be effective in both normal-weight and obese patients with type 2 diabetes mellitus, obese patients especially benefit from metformin therapy because of the absence of weight gain as glucose levels gradually fall.

Thiazolidinediones The newest class of oral drugs are thiazolidinediones (TZDs) [*see Table 8*],[208] which were exemplified by the no longer available but best studied drug, troglitazone . These agents work predominantly in muscle and adipose tissue to decrease insulin resistance [*see Figure 15*].[202,209] Because insulin resistance is seen in almost all patients with type 2 diabetes mellitus, the advent of the TZDs raised expectations that they might be singularly effective. Like metformin, TZD drugs need the presence of insulin and are especially effective in obese patients. They also decrease hepatic glucose production to some extent.[202] As monotherapy, they decrease FPG by 50 to 70 mg/dl and PPG by slightly more than that.[209] HbA_{1c} decreases by about 1.0% to 1.5%. Plasma insulin levels also decrease as glucose levels fall.[209] TZD drugs act by binding to a metabolically important receptor, the peroxisome proliferator-activated receptor (PPAR), and they thereby regulate the expression of multiple genes.[210] Their clinical effects take 4 to 12 weeks to become evident. In patients with marked elevation of FPG, a midrange dose is appropriate to start with (e.g., 4 mg rosiglitazone or 30 mg pioglitazone). Otherwise, the lowest dose is appropriate, and dose changes should be made at 4- to 12-week intervals.

TZD drugs can cause weight gain, which is partly fat tissue and partly extracellular fluid.[208] The accumulation of extracellular fluid presents as edema, which can be troublesome when concurrent congestive heart failure exists, and a small dilutional fall in hemoglobin and hematocrit. Some findings suggest that the adipose tissue gain is largely subcutaneous rather than visceral.[211] In clinical research trials, troglitazone therapy was accompanied by elevations of ALT and AST to more than three times the upper limit of normal in 2% of treated patients, compared with 0.6% of patients given placebo. However, after troglitazone was approved by the FDA, more than 60 cases of hepatic failure that necessitated liver transplantation or resulted in death, or both, were reported out of a user base of about one million persons. The FDA eventually withdrew approval, first for the prescription of troglitazone as monotherapy and later for all indications. In clinical research trials, neither rosiglitazone nor pioglitazone caused AST and ALT elevations in excess of those caused by placebo, but these drugs have not been used enough to provide a guarantee that they will never cause idiosyncratic liver toxicity similar to that caused by troglitazone. Therefore, the FDA has mandated that these drugs be monitored by ALT measurements every 2 months for the first year of use. Neither rosiglitazone nor pioglitazone should be prescribed if the ALT level is greater than 2.5 times the upper limit of normal, and the drugs should be stopped if such levels are reached.

TZD drugs have exhibited effects in addition to glucose lowering that may be beneficial for treating cardiovascular complications.[212-219] Troglitazone and pioglitazone suppress formation of PAI-1, an action that enhances fibrinolysis.[213,214] TZD drugs tend to decrease serum triglyceride levels and increase serum HDL cholesterol levels, but they also increase serum LDL cholesterol levels.[208] In addition, troglitazone has been reported to shift the LDL spectrum from small, dense atherogenic particles to larger, more buoyant, less atherogenic particles.[219] Endothelial function also likely improves.[216,217] A decrease in carotid artery intimal-medial thickness[217]—a marker of atherosclerosis—as well as decreases in vasospastic angina[215] and in recurrence of intimal hyperplasia after coronary angioplasty[218] have been reported in small series of patients treated with troglitazone for only 6 months.[216,217] Whether TZD drugs will decrease rates of cardiovascular events through such actions remains to be seen.

Insulin About 40% of patients with type 2 diabetes mellitus in the United States are estimated to be taking insulin. A small proportion of these patients may have delayed-onset type 1 diabetes mellitus and may offer serologic evidence of beta cell autoimmunity. However, most of these patients represent the end stage of type 2 diabetes mellitus. A small number of such patients, some of whom are even obese, present initially with clear-cut biologic evidence of insulin deficiency. This evidence includes marked recent loss of weight and muscle mass, debilitating fatigue and weakness, severe polyuria and polydypsia, considerable hypertriglyceridemia, ketonuria, and FPG often exceeding 300 mg/dl. These patients should be started on insulin immediately—as in patients with type 1 diabetes mellitus. After usually rapid clinical and biochemical improvement, insulin-dose requirements may decrease progressively. Patients can sometimes be tapered off insulin and be given a trial of an SU drug. This sequence has been reported in certain groups of African Americans.[220,221]

Much more commonly, the need for insulin treatment has arisen because of eventual failure of oral drug therapy, particularly SU drugs. For normal-weight individuals in this situation, it is best to simply switch them to insulin. Some patients may still be managed on a single dose of intermediate- or long-acting insulin (starting dose of NPH, Lente, or glargine of 0.15 to 0.20 U/kg) in

the morning[222] or at bedtime if the FPG is being specifically targeted.[223] The latter is a particularly attractive way to lessen glycemia without stimulating weight gain.[224] Other patients may need intermediate- or long-acting insulin twice a day, usually in a ratio of breakfast dose to bedtime dose of from 1:1 to 2:1. As endogenous postprandial insulin secretion declines further, regular or lispro insulin or insulin aspart [*see* Type 1 Diabetes Mellitus, *above*] must be added before meals. To approach normal glycemia, the doses of rapid, short-acting insulin are best adjusted according to the premeal blood glucose level, the carbohydrate content of the meal, or both. For all practical purposes, some patients with type 2 diabetes mellitus closely resemble patients with type 1 diabetes mellitus in the insulin regimens they require.

For stable patients incapable of accurately mixing different insulins in one syringe because of visual or cognitive impairment, premixed combinations of NPH with regular or lispro insulin are available in varying proportions; these combinations include 70% NPH/30% regular, 50% NPH/50% regular, and 75% NPH/25% lispro. These mixtures all suffer from the inflexibility of neither the dose of NPH nor the dose of the regular or lispro insulin being able to be altered individually. For example, a patient with satisfactory postbreakfast or prelunch blood glucose levels but elevated predinner blood glucose levels would benefit from an increase in the morning NPH insulin dose but not necessarily from an increase in the morning regular or lispro insulin dose. Premixed insulins are not suitable for bedtime use unless an uncommonly large snack is eaten. Despite the above objections, premixed insulins are convenient for patients and for family members who have therapeutic responsibilities.

Whatever insulin regimens are chosen, obese patients with type 2 diabetes mellitus often need large daily doses, which many practitioners are unaccustomed to prescribing. Doses of 1 U/kg body weight are not unusual, and doses of up to 400 U daily have been required to achieve glycemic targets in morbidly obese individuals.[225,226] Concern has been raised in the past that insulin might have atherogenic effects because epidemiologic studies (mostly in nondiabetic individuals) have shown an association between insulin resistance, fasting or postprandial plasma insulin levels, and future risk of cardiovascular disease.[227] In the UKPDS[37] and in the University Group Diabetes Program,[228] exogenous insulin did not increase the rate of myocardial infarction or of cardiovascular death. It can be argued that the insulin doses used in those trials were not very large or that an adverse effect from an atherogenic property of insulin was offset by a beneficial effect resulting from a decrease in glycemia. In any event, there is not enough evidence of cardiovascular danger from exogenous insulin to justify withholding doses necessary to achieve near-normal glycemia. In two randomized clinical trials[37,229] and in a large retrospective study,[192] the incidence of serious hypoglycemic episodes was about two to three events per 100 patient-years. In elderly patients, however, one out of 20 severe hypoglycemic events can be accompanied by such complications as stroke, transient ischemic attack, myocardial infarction, injury, and death.[190] Weight gain—in rare cases, even to degrees that have resulted in sleep apnea—is a major adverse effect of insulin therapy and is one justification for combining insulin with a drug such as metformin, which can restrict weight gain to some extent.[230]

Combination Therapy

Improved understanding of the pathogenesis of hyperglycemia in type 2 diabetes mellitus and longer experience with oral drug monotherapy have greatly increased interest in and popularity of using combinations of oral drugs. In patients with considerable hyperglycemia, none of the current drugs reliably normalize HbA_{1c} when used alone, probably because they act primarily by correcting single abnormalities [*see Figure 15*]. Thus, to reach aggressive therapeutic targets [*see Table 3*], combinations are needed [*see Table 9*]. Moreover, all forms of monotherapy—including insulin used conventionally—fail after a number of years, with the possible exception of TZD drugs, for which long enough experience is still lacking. This need for combination therapy was best shown by the UKPDS experience.[37,188] Combination therapies attack two or more different causes of hyperglycemia simultaneously—for example, reducing insulin resistance in the liver with metformin while increasing insulin secretion with an SU drug[203] or meglitinide.[231] Moreover, as a practical matter, when monotherapy fails after initial success, substituting another drug from a different drug class has not been effective (except for insulin), as has been shown in trials that unsuccessfully attempted to substitute metformin[203] or a TZD drug[232] for an SU drug. By contrast, addition of either metformin[203] or a TZD[232] to an SU drug did lower HbA_{1c} significantly. The combinations of metformin with repaglinide,[231] metformin with a TZD drug,[202] and repaglinide with a TZD drug[233] have also been more effective than any of these agents given alone. Pharmaceutical companies have responded to these considerations by marketing combination pills containing metformin and either glyburide or rosiglitazone for use as initial drug therapy. The single tablet may improve compliance with a two-drug regimen.

α-Glucosidase inhibitors complement the different actions of each of the other drugs, including insulin,[198] and their combinations. All other oral drugs are effective when added to SU drugs, except possibly repaglinide or nateglinide, for which data are still lacking. Metformin and a TZD drug also work in triple combination with an SU drug or meglitinide. Combinations of oral drugs may at least postpone having to switch the patient to progressively more intensive insulin therapy as last recourse. Furthermore, the progressive rise in plasma glucose levels seen in patients on monotherapy in the UKPDS was attributable to declining beta cell function.[234] Thus, pathophysiologically rational combinations of oral drugs, if used much earlier in patients with type 2 diabetes mellitus, might even preserve beta cell function longer than was previously achieved with the initial monotherapy approach.

When adding drugs, particularly to insulin, it is usually wise to start with the lowest dose of the drug being added to the regimen and to increase the dose as though it were being used as monotherapy. Self–blood glucose testing at times of the day appropriate for the added drug should be used as a safety check and a guide to efficacy. For metformin, TZD drugs, SU drugs, and bedtime insulin, the FBG is especially helpful. For repaglinide, nateglinide, α-glucosidase inhibitors, premeal regular insulin, lispro insulin, or insulin aspart, postprandial blood glucose levels are important guides to therapy. Patients should be given blood glucose guidelines for when to call the physician (e.g., when FBG is consistently less than 100 mg/dl).

Combination therapy can be quite expensive, even when it results in a lower insulin requirement.[235] The primary aim should always be to decrease the HbA_{1c}. Reduction in insulin dose, number of injections, or both should be thought of only as a secondary benefit.

MANAGEMENT OF HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC COMA

Type 2 diabetes mellitus seldom gives rise to DKA unless the patient experiences a severe medical stress. On the other hand,

hyperosmolar hyperglycemic nonketotic coma (HHNC) is a common and feared acute complication characterized by extreme hyperglycemia (> 600 mg/dl) and serum hyperosmolarity (> 320 mOsm/L) but with little or no ketosis.[110,236,237] The CNS effects of extreme hyperosmolarity range from somnolence or confusion to coma but notably can also include focal or generalized seizures as well as focal neurologic deficits that disappear with treatment. The absence of severe ketonemia is usually attributed to enough residual insulin secretion that lipolysis is not as unrestrained as in type 1 diabetes mellitus with DKA. HHNC is marked by extreme dehydration, in which the deficit of free water is prominent and the circulatory volume is often seriously compromised. Thus, hypotension; extemely dry skin and mucous membranes; and gross elevation of hematocrit, urea nitrogen, creatinine, and albumin are frequent. Secondary lactic acidosis[110] is not uncommon, so that the serum bicarbonate level may be low and the anion gap increased. The increased viscosity of the blood predisposes to thrombotic events in the cerebral and coronary artery circulations. However, stroke and myocardial infarction, along with pancreatitis and sepsis, may also precipitate the syndrome. It has also been caused by drugs such as hydrochlorothiazide, phenytoin, and glucocorticoids. Elderly patients living in nursing homes are particularly vulnerable to HHNC because their thirst mechanisms are less sensitive to a rising serum osmolality and because dementia, increasing obtundity, or institutional conditions may combine to reduce water intake to less than urinary and insensible water losses. At presentation, serum sodium level is usually elevated or surprisingly normal in the face of extreme hyperglycemia (i.e., the expected pseudohyponatremia is absent). Whatever the presenting level of serum sodium is, it will rise, sometimes markedly, when glucose levels decline with insulin treatment.

Fluid replacement is the most important component of therapy. Restoration of circulating volume is an urgent first priority. One to two liters of isotonic 0.9% saline is therefore given rapidly initially, followed by 0.45% saline. Later, when plasma glucose levels have declined to 250 to 300 mg/dl, 5% glucose in water or in 0.2% saline is given. Total fluid deficits of as much as 12 L may have to be replaced. Insulin treatment, as for DKA, is started after at least 1 or 2 L of 0.9% saline has been administered. Potassium must be added to intravenous fluids to prevent hypokalemia caused by insulin action. It may take days of fluid replacement, the tonicity of which must be carefully adjusted to achieve a gradual steady decrease in serum osmolality and sodium levels, before central nervous system function returns to normal or at least to baseline. The mortality in HHNC is still high. Infection, especially of the urinary tract, even if only suspected, should be treated with broad-spectrum antibiotics. Papillary necrosis may be seen. Patients with histories of arterial and venous thrombosis can benefit from low-dose prophylactic heparin administration.

Cardiovascular Complications of Diabetes Mellitus

Diabetes as an independent risk factor for cardiovascular disease[238] in women is now well established and is so great that it equalizes the risk of cardiovascular disease in men.[239] The risk of a first myocardial infarction in patients with diabetes is equal to that in nondiabetic individuals who have already suffered such an event.[240] Furthermore, acute and subsequent mortality is greater with diabetic-related myocardial infarctions than with nondiabetic myocardial infarctions.[241] In type 1 diabetes, cardiovascular disease is often a fatal accompaniment of end-stage renal disease (ESRD),[242] although even in patients without ESRD, cardiovascular complications may occur earlier in life than usual. Cardiovascular complications are the most prominent cause of morbidity and the most frequent cause of mortality in type 2 diabetes mellitus.[243,244] Mortality in individuals with diabetes is higher than that in nondiabetic persons of all age and racial groups and both sexes.[244] The decline in heart disease mortality noted in recent years in the United States was less in diabetic persons than in nondiabetic persons, and mortality even increased in women with diabetes.[245] The same common cardiovascular disease risk factors important in nondiabetic individuals are clustered in individuals with type 2 diabetes mellitus[129] as part of the metabolic syndrome. The pathologic picture of atherosclerosis in diabetic persons is similar to that in nondiabetic individuals, and the same processes lead to ischemic events. Thus, in regard to cardiovascular disease, the difference between diabetes and nondiabetes appears largely quantitative, although diabetes remains an independent risk factor even after adjusting for other known risk factors.[238]

Intensive treatment of type 1 or type 2 diabetes mellitus to achieve near-normal glycemia has not been proved to reduce the incidence of cardiovascular complications. The UKPDS reported that intensive treatment with insulin or SU drugs decreased myocardial infarction by 16%, with a *P* value of less than 0.052.[37] Data from several populations,[246-249] and the UKPDS[250] have shown that HbA_{1c} is a risk factor for cardiovascular events and death. Randomized clinical trials are under way to test the question of whether improved glycemic control or particular blood glucose lowering strategies will decrease cardiovascular outcomes in various stages of type 2 diabetes mellitus. Because we still cannot always eliminate whatever risk is incurred from hyperglycemia or insulin resistance per se, we must work assiduously to minimize or negate the adverse effects of hypertension, dyslipidemia, smoking, obesity, and physical inactivity on the cardiovascular system.

HYPERTENSION

Aggressive treatment of hypertension in diabetes mellitus is mandatory for three important reasons: (1) it decreases the risk of cardiovascular disease and mortality,[251] (2) it reduces or at least delays progression of diabetic nephropathy to ESRD,[252-254] and (3) it may decrease the risk of hemorrhage from proliferative retinopathy. The most recent American Diabetes Association guidelines[81] recommend a target blood pressure of 130/80 mm Hg, equivalent to a mean blood pressure of 97 mm Hg (mean blood pressure is easily calculated as one third systolic plus two thirds diastolic). However, even lower blood pressure targets may eventually prove to be advisable.

ACE inhibitors have enjoyed first-choice status in treatment because even in nonhypertensive diabetic patients, these agents decrease albumin excretion and the rate of decline in glomerular filtration rate.[254,255] Similar benefits are offered by angiotensin receptor blockers (ARBs)[256-258]; the ARB losartan also decreased cardiovascular disease events more than did the beta blocker atenolol.[259] Low-dose diuretics (chlorthalidone or hydrochlorothiazide) and beta blockers are also very effective antihypertensive agents in diabetes; they decrease risks of cardiovascular disease events and mortality as well as renal failure. However, the possible adverse effects of these agents on glycemic control and serum lipids must be monitored. Atenolol and captopril were equally effective in lowering blood pressure and reducing cardiovascular events and death in the UKPDS.[260] In the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),[261] which included approximately 12,000 diabetic patients, 12.5 to 25 mg of chlorthalidone was at least as effective

as lisinopril and amlodipine in blood pressure reduction and was associated with equal rates of nonfatal myocardial infarction and CHD. However, the cheaper chlorthalidone was superior to the other two agents in preventing heart failure and was superior to the ACE inhibitor lisinopril in preventing strokes and a combined cardiovascular disease end point. The role of calcium channel blockers is somewhat uncertain, as a study with nisoldipine has shown an adverse effect in diabetic patients.[262] At present, calcium channel blockers are probably best used after ACE inhibitors, diuretics, and possibly beta blockers fail to achieve the target blood pressure.[254,255] Central alpha$_2$ agonists (e.g., clonidine), alpha$_1$ antagonists (e.g., prazosin, terazosin, and doxazosin), and combined alpha and beta antagonists (e.g., labetalol) also can be used, although orthostatic hypotension may limit their utility, particularly in patients with autonomic neuropathy.

DYSLIPIDEMIA

Severe hypertriglyceridemia may complicate DKA in type 1 diabetes mellitus, but it clears rapidly with insulin treatment. Serum triglyceride levels are usually elevated—sometimes strikingly so—in uncontrolled type 2 diabetes mellitus, and they are almost invariably accompanied by decreased HDL levels, an atherogenic combination. LDL levels are normal or slightly elevated; however, the LDL component may include a higher proportion of small, dense, more atherogenic particles. Restriction of saturated fat and calories, elimination of excess weight, exercise, and improved glycemic control reduce triglycerides and increase HDL.[262] When these measures are insufficient, gemfibrozil, fenofibrate, or benzafibrate should be prescribed with the purpose of decreasing triglycerides to less than 150 mg/dl and increasing HDL to greater than 35 mg/dl in men and greater than 45 mg/dl in women. For LDL levels greater than 100 mg/dl in patients with or without established coronary artery disease, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) are the drugs of choice. Simvastatin, pravastatin, and lovastatin have all been shown to decrease cardiovascular events in diabetic patients. Atorvastatin may have the greatest efficacy in lowering LDL and triglyceride levels. If necessary, tolerated doses of bile acid resins may be added. Niacin would be ideal monotherapy because it powerfully lowers triglyceride and LDL levels and increases HDL levels; however, its side effects often discourage compliance, and niacin can also increase blood glucose levels. An extended-release form of niacin, Niaspan, may be more acceptable and effective. If niacin is used as monotherapy or in combination with statins, the daily dosage should not exceed 3 g. Both niacin and statins require the monitoring of serum ALT levels.

MEASURES TO REDUCE RISK OF CARDIOVASCULAR DISEASE

Smoking

Referral to successful smoking-cessation programs and use of oral or dermal nicotine preparations during withdrawal from tobacco should be employed as needed to rid patients of this serious risk factor for cardiovascular disease. Success appears to be directly related to the amount of counseling and support provided by physicians or other professionals.[263]

Aspirin

In the Early Treatment of Diabetic Retinopathy Study, administration of 650 mg of aspirin a day resulted in a statistically significant 17% reduction in the risk of fatal plus nonfatal myocardial infarctions.[264] All-cause mortality and cardiovascular disease mortality tended to decrease, whereas strokes tended to increase, but none of these differences were statistically significant. Preventive use of aspirin is now recommended by the American Diabetes Association for patients who already have cardiovascular disease or who have other risk factors for cardiovascular disease.[265,266]

ACE Inhibitors

In the large, multicentered, randomized 5-year Heart Outcomes Prevention Evaluation (HOPE) trial,[267] ramipril in a single daily dose of 10 mg decreased major cardiovascular events, including myocardial infarction, stroke, heart failure, revascularization procedures, and death by 20% to 32% when compared with placebo. The 9,300 patients were at high risk at entry, and 38% had diabetes. All the diabetic patients benefited from ramipril therapy. Notably, many of the patients were normotensive at baseline, and the beneficial effect of the ACE inhibitor was not thought to be accounted for by the small decrease in average blood pressure. Patients with previous cardiovascular disease also benefited. The data indicated that treatment of 100 patients with ramipril for 4 years would prevent 15 events in seven patients.

Antioxidants

The HOPE study also compared the effect of 400 IU of vitamin E daily with that of placebo. Subjects received no benefit from vitamin E.[268] Although some observational and experimental studies have shown an association between antioxidants and protection from atherosclerosis, there are no firm data on which to base a recommendation for their routine use in diabetes.

MANAGEMENT OF SYMPTOMATIC CORONARY ARTERY DISEASE

Beta blockers, nitrates, and calcium channel blockers can all be used as in nondiabetic individuals, with the proviso that patients treated with insulin or beta cell stimulants should be cautioned about hypoglycemia. When a revascularization procedure has been deemed necessary, coronary artery bypass surgery has been reported to be superior to angioplasty in 5-year survival and recurrent myocardial infarction rates in patients receiving pharmacologic treatment for type 2 diabetes mellitus.[269] In patients without mandatory indications for immediate surgical intervention, such as significant left main coronary artery stenosis, a clinical research trial is currently attempting to determine whether a prompt revascularization procedure is superior to aggressive medical therapy. One study has shown that normalization of blood glucose levels with intravenous insulin during the first 3 days of an acute myocardial infarction, followed by intensive blood glucose control on an outpatient basis for at least 3 months, significantly decreased mortality for up to 3.5 years.[270] If intensive control of glycemia is used in patients with cardiovascular disease, prevention of hypoglycemia should especially be emphasized because, in rare instances, it may precipitate myocardial infarction or stroke.

Prevention and Treatment of Microvascular Complications

As noted above, intensive treatment of both type 1 and type 2 diabetes mellitus, aiming at normoglycemia, reduces the risks of development or progression of diabetic retinopathy, nephropathy, and neuropathy. The earlier such treatment is begun, the greater the benefit.[39] However, once these complications have reached stages of major clinical impact, their response to intensive glycemic control is unknown or at least unproved, with the possible exception of pancreas transplantation.[104] Fortunately,

there are forms of therapy for advanced complications that may ameliorate or prevent their worst manifestations.[271,272]

RETINOPATHY

Laser treatment of high-risk proliferative retinopathy and of macular edema has been demonstrated to preserve vision.[273] For proliferative retinopathy, panretinal scatter photocoagulation is performed to ablate ischemic retina in the periphery capable of producing VEGF. For macular edema, finely focused laser treatment is performed to close visibly leaking perimacular vessels that are demonstrated by fluorescein angiography. The role of the internist and ophthalmologist is to detect retinopathy requiring laser therapy before irreversible damage and loss of vision occur. Although fundus photography is the most sensitive means of detecting early retinopathy, ophthalmologists and even well-trained endocrinologists and internists can detect retinopathy by direct ophthalmoscopy.[274] An examination with the pupil dilated is preferable, but examination in a completely blackened room can be reasonably effective. In type 1 diabetes mellitus, significant retinopathy (beyond microaneurysms) seldom occurs before 5 years' duration, so that regular yearly ophthalmologic examinations do not need to commence until then. By contrast, 20% to 40% of patients with type 2 diabetes mellitus already have detectable retinopathy at the time of clinical onset and diagnosis.[275] Therefore, yearly ophthalmologic examinations should begin at the time of diagnosis. Pregnancy is a recognized risk factor for progression of retinopathy in type 1 diabetes mellitus,[276] and ophthalmologic examinations should be performed at the beginning of pregnancy and thereafter with a frequency dependent on the findings of the first examination. For patients with vitreous hemorrhage that does not clear or significant vitreous scarring and debris, vitrectomy can be performed. Fibroproliferative scars can be excised, and a detached retina can be reattached. The vitreous is replaced with a salt solution. In selected cases, these procedures can restore vision.

NEPHROPATHY

The best preventive approach for diabetic nephropathy in both type 1 and type 2 diabetes mellitus is to maintain a normal blood pressure.[257,277] In normotensive patients with type 1[278] and type 2[279] diabetes mellitus who develop microalbuminuria (30 to 300 mg/day), clinical trials have shown that ACE inhibitor or ARB treatment decreases the rate of progression from microalbuminuria to proteinuria to early renal insufficiency. Maintaining blood glucose near normal with intensive treatment also significantly reduces the risk of diabetic nephropathy.[32,37] If ESRD does develop, a renal transplant is the preferred replacement therapy; home peritoneal dialysis is superior to chronic hemodialysis because the latter is often complicated by vitreous hemorrhage, amputations, and septic episodes. With all forms of therapy for ESRD, mortality is higher in diabetic patients than nondiabetic patients largely because of cardiovascular complications.[280]

NEUROPATHY

Management of diabetic neuropathy is still largely symptomatic[271,272] and often inadequate. Gabapentin[281] in doses of up to 3 g/day has been added to the list of agents that include bedtime tricyclic antidepressants (e.g., nortriptyline), carbamazepine, and topical capsaicin for relief of pain and dysesthesias. Intensive blood glucose control may benefit patients with diabetic amyotrophy and radiculopathy. Prevention of foot ulcers remains very important; patient self-examination of the feet daily and physician-nurse examination at each office visit unequivocally reduce the risk of foot ulcer and amputation.[282] When a foot ulcer does occur, it should be treated aggressively with broad-spectrum antibiotics effective against staphylococci and anaerobes, vigorous debridement as necessary, radiographic examination for osteomyelitis, and sometimes special weight-bearing casts.[283] The use of locally applied growth factors appears promising to reduce healing time.[283] Aggravating effects of ischemia may be alleviated by revascularization of the leg when it is still possible to abort gangrene. Appropriate specialists should be consulted early for achievement of the best outcomes.

Management of autonomic neuropathy is especially challenging. Gastroparesis can benefit from frequent small feedings and either parenteral or liquid oral preparations of metoclopramide[284] or erythromycin.[285] Intermittent intubation to decompress a dilated full stomach may be required to relieve persistent vomiting or painful bloating. A feeding jejunostomy can be considered for intractable cases. Diarrhea sometimes responds to tetracycline antibiotics; clonidine and occasionally somatostatin are effective. Bladder dysfunction may be improved by oral bethanechol and regular timed voiding, but self-catheterization is necessary in severe cases of atony. Use of indwelling catheters should be minimized because of the danger of bacterial or fungal infection. Orthostatic hypotension is benefited by compression stockings, ample sodium intake, and fluorohydrocortisone. The use of midodrine is limited by the risks of excessive hypotension or urinary retention. Male impotence can be satisfactorily treated by penile injection or urethral insertion of alprostadil; by use of a simple vacuum pump; or, increasingly rarely, by implantation of a penile prosthesis. Sildenafil is effective for diabetic impotence,[286] but it may be dangerous in diabetic men with established or unsuspected coronary disease.

Diabetes Mellitus during Pregnancy

Women in their reproductive years with known diabetes of any type should be instructed to inform their physicians when they have decided to have a child. Conception when diabetes control is inadequate markedly increases the risk of major congenital abnormalities. This risk can be reduced to the nondiabetic background rate when control is excellent.[287,288] Therefore, the patient's HbA_{1c} should be brought as close to normal as possible before conception. One recent recommendation is that the average of preprandial and postprandial home blood glucose test results should be less than 126 mg/dl and HbA_{1c} should be brought to at least less than 7.0%.[288] The patients taking oral hypoglycemic agents should be switched to insulin and excellent control established before conception. Nondiabetic women should be screened for gestational diabetes mellitus (GDM) during weeks 24 to 28 of pregnancy by glucose loading.

Throughout pregnancy, normoglycemia (relative to the normal pregnant state) is required to prevent intrauterine death and perinatal morbidity and mortality. Preprandial blood glucose targets during pregnancy are 60 to 90 mg/dl and postprandial targets are less than 120 to 140 mg/dl.[289,290] Most patients with GDM detected by routine screening can be tried on diet treatment for 1 to 2 weeks. In obese women, either 1,500 kcal or 35 kcal/kg prepregnancy weight has been recommended.[287] In 15% to 20% of cases, persistence of FBG of at least 105 mg/dl or 2-hour postprandial values of at least 120 to 140 mg/dl mandates institution of insulin treatment. The blood glucose control targets can then often be achieved with injections of NPH plus regular insulin before breakfast, regular insulin before supper, and NPH

insulin at bedtime. Lispro insulin has not yet been approved for use during pregnancy. Pregnant women with type 1 diabetes mellitus need to continue intensive treatment as described previously. Pregnant women with type 2 diabetes mellitus often respond to insulin regimens as described for GDM. After delivery, insulin requirements disappear almost instantaneously in patients with GDM and may decrease strikingly from those of the third trimester in women with type 1 diabetes mellitus.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

I RENAL FUNCTION AND DISORDERS OF WATER AND SODIUM BALANCE

Richard H. Sterns, m.d., f.a.c.p.

Overview of Body Fluid Homeostasis

Life takes place in an aqueous solution. Cells, the blood bringing nutrients and oxygen to them, and the interstitial fluid bathing them are all mostly water. Each day, water and salt are lost and replaced. To maintain stability of the internal milieu, body fluids are processed by the kidney, guided by intricate physiologic control systems that regulate fluid volume and composition.

Distribution and Composition of Body Water

Water accounts for approximately half of an adult human's body weight. Because fat contains little water, individuals with more body fat have less body water. On average, total body water constitutes 60% of lean body weight in young men, 50% in young women and older men, and 45% in older women. Two thirds of body water is intracellular, and the remainder is contained in the extracellular fluid compartment, which includes intravascular (plasma) and interstitial fluid. Small amounts of water are also contained in bone, dense connective tissue, digestive secretions, and cerebrospinal fluid.[1]

Extracellular solutes are predominantly sodium salts (primarily a mixture of NaCl and $NaHCO_3$). Thus, extracellular fluid can be thought of as saltwater. Except for protein (present at a higher concentration in plasma [approximately 1 mmol/L] than in interstitial fluid), the compositions of the intravascular and interstitial subdivisions of the extracellular fluid compartment are similar.

The sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) pump on cell membranes keeps intracellular sodium at low levels. Potassium, the dominant intracellular cation, is electrically balanced, in large part, by anionic charges on impermeant macromolecules. Stability in the number of intracellular anionic charges makes the total solute content of cells much less variable than that of the extracellular fluid.

Osmolality

Extracellular and intracellular fluids contain different types of solutes, but the concentrations of solutes inside and outside of cells are equal. Concentration differences exist only transiently because they create an extremely strong force for water movement across cell membranes. Osmotic pressure moves water rapidly to the fluid compartment with the higher solute concentration until concentrations once again become equal. The osmotic pressure responsible for water movement across cell membranes depends on the total number of solute particles (osmoles) dissolved in solution, a property known as osmolality.[2] Osmolality is usually expressed as milliosmoles of solute per kilogram of solvent (mOsm/kg), but it can be thought of more simply as the number of millimoles of solute particles per liter of solution. A solute particle's contribution to osmolality is independent of its charge and molecular size. Ionic substances such as sodium chloride that dissociate in solution contribute more than one osmotically active particle. Sodium salts, glucose, and urea, commonly measured as blood urea nitrogen (BUN), are responsible for most of the solute particles normally present in extracellular fluid. Plasma osmolality can be measured directly with an osmometer or can be estimated with reasonable accuracy from the concentrations of the major extracellular solutes, as follows:

$$P_{osm} \cong 2 \times \text{plasma } [Na^+] + \frac{[\text{glucose}]}{18} + \frac{\text{BUN}}{2.8}$$

The multiple of 2 reflects the anions accompanying sodium ions, and 18 and 2.8 are the corrections required to convert glucose and urea nitrogen concentration from mg/dl (the units used by most laboratories in the United States) to mmol/L. Exogenous solutes (e.g., ethanol, methanol, ethylene glycol, glycine, mannitol) are measured by osmometers but are not included in the formula shown above. A discrepancy between the measured and the calculated plasma osmolality values (an osmolar gap) is useful clinically as a way to recognize the presence of an exogenous solute.[2]

Fluid Movement between Body Fluid Compartments

The intravascular and interstitial subdivisions of the extracellular fluid compartment are separated by capillary walls that are freely permeable to small extracellular solutes but relatively impermeable to plasma proteins. Protein-free saltwater continuously moves across the capillary endothelial barrier by filtration, driven by a hydrostatic pressure gradient (generated by contractions of the heart), which forces fluid from the capillary into the interstitium, and an oncotic pressure gradient (the consequence of the osmotic force created by intravascular protein), which draws interstitial fluid into capillaries [*see Figure 1*]. These so-called Starling forces, which regulate the disposition of fluid within the extracellular compartment, determine how much of the extracellular saltwater is contained in intravascular plasma and how much is in interstitial fluid [*see* Disorder of Saltwater Excess: Edematous States, *below*]. Sodium salts, urea, glucose, and other small extracellular solutes freely cross the capillary wall, achieving similar concentrations in the interstitial fluid and plasma. Thus, changes in plasma osmolality do not influence water movement between the intravascular and the interstitial fluid compartments.

Fluid movement between the extracellular and the intracellular fluid compartments is unaffected by Starling forces. Rather, transcellular water movement is driven by osmotic forces, a function of the concentration of solutes in the extracellular fluid. A decrease in extracellular solute concentration (hypotonicity) drives water into cells, causing cell swelling; an increase in the concentration of exclusively extracellular solutes (hypertonicity) draws fluid out of cells, dehydrating them.

Not all solutes contribute to the tonicity of extracellular fluid.[2] Permeant solutes such as urea and ethanol readily cross cell membranes, achieving equal concentrations in the extracellular and intracellular fluid compartments without driving transcellular water movement and without affecting cell volume. Such solutes, which increase plasma osmolality without altering plasma tonicity, are sometimes called ineffective osmoles. Impermeant solutes are excluded from cell water either by active trans-

port (e.g., sodium ions) or because the cell membrane is impermeable to them (e.g., mannitol). Such solutes, which cause both hyperosmolality and hypertonicity, are sometimes called effective osmoles.

Body Fluid Tonicity and the Plasma Sodium Concentration

Normally, sodium salts are the major effective osmoles in extracellular fluid, and potassium salts are the major effective osmoles in cells. Given that effective osmolality is equal in all fluid compartments, body fluid tonicity can be described by the following equation:

$$\text{Tonicity} \cong$$

$$2 \times \text{plasma } [Na^+] \cong \frac{2\,(\text{exchangeable } Na^+ + \text{exchangeable } K^+)}{\text{total body water}}$$

therefore,

$$\text{Plasma } [Na^+] \cong \frac{\text{exchangeable } Na^+ + \text{exchangeable } K^+}{\text{total body water}}$$

(Only the exchangeable fractions of sodium and potassium are included in the equation, because one third of body sodium is bound to bone and is osmotically inactive.)

Thus, the plasma sodium concentration is, in effect, a measure of the concentration of tonicity of all body fluids.[3] In the absence of an osmolar gap, the plasma sodium concentration is a more valid measure of body fluid tonicity than is plasma osmolality (which includes the ineffective osmole urea). With a few exceptions, most notably hyperglycemia, a low plasma sodium concentration indicates hypotonicity and cell swelling, whereas a high plasma sodium concentration indicates hypertonicity and cellular dehydration.

RENAL PROCESSING OF BODY FLUIDS

Glomerular Filtration

Approximately 170 L of extracellular saltwater containing over 25,000 mmol of sodium are filtered by the glomerulus each day. Although glomerular hydrostatic pressure is considerably higher than the pressure of other capillary beds, the Starling forces that control fluid movement between intravascular and interstitial fluid also drive glomerular filtration. The glomerular filtrate contains the same concentrations of sodium and other solutes as interstitial fluid and is nearly protein free.

Tubular Reabsorption

On a conventional diet, all but 2 L of filtered fluid and all but 175 mmol of filtered sodium is reabsorbed by the renal tubules. Regulation of tubular reabsorption of salt and water is the key to renal regulation of body fluid balance.[4]

At the end of the proximal tubule, the remaining filtrate has the same sodium concentration as plasma; as the filtrate passes through downstream tubular segments, it undergoes major changes in composition. In these more distal segments, sodium and water reabsorption are uncoupled; salt can be reabsorbed without water, and water can be reabsorbed without salt. Thus, depending on conditions, the sodium concentration of the final urine can vary from less than 1 mEq/L to nearly 300 mEq/L, and urine osmolality can vary from one sixth (50 mOsm/kg) to four times (1,200 mOsm/kg) that of plasma.

The process of sodium reabsorption is mediated by carriers or channels embedded in the tubular cell's luminal and basolateral (blood side) membranes. In each nephron segment, sodium reabsorption is powered by the Na^+,K^+-ATPase, which is located on the blood side of the tubular cell [*see Figure 1*]. This sodium pump exports sodium from the cell, lowering the intracellular sodium concentration. The lowered concentration of cellular sodium creates an electrochemical gradient driving sodium from the tubular lumen into the cell. Tubular segments at various regions of the nephron utilize different luminal mechanisms for sodium reabsorption [*see Table 1 and Figure 2*]. Luminal exchangers, cotransporters, and ion channels along the nephron are subject to physiologic control, and they can be inhibited pharmacologically by specific diuretic agents.[5] Mutations in these transport proteins are responsible for well-defined clinical disorders.[6]

The luminal membrane of the collecting duct is impermeable to water in the absence of arginine vasopressin, an antidiuretic hormone (ADH). Thus, when plasma ADH levels are low, this segment progressively reduces the osmolality and sodium concentration of the final urine and permits the excretion of large volumes (as much as 20 L daily) of dilute urine. In the presence of ADH, water channels—called aquaporins—are inserted in the luminal membrane of the distal tubule and collecting duct.[7,8] When plasma levels of ADH are high, water is attracted osmotically from the tubular lumen to the hypertonic medullary interstitium, permitting excretion of a small volume (as little as 0.5 L daily) of concentrated urine.

REGULATION OF BODY FLUID VOLUMES

Saltwater (isotonic saline) is confined to the extracellular space. Accumulation of saltwater expands extracellular volume; loss of saltwater causes volume depletion. In either case, changes in saltwater balance do not alter the plasma sodium concentration or cell volume. By contrast, so-called electrolyte-free water, or pure water, is distributed throughout body fluids, affecting both extracellular and intracellular fluid compartments. Because only one third of body water is extracellular, electrolyte-free water has only one third the impact on extracellular

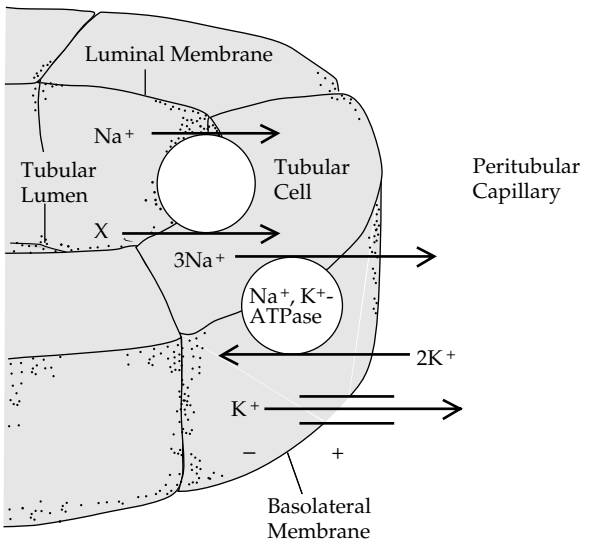

Figure 1 **Sodium reabsorption by the renal tubules is driven by the Na^+, K^+-ATPase pump in the basolateral (blood side) membrane, which maintains a low sodium concentration within the tubular cell. Filtered sodium in the tubular lumen enters the cell down its concentration gradient via a transmembrane carrier (which may also transport another solute, X) or via a channel in the luminal membrane [*see Figure 2*].**

Table 1 Sodium Transport in Different Nephron Segments

Nephron Segment	*Glomerular Filtrate Reabsorbed*	*Mechanism of Luminal Sodium Entry*	*Physiologic Regulation*	*Diuretic Site of Action*
Proximal tubule	60%–70%	Na^+-H^+ exchange; cotransport with glucose and other organic solutes	Angiotensin II; renal nerves; peritubular Starling forces	Carbonic anhydrase inhibitors (e.g., acetazolamide)
Loop of Henle	20%–25%	Na^+-K^+-$2Cl^-$ cotransport	Flow dependent; peritubular Starling forces	Loop diuretics (e.g., furosemide, bumetanide, ethacrynic acid)
Distal tubule	5%	Na^+-Cl^- cotransport	Flow dependent	Thiazide diuretics
Collecting tubule	4%	Na^+ channels	Aldosterone; atrial natriuretic factor	Potassium-sparing diuretics (e.g., amiloride, triamterene, spironolactone)

volume that saltwater has; however, unlike saltwater balance, electrolyte-free water balance has a major impact on the plasma sodium concentration, body fluid tonicity, and cell volume.

Extracellular and intracellular fluid volumes are maintained by separate but interacting control systems [*see Table 2*]; the extracellular system primarily regulates urinary sodium excretion, whereas the intracellular system regulates the intake and excretion of water. Extracellular fluid volume maintains a proper degree of vascular fullness, a variable that is sensed by atrial stretch receptors and arterial baroreceptors. Intracellular volume is regulated by hypothalamic osmoreceptor cells that swell or shrink in response to changes in plasma tonicity.

Control of Extracellular Fluid Volume

In a healthy person, the amount of sodium in the extracellular space can vary considerably, depending on dietary salt intake; however, the extracellular sodium concentration remains almost constant because of physiologic control systems that tightly regulate water intake and excretion. In healthy persons, more salt in the extracellular space means an expanded extracellular fluid volume, and less salt means a smaller extracellular volume; but in either case the extracellular sodium concentration does not change.

Sodium balance and intravascular volume are affected by numerous hormonal and nonhormonal mediators; in addition to aldosterone and angiotensin—the best known mediators of sodium excretion—the sympathetic nervous system, natriuretic peptides, and changes in the renal circulation all play important regulatory roles [*see Table 2*].[9] Because of redundancy and overlap in the control system, failure of a single factor does not cause major, sustained abnormalities in intravascular volume. The relative importance of the various mediators that affect urinary sodium excretion are incompletely understood, and it is likely that some sodium regulatory factors remain undiscovered.

Control of Intracellular Fluid Volume

Water balance and cell volume are controlled by a single hormonal mediator, arginine vasopressin [*see* Tubular Reabsorption, *above*], which is released into the systemic circulation by the neurohypophysis [*see Table 2 and Figure 3*]. The hormone activates V_2 receptors on the basolateral membrane of principal cells in the renal collecting duct, initiating a cyclic adenosine monophosphate–dependent (cAMP-dependent) process that culminates in the insertion of water channels (aquaporins) into the cells' luminal membranes.[7,8] Modulation of the number of aquaporins controls urine osmolality and the rate of water excretion by the kidney. Vasopressin's short half-life in the circulation and continuous shuttling of aquaporins between the collecting duct's cell membrane and cytosol ensure that urinary water excretion responds rapidly to changes in body fluid tonicity.

Vasopressin levels are normally unmeasurable when the plasma sodium concentration falls to 135 mEq/L or lower [*see Figure 3*]. Low levels of the hormone result in the excretion of large volumes of a maximally dilute urine (50 mOsm/kg). Above a sodium level of 135 mEq/L, plasma vasopressin levels are linearly related to the plasma sodium concentration and increase measurably in response to changes in the plasma sodium concentration of as little as 1 mEq/L. Once the plasma sodium concentration reaches approximately 142 to 144 mEq/L, plasma vasopressin levels are high enough to promote the excretion of maximally concentrated urine (1,200 mOsm/kg). A rising plasma sodium concentration also causes hypothalamic cell volume receptors to relay signals to nearby thirst centers. Mediated by thirst and changes in vasopressin secretion, the plasma sodium concentration is normally prevented from rising above 144 mEq/L or falling below 135 mEq/L.

Under day-to-day conditions, water intake, vasopressin secretion, and urinary free-water excretion primarily respond to changes in the plasma sodium concentration created by variations in electrolyte-free water balance. Unlike sodium excretion, which is affected only by changes in intravascular volume, free-water excretion can be affected by two types of stimuli: intravascular volume and tonicity. Under pathologic conditions, osmotic control of vasopressin secretion and thirst can be overridden by hemodynamic stimuli. The hypothalamic neurons that secrete vasopressin receive neural input from baroreceptors in the great vessels and volume receptors in the atria. When these receptors are stimulated by hypotension or by a major reduction in plasma volume, impulses are carried via cranial nerves IX and X.[8] Vasopressin and thirst responses to hypovolemia and hypotension can be regarded as backup systems that serve to maintain arterial blood volume under emergency conditions, sacrificing tonicity to tissue perfusion.

CELL VOLUME REGULATION IN HYPOTONICITY AND HYPERTONICITY

Cell volume is determined by the amount and concentration of intracellular solute. Because intracellular and extracellular solute concentrations must be equal, the relation between cell water and extracellular osmolality can be described by the following equation:

$$\text{Cell water} = \frac{\text{cell solute content}}{\text{extracellular osmolality}}$$

Normally, water intake and excretion are modulated to maintain body fluid tonicity within a narrow physiologic range. However, under pathologic conditions, body cells can be exposed to a hypotonic or hypertonic milieu.[10] The first response to osmotic stress is a compensatory adjustment to intracellular electrolytes: loss of potassium in hypotonicity and accumulation of sodium and potassium in hypertonicity. With time, changes in organic solutes dominate the response.

Most cells maintain relatively high concentrations of small, osmotically active organic molecules known as organic osmolytes. Organic osmolytes are nonperturbing solutes; unlike sodium and potassium, their intracellular concentrations may vary widely without affecting tertiary protein structure. Cells accumulate organic osmolytes under hypertonic conditions and lose them when confronted with hypotonicity.

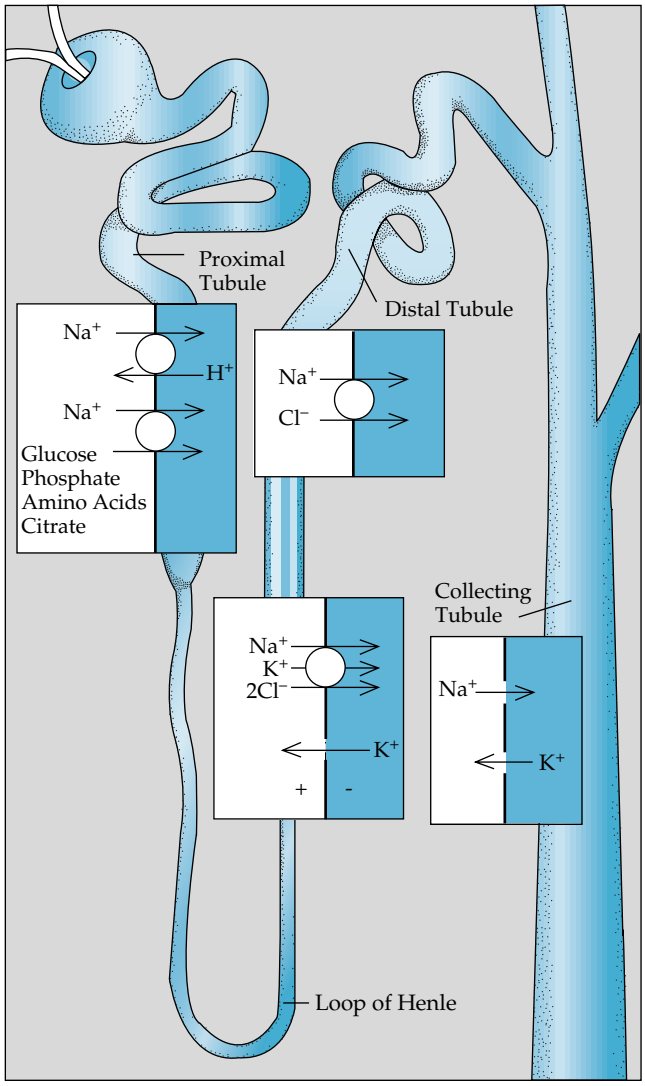

Figure 2 **In each tubular segment, sodium enters the tubular cell passively, down the favorable electrochemical gradient created by the Na^+, K^+-ATPase pump. Luminal sodium enters by a different mechanism in each of the nephron segments. The proximal tubule reabsorbs filtered bicarbonate and other solutes, such as glucose, phosphate, amino acids, and citrate. An Na^+, K^+, $2Cl^-$ transporter mediates Na^+ entry into the ascending limb of the loop of Henle. The distal tubule has an Na^+, Cl^- cotransporter. Na^+ enters the principal cells of the cortical collecting tubules through Na^+ channels in the luminal membrane.**

The need for cell volume regulation is most imperative in the brain, where the rigid calvaria places sharp limits on the degree of tissue expansion or contraction that can be tolerated.[10-13] An increase in brain water content of more than about 5% to 10% is incompatible with life. Variations in the intracellular concentration of organic osmolytes provide the brain with an astonishing ability to adapt to chronic osmotic disturbances. However, because changes in the osmolyte content of brain cells require a few days to develop fully, the brain is imperiled by rapid osmotic changes. Thus, acute hyponatremia or hypernatremia may be fatal at plasma sodium concentrations that are well tolerated chronically.

With sustained osmotic disturbances, adaptations that protect against brain swelling and shrinkage also predispose to injury when the osmotic disturbance is suddenly corrected. In chronic hyponatremia, cellular solutes lost in the adaptive phase must be recovered when the plasma sodium concentration returns to normal—a process that may require several days. Unless solute recovery keeps pace with the rising extracellular osmolality, brain cells will become dehydrated.[11,12] This phenomenon may cause clinical complications [*see* Complications of Therapy: Myelinolysis and Osmotic Demyelination Syndrome, *below*]. Similarly, in chronic hypernatremia, accumulated solutes must be shed during correction of the electrolyte disturbance.[10,13] Cells that have become acclimated to a hypertonic environment lose organic osmolytes slowly because of slow turnover of the efflux mechanism, slow downregulation of hypertonically stimulated uptake pathways, or both. Thus, when chronic hypernatremia is corrected rapidly, brain cells swell to a greater than normal volume.

Disorder of Water Excess: Hyponatremia

Hyponatremia simply means a low plasma sodium concentration. In most cases, hyponatremia is associated with a low plasma osmolality level and body fluids that are too dilute (hypotonic hyponatremia). However, there are exceptions to this rule [*see* Differential Diagnosis for Hyponatremia, *below*].

PATHOGENESIS OF HYPONATREMIA

Hypotonic hyponatremia results from two basic mechanisms, individually or together: (1) massive water intake, exceeding the capacity to excrete electrolyte-free water, or (2) impaired water excretion. Normally, the capacity for water excretion is rather large. In the absence of vasopressin, urine osmolality falls to approximately 50 mOsm/kg. A typical United States diet provides 600 to 900 mOsm of electrolytes and urea that must be excreted each day. At this rate of solute excretion, the volume of maximally dilute urine equals 12 to 18 L. Water intake can occasionally exceed the normal excretory capacity, primarily in psychotic patients who frantically ingest gallons of water over a few hours[14] and in very heavy beer drinkers who ingest large volumes of fluid but take in small amounts of salt and protein.[15] More commonly, hyponatremia occurs in patients with a diminished ability to excrete free water.[8,12]

Impaired Water Excretion

Water excretion is obviously compromised in severe renal failure; oliguric patients become hyponatremic if they are given too much water. However, most cases of hyponatremia occur in patients whose normal kidneys are unable to excrete maximally di-

Table 2 Control of Body Fluid Volumes

	Saltwater Balance	*Electrolyte-Free Water Balance*	
		Day to Day	*Emergency Backup*
Regulated variable	Extracellular volume Vascular fullness	Cell volume	Arterial filling
Clinical indicator	Blood pressure Edema	Plasma sodium concentration	Blood pressure Edema
Sensors	Baroreceptors, atrial volume receptors	Hypothalamic osmoreceptors	Baroreceptors, atrial volume receptors
Mediators	Renin-angiotensin-aldosterone system Sympathetic nervous system Atrial natriuretic peptide Starling forces in peritubular capillaries	Antidiuretic hormone (arginine vasopressin) Thirst	Antidiuretic hormone (arginine vasopressin) Thirst
Affected variable	Urinary sodium excretion	Urine osmolality Water intake	Urine osmolality Water intake

lute urine. A pathologically low plasma sodium concentration occurs when water is taken in at a time when renal diluting mechanisms are not functioning maximally because either (1) diuretics or tubular transport defects are blocking sodium reabsorption in the renal diluting segments or (2) ADH levels are elevated.

Nonosmotic Release of Vasopressin

Vasopressin is a water-retaining hormone that is released when water is needed. Because hypotonic hyponatremia normally inhibits vasopressin secretion, detectable vasopressin in a patient who is hyponatremic indicates that a nonosmotic stimulus for vasopressin release must be present. Vasopressin action increases the urine osmolality, which can be thought of as a bioassay for the hormone.

Hemodynamic stimuli for vasopressin Hypovolemia, heart failure, and cirrhosis are the most common nonosmotic stimuli for ADH secretion.[16-18] The hemodynamic abnormalities that stimulate vasopressin release also promote sodium reabsorption by the renal tubules; thus, these conditions result in both sodium and water retention.

Inappropriate antidiuretic hormone secretion Nonosmotic release of vasopressin without a hemodynamic stimulus to account for it is considered "inappropriate." Patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) retain water because of nonosmotic release of vasopressin and abnormal thirst mechanisms but have no abnormality in sodium balance, evidence of volume depletion, or tendency to form edema; in the steady state, sodium excretion matches intake.[8,12,19,20] Because of water retention, SIADH causes mild, subclinical volume expansion. Any additional volume expansion is met by a brisk increase in urinary sodium excretion.

Reset osmostat Reset osmostat is a variant of SIADH, commonly seen in patients with chronic, debilitating illness; it is also a characteristic of normal pregnancy. Patients with this condition are able to dilute their urine normally but at a lower set point than in normal individuals. Such patients are thus mildly hyponatremic, but unlike other patients with SIADH, they are not predisposed to progressive water retention and do not require dietary water restriction or other measures used to treat chronic hyponatremia.[11] Reset osmostat can, however, be seen in malignancies, and like other causes of SIADH, it requires a diagnostic evaluation to determine its cause.

Urinary Electrolyte Losses: Desalination and Hyponatremia

If the urine is concentrated, urinary sodium and potassium losses can contribute to the pathogenesis of hyponatremia. The plasma sodium concentration can be reduced either by loss of sodium or potassium or by water gain. However, to lower the plasma sodium concentration, electrolytes must be lost in urine that has a higher electrolyte concentration than plasma. The combination of high vasopressin levels (which concentrate the

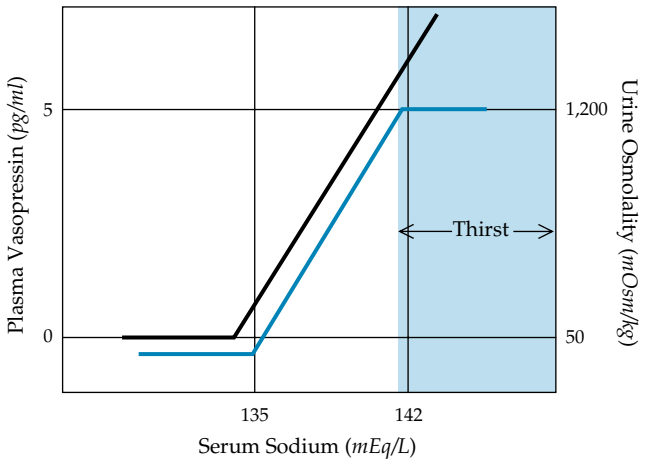

Figure 3 **Graph depicts the normal relation between plasma vasopressin levels and urine osmolality (black line) and the plasma sodium concentration (blue line). Plasma vasopressin levels change within minutes in response to changes in plasma sodium, and urine osmolality changes within minutes in response to changes in vasopressin levels. When hydration reduces the plasma sodium level below 135 mEq/L, plasma vasopressin becomes undetectable and the urine becomes maximally dilute (osmolality, 50 mOsm/kg). Between sodium concentrations of 135 and 142 mEq/L, vasopressin levels are linearly related to the plasma sodium, causing nearly a 100 mOsm/kg increase in urine osmolality for every 0.5 mEq/L increase in sodium concentration. Above a plasma sodium concentration of 142 mEq/L, the urine is maximally concentrated; increased water intake, mediated by thirst, then becomes the major defense against progressive hypernatremia.**

urine) and a high rate of sodium and potassium excretion can yield hypertonic urine capable of generating free water, which in essence desalinates the plasma.[21]

DIFFERENTIAL DIAGNOSIS FOR HYPONATREMIA

Several conditions can lower the plasma sodium concentration without causing hypotonicity and are referred to as nonhypotonic hyponatremia [*see Table 3*]. The diagnostic and therapeutic approach to these conditions differs fundamentally from the approach to hypotonic hyponatremia. Thus, it is important that nonhypotonic hyponatremia be excluded whenever a low plasma sodium concentration is encountered.

Hyperglycemic Hyponatremia

Hyperglycemia lowers the plasma sodium concentration; in the absence of insulin, glucose is an effective osmole that holds water in the extracellular space, diluting extracellular sodium. A variety of correction factors have been offered to quantify this effect.[22] However, a precise correction factor is probably unobtainable because in practice, hyperglycemia develops, in part, from the ingestion of glucose with water and resolves, in part, from the urinary excretion of glucose with water.[23] As a rough estimate, the serum sodium concentration decreases 2 mEq/L for every 100 mg/dl increase in blood glucose.

Exogenous solutes such as mannitol and maltose (a sugar contained in intravenous immunoglobulin preparations) are confined to the extracellular space and have an effect on the plasma sodium concentration similar to that of hyperglycemia. When the clinical setting suggests that these solutes might be responsible for hyponatremia, their presence can be confirmed by measuring the plasma osmolality and comparing it with the calculated value to identify an osmolar gap [*see* Osmolality, *above*].[2,11]

Postprostatectomy Syndrome and Hysteroscopic Hyponatremia

Irrigants containing mannitol, sorbitol, or glycine are used for endoscopic transurethral and intrauterine procedures [*see Table 3*].[2,24] Occasionally, several liters of irrigant may be absorbed systemically, reducing the plasma sodium in a matter of minutes. Immediately after surgery, the serum sodium concentration is much lower than would be anticipated, because the electrolyte-free solution is initially confined to the extracellular space. Glycine, the most commonly used irrigant in the United States, is metabolized to ammonia and eventually to urea and glucose. Hyperammonemia may be responsible for most of the symptoms in patients with postprostatectomy syndrome and hysteroscopic hyponatremia, and glycine itself has direct neuroinhibitory effects and may cause hypotension, bradycardia, and visual disturbances.

Pseudohyponatremia

High plasma concentrations of lipid or protein cause mild nonhypotonic hyponatremia because of an artifact of laboratory measurement [*see Table 3*].[2,11,25] With extremely high concentrations of triglycerides (enough to give serum a milky appearance), hypercholesterolemia with lipoprotein X from obstructive or cholestatic jaundice, or very high serum protein levels (from multiple myeloma or Waldenström macroglobulinemia), plasma water may constitute a smaller fraction of the plasma sample than normal, which can result in an underestimate of the "true" sodium concentration. The plasma osmolality and the sodium concentration in plasma water (as measured in an undiluted sample by a sodium-sensitive electrode) are unaffected. There are no symptoms, and no therapy is required.

ACUTE HYPONATREMIA (WATER INTOXICATION)

The term water intoxication was coined in the early 1920s to describe a neurologic syndrome that develops when large volumes of water are retained within a relatively short period of time (< 48 hours). The syndrome is often referred to as acute hyponatremia.[12,26]

Etiology

Acute hyponatremia develops when water intake is high and electrolyte-free water excretion is impaired. Potentially, hyponatremia can develop rapidly in any patient predisposed to water

Table 3 Causes of Nonhypotonic Hyponatremia

Condition	*Plasma Osmolality*	*Pathogenesis*	*Therapeutic Implications*
Hyperglycemia	High	Extracellular glucose osmotically draws water into the ECF, diluting extracellular sodium	During treatment of hyperglycemia, anticipate 3 mEq/L increase in serum sodium for every 200 mg/dl reduction in blood sugar
Intravenous hypertonic mannitol therapy	High	Water shift from ICF to ECF as with hyperglycemia	Mannitol is rapidly excreted when renal function is normal
Intravenous γ-globulin therapy	High	Maltose present in solution acts like mannitol	Measure plasma osmolality when hyponatremia is suspected
Irrigant absorption (prostatectomy or intrauterine surgery)	Normal or low (when hypoosmolar irrigants are used)	Absorbed solute—mannitol, sorbitol, or glycine (most common)—initially confined to ECF, causing severe hyponatremia but little change in plasma osmolality	Mannitol is rapidly excreted; sorbitol is metabolized, causing late-onset hypotonic hyponatremia; glycine is neurotoxic and causes transient blindness and is metabolized to ammonia, causing encephalopathy; consider hemodialysis
Pseudohyponatremia (severe hyperlipidemia, multiple myeloma, macroglobulinemia)	Normal	Laboratory artifact; plasma water constitutes a smaller fraction of the plasma sample, causing a more serious underestimate of the true sodium concentration	Suspect when serum is lactescent; compare measured plasma osmolality with calculated osmolality or measure plasma sodium with direct-reading sodium electrode

ECF—extracellular fluid ICF—intracellular fluid

Table 4 Causes and Treatment of Acute Hyponatremia

Causes	*Pathogenesis*	*Effect of Treatment*	*Recommendations*
Postoperative stress*	Vasopressin is secreted in response to surgical stress for 2 or more days; free water from hypotonic I.V. fluids is retained and sodium and potassium are excreted in urine at high concentrations	Normal saline ineffective for correction—administered sodium is excreted in concentrated urine, "desalinating" isotonic fluid and causing water retention	Avoid hypotonic fluid (e.g., D5W, 0.45% saline) and excessive volumes of isotonic fluid (lactated Ringer solution or 0.9% saline) after surgery; treat symptomatic hyponatremia with 3% saline and furosemide
Oxytocin	Used in obstetrics to induce labor; direct antidiuretic effect of drug mimics SIADH; free water from I.V. fluids retained	Urine becomes dilute when oxytocin is discontinued	Avoid administration of oxytocin in or with hypotonic fluids; treat hyponatremia by discontinuing drug
Cyclophosphamide	Drug has antidiuretic effect that persists for as long as 12 hours; patients are encouraged to drink large volumes of water to prevent chemically induced cystitis	Normal saline ineffective for correction as in other causes of persistent SIADH	Treat symptomatic hyponatremia with 3% saline and furosemide
Psychotic self-induced water intoxication	Extreme polydipsia (> 1 L/hr) common in patients with severe psychosis; retained water causes hyponatremia by late afternoon or evening, and water diuresis restores normonatremia by morning	Normal ability to dilute urine in most patients so hyponatremia self-corrects when water intake stops; some patients have vasopressin release (often transient) from stress, smoking, or medications (e.g., carbamazepine)	Monitor diurnal weight in institutionalized patients for early detection; avoid antidiuretic medications; treat hyponatremia with water restriction; use hypertonic saline and furosemide for occasional patient with SIADH
Marathon running	Extracellular volume depletion caused by saltwater losses from sweating and possibly stress are nonosmotic stimuli for vasopressin secretion; large volumes of sugar water consumed during race are retained	Isotonic saline restores ability to dilute urine	3% saline without furosemide for seizures; isotonic saline and water restriction for more moderate symptoms
Ecstasy (methylenedioxymethamphetamine [MDMA]) use	Excessive fluid intake and inappropriate antidiuretic hormone secretion, induced by MDMA, is implicated	Isotonic saline ineffective; self-correction typical but may be delayed	Hypertonic saline for severe symptoms

*Excluding irrigant absorption syndromes [*see Table 3*].
D5W—5% dextrose in water SIADH—syndrome of inappropriate antidiuretic hormone

retention who takes in a large volume of water in a short period of time. However, this is likely to occur in a limited number of settings [*see Table 4*], and such instances account for most cases of severe symptomatic hyponatremia and for most of the recorded fatalities.

Postoperative hyponatremia Vasopressin is released immediately after surgical procedures in what appears to be a stress response [*see Table 4*].[21,27] Particularly during the first 24 hours, the concentration of urinary cations (sodium plus potassium) may greatly exceed the plasma sodium concentration. As a result, even isotonic fluids may be "desalinated" and can lower the plasma sodium concentration.[21] Thus, all hypotonic fluids and excessive amounts of isotonic fluids should be avoided after surgery. As noted, endoscopic prostatectomy and intrauterine procedures can cause hyponatremia if the irrigant used in the procedures is absorbed systemically. The management of irrigant absorption syndromes differs from that of other causes of postoperative hyponatremia [*see* Postprostatectomy Syndrome and Hysteroscopic Hyponatremia, *above*].[27]

Oxytocin infusions Oxytocin, which is used in obstetrics to induce labor, has a direct antidiuretic effect. If the drug is administered in 5% dextrose in water (D5W), which was formerly a common practice, symptomatic hyponatremia may emerge after the infusion of less than 3 L of fluid [*see Table 4*].[11] Termination of the infusion permits a water diuresis and correction of hyponatremia; however, the syndrome is best avoided by using isotonic saline as a vehicle for the drug.

Cyclophosphamide infusion Intravenous cyclophophamide impairs water excretion by an unknown mechanism.[28] The antidiuretic effect of the drug begins 4 to 12 hours after injection and persists for as long as 12 hours. Patients receiving cyclophosphamide are particularly susceptible to hyponatremia because they are encouraged to drink large volumes of water to prevent chemically induced cystitis [*see Table 4*].

Psychotic self-induced water intoxication Extreme polydipsia is relatively common in patients with psychiatric illnesses, particularly schizophrenia, and it may lead to symptomatic hyponatremia [*see Table 4*].[14] Daily intake of 10 to 15 L has been documented, and much of the intake may take place over a few hours. Many patients become hyponatremic in the late afternoon and evening; however, water diuresis typically restores normonatremia by the following morning. Occasionally, individuals drink enough water to produce seizures. By monitoring diurnal changes in body weight, water intoxication can be recognized before the onset of severe neurologic symptoms. Transient release of vasopressin (most commonly provoked by nau-

sea and vomiting) may contribute to water retention. There is little evidence that any of the major tranquilizers has a significant antidiuretic effect; however, carbamazepine, an anticonvulsant, enhances sensitivity to vasopressin.

Water intoxication during exercise Hyponatremia is disturbingly common in nonelite marathon runners; it is associated with slow finishing times and with excessive consumption of fluids while running, as evidenced by substantial weight gain.[29,30] Severe symptomatic hyponatremia has mostly been reported after participation in marathons or ultramarathons, but symptomatic hyponatremia may also occur after recreational running and military fitness training.

Water intoxication from the drug ecstasy During the 1990s, 3,4-methylenedioxymethamphetamine (MDMA, or ecstasy) gained widespread popularity as a recreational drug taken at dances.[31] When malignant hyperthermia was recognized as a complication associated with this drug, MDMA users were advised in underground magazines and the lay press to drink plenty of fluids. Subsequently, acute water intoxication emerged as a potentially lethal complication of the drug [*see Table 4*]. Excessive fluid intake and SIADH, induced by MDMA, have been implicated.

Diagnosis

Symptoms of water intoxication include headaches, weakness, nervousness, and vomiting, progressing to disorientation, delirium, tremulousness, and ultimately convulsions and coma.[12,26] The pupils are often dilated, and bilateral Babinski signs may be present. On occasion, patients may present with hemiparesis, mimicking a cerebrovascular accident. The syndrome reflects cerebral edema, which can lead to herniation of the brain and death. Clinical findings may emerge explosively. Complaints of headache and mild confusion may be followed within hours by respiratory arrest and, in some cases, neurogenic pulmonary edema. For reasons that remain obscure, almost all reported fatalities from acute postoperative hyponatremia have been in women (usually of childbearing age) and young children. Fatal cases of acute hyponatremia from other etiologies have been recorded in men and women.

Acute hyponatremia should be suspected in any patient who has unexplained neurologic symptoms, especially in psychiatric patients, marathon runners, users of ecstasy, and patients receiving hypotonic fluids intravenously (e.g., after surgery). Serum electrolyte levels should be obtained immediately. In the proper setting, a tentative diagnosis of water intoxication is advisable when symptoms develop in a patient whose serum sodium concentration is lower than 130 mEq/L (provided that causes of nonhypotonic hyponatremia have been excluded). Although severe neurologic symptoms do not usually appear until the sodium level has fallen below 120 mEq/L, some patients (particularly young women and children) may be unusually susceptible to brain edema when they become acutely hyponatremic; in rare cases, fatalities have been reported at plasma sodium concentrations between 120 and 128 mEq/L.[21,27]

Elderly patients can tolerate acute hyponatremia better than the young, because brain atrophy affords more room for brain cell swelling. The same water load per kilogram of body weight can cause a much more severe degree of acute hyponatremia when water is ingested rapidly, especially if the person has a much smaller muscle mass (the reservoir for a water load that limits brain cell swelling). When the serum sodium concentration is falling rapidly, the arterial sodium concentration (to which the brain responds) may be lower than the venous sodium concentration (which is measured in most clinical electrolyte assays).[32]

Computed tomography demonstrates cerebral edema in severe cases of water intoxication, and it rules out other potential explanations for neurologic findings. However, when symptoms are severe, therapy should not be delayed while imaging studies are being obtained.

Treatment

Free-water intake should be stopped immediately whenever water intoxication is suspected. Hypertonic saline is the treatment of choice for water-intoxicated patients who cannot autocorrect their electrolyte disturbance, including patients with neurogenic pulmonary edema.[26,27] Each 1 ml of 3% saline contains 0.5 mEq of sodium. Because there are approximately 0.5 L of body water for every 1 kg of body weight, 1 ml of 3% saline per 1 kg of body weight can be expected to increase the plasma sodium concentration by 1 mEq/L. For patients with severe neurologic symptoms, an infusion of 3% saline at 1 to 2 ml/kg/hr will increase the plasma sodium concentration by approximately 1 to 2 mEq/L/hr, a rate that is considered appropriate for initial therapy. Hypertonic saline is best infused in 100 ml containers to avoid inadvertently giving an excessive dose. Concurrent administration of a loop diuretic (furosemide, bumetanide, or torsemide) is advisable. The diuretic prevents volume overload and, by blocking sodium reabsorption in the loop of Henle, impedes the formation of concentrated urine.

The goal of therapy in acute hyponatremia is to decrease the severity of cerebral edema and to stop seizures. A 4 to 6 mEq/L increase in plasma sodium concentration is usually sufficient to accomplish these goals. Thus, the plasma sodium concentration should be monitored frequently during therapy, and emergency treatment with hypertonic saline should be stopped after 2 to 3 hours. Once initial therapy with high-dose hypertonic saline has been completed, more conservative measures should be substituted to gradually return the plasma sodium concentration to normal. To avoid complications from excessive correction of hyponatremia, the plasma sodium concentration should not be intentionally increased by more than 12 mEq/L during the first day of therapy or by more than 6 mEq/L/day thereafter.

CHRONIC HYPONATREMIA

The distinction between acute and chronic hyponatremia is somewhat arbitrary. Commonly, hyponatremia is considered chronic when it has evolved over the course of 48 hours or more.[11,12,26] Although the precise duration of an electrolyte disturbance cannot be known when it develops outside the hospital (except for psychotic water drinkers, marathon runners, and users of ecstasy), outpatients can be assumed to have chronic hyponatremia.[33] Prolonged hyponatremia cannot occur unless there is a sustained defect in water excretion. Except for patients with renal failure, virtually all chronically hyponatremic patients have some abnormality in vasopressin secretion.

Etiology

Advanced renal failure A low glomerular filtration rate limits the ability to excrete electrolyte-free water. Many patients with advanced renal failure excrete urine that has the same osmolality as plasma regardless of physiologic conditions (fixed

isosthenuria). In acute oliguric renal failure, the ability to excrete free water is virtually nil; administration of hypotonic fluids must be scrupulously avoided to avoid hyponatremia.

Diuretics Thiazide diuretics are commonly the sole cause or a major contributing factor of hyponatremia requiring hospital admission.[33,34] For unknown reasons, severe hyponatremia caused by thiazides affects elderly women much more often than other groups. By blocking the reabsorption of sodium and chloride in the distal tubule, thiazides and metolazone prevent the generation of maximally dilute urine.[35] Because sodium reabsorption in the ascending limb of the loop of Henle is left unaffected by these agents, they permit excretion of maximally concentrated, hypertonic urine and can lead to simultaneous retention of water and depletion of sodium and potassium. Extraordinarily severe hyponatremia can result from thiazides, with plasma sodium levels as low as 100 mEq/L. Vasopressin levels are usually elevated in patients who present with thiazide-induced hyponatremia, sometimes because of diuretic-induced volume depletion but more often because of the stress of minor intercurrent illnesses. Patients with thiazide-induced hyponatremia do not usually appear clinically volume depleted, presumably because retained water partially sustains extracellular fluid volume. Patients who have become hyponatremic on thiazides should not be given these agents again; recurrent episodes of severe hyponatremia are common.

Hypovolemia Hypovolemic hyponatremia is most often associated with gastrointestinal fluid losses caused by vomiting, diarrhea, or laxative abuse. Surprisingly, particularly in alcoholics, patients who continue to drink while vomiting repeatedly can still absorb enough ingested water to become hyponatremic. Electrolyte losses in the vomitus, combined with urinary sodium and potassium losses that result from metabolic alkalosis, lower the plasma sodium concentration.

Beer potomania Patients who subsist on beer (a practice known as beer potomania) are susceptible to hyponatremia because of their low rates of solute excretion (beer contains little protein or electrolyte). Reduced delivery of the glomerular filtrate to distal diluting sites limits the amount of water that can be excreted. Nonosmotic stimuli to vasopressin secretion caused by nausea or gastrointestinal fluid losses or by treatment with thiazide diuretics are often contributing factors.[15]

Edematous conditions Any disease that can cause edema also predisposes to water retention and hyponatremia. The same hemodynamic factors that promote sodium retention are nonosmotic stimuli for vasopressin release.[8,16-18] Elevated vasopressin levels have been reported in hyponatremic patients with congestive heart failure, cirrhosis, and nephrotic syndrome. In heart failure, hyponatremia is associated with a low cardiac output and a poor prognosis.

SIADH Nonosmotic release of vasopressin that has no hemodynamic explanation is termed inappropriate [*see Table 5*].[12,19] A number of tumors (most commonly small cell carcinoma of the lung) ectopically synthesize and secrete vasopressin.[36] Unexplained, persistent hyponatremia should be considered a marker for an underlying malignancy.

SIADH may also complicate the course of a wide variety of conditions in which there is damage to or inflammation of the central nervous system.[8,12] In patients with subarachnoid hemorrhage, natriuretic peptides released by the brain may directly promote urinary sodium loss, regardless of extracellular volume (cerebral salt wasting).[37,38] Urinary salt losses combined with vasopressin-induced water retention are responsible for hyponatremia. SIADH is a common complication of chest infection. Antidiuretic activity has been demonstrated by bioassay in patients with tuberculous lung tissue, and tuberculosis causes SIADH.[11] In pneumonia, vasopressin levels are increased during the acute phase of the disease and return to baseline within a few days. Isolated glucocorticoid deficiency caused by anterior pituitary dysfunction also causes hyponatremia; patients with hypopituitarism develop SIADH but, unlike patients with Addison disease, have normal levels of mineralocorticoid and do not become hypovolemic or hyperkalemic. Hyponatremia caused by glucocorticoid deficiency promptly resolves when cortisol is replaced. Hypothyroidism also causes SIADH; hyponatremia gradually resolves when thyroid hormone replacement is given.[39]

A number of therapeutic agents can induce SIADH.[12,40] Nonsteroidal anti-inflammatory drugs (NSAIDs) decrease water excretion because they inhibit formation of prostaglandin E_2,

Table 5 Causes of the Syndrome of Inappropriate Antidiuretic Hormone

Tumors	Bronchogenic (small cell) Pancreatic Duodenal Urethral Nasopharyngeal Leukemia Hodgkin disease Thymoma
Neurologic disorders	Psychosis Trauma Neoplasms (primary and metastatic) Vascular (hemorrhage, infarction, and vasculitis) Infection (meningitis, brain abscess, and encephalitis) Miscellaneous (Guillain-Barré syndrome, multiple sclerosis, hydrocephalus, Shy-Drager syndrome)
Pulmonary disorders	Infectious (bacterial, viral, and fungal pneumonia and tuberculosis) Functional (asthma, acute respiratory failure, and mechanical ventilation)
Endocrine diseases	Glucocorticoid deficiency (hypopituitarism) Hypothyroidism
Drugs	Antidiuretic hormones (vasopressin, DDAVP, and oxytocin) Psychotropic agents (tricyclic antidepressants, serotonin reuptake inhibitors, monoamine oxidase inhibitors, and carbamazepine) Ecstasy (MDMA) Antineoplastic agents (cyclophosphamide, vincristine, and vinblastine) Nonsteroidal anti-inflammatory drugs Diabetic agents (chlorpropamide and tolbutamide) Miscellaneous (bromocriptine and nicotine)
Other causes	Postoperative stress Alcohol withdrawal AIDS Nausea

DDAVP—1-desamino-8-D-arginine vasopressin

which modulates vasopressin action.[8] Rare cases of hyponatremia solely attributable to NSAIDs have been reported, but these commonly used agents may exacerbate other causes of hyponatremia.

Hyponatremia in AIDS Hyponatremia is an extremely common finding in AIDS patients.[41] Many AIDS patients have features of SIADH associated with opportunistic infections that cause pneumonia and meningitis. Others have clinical signs of volume depletion without low urine sodium values, a finding that may indicate coexistent renal disease or adrenal insufficiency.[42] Hyponatremia often occurs when antibiotics are administered in hypotonic intravenous solutions.

Diagnosis

Hyponatremia should be approached in a systematic fashion. First, the various disorders that can lower the plasma sodium concentration without causing hypotonicity should be excluded [*see* Differential Diagnosis for Hyponatremia, *above*]. Once it has been established that hypotonic hyponatremia is present, the mechanism for impaired water excretion is identified (hypovolemia versus an edematous condition versus SIADH), and the differential diagnosis that applies to that mechanism is considered. The most challenging goals of the diagnostic process are to determine whether chronic SIADH is present and, if it is, to define the specific disease responsible for the syndrome.

Clinical manifestations Because cerebral edema is usually not severe, the symptoms of chronic hyponatremia are much more subtle, vague, and nonspecific than those of acute water intoxication[12,26]; indeed, patients with chronic hyponatremia are often asymptomatic at sodium levels that may be lethal to a patient with acute water intoxication. As the plasma sodium concentration falls below 115 to 120 mEq/L, patients often experience anorexia, nausea, vomiting, muscle weakness, and muscle cramps. They may be irritable and show personality changes, becoming uncooperative, confused, hostile, or simply slow to respond. At plasma sodium concentrations below 110 mEq/L, gait disturbances, falling, stupor, tremulousness, and, more rarely, seizures may occur.

Chronic hyponatremia itself is rarely, if ever, fatal. However, chronically hyponatremic patients may develop life-threatening acute hyponatremia if they rapidly drink water or are infused with a large volume of hypotonic fluid. Because hyponatremia can be a marker for severe underlying illness, hospitalized patients with hyponatremia often have a high mortality, dying with but not of chronic hyponatremia. There is little evidence that chronic hyponatremia itself leads to permanent sequelae, even when the plasma sodium concentration falls below 105 mEq/L.[33,43] However, patients with prolonged, severe hyponatremia are susceptible to iatrogenic injury if their electrolyte disturbance is corrected too rapidly [*see* Treatment, *below*].

History and physical examination The history in patients with chronic hyponatremia should include information about diet, fluid intake, gastrointestinal fluid losses, and use of diuretics, antidepressants, or other antidiuretic drugs. During the physical examination, physicians should look for clinical signs of volume depletion or an edematous condition. Evidence of volume depletion may not always be definitive, however. For example, vomiting may be a symptom rather than the cause of hyponatremia; extreme hyponatremia may occasionally impair baroreceptor reflexes, causing postural hypotension and a false impression of volume depletion; and retained water may mask underlying volume depletion. When the distinction between hyponatremia caused by hypovolemia and hyponatremia caused by SIADH is not obvious, laboratory clues may helpful.

Laboratory tests Measurement of the urinary sodium concentration, chloride concentration, or both is often the most helpful test.[44] Water retention caused by hypovolemia or by an edematous condition is usually associated with a urinary sodium concentration lower than 20 mEq/L in a spot sample. Hypovolemia caused by upper gastrointestinal fluid losses is an important exception. Loss of gastric fluid causes a metabolic alkalosis that may increase urinary sodium excretion despite volume depletion; the diagnosis can be made by measuring the urine chloride concentration, which is reduced in this condition. In SIADH, urinary sodium matches intake; because the urine is usually concentrated, the urinary sodium concentration exceeds 40 mEq/L unless dietary sodium intake is very low. Measurements of the BUN and serum uric acid complement these measurements. When a hemodynamic abnormality is responsible for hyponatremia, the kidney is underperfused, urea and uric acid clearances are diminished, and the BUN and serum uric acid levels are usually elevated. Conversely, SIADH is a volume-expanded state, and BUN and uric acid levels are usually low. Uric acid is a more reliable indicator of volume status than the BUN, because the latter value is affected by dietary protein intake as well as renal clearance.

Assessment of acid-base and potassium balance may provide helpful clues to the diagnosis. The serum potassium and bicarbonate levels are normal in SIADH. Hypokalemia and metabolic alkalosis suggest diuretic therapy or vomiting, which can be surreptitious. Hyperkalemia and metabolic acidosis suggest the possibility of adrenal insufficiency. Hypokalemia and acidosis can result from diarrhea, and their presence may raise the possibility of surreptitious laxative abuse.

Withdrawal of hyponatremic drugs When a patient is taking a drug that can cause hyponatremia, it is important to exclude another underlying cause of hyponatremia before attributing the electrolyte disturbance to the medication. For example, thiazide diuretics can exacerbate hyponatremia caused by SIADH. The best way to confirm a diagnosis of drug-induced hyponatremia is to eliminate the offending agent and be sure that water excretion returns to normal when the patient is off the drug. Full resolution of hyponatremia and full recovery of diluting function may be delayed for a week or two in patients with thiazide-induced hyponatremia. During repair of sodium and potassium deficits, transient resetting of the osmostat is common and should not necessarily prompt an extensive search for an underlying cause.

Response to therapy On occasion, evidence regarding the cause of hyponatremia can be equivocal. In such cases, the patient's response to isotonic saline (or a generous oral salt intake and the passage of time) is the best clue to the diagnosis. Patients with subclinical edematous conditions will retain the administered sodium, developing clinically obvious edema. Volume-depleted patients initially retain the administered sodium, but as soon as hypovolemia is corrected, the urine becomes dilute, the rate of urinary sodium excretion increases to match intake, and hyponatremia improves as water is excreted in the urine. Uri-

nary sodium excretion promptly increases in patients with SIADH, but the urine remains concentrated and hyponatremia persists. Isotonic saline should be given with extreme caution to patients with very low plasma sodium concentrations; in SIADH, saline can exacerbate hyponatremia, whereas in volume depletion, hyponatremia may correct too rapidly.

Identifying a specific cause for SIADH SIADH is a mechanism for developing hyponatremia, not a diagnosis. In all patients with SIADH, a specific etiology for inappropriate vasopressin secretion should be sought. When hyponatremia develops during hospitalization, the cause is sometimes obvious (e.g., pneumonia, meningitis, or acute respiratory failure) and no further testing is indicated. In a patient with clinical features of SIADH but no obvious cause for it, a more extensive evaluation is indicated. The workup should include a careful search for malignancy and central nervous system pathology and an endocrine evaluation to exclude hypothyroidism and hypocortisolism. Sometimes, no cause for SIADH is found, especially in elderly patients and patients with psychiatric disorders, mental retardation, or alcoholism.[45] Careful follow-up is important, because malignancies may become clinically apparent after several years in so-called idiopathic SIADH.

Treatment

Patients with very low plasma sodium concentrations usually have some neurologic symptoms, and they are at risk of sustaining injuries from falls. However, unlike acute water intoxication, chronic hyponatremia poses little risk of an explosive onset of seizures or a fatal outcome, provided that water is withheld and the plasma sodium concentration is not allowed to fall any further. On the other hand, patients with chronic hyponatremia are at considerable risk for neurologic injury caused by overaggressive correction. Thus, there are four major goals in managing chronic hyponatremia: (1) prevention of a progressive decrease in plasma sodium concentration; (2) amelioration of hyponatremic symptoms by promptly but carefully increasing the plasma sodium concentration (an increase of at least 4 mEq/L/day is desirable in most cases); (3) avoidance of excessive correction; and (4) gradual restoration and maintenance of a normal plasma sodium concentration.

Free-water restriction should be instituted in all patients until the plasma sodium concentration has begun to increase. Intravenous fluids should be at least isotonic, and oral fluid intake should be limited to 500 to 1,000 ml/day, depending on the severity of the electrolyte disturbance. In patients with reversible defects in water excretion, limitations on free-water intake should be lifted once the plasma sodium concentration has begun to increase.

Attempts to calculate the dose of sodium chloride needed to correct hyponatremia are doomed to failure. The increase in plasma sodium concentration depends on the amounts of administered sodium and potassium that the body retains, as well as on the amount of electrolyte-free water that is eliminated in the urine. Indeed, in some cases, the plasma sodium concentration will return to normal solely because of a water diuresis, with no sodium given.

The measures required to increase the plasma sodium concentration, along with the likelihood of inadvertent rapid correction, vary depending on the cause of hyponatremia. For therapeutic purposes, the causes can be divided into reversible and persistent defects in water excretion.

Reversible defects in water excretion Hyponatremia corrects easily when the cause of defective water excretion can be eliminated by volume expansion, by withdrawal of a therapeutic agent, or by treatment of an underlying illness [*see Table 4*]. In patients with reversible defects in water excretion, avoiding excessive correction may become a major challenge.

Hypovolemic hyponatremia responds readily to 0.9% sodium chloride because the sodium concentration of isotonic saline is higher than the cation concentration of the excreted urine. Once the volume deficit is repaired and the hemodynamic stimulus to vasopressin secretion is removed, the urine becomes dilute and a water diuresis may rapidly return the plasma sodium concentration to normal. Similarly, patients with diuretic-induced hyponatremia are extremely susceptible to rapid correction; restoration of the renal diluting mechanism when the diuretic is discontinued and replacement of sodium and potassium deficits contribute to the increase in plasma sodium concentration.

Intravenous saline should be discontinued once clinically apparent hypovolemia has been corrected and the plasma sodium concentration has begun to increase. Saline should be given cautiously, if at all, to hypokalemic patients who require potassium replacement. During repair of a potassium deficit, potassium enters cells, displacing sodium, which then returns to the extracellular fluid; administered potassium is therefore as effective as sodium in raising the plasma sodium concentration. Diuretic-induced hyponatremia does not usually necessitate use of intravenous saline; for most patients, an adequate diet, replacement of potassium deficits, and discontinuance of thiazide diuretics are sufficient. In severely hyponatremic patients, the plasma sodium concentration should be monitored every 6 to 8 hours for the first 2 to 3 days of therapy. If it appears that a water diuresis is going to increase the plasma sodium by more than the desired amount, replacement of fluid losses with oral water or D5W may become necessary.

Persistent defects in water excretion: SIADH Patients with SIADH tend to be resistant to rapid changes in plasma sodium concentration (unless the cause of SIADH is short-lived). Water restriction is the cornerstone of therapy, but if used alone, water restriction often leads to an extremely slow resolution of hyponatremia. Isotonic saline is ineffective and may even be counterproductive. Furosemide and other loop diuretics are often useful therapeutic adjuncts because by blocking sodium reabsorption in the ascending limb of the loop of Henle, they interfere with the renal-concentrating mechanism, partially blocking the effect of vasopressin. Loop diuretics can be combined with oral salt or a slow infusion (approximately 15 ml/hr) of 3% saline. Oral and intravenous urea have been used extensively to treat SIADH in some parts of Europe, but experience with this agent in the United States is very limited. Demeclocycline, a tetracycline that blocks the effect of vasopressin on the collecting duct, is another therapeutic option in chronic SIADH; however, its expense and long duration of action limit its effectiveness. Several orally active vasopressin receptor blockers have been developed and are currently in clinical trials.[46,47]

Persistent defects in water excretion: edematous conditions and renal failure Saline should rarely, if ever, be given to correct hyponatremia in edematous patients or patients with renal failure (except for those with prerenal azotemia). Because it has no effect on water excretion, 1 L of 0.9% saline will increase the plasma sodium concentration by only 1 mEq/L.[12] In addition,

saline exacerbates edema and ascites in patients with cirrhosis and may cause pulmonary edema in patients with heart failure or renal failure.

Although thiazide diuretics are contraindicated, loop diuretics are the mainstay of treatment of hyponatremia for patients with edematous conditions because they increase free-water excretion and improve hyponatremia, particularly when dietary salt intake is increased. There is a natural inclination to discontinue loop diuretics when severely edematous patients develop hyponatremia. The usual problem, however, is oliguria and diuretic resistance rather than overdiuresis; the proper response is to increase the dose of loop diuretics and restrict water intake. The combination of a loop diuretic and an angiotensin-converting enzyme (ACE) inhibitor is particularly effective in patients with heart failure. The beneficial effect of an ACE inhibitor can be explained by reduced thirst and vasopressin secretion attributable to angiotensin II and by a direct effect on the hydro-osmotic effect of vasopressin, mediated by prostaglandins.[11]

Hyponatremia in edematous conditions is mediated by vasopressin. Clinical trials have shown that vasopressin receptor antagonists can be effective in managing patients with hyponatremia and edema.[46,47]

Treatment of hyponatremic seizures A small percentage of chronically hyponatremic patients with very low plasma sodium concentrations present with seizures. Regardless of the suspected duration or cause of the electrolyte disturbance, active seizures may be resistant to anticonvulsants alone and should be treated with hypertonic saline. The therapeutic approach is similar to that used for patients with acute water intoxication, except that even more vigilance is required to prevent an excessive increase in plasma sodium concentration once emergency measures have been discontinued.[12,26]

Table 6 Causes of Hypernatremia

Electrolyte-free water losses	Extrarenal Insensible loss (skin and lungs) Renal Neurogenic (central) diabetes insipidus Nephrogenic diabetes insipidus Congenital X-linked (V_2 vasopressin receptor defect) Recessive (aquaporin defects) Acquired Electrolyte abnormalities: hypokalemia, hypercalcemia Drugs: lithium, demeclocycline, methoxyflurane Pregnancy (vasopressinase) Excess urea excretion
Hypotonic losses	Extrarenal Sweat Upper GI tract Osmotic cathartics Renal Glycosuria, mannitol, glycerol, diuretics
Salt poisoning	Oral Parenteral $NaHCO_3$, 3% or 5% I.V. saline, therapeutic abortion (inadvertent 29% I.V. saline) Hemodialysis with hypertonic dialysate

Complications of Therapy: Myelinolysis and Osmotic Demyelination Syndrome

Excessive correction of chronic hyponatremia may be complicated by neurologic injury.[43,48] Typically, the patient's hyponatremic symptoms improve as the plasma sodium concentration increases, but after a delay of one to several days, new findings emerge. The patient may become confused and may exhibit psychotic or catatonic behavior, pathologic crying, or a movement disorder. Swallowing dysfunction, progressive unresponsiveness, and a spastic quadriparesis may develop. In severe cases, locked-in syndrome occurs—that is, the patient is awake but unable to move or respond. The stereotypical pattern of delayed neurologic deterioration after rapid correction of hyponatremia has been named the osmotic demyelination syndrome, because these clinical features are associated with brain lesions (myelinolysis) characterized by disruption of myelin and sparing of neurons and axons.[48-50] Lesions, which are best identified by magnetic resonance imaging, are typically found in the center of the basal pons (central pontine myelinolysis), but histologically similar lesions may also occur in a symmetrical distribution in extrapontine areas of the brain where there is a close admixture of gray and white matter. The osmotic demyelination syndrome has been reproduced in animal studies[49]; these experiments have shown that the disorder is a complication of rapid correction of hyponatremia rather than the electrolyte disturbance itself. Observational studies in severely hyponatremic patients suggest that this therapeutic complication can be avoided if correction rates are maintained below 10 to 12 mEq/L/day and 18 mEq/L/48 hr. It should be emphasized that these values are limits and not goals. Because large increases in the serum sodium concentration are seldom required to relieve hyponatremic symptoms and because unintentional excessive correction is common, the goal of therapy should be to increase serum sodium concentration by 8 mEq/L/day or less.[12]

Disorder of Water Deficiency: Hypernatremia

PATHOGENESIS

Persistent hypernatremia results from one of two basic mechanisms: water is lost and not adequately replaced or, less commonly, too much salt is taken in without enough water [*see Table 6*].[13,51-53] In either case, electrolyte-free water is needed to return the plasma sodium concentration to normal. Because thirst is the primary defense against hypertonicity, persistent hypernatremia indicates a defect in water intake. A maximally concentrated urine minimizes but does not prevent water losses. Insensible water losses from the skin and lungs are unavoidable, and urea excretion obligates some urinary losses. Maintenance of a normal serum sodium concentration (135 to 142 mEq/L) requires that daily water losses be replaced.

Most hypernatremic patients are too sick, too young, or too old to obtain water themselves or ask for it.[13,51] Sometimes, the thirst sensation itself is impaired, so that the patient has no desire to drink when the plasma sodium concentration increases above the normal range. Inadequate water intake by itself will lead to hypernatremia. When impaired intake is coupled with excessive water losses, severe hypernatremia results.

ETIOLOGY

Electrolyte-free water can be lost as pure water, with no accompanying electrolyte, or it can be lost in hypotonic fluids,

which have lower electrolyte concentrations than plasma. Hypotonic losses can be thought of as mixtures of isotonic fluid and free water. Pure-water and hypotonic fluid losses, the most common causes of hypernatremia, are typically associated with a contracted extracellular fluid volume.[13] However, this is not always the case. When hypernatremia is caused by a rapid intake of salt (acute salt poisoning), the extracellular volume expands because of water drawn from the intracellular space.[51] In critically ill patients, extracellular volume expansion with edema often coexists with hypernatremia[52,54]; the finding reflects free-water losses in patients who become edematous after fluid resuscitation for shock or underlying conditions such as congestive heart failure, renal disease, and hepatic cirrhosis.

Pure-Water Losses

When pure-water losses are responsible for hypernatremia, each body-fluid compartment loses an equal percentage of its volume.[13,51] Plasma constitutes only one twelfth of total body water (one quarter of extracellular fluid volume), and plasma volume is defended by oncotic pressure, which increases with water loss. Thus, plasma volume contracts by less than 83 ml for each 1 L of water lost; clinical signs of hypovolemia are unusual unless the water deficit is extremely large.

Insensible water losses Water is constantly lost by evaporation from the skin and lungs and must be replaced to avoid dehydration. Daily insensible water losses, normally about 0.5 L, can be increased severalfold by high environmental temperature, fever, or hypermetabolic states such as thyrotoxicosis.

Increased urea excretion Although urea is an ineffective osmole that freely crosses most cell membranes, urinary urea excretion can play an important role in water balance. High rates of urea excretion caused by very high protein diets, catabolism, or recovery from renal failure obligate increased rates of water loss. When the urine solute is composed almost exclusively of urea, the urine becomes an electrolyte-free water solution, regardless of its osmolality.

Diabetes insipidus Because sodium excretion is unaffected in diabetes insipidus (see below), the excess fluid lost in the urine is pure water. As long as water is available and the patient is able to drink, hypernatremia does not occur. Without water replacement, however, hypernatremia develops within a few hours.

Hypotonic Losses

Hypernatremia caused by hypotonic fluid loss is associated with extracellular volume depletion.

Sweat Sweat is a hypotonic solution containing water, sodium, potassium, and chloride. Sweat glands respond to aldosterone by lowering the sodium concentration and increasing the potassium concentration of their secretions.

Gastric fluid losses Fluid lost by vomiting or nasogastric suction is hypotonic to plasma. Without adequate water replacement, large gastric fluid losses can cause hypernatremia.

Osmotic cathartics Fecal losses of water contain electrolytes at a concentration comparable to that of plasma, except when osmotic cathartics such as sorbitol or lactulose are given. These cathartic agents osmotically attract electrolyte-free water to the intestinal lumen, leading to hypotonic fluid losses. Oral sorbitol is a nonabsorbable solute, given with sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia or with charcoal to treat poisoning; the sorbitol osmotically attracts electrolyte-free water into the intestinal lumen, where it is eliminated in the stool. Similarly, lactulose, which is used to treat hepatic encephalopathy, can promote large electrolyte-free water losses, causing a high incidence of hypernatremia unless the lost water is replaced.

Osmotic diuretics and glycosuria Glucose in the extracellular fluid acts as an effective osmole that attracts water to the extracellular fluid, dehydrating cells and lowering the plasma sodium concentration.[23,51] Excretion of glucose in the urine acts as an osmotic diuretic that can provoke the loss of several liters of hypotonic fluid. Electrolyte-free water losses induced by glycosuria raise the plasma sodium concentration, offsetting the hyponatremic effect of the high blood glucose levels. Intravenous hypertonic mannitol has a similar effect on body fluids.

Acute Salt Poisoning

Water losses increase the serum sodium concentration over hours or days. The oral ingestion of large amounts of salt without water—1 tbsp of salt contains nearly 350 mEq of NaCl, enough to increase the plasma sodium concentration by 8 mEq/L—or the intravenous infusion of hypertonic salt solutions can increase the plasma sodium concentration much more rapidly (i.e., cause acute salt poisoning).[13,51]

DIAGNOSIS

Clinical Manifestations

An acute onset of hypernatremia (seen almost exclusively in acute salt poisoning) causes the brain to shrink, leading to vascular injury and intracranial bleeding. Patients present with seizures, coma, hyperventilation, hyperreflexia, hypertonia, and high fever. Acutely hypernatremic patients with plasma sodium levels above 170 mEq/L often die.[13,51]

Given time to adapt, brain cells protect their volume by accumulating organic osmolytes, preventing the hemorrhages caused by acute hypernatremia. Thus, the clinical manifestations of chronic hypernatremia are less dramatic than those seen in acute salt poisoning, ranging from lethargy to coma, depending on the severity of the electrolyte disturbance.[13,51,53]

The clinical signs of pure-water loss and acute salt poisoning are primarily neurologic. Hypotonic fluid losses may be associated with signs and symptoms of extracellular fluid volume depletion in addition to symptoms related to hypernatremia.

Recognition of Water Deficit

The plasma or serum sodium concentration can be used to determine how much water is needed to restore normotonicity; it seriously underestimates the magnitude of the water deficit in diabetic patients with hyperglycemic dehydration [*see* Diabetic Dehydration, *below*]. In patients without severe hyperglycemia, the percentage increase in the serum sodium concentration approximates the percentage decrease in total body water, as stated more precisely in the following equation:

$$\text{Water deficit} = \text{normal body water} \times (1 - \text{serum } [Na^+]/140)$$

The value for body water is based on the patient's usual body weight (often an estimate), age, and sex.

The calculated water deficit is the amount of water that will return the serum sodium concentration to normal. It reveals nothing about the volume status of the extracellular fluid. Extracellular fluid volume deficits (or surfeits) must be estimated from the history and physical examination, not from the serum sodium concentration.

TREATMENT

Correction of severe extracellular volume depletion takes precedence over correction of hypernatremia. When the patient is hypotensive, initial therapy should include a rapid infusion of isotonic saline to quickly achieve hemodynamic stability. In hemodynamically stable patients, pure-water losses should be replaced with pure water, and isotonic saline is not required. Edematous patients with hypernatremia can be given diuretics along with electrolyte-free water to replace urinary electrolyte-free water losses; the net effect is reduction of the extracellular volume surfeit and restoration of normotonicity and cell volume.

Electrolyte-free water can be given intravenously as D5W to patients who are unable to drink. Dextrose solutions cannot be infused more rapidly than approximately 500 ml/hr. Faster infusions provide more glucose than can be metabolized and therefore cause hyperglycemia, glycosuria, and urinary water losses, which are counterproductive to the correction of hypertonicity. Water replacement should not be based on formulas alone; the serum sodium concentration and urine output should be monitored frequently so that the fluid prescription can be adjusted appropriately.

Rate of Correction

In the vast majority of cases, the onset of hypertonicity is slow enough for brain adaptations to minimize cerebral dehydration. Organic osmolytes that accumulate in the adaptation to hypernatremia are slow to leave the cell during rehydration. If hypernatremia is corrected too rapidly, cerebral edema results.[13,51] To be safe, the serum sodium concentration should be reduced by no more than 10 to 12 mEq/L/day. To achieve the desired rate of correction, electrolyte-free water intake should exceed free-water losses by no more than 2 L daily.

Acute salt poisoning causes devastating brain injury that is largely irreversible. In rare cases when acute salt poisoning can be rapidly diagnosed (e.g., in a case of inadvertent intravenous infusion of hypertonic saline during therapeutic abortion), an effort to prevent a neurologic catastrophe can be made with rapid infusions of electrolyte-free water along with a loop diuretic before the results of the serum electrolyte measurements are known.

Diabetic Dehydration

Hypertonicity associated with diabetes mellitus is a complex disorder.[23] The osmotic diuresis induced by glycosuria results in both saltwater and electrolyte-free water losses; the accumulation of glucose in the extracellular fluid adds impermeant solute, which contributes to hypertonicity and neurologic symptoms. Severely dehydrated hyperglycemic patients may not appear hypovolemic at first, because the high glucose concentration in the extracellular fluid osmotically attracts water from cells, masking the loss of saltwater. With correction of hyperglycemia, marked hypovolemia may emerge. Initial treatment should include 1 to 2 L of isotonic saline in anticipation of this complication, even in patients who are initially normotensive. With volume expansion, excess glucose will be excreted in the urine, creating an ongoing requirement for both saline and electrolyte-free water. An infusion of 0.45% saline at a rate that exceeds urine output will serve to replace the electrolyte-free water deficit and remaining saltwater deficits. The serum sodium concentration, blood glucose level, and urine output should be monitored carefully so that fluid replacement can be tailored to the patient's needs.

Rapid correction of hypertonicity should be avoided in severely hyperglycemic patients because of the risk of cerebral edema. This problem is of particular concern in young children with diabetic ketoacidosis. For this reason, in young patients, the serum sodium concentration should be allowed to increase as the blood glucose level falls (i.e., 0.5 mmol/L increase in serum sodium for every 18 mg/dl decrease in plasma glucose), maintaining a near-constant effective osmolality, especially in the first 12 to 16 hours. In children, hypotonic fluids should probably be avoided during the first day of therapy.[55]

Patients with oliguric renal failure do not become dehydrated when they become severely hyperglycemic. Such patients often experience hypertension or congestive heart failure because of fluid shifts from cells to the extracellular fluid. Even after adjusting for the effect of hyperglycemia, the serum sodium concentration is often low. Insulin is the only required treatment; neither isotonic saline nor 0.45% saline is indicated.

Disorder of Water Conservation: Diabetes Insipidus

PATHOGENESIS

Diabetes insipidus (DI) may be neurogenic or nephrogenic. Neurogenic DI is caused by deficient secretion of vasopressin[8,56,57]; nephrogenic DI results from the kidney's unresponsiveness to normally secreted hormone.[58] In both disorders, patients present with polyuria (loosely defined as the passage of excessive volumes of urine—generally more than 3 to 4 L daily) and polydipsia (excessive thirst). Most patients with polyuria do not become hypernatremic, because thirst maintains electrolyte-free water balance. The causes and treatment of neurogenic, or central, DI are discussed elsewhere [*see 3:V Pituitary*].

Defective responsiveness to vasopressin (nephrogenic DI) may be inherited as an X-linked trait, caused by a mutation in the gene encoding for the V_2 vasopressin receptor, or as an autosomal recessive trait caused by a mutation in the gene encoding for the vasopressin-responsive water channel (aquaporin 2). Acquired nephrogenic DI may be caused by lithium or demeclocycline therapy, hypokalemia, or hypercalcemia; or it may complicate a number of renal diseases [*see Table 6*]. Vasopressin-resistant DI may emerge during the late stage of pregnancy as a result of vasopressinase released by the placenta; many affected patients have underlying, subclinical partial neurogenic or nephrogenic DI that has been exacerbated by increased catabolism of circulating vasopressin.

DIAGNOSIS

Clinical Manifestations

Patients with DI complain of polyuria, nocturia (the need to urinate during the night), and polydipsia. The only significant physical findings or laboratory abnormalities are those of the underlying cause.

Laboratory Tests

A diagnosis of DI can be made if the urine osmolality is less

than 250 mOsm/kg despite hypernatremia.[8] When the disorder is suspected in a polyuric patient whose serum sodium concentration is normal or borderline, the urine osmolality level can be monitored while the patient is deprived of water, allowing the serum sodium level to increase to higher than 144 mEq/L. Exogenous vasopressin increases urine osmolality by more than 150 mOsm/kg in patients with neurogenic, but not nephrogenic, DI. It is possible to misdiagnose DI in patients who actually have a primary thirst disorder. Excessive water intake suppresses vasopressin secretion and causes polyuria with dilute urine. Because patients with primary polydipsia secrete vasopressin normally, they do not become hypernatremic during diagnostic water deprivation. Correlation with plasma vasopressin levels is often necessary in borderline cases. Polyuric patients whose urine osmolality equals or exceeds plasma osmolality should be distinguished from patients with DI; polyuria in such cases is usually caused by excessive excretion of salt, urea, or glucose or by an osmotic diuretic (solute diuresis).

Magnetic resonance imaging of the brain can be helpful in the evaluation of patients with suspected DI.[8,57] In 85% to 90% of healthy adults and children, the posterior pituitary emits a hyperintense signal, or so-called bright spot, on T_1-weighted magnetic resonance images, apparently related to the vasopressin release of the gland. This bright spot is also normal in 85% to 90% of patients with primary polydipsia, but it is almost always absent or greatly diminished in patients with pituitary DI.

TREATMENT

When access to water is limited, patients with DI are more susceptible to dehydration than normal persons. Thus, water losses must be carefully replaced during superimposed illnesses. Neurogenic DI is best treated with a synthetic antidiuretic hormone, 1-desamino-8-D-arginine vasopressin (DDAVP), which can be given parenterally or intranasally.[8,57] Chlorpropamide or carbamazepine (both of which enhance vasopressin action) or thiazide diuretics (which limit the ability to maximally dilute the urine) can be used in patients with mild disease. Limiting dietary salt and protein intake is also helpful. Nephrogenic DI can also be treated with dietary measures or with thiazides and indomethacin (which helps concentrate the urine by inhibiting prostaglandin synthesis). Lithium-induced nephrogenic DI may be improved by amiloride, which blocks lithium entry into the collecting duct cell.

Disorder of Saltwater Excess: Edematous States

Edema, a swelling of the soft tissues that can be indented or pitted by the examiner's fingers, is the clinical manifestation of an expanded interstitial fluid volume. To be detected clinically, interstitial volume must increase by at least 2.5 to 3 L, nearly equaling the total amount of fluid in the intravascular space. Thus, generalized edema requires an increase in the total amount of saltwater in the extracellular space, and it implies retention of dietary or infused sodium, with an impaired ability to excrete saltwater.

PATHOGENESIS

Excess fluid collects in the interstitial space in response to Starling forces, which govern the movement of extracellular fluid into and out of the vasculature. Edema occurs when there is increased capillary blood pressure, decreased plasma oncotic pressure, increased capillary permeability to protein, or obstruction to lymph flow.

When fluid overflows from an overfilled vascular space into the interstitium, impaired sodium excretion is clearly implicated. However, even when edema formation results from decreased oncotic pressure or increased capillary permeablity, renal sodium retention is required to replace the saltwater that has been lost from the vasculature.

ETIOLOGY

Primary Renal Sodium Retention: Edema Caused by Renal Disease

Nephrotic syndrome The nephrotic syndrome is characterized by heavy urinary protein losses (in excess of 3 g/day), hypoalbuminemia, and edema.[59] The syndrome, which can be seen in a variety of glomerular diseases, is caused by increased permeability of the glomerular capillary to protein. Traditionally, edema in the nephrotic syndrome has been ascribed to decreased plasma oncotic pressure. This no longer appears to be the sole explanation. Correction of hypoalbuminemia by infusing albumin does not consistently improve the edema, and in steroid-responsive cases, edema may resolve before hypoalbuminemia improves. Thus, in most patients, primary sodium retention by the kidney, independent of an underfilled vasculature, plays a major contributing role.

Nephritic edema Glomerular diseases characterized by proliferation of mesangial cells (e.g., diffuse proliferative glomerulonephritis and membranoproliferative glomerulonephritis) often cause primary sodium retention that is not associated with heavy proteinuria or hypoalbuminemia (the nephritic syndrome). Patients with nephritic edema are typically hypertensive and may present with congestive heart failure because of an overexpanded vascular volume.

Secondary Renal Sodium Retention: Edema Caused by Extrarenal Disease

In congestive heart failure and hepatic cirrhosis, the body responds as if it were volume depleted. Despite an expanded interstitial fluid volume, as well as increased total body sodium content, the kidney avidly retains salt and water. The normal renal response to a high salt intake is lost, and progressive salt retention occurs. In these conditions, volume-regulatory mechanisms are responding to reduced fullness of the arterial portion of the vascular system, which normally contains about 15% of the total blood volume.

Congestive heart failure Advanced stages of the many disorders that affect the pericardium, myocardium, or heart valves can produce congestive heart failure, a disorder characterized by renal sodium retention and interstitial edema in systemic or pulmonary capillary beds.[16,17] Arterial receptors are activated when cardiac output falls (low-output heart failure) or when cardiac output is not high enough to compensate for decreased peripheral resistance (high-output failure).

Cirrhosis Patients with severe liver disease may exhibit profound salt retention, often excreting less than 10 mEq of sodium in the urine each day. Scarring of the hepatic parenchyma increases resistance to blood flow in the postsinusoidal venules, resulting in high sinusoidal pressures and venous hypertension throughout the portal system. Portal hypertension and hypoalbuminemia promote the formation of ascites. In addition, cirrho-

sis results in vasodilatation from endotoxins, vasodilatory prostaglandins, nitric oxide, various gut hormones, and other mediators. The combined effects of blood pooling in the splanchnic circulation (caused by portal hypertension) and systemic vasodilatation lead to underfilling of the arterial circulation and subsequent activation of sodium-retaining factors.[60]

Idiopathic edema Idiopathic edema is a benign disorder of young, menstruating women who have no cardiac, hepatic, or renal disease.[61] Fluid retention often begins premenstrually and then becomes persistent. Depression and neurotic symptoms are commonly present, and affected patients are often weight conscious and markedly concerned about even minor degrees of edema. Some patients episodically fast for days at a time and then accumulate edema on refeeding. In many others, diuretics play an important role in the pathogenesis of idiopathic edema. Long-term diuretic or cathartic use leads to persistent hypovolemia and chronic activation of sodium-retaining mechanisms, which include hypertrophy of the nephron segments distal to the site of action of the diuretic. When the diuretic is stopped, marked sodium retention occurs because the sodium-retaining forces cannot be shut off rapidly. The patient thus becomes convinced of the need for diuretics, and the cycle continues.

DIAGNOSIS

The symptoms and laboratory findings associated with edematous conditions depend on the underlying cause. Dyspnea on exertion and orthopnea provoked by pulmonary interstitial edema are prominent features in patients with left ventricular failure or nephritic edema, but these symptoms are usually absent when edema is caused by right heart failure, nephrotic syndrome, or cirrhosis. Mild peripheral edema develops in the dependent portions of the anatomy and is usually asymptomatic. Although more severe edema, which can extend to the thighs and buttocks, may be uncomfortable, it is usually harmless. A large volume of ascites not only causes discomfort but also may elevate the diaphragm, causing shortness of breath; may promote reflux of gastric fluid, causing bleeding from esophageal varices; or may become infected spontaneously.

The diagnosis of edema should be approached systematically; the physician should look for evidence of heart, renal, or liver disease. A diagnosis can usually be made from the history and physical examination, urinalysis, liver function tests, and chest x-ray. More puzzling cases may require echocardiography or, rarely, right heart catheterization. Plasma levels of B-type natriuretic peptide (BNP) are increased in patients with heart failure. Used in conjunction with other clinical information, rapid-measurement BNP is useful in establishing or excluding the diagnosis of congestive heart failure in patients who present with acute dyspnea.[62]

TREATMENT

Dietary salt restriction is important for patients with edema, but this measure alone is impractical or insufficient when urinary sodium excretion is reduced to very low levels. Thus, most edematous patients whose underlying condition cannot be reversed require treatment with diuretics.[5,63] Salt restriction and diuretics are adjunctive treatments for heart failure. Therapy is also directed at improving cardiac performance by using digoxin and vasodilators to reduce afterload. Recombinant human BNP (nesiritide) has become available for the treatment of acute decompensated heart failure. The agent reduces pulmonary capillary wedge pressure and systemic vascular resistance, improves cardiac performance, and has a diuretic effect, in part because of its effect on sodium reabsorption in the distal nephron.[64]

Ascitic fluid is a separate compartment of the extracellular fluid compartment that is much more difficult to mobilize than peripheral edema. Thus, cirrhotic patients who have ascites but no peripheral edema are susceptible to intravascular volume depletion when they are treated with diuretics; weight loss should thus be limited to 0.5 kg daily. Repeated large-volume paracenteses combined with intravenous albumin is a safe and effective alternative to diuretics that avoids intravascular volume depletion.[65] The subsequent administration of diuretics prevents reaccumulation of ascitic fluid.

Use of Diuretics

Diuretics increase saltwater excretion by impairing tubular reabsorption of the sodium filtered by the glomerulus. The diuretic effect is dose-dependent; the maximum response is determined by the diuretic's site of action within the nephron, the filtered load of sodium, and the amount of sodium reabsorbed by nephron segments unaffected by the diuretic.

Mechanism of action All diuretics except spironolactone are specific inhibitors of luminal transporters and must gain access to the tubular fluid to block sodium reabsorption.[5,63] Because diuretic agents are highly protein bound, they are not readily filtered at the glomerulus; instead, they are actively transported into the urine by the organic acid (in the case of agents such as acetazolamide, thiazides, and loop diuretics) or organic base (in the case of agents such as amiloride and triamterene) via secretory pumps in the proximal tubule. A dose-response curve links the amount of drug reaching the urine to the amount of sodium excretion that is elicited [*see Figure 4*]. Spironolactone binds to the cytosolic receptor for aldosterone, and its diuretic action, unlike that of other diuretics, does not depend on secretion into the tubular lumen.

The most potent agents are those that block sodium transport in the loop of Henle. At high doses, loop diuretics almost totally block sodium reabsorption in this nephron segment, causing about 20% of the filtered load of sodium to be excreted in the urine; at low glomerular filtration rates, the same percentage of filtered sodium is excreted, but the total amount is reduced. Conditions such as volume depletion, heart failure, and cirrhosis, which cause avid sodium reabsorption in the proximal and distal tubules, blunt the maximum response to the diuretic. Because gastrointestinal absorption of diuretics is often delayed in edematous conditions (presumably because of bowel edema), higher oral doses must be used to achieve adequate blood levels. In renal disease and cirrhosis, organic anions such as hippurate and bile acids compete with the diuretic for secretion into the proximal tubule; thus, higher plasma levels may be required to achieve adequate drug levels in the urine. Similarly, severe hypoalbuminemia can diminish drug secretion into the tubular lumen, because albumin binding of most diuretics maximizes the rate of diuretic delivery to the organic anion secretory pump in the proximal tubule. Reduced renal blood flow also limits delivery of drug to the tubular lumen. Some patients with advanced cirrhosis who are resistant to furosemide respond to spironolactone, a generally weak diuretic whose effectiveness does not depend on tubular secretion.

Agents that act in the proximal tubule, loop of Henle, or distal tubule cause potassium wasting and hypokalemia because they

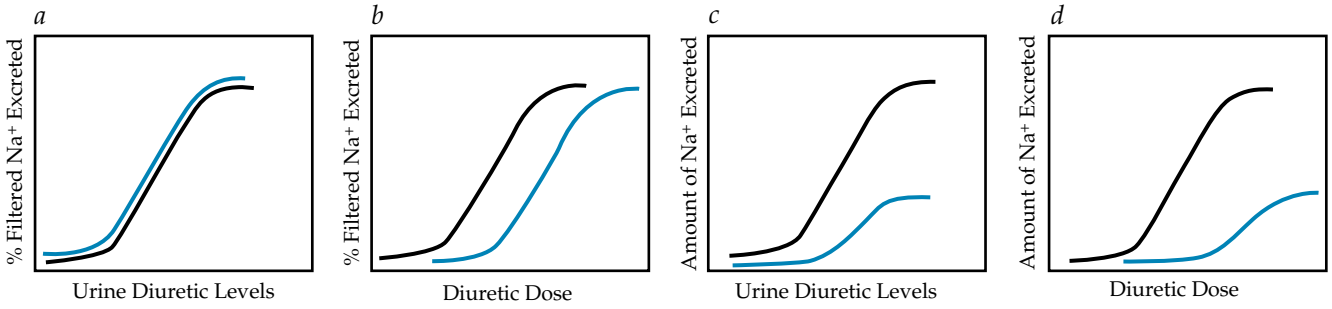

Figure 4 **Dose-response curves for a loop diuretic in patients with normal (black line) and reduced (blue line) renal function. Urinary sodium excretion responds to diuretic levels in the tubular lumen (as reflected by urinary drug levels). The diuretic effect reaches a maximum at approximately 20% of the filtered load of sodium regardless of renal function (*a*). Secretion of the diuretic into the tubular lumen is reduced in renal failure; thus, higher doses are required in azotemic patients to achieve the same urinary drug levels found in patients with normal renal function (*b*). Because the filtered load of sodium is reduced in patients with renal failure, absolute sodium excretion is also reduced, even at high doses (*c* and *d*).**

increase delivery of tubular fluid to the cortical collecting tubule, where potassium secretion is flow dependent. Potassium-sparing diuretics, which act in the cortical collecting tubule, cause hyperkalemia because sodium reabsorption at this site favors potassium secretion. The carbonic anhydrase inhibitor acetazolamide causes metabolic acidosis, as do the potassium-sparing diuretics. Thiazides and loop diuretics cause metabolic alkalosis because of increased distal delivery of sodium to sites where sodium reabsorption stimulates hydrogen ion secretion.

Clinical strategies Diuretic doses should be adjusted to achieve explicit therapeutic goals. Outpatient therapy is usually designed to produce a gradual loss of fluid, with the dose being increased until a desired target weight is reached. The patient should be instructed to keep a daily log that records weight and diuretic dose. Patients are instructed to stop the diuretic if their weight falls too low, resuming at a lower dose when enough saltwater has been retained to restore the target weight.

Inpatient diuretic management should also employ the target-weight concept, but dose adjustments can be made more often and more aggressively, particularly at the start of therapy. It is important to rapidly define the dose that can deliver enough drug to the tubular lumen to reach the steep portion of the dose-response curve. Once an effective dose is defined, larger doses of diuretic provide little benefit. If a greater response is needed, the effective dose should be repeated several times during the day, or alternatively, a continuous infusion can be given to maintain effective urinary drug levels. Continuous infusion of loop diuretics induces a slightly larger natriuretic response than does bolus administration and is associated with a shorter hospital stay in patients with advanced heart failure.[66]

Diuretic resistance Resistance to high doses of loop diuretics may be overcome by administering loop diuretics in combination with a thiazide or metolazone. Acetazolamide may be used along with or in place of a thiazide or metolazone. This strategy blocks sodium reabsorption at several sites along the nephron, avoiding resistance caused by increased sodium reabsorption proximal or distal to the loop of Henle. Careful monitoring is extremely important, because these combinations can be extremely potent, causing large potassium and sodium losses.

Diuretic complications All diuretic agents may cause volume depletion and azotemia, but these complications are most likely to occur with loop diuretics.[4] Hypokalemic alkalosis, hyperglycemia, and hyperuricemia (sometimes with clinical gout) are common dose-dependent complications of both thiazides and loop diuretics. Thiazides decrease calcium excretion and may cause hypercalcemia in patients with underlying conditions that increase gastrointestinal calcium absorption (e.g., sarcoidosis) or bone reabsorption (e.g., hyperparathyroidism). Thiazides are also much more likely to cause hyponatremia than other agents and should be avoided in patients who habitually drink large amounts of fluid. Potassium-sparing agents (e.g., triamterene, amiloride, and spironolactone) may cause hyperkalemia; these agents should generally not be given with potassium supplements, and they should be used with caution in patients with renal insufficiency (particularly diabetic nephropathy) and patients taking ACE inhibitors or angiotensin receptor blockers. Loop diuretics can predispose to hearing loss, particularly when high doses are administered by bolus injection to patients receiving other ototoxic drugs.[35] Hearing loss from ethacrynic acid is more likely to be permanent.

Disorder of Saltwater Deficiency: Volume Depletion

PATHOGENESIS

Volume depletion occurs when saltwater is lost from the extracellular fluid at a rate that exceeds intake. Saltwater can be lost from the gastrointestinal tract, kidney, or skin, or it can result from extravascular sequestration (third-space losses) in the abdominal cavity or in traumatized tissues.

Underfilling of the arterial circulation triggers a cascade of physiologic responses that preserve blood flow to vital organs. Volume receptors and baroreceptors activate the sympathetic nervous system and the renin-angiotensin-aldosterone system. Except when renal salt wasting is the cause, these responses reduce urinary sodium excretion so that nearly all ingested salt is retained. Volume-depleted persons also become thirsty; ingested water is retained because vasopressin, released in response to volume depletion, concentrates the urine, decreasing water excretion. The plasma sodium concentration can be high, normal, or low in volume-depleted persons, depending on electrolyte-free water intake and excretion. Vasoconstriction maintains the systemic blood pressure and also reduces renal blood flow. Initially, efferent arteriolar resistance, mediated by angiotensin II, predominates, sustaining intraglomerular pressure and the

glomerular filtration rate; in more severe hypovolemia, renal blood flow is further reduced and glomerular filtration falls.

ETIOLOGY

Because renal sodium conservation can reduce urinary sodium losses to less than 10 mmol/day, volume depletion is unlikely to occur from decreased intake alone. The small bowel and colon are the most common sources of isotonic fluid loss. Spectacular amounts of isotonic saltwater can be lost in diarrhea. For example, rice-water stool losses in cholera can reach 20 L/day, causing death within a few hours without fluid replacement. Small bowel obstruction causes pooling of several liters of saltwater within the bowel lumen. Fluid may also be sequestrated in the abdominal cavity in patients with pancreatitis or peritonitis. Sequestration of fluid in the soft tissues may also complicate crush injuries with rhabdomyolysis or burns.

Renal salt wasting can cause volume depletion, but only a few disorders can cause enough renal salt loss to be clinically apparent. Diuretics and osmotic diuresis caused by glycosuria are the most frequent causes of renal salt wasting. Transient renal salt wasting may occur in the recovery phases of acute tubular necrosis or obstructive uropathy, and it can also occur in toxic nephropathies. Renal salt wasting also occurs in adrenal insufficiency.

DIAGNOSIS

Clinical Manifestations

Minor degrees of volume depletion (less than 10% of plasma volume, equivalent to the loss of one unit of blood) cause an increase in heart rate and may also be associated with complaints of fatigue, thirst, or muscle cramps. With modest hypovolemia, arteriolar vasoconstriction is sufficient to maintain the blood pressure when the patient is recumbent. However, dizziness and hypotension emerge on standing or during physical exertion. Severe fluid losses cause hypotension in recumbency and, ultimately, signs of tissue ischemia and shock (e.g., cool, clammy extremitites, decreased urine output, lethargy, and confusion). Irreversible tissue injury may occur if this condition is allowed to continue.

Loss of weight within a short period is the most reliable sign of volume depletion. Physical findings include a low jugular venous pulse rate and orthostatic changes in blood pressure and heart rate.[67,68] However, because postural hypotension can occur in up to 30% of normovolemic persons older than 65 years, these changes must be interpreted with caution. Decreased skin turgor and dry mucous membranes are generally unreliable findings in volume-depleted adults; these signs can be absent in severe hypovolemia, and they can be present (particularly in mouth breathers and the elderly) when the patient is actually volume overloaded. The presence of edema makes true volume depletion unlikely.

Laboratory Tests

Laboratory findings are related to the decreased volume of intravascular saltwater and to decreased renal perfusion. The hematocrit increases in proportion to the contraction of plasma volume, and the serum albumin may be increased as well. Urinary sodium is usually less than 20 mEq/L except in metabolic alkalosis (in which the urine chloride is low) or when renal sodium wasting is the cause of the condition.[44,69] Renal blood flow is reduced, but unless the patient is frankly hypotensive, the glomerular filtration rate is maintained by vasoconstriction of the efferent glomerular arteriole. Thus, except in severe volume depletion, the serum creatinine changes very little. Unlike creatinine, urea is reabsorbed from the glomerular filtrate. Thus, in volume depletion (prerenal azotemia), the BUN is increased disproportionately to the increase in creatinine.[69] Azotemia may be blunted in patients with a poor dietary-protein intake and may be exacerbated in patients who are catabolic, bleeding, or receiving steroid therapy.

TREATMENT

Patients with mild volume depletion can be treated by increasing their dietary intake of salt, relying on normal thirst mechanisms to provide the appropriate amount of water. For most patients, the familiar (but misguided) order to drink fluids should be replaced with an order to salt one's food. Even severe volume depletion can be treated with oral solutions containing electrolytes, sugar, and amino acids.[70] Glucose and amino acids promote intestinal absorption of sodium through cotransport mechanisms similar to those found in the proximal tubule of the kidney. Rice-based oral replacement solutions have been a major advance in the treatment of diarrhea in developing countries.

Intravenous fluids are necessary when fluids cannot be taken orally. If the patient is hypotensive, isotonic saline should be given as rapidly as possible until tissue perfusion is adequate. Colloid-containing solutions have no proven advantage over crystalloids.[71] There is no accurate way to estimate the total fluid deficit in hypovolemia other than continued clinical observation of the patient's response to therapy.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

II DISORDERS OF ACID-BASE AND POTASSIUM BALANCE

Robert M. Black, M.D.

Acid-Base Disorders

The blood pH is normally maintained at 7.38 to 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration ($[H^+]$) because blood pH is the negative logarithm of $[H^+]$, as expressed by the following equation:

$$pH = -\log_{10}[H^+]$$

The $[H^+]$ at a physiologic blood pH of 7.40 is 40 nEq/L [*see Figure 1*]. An increase in the $[H^+]$—a fall in the blood pH—is termed acidemia. A decrease in the $[H^+]$—a rise in the blood pH—is termed alkalemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively. Because abnormalities of acid-base metabolism are often associated with potassium imbalance, clinical approaches to hypokalemia and hyperkalemia are also discussed in this chapter.

Normal Acid-Base Physiology

The normal adult diet generates an excess 70 to 100 mEq of acid that must be eliminated every day. Failure to do so results in a persistent fall in the blood pH resulting from a rise in the plasma H^+ ion concentration. The balance of acid-base homeostasis is maintained in part by the relation between the arterial carbon dioxide tension (P_aCO_2) and plasma bicarbonate concentration ($[HCO_3^-]$), as noted in the following equation, a nonlogarithmic expression of the Henderson-Hasselbach equation[1]:

$$[H^+] = 24 \times P_aCO_2/[HCO_3^-]$$

A fall in plasma $[HCO_3^-]$ caused by either gastrointestinal or renal bicarbonate losses also increases the $[H^+]$ and lowers blood pH.

Renal Reabsorption of Bicarbonate

The plasma $[HCO_3^-]$ is normally maintained at approximately 25 mEq/L by the daily reabsorption of the filtered bicarbonate load (about 4,500 mEq) by the kidneys. If the filtered bicarbonate were not reabsorbed, the plasma $[HCO_3^-]$ would fall, as would the blood pH. Thus, maintenance of a normal plasma $[HCO_3^-]$ requires reabsorption of essentially all of the bicarbonate filtered across the glomerular capillaries each day.

Most bicarbonate reabsorption (almost 90%) occurs in the proximal convoluted tubule [*see Figure 2*]; in contrast, the distal nephron reclaims very little bicarbonate. The difference is a result of a complex process, which is facilitated by the greater quantity of carbonic anhydrase in the lumen of the proximal tubule.

Renal Excretion of Acid

In addition to reabsorbing essentially all filtered bicarbonate, the kidneys excrete the daily dietary acid load, derived mainly from sulfur-containing amino acids. The hydrogen ions that are excreted in the final urine are secreted mainly in the collecting tubules [*see Figure 3*]. This secretory process is facilitated indirectly by aldosterone and directly by acid-sensing renal tubular cells.[2]

The daily acid load is excreted into the collecting tubules by the H^+-ATPase pumps located in the luminal membrane of the intercalated cells. This secretory process is inhibited by a trivial quantity of free hydrogen ions that lower the urine pH below the critical level of 4.0 to 4.5. This limitation is normally overcome by the presence of urinary buffers that combine with free hydrogen ions, thus permitting continued secretion of acid. There are several urinary buffers, the most important of which is ammonia because it is the only buffer that can increase substantially in the presence of an acid load. Limitation of the capacity to generate adequate urinary ammonia, as occurs in renal insufficiency, usually leads to acidosis.

The major site of ammonia production in the kidney is the proximal tubule [*see Figure 4*]; ammonia moves from the proximal tubule to the collecting tubule, where it is eliminated [*see Figure 5*]. The quantity of ammonia produced is stimulated both by acidemia and by hypokalemia. Conversely, alkalemia and hyperkalemia limit renal tubular ammonia production and acid excretion.

Metabolic Acidosis

Metabolic acidosis results whenever a primary decrease in the plasma $[HCO_3^-]$ occurs. Such a decrease may be caused by several factors: exogenous acid administration, endogenous acid production, impaired renal hydrogen secretion, and bicarbonate losses from the kidney or in gastrointestinal secretions. Calculation of the plasma anion gap is particularly useful in identifying the specific cause of metabolic acidosis and in narrowing the differential diagnosis.

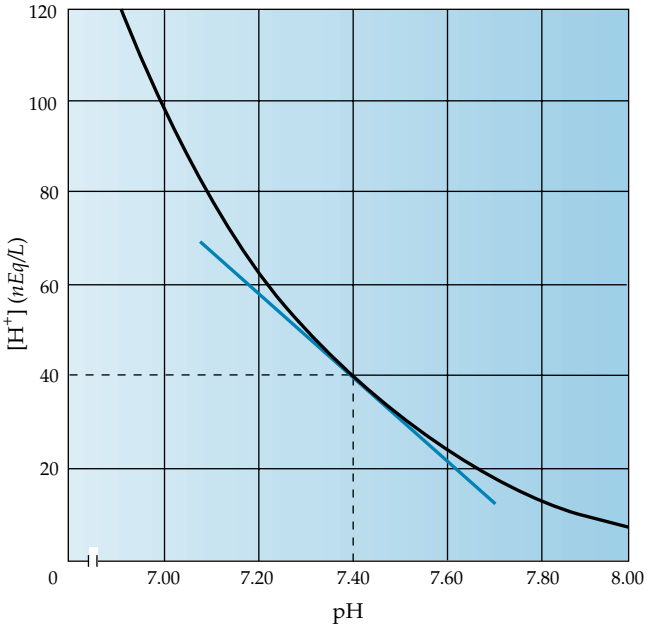

Figure 1 **The relation between the plasma hydrogen ion concentration ($[H^+]$) and the pH of the blood ($pH = -\log_{10}[H^+]$).**

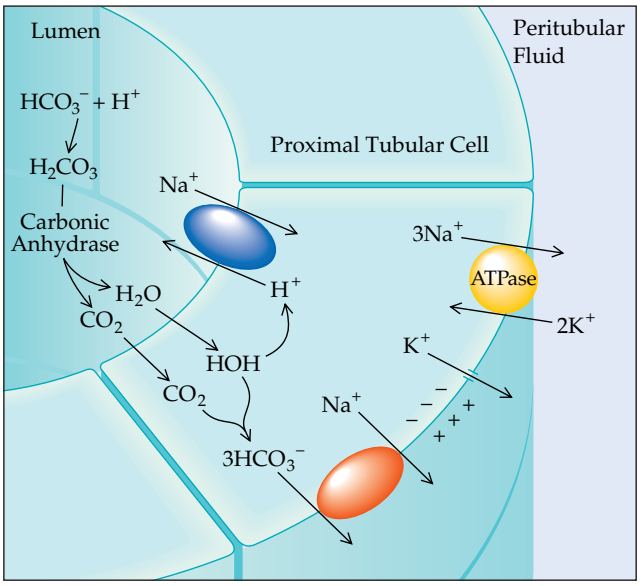

Figure 2 **Proximal tubular bicarbonate reabsorption is activated by the Na^+,K^+-ATPase pump in the peritubular cell membrane. Exchanging peritubular K^+ for intracellular Na^+ keeps the intracellular [Na^+] low, allowing Na^+ to move down its concentration gradient from the tubular lumen through the Na^+-H^+ antiporter to the cell interior. HCO_3^- filtered across the glomerular capillaries combines with secreted H^+ to form H_2CO_3. Rapid dissociation of H_2CO_3 to CO_2 and H_2O in the presence of luminal carbonic anhydrase permits movement into the cell, where redissociation occurs. Ultimately, the reabsorbed H^+ is resecreted in exchange for Na^+, and HCO_3^- moves down an electrical gradient from the cell interior to the peritubular space, where it is reabsorbed into the systemic circulation.**

Anion Gap in Metabolic Acidosis

The anion gap (measured in mEq/L) refers to the difference between the plasma concentrations of the major measured cation (sodium) and the major measured anions (chloride and bicarbonate), as described by the following equation:

$$\text{Anion gap} = [Na^+] - ([HCO_3^-] + [Cl^-])$$

The normal anion gap ranges from 3 to 13 mEq/L, with a mean of about 10 mEq/L. It is composed mainly of plasma proteins (primarily albumin) that carry a negative charge. In the setting of severe hypoalbuminemia, the baseline anion gap may be less than 3 mEq/L, because the anion gap falls by approximately 2.5 mEq/L for every 1 g/dl reduction in the serum albumin concentration.

The most important clinical use of the anion gap is to identify the etiology of metabolic acidosis.[3] The disorders that cause metabolic acidosis fall into two categories: (1) those that cause a fall in the plasma [HCO_3^-] while concomitantly raising the anion gap and (2) those that cause a fall in the plasma [HCO_3^-] without affecting the anion gap. In the latter setting, the plasma [Cl^-] increases, giving rise to a hyperchloremic metabolic acidosis.

Causes of Metabolic Acidosis with a High Anion Gap

Several disorders, as well as the ingestion of toxins, can cause metabolic acidosis with an increased anion gap [*see Table 1*].

Renal failure Advanced renal failure is the most common cause of metabolic acidosis with an increased anion gap in the outpatient setting. The retention of hydrogen ions leads to a fall in the plasma [HCO_3^-]. Because sulfate and phosphate (which are the accompanying anions) are excreted in the urine while chloride is retained, the anion gap remains normal during the early course of acidosis in renal failure. As renal failure progresses (creatinine > 3.0 mg/dl), these ingested anions and metabolic waste products can no longer be excreted normally. At this point, the anion gap increases. There is, however, no linear correlation between the degree of acidemia (or hypobicarbonatemia) and the level of the anion gap. In uncomplicated renal failure, the plasma [HCO_3^-] rarely decreases to less than 12 mEq/L, and the anion gap characteristically remains less than 20 mEq/L.

Lactic acidosis Lactic acidosis is the most common cause of high-anion-gap metabolic acidosis observed in hospitalized patients. Lactic acid production usually increases as a result of hypotension or sepsis, both of which cause true or relative tissue is-

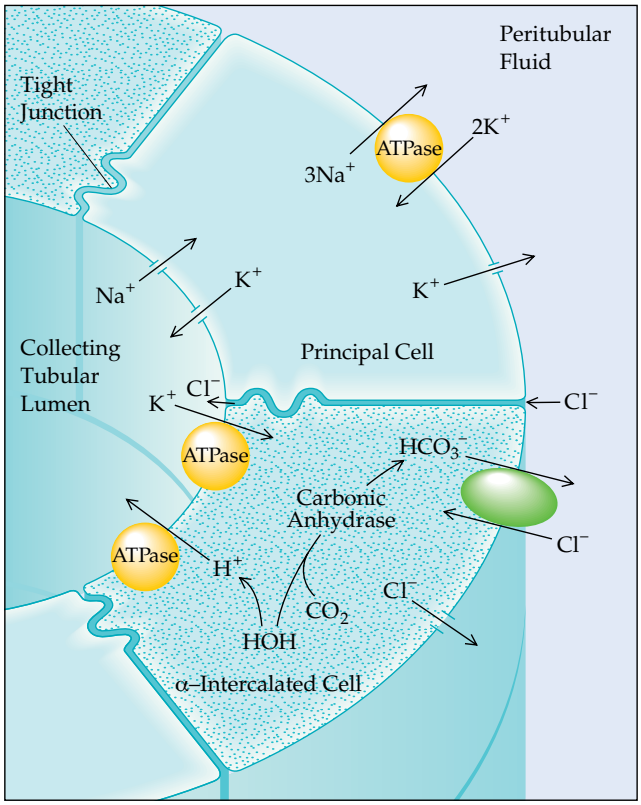

Figure 3 **Secretion of H^+ from the cortical collecting tubule is indirectly linked to Na^+ reabsorption. Intracellular potassium is exchanged for sodium in the principal cells, whereas H^+ is actively transported by an ATPase pump from the α-intercalated cells. Aldosterone stimulates H^+ secretion by entering the principal cell, where it opens Na^+ channels in the luminal membrane and increases Na^+,K^+-ATPase activity. The movement of cationic Na^+ into the principal cells then creates a negative charge within the tubular lumen. K^+ moves from the principal cells and H^+ from the α-intercalated cells down this electrochemical gradient and into the lumen. (When K^+ is depleted, principal cell K^+ secretion is reduced, and K^+ reabsorption via an ATPase pump in the α-intercalated cell is stimulated.) Aldosterone apparently also stimulates the H^+-ATPase directly in the intercalated cell, further enhancing H^+ secretion. HCO_3 is returned to the blood across the peritubular membrane in exchange for Cl^-, thus maintaining electroneutrality.**

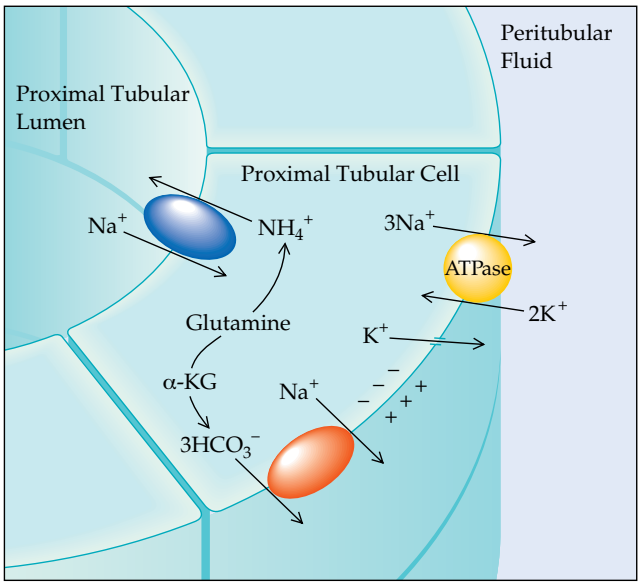

Figure 4 **All of the ammonia used to buffer urinary H^+ in the collecting tubule is synthesized in the proximal convoluted tubule, and glutamine is assumed to be the main source of this ammonia. As glutamine is metabolized, α-ketoglutarate (α-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted into the peritubular fluid by an Na^+-HCO_3^- cotransporter.**

chemia. The oxidative pathways of pyruvate metabolism become markedly impaired in states of mitochondrial dysfunction, such as those induced by tissue hypoxemia. This setting enhances the conversion of pyruvate to lactate. The liver and, to a lesser degree, the kidneys are the major organs that remove lactate from the circulation. In both organs, lactate is converted back to pyruvate and then to carbon dioxide and water via the tricarboxylic acid cycle. When normal tissue perfusion is restored, metabolism of lactate ($CH_3CHOHCOO^-$) in these organs rapidly regenerates the bicarbonate used initially to buffer the acid load, a process that is largely independent of renal acid excretion and that is summarized by the following equation:

$$CH_3CHOHCOO^- + 3O_2 \rightarrow 2CO_2 + 2H_2O + HCO_3^-$$

The normal rate of lactate production can reach 320 mEq/hr (e.g., during exercise), a rate that is usually greater than the rate of lactate production in lactic acidosis. This finding indicates that for lactic acid to accumulate, lactate metabolism must also be impaired. In shock, for example, the marked reduction in hepatic perfusion slows lactate clearance.

Certain medications can also cause lactic acidosis—for example, metformin therapy in diabetics with renal failure and antiretroviral therapy in people with AIDS.[4]

The anion gap is almost always elevated above baseline in lactic acidosis. Because the renal excretory threshold for lactate is 6 to 8 mEq/L and the normal lactate level is less than 1 mEq/L, excess lactate accumulates in the blood, rather than being eliminated in the urine, thus contributing to the increased anion gap.

D-Lactic acidosis is an unusual form of lactic acidosis that is most often seen in patients who have undergone ileal bypass or small bowel resection.[5] In each of these cases, short bowel syndrome can occur, resulting in increased bacterial metabolism of carbohydrate to D-lactic acid because of local overgrowth. In D-lactic acidosis, the anion gap rises initially but may fall over time because renal tubular reabsorption of D-lactate is inefficient in comparison with the reabsorption of L-lactate.

Ketoacidosis Acidosis caused by overproduction of the keto acids acetoacetic acid and β-hydroxybutyric acid occurs when insulin deficiency, fasting, or insulin resistance impairs glucose use. In these settings, ketone bodies are overproduced (a condition termed ketosis) and serve as an alternative source of energy for many cells. The initial ketone formed is acetoacetic acid, which may then be reduced to β-hydroxybutyric acid or nonenzymatically decarboxylated to acetone. Although acetone is chemically neutral, the other ketones are organic acids, and their accumulation leads to metabolic acidosis. The following equation summarizes the reactions:

$$\text{Acetoacetic acid} \longleftrightarrow \beta\text{-hydroxybutyric acid} \longrightarrow \text{acetone}$$

The anion gap characteristically increases in ketoacidosis. Acetoacetate and β-hydroxybutyrate are the major unmeasured anions that accumulate, although a concomitant lactic acidosis may be observed in some patients. The plasma [HCO_3^-] may be markedly depressed in diabetic ketoacidosis; in contrast, the acidemia is generally mild and the plasma bicarbonate rarely less than 18 mEq/L in starvation, or fasting, ketosis.

In patients with ketoacidosis, isotonic fluid replacement leads to ketonuria. At the initiation of fluid replacement, the anion gap is elevated, but it begins to fall as the rate of urinary excretion of acetoacetate and β-hydroxybutyrate exceeds the rate of production. Ultimately, normalization of the anion gap results at a time when the plasma [HCO_3^-] is still low.

Rhabdomyolysis Massive muscle breakdown is an important cause of metabolic acidosis.[6] The retention of metabolic acids and such inorganic anions as phosphate appear to contribute to the increased anion gap. Metabolic acidosis is more likely to develop when concomitant renal failure is present [*see 10:VI Acute Renal Failure*].

Ingested agents and toxins Salicylates and the alcohols ethylene glycol (a component of antifreeze and solvents) and methanol, or wood alcohol (a component of shellac, varnish, deicing solutions, and other commercial preparations), are the most frequent causes of metabolic acidosis among ingested agents and toxins. Ethyl alcohol ingestion is not associated with a high-anion-gap acidosis unless accompanied by either lactic acidosis or ketoacidosis.

The most common acid-base abnormality observed with salicylate intoxication in adults is respiratory alkalosis caused by direct stimulation of the medullary respiratory center [*see* Respiratory Acidosis and Alkalosis, *below*]. In adults, the presence of respiratory alkalosis appears to be a prerequisite for the development of metabolic acidosis, because an isolated metabolic acidosis is rare. Moderate to severe salicylate intoxication, on the other hand, leads to a mixed respiratory alkalosis and a high-anion-gap metabolic acidosis. Methanol and ethylene glycol can produce fatal intoxication, and both can cause a plasma osmolal gap, which refers to the difference between the plasma osmolality (P_{osm}) measured by the laboratory and that calculated by the following formula:

$$\text{Calculated } P_{osm} = (2 \times \text{plasma } [Na^+]) + (\text{glucose concentration}/18) + (\text{blood urea nitrogen}/2.8)$$

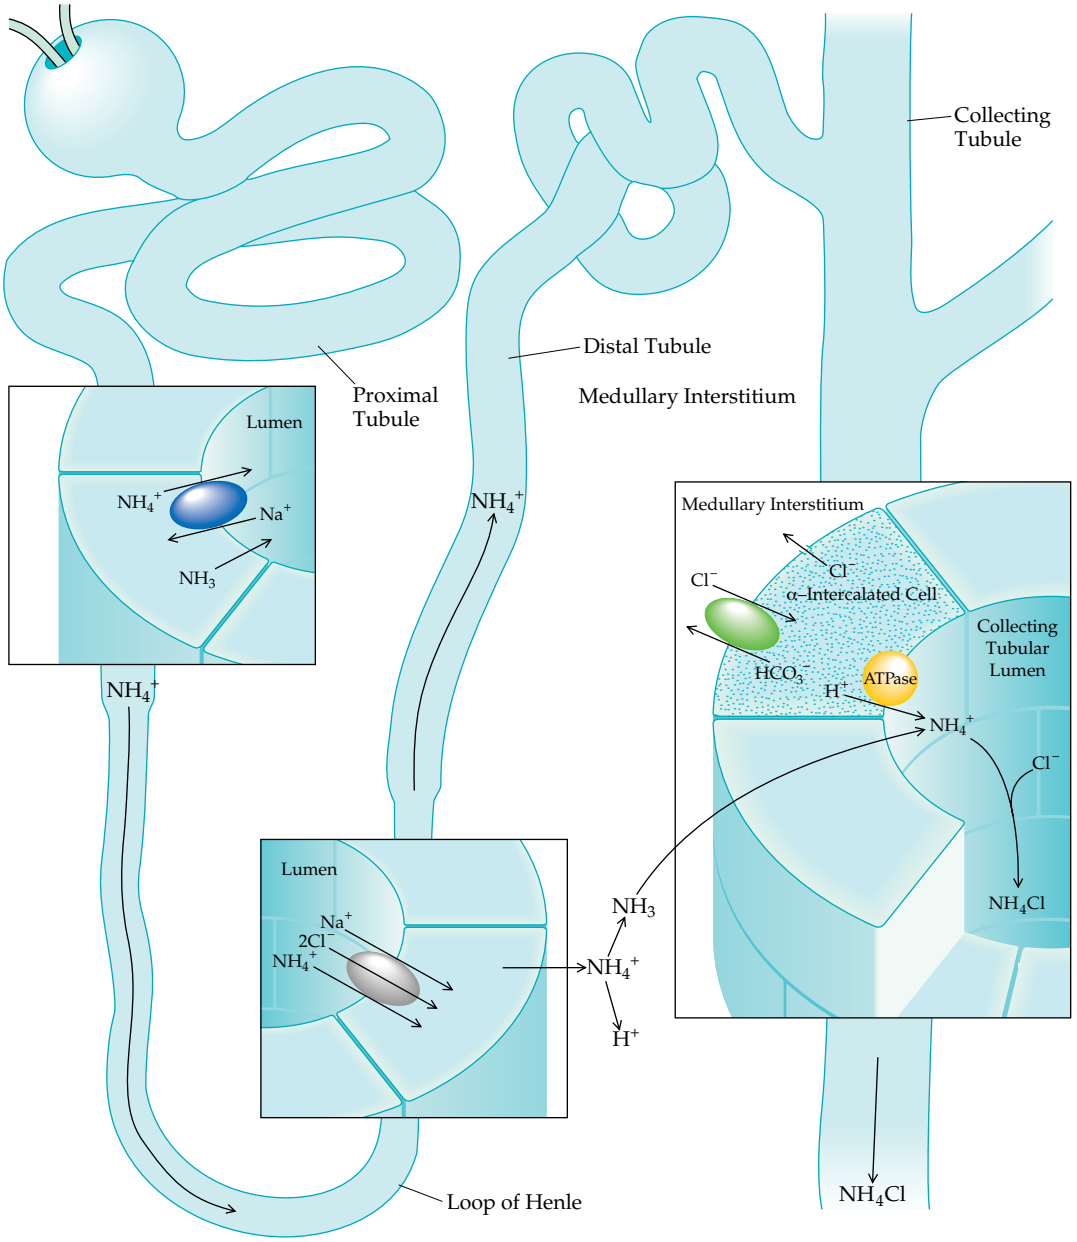

Figure 5 **The ammonia used to buffer urinary hydrogen ions is synthesized in the proximal convoluted tubule. It then diffuses into the proximal tubular lumen or can become acidified within the cell, forming ammonium, which can enter the tubular lumen by substituting for hydrogen ions on the Na^+-H^+ antiporter. Ammonium flows through the thick ascending limb of the loop of Henle, where it is transported from the tubule into the medullary interstitium by replacing potassium on an Na^+-K^+-$2Cl^-$ transporter. In the interstitium, ammonium dissociates to ammonia, which diffuses down its concentration gradient into the lumen of the collecting tubule. Here, ammonia combines with secreted H^+ to form ammonium; NH_4^+ is then excreted as NH_4Cl to maintain electroneutrality. A bicarbonate molecule is regenerated for each H^+ eliminated in the urine.**

A high plasma osmolal gap (with the measured level at least 10 mOsm/kg higher than the calculated value) can be detected only when the P_{osm} is measured by freezing-point depression. In contrast, the osmotic contribution of volatile alcohols is not included when a vapor-pressure osmometer, which assumes that only water is in the vapor phase, is used.[7] Furthermore, the presence of an osmolal gap is not specific for these ingestions, and confirmation of the diagnosis requires plasma assays for the individual drugs [*see* Diagnosis, *below*].

Causes of Metabolic Acidosis with a Normal Anion Gap

A normal anion gap in metabolic acidosis can arise from several causes, including administration of inorganic acids such as hydrochloric acid, loss of bicarbonate from the gastrointestinal tract (e.g., in diarrhea) or the kidneys (e.g., type 2 renal tubular acidosis [RTA]), and impaired renal excretion of hydrogen ions (e.g., renal insufficiency and type 1 RTA) [*see Table 2*]. In the resultant conditions, electroneutrality is maintained by a decrease in plasma bicarbonate and replacement by chloride. Conse-

*May also be associated with a normal-anion-gap acidosis.

quently, these disorders are sometimes collectively referred to as the hyperchloremic acidoses.

Acid and chloride administration The infusion of amino acid solutions during parenteral nutrition supplies abundant hydrochloric acid. In certain settings, administration of a sodium chloride solution also may lower the plasma [HCO_3^-] by dilution (a condition termed expansion acidosis), leading to a fall in blood pH.

Bicarbonate or other alkali losses Bicarbonate can be lost from the body via the gastrointestinal tract or the kidneys. Compared with blood, bowel contents are alkaline because pancreatic and biliary secretions add bicarbonate, which is later exchanged for chloride in the ileum and colon to maintain a normal acid-base status. Gastrointestinal losses of bicarbonate (or bicarbonate precursors such as lactate and acetate) are most commonly observed in patients with severe diarrhea. The diagnosis of diarrhea as the cause of a normal-anion-gap acidosis is usually apparent from the patient's history [*see* Diagnosis, *below*]. Hypokalemia resulting from stool potassium losses also supports the diagnosis.

Less commonly, metabolic acidosis resulting from gastrointestinal alkali losses is caused by pancreatic fistulas, biliary drainage, or urinary diversions to the colon or small bowel.[8] It also occurs after pancreatic transplantation in patients who lose bicarbonate via a pancreas-bladder anastomosis.

Renal bicarbonate losses cause the acidemia observed in type 2, or proximal, RTA and in patients who are posthypocapnic. In type 2 RTA, the normal threshold for bicarbonate reabsorption is reduced. Therefore, bicarbonate can no longer be reabsorbed at a rate adequate to maintain the normal plasma level of about 25 mEq/L. During this phase, bicarbonaturia occurs, leading to a urine pH of greater than 5.3. Bicarbonate wasting ceases, however, once the fall in plasma [HCO_3^-] has stabilized; at this time, the urine pH may be less than 5.

Proximal RTA can be observed in a number of circumstances, including the administration of carbonic anhydrase inhibitors and in some patients with multiple myeloma. In multiple myeloma, toxic damage to the proximal tubular cells by the filtered myeloma light chains often leads to a generalized reduction in proximal reabsorption (including glucose and phosphate) in addition to bicarbonate. This group of maladies, caused by proximal tubular dysfunction, is called the Fanconi syndrome.[9,10]

Hypocapnia leads to a fall in the proximal tubular reabsorption of bicarbonate. After 1 to 3 days, the plasma level of bicarbonate decreases. Because this renal adaptive process requires the same time to cease, a sudden increase in the P_aCO_2 does not immediately alter proximal bicarbonate reabsorption. This posthypocapnic metabolic acidosis resolves spontaneously within 24 to 72 hours.

RTA—renal tubular acidosis

Reduced renal hydrogen ion excretion Reduced renal acid excretion is observed in three conditions: renal insufficiency, type 1 (distal) RTA, and type 4 RTA (hypoaldosteronism) [*see Tables 3 and 4*]. The acidosis of renal failure is primarily caused by a reduction in the number of nephrons. In contrast, type 1 RTA is characterized by a reduction in renal acid excretion by each nephron. Because the total quantity of ammonia that can be synthesized is also reduced in renal failure, the urine pH is lower than 5.3 in most patients.

Type 1 RTA, which may be acquired in association with a number of disorders, such as Sjögren syndrome, occurs most commonly when hydrogen ions cannot be pumped out of the α-intercalated cells into the collecting tubular lumen or when they leak back into the cell from the tubule lumen [*see Figure 3*]. The mutations underlying congenital type 1 RTA may be caused by mechanisms similar to those found in the acquired form or by translocation of the Cl^-/HCO_3^- transporter, from the basolateral to the apical (luminal) membrane of the α-intercalated cells.[11] As a result, the urine cannot be maximally acidified, and the urine pH is always higher than 5.3. Furthermore, hypokalemia is characteristically present, in part because of enhanced distal nephron Na^+-K^+ exchange, a process that is necessary to maintain sodium balance because hydrogen ions cannot be secreted in response to sodium reabsorption.

A hyperkalemic form of distal RTA also has been described; it occurs most often in patients with urinary tract obstruction. This disorder is characterized by extensive tubular injury involving aldosterone-sensitive hydrogen secretion as well as aldosterone-independent hydrogen secretion. The urine pH in patients with this disorder is above 5.3.

The most important clinical complication of hypokalemic type 1 RTA is the formation and deposition of calcium phosphate salts that can cause calculi throughout the kidney (nephrocalcinosis). A major factor contributing to crystal formation is hypocitraturia

*May also cause type 2 RTA [*see Table 5*].
†May also cause metabolic acidosis with an elevated anion gap [*see Table 1*].

caused by an increase in proximal tubular citrate reabsorption. Because calcium citrate is significantly more soluble than calcium phosphate, a decrease in urinary citrate facilitates the precipitation of calcium phosphate crystals in the collecting tubular lumen.

Type 4 RTA may be caused by a number of medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin II blockers, cyclosporine, and heparin. However, it is most often observed in patients with diabetes mellitus [*see* Plasma Potassium Disorders, Hyperkalemia, *below*]. The most common electrolyte disturbance in type 4 RTA is hyperkalemia (plasma $[K^+] > 5.0$ mEq/L), which is caused by impaired luminal reabsorption of sodium ions and, thus, reduced potassium ion secretion by the principal cells of the collecting tubule [*see Figure 3*]. This defect is caused by a reduction in aldosterone production or action. In contrast to hypokalemia, high plasma potassium levels impair renal ammonia production. Insufficient urinary buffer in the form of ammonia limits hydrogen ion secretion in the collecting tubule. Despite this reduced ability to excrete hydrogen ions, the urine is usually acidified (pH < 5.3). This apparently paradoxical finding occurs because the limited urinary buffer permits the free urine $[H^+]$ to exceed the secretory capacity of the α-intercalated cells, thus limiting further hydrogen ion transport from the cells and into the collecting tubular lumen. In contrast to patients with type 1 RTA, patients with type 4 RTA can excrete some acid, albeit in inadequate quantities; consequently, the urine pH is typically lower than 5.3 in patients with this disorder.

Potassium Imbalance in Metabolic Acidosis

Hyperkalemia may be observed in patients with normal anion gap metabolic acidosis; in respiratory acidosis, the shift of potassium from cells to plasma is smaller. A fall in the plasma $[HCO_3^-]$ leads to an exchange of extracellular hydrogen ions for intracellular potassium ions. This defense mechanism permits intracellular buffering of hydrogen ions; the H^+-K^+ exchange maintains electroneutrality. Therefore, the patient who has diarrhea with a normal-anion-gap metabolic acidosis and a low plasma $[K^+]$ has significantly greater potassium depletion than the patient with the same plasma $[K^+]$ and a normal blood pH.

In contrast to what occurs in patients with a normal-anion-gap metabolic acidosis, potassium shifts caused by acidemia are less pronounced in patients with endogenous organic acidoses (e.g., lactic acidosis and ketoacidosis).[12] When hyperkalemia develops in this setting, it is typically caused by renal failure, cellular catabolism that permits leakage of potassium from cells (lactic acidosis), or insulin deficiency and hyperglycemia, both of which promote potassium exit from cells.

Diagnosis

Clinical manifestations Kussmaul respirations suggest the presence of metabolic acidosis. The increase in tidal volume, rather than respiratory rate, that characterizes these ventilatory changes results from stimulation of the brain stem respiratory system by the low pH.

Secondary hypotension also may be observed in severely acidemic persons. In this setting, the reduced blood pressure results from depressed myocardial contractility and arterial vasodilatation, which are induced by the decreased blood pH. Initially, elevated levels of circulating catecholamines counter the cardiovascular effects of acidemia; however, at a blood pH below 7.15 to 7.20, the effects of acidemia may predominate.[13] Reentrant arrhythmias and a reduction in the threshold for ventricular fibrillation can occur, whereas the defibrillation threshold remains unaltered.

The symptoms of metabolic acidosis caused by renal failure depend on the cause, the rapidity with which the renal failure develops, and concomitant conditions that may be present (e.g.,

Table 4 Causes of Type 4 RTA and Aldosterone Resistance

Disorder	*Cause*
Type 4 RTA	Reduced activity of the renin-angiotensin system
	Hyporeninemic type 4 RTA (diabetes most common)
	Nonsteroidal anti-inflammatory drugs (with the possible exception of sulindac)
	Angiotensin-converting enzyme inhibitors
	Angiotensin II receptor blockers
	Cyclosporine
	AIDS*
	Reduced aldosterone synthesis
	Low cortisol levels
	Primary adrenal insufficiency
	Enzymatic deficiencies (primarily adrenal hyperplasia)
	Normal cortisol levels
	Heparin
	Immediately after removal of adrenal adenoma in primary aldosteronism
	Enzymatic deficiencies
Aldosterone resistance (normal or increased aldosterone levels)	Potassium-sparing diuretics, trimethoprim
	Pseudohypoaldosteronism (hereditary or acquired)
	Hyperkalemic type 1 RTA†

*Adrenalitis causing type 4 RTA may also occur in persons who are seropositive for HIV.
†In this setting, the urine is alkaline (pH > 5.3).

congestive heart failure). There may be no abnormal clinical symptoms, despite the presence of azotemia and acidemia.

Ketoacidosis is often associated with increased thirst and polyuria. It is frequently precipitated by an unrelated insult, such as an infection, that may dominate the clinical presentation.

The distinctive characteristics of rhabdomyolysis are myalgia and myoglobinuria, the latter of which leads to reddish urine that has no significant red cells. In many patients, however, neither finding is present. Despite the lack of findings, serum creatine kinase levels are uniformly elevated.

The symptoms and signs of lactic acidosis are characteristically those of the underlying disturbance causing the disorder—namely, hypotension or sepsis. Most commonly, patients exhibit evidence of hypoperfusion, such as low blood pressure and cool or mottled extremities. Less commonly, a medication (e.g., metformin) may be the cause. Patients with D-lactic acidosis may present with encephalopathy. L-Lactate dehydrogenase is the standard assay for the diagnosis of lactic acidosis; because this test does not measure D-lactic acid, a specific enzymatic assay for D-lactate (i.e., one that uses D-lactic dehydrogenase) is necessary to confirm the diagnosis of D-lactic acidosis.

In addition to acid-base changes, clinical findings that may accompany severe salicylate intoxication include tinnitus, hyperpyrexia, vasodilatation leading to shock, and peripheral or pulmonary edema. Symptoms of acidosis caused by ingestion of methanol or ethylene glycol [*see* Ingested Agents and Toxins, *above*] may develop 12 to 36 hours after ingestion. In addition to acid-base changes, the initial symptoms that occur after ingestion of methanol include weakness, nausea, headache, and decreased vision, which can progress to blindness, coma, and death. Fundoscopic examination may reveal a retinal sheen caused by retinal edema. After ethylene glycol is ingested, the earliest findings are neurologic abnormalities that range from drunkenness to coma. If the patient is not treated, these changes may be followed first by cardiopulmonary symptoms (tachypnea and pulmonary edema) and then by flank pain and renal failure caused by calcium oxalate crystal deposition, which may be seen in the urine sediment [*see Figure 2 in 10:XII Nephrolithiasis*].

Laboratory tests The diagnosis of metabolic acidosis is made relatively easily in the presence of a low blood pH and a low plasma [HCO_3^-]. The anion gap can then be used to identify a specific cause. The finding of concomitant hypokalemia or hyperkalemia may also be useful.

Once the presence or absence of a high serum anion gap is determined, the respiratory defense against acidemia can be evaluated. The respiratory response begins immediately, although it may not be maximal for 12 to 24 hours. The appropriate respiratory compensation can be calculated by using the Winter[14] formula:

$$\text{Expected } P_{CO_2} = 1.5\,[HCO_3^-] + 8 \pm 2$$

The respiratory compensation is inadequate when the measured P_aCO_2 is higher than the expected value and is excessive when the P_aCO_2 is lower than the expected value. When these inadequate or excessive responses occur, a superimposed respiratory acidosis or respiratory alkalosis, respectively, is present [*see* Respiratory Acidosis and Alkalosis, *below*]. For example, if the serum [HCO_3^-] were 16 mEq/L in a patient with a low blood pH (metabolic acidosis), the expected P_{CO_2} would be approximately 32[(1.5 × 16) + 8] mm Hg. A P_{CO_2} below this value indicates a superimposed respiratory alkalosis.

Another laboratory calculation, the urinary anion gap, may be useful in defining the cause of metabolic acidosis when the serum anion gap is normal. For example, although the diagnosis of diarrhea is usually apparent from the patient's history and the presence of hypokalemia, a profile of plasma electrolytes similar to that in persons with diarrhea may be observed in patients with type 1 RTA. These disorders can usually be distinguished by the urine pH; the urine tends to be acidic (pH < 5.3) in patients with diarrhea and tends to be alkaline (pH > 5.3) in patients with type 1 RTA. In some patients with diarrhea, however, the urine may be alkaline, presumably because ammonia production (induced by hypokalemia) increases to such an extent that urinary buffer is produced in excess of hydrogen ion secretion.

Calculation of the urinary anion gap, as shown in the following equation, may be quite useful in providing an estimate of urinary ammonia secretion:

$$\text{Urinary anion gap} = (\text{urinary } [Na^+] + \text{urinary } [K^+]) - \text{urinary } [Cl^-]$$

Whenever secreted hydrogen ions are excreted as ammonium chloride ($NH_4^+Cl^-$), an increase in urinary chloride excretion results. The increase in urinary chloride excretion decreases the urinary anion gap, leading to a negative value in most patients with diarrhea. By comparison, in type 1 RTA, the urinary anion gap is positive. As an example, a patient with a normal anion gap metabolic acidosis (e.g., [HCO_3^-] = 10 mEq/L), a low potassium level (hypokalemia), and an alkaline urine pH (6.0) could have diarrhea or type 1 RTA. If the urine [Na^+] were 50 mEq/L, the urine [K^+] were 28 mEq/L, and the urine [Cl^-] were 55 mEq/L, the urinary anion gap would be +23, supporting a diagnosis of RTA.

Despite the potential value of the urinary anion gap in estimating urinary $NH_4^+Cl^-$ excretion, the presence of certain anions (e.g., β-hydroxybutyrate and acetoacetic acid) can contribute to a positive urinary gap. This may erroneously suggest that metabolic acidosis is caused by RTA rather than diarrhea. The urinary osmolal gap, which largely represents ammonium salts, can be used to confirm that the positive urinary anion gap is the result of type 1 RTA**.** The urinary osmolal gap is the difference between the urinary osmolality (U_{osm}) measured by the laboratory and that calculated by the following formula:

$$\text{Calculated } P_{osm} = (2 \times \text{plasma } [Na^+]) + (\text{glucose concentration}/18) + (\text{blood urea nitrogen}/2.8)$$

The multiple of 2 accounts for the anions accompanying sodium and potassium, whereas the divisors 2.8 and 18 reflect adjustments required to convert the blood urea nitrogen and glucose findings from the routinely used units of mg/dl to mmol/L or mOsm/kg. The normal urinary osmolol gap is 80 to 100 mmol/L, reflecting an NH_4^+ excretion rate of about half this value—namely, 40 to 50 mEq/L—as a result of the accompanying anion chloride. In the presence of metabolic acidosis, the value should be significantly increased; a normal or lower value in an individual with metabolic acidemia strongly supports impaired $NH_4^+Cl^-$ excretion—and, ultimately, type 1 RTA—as the underlying cause for the positive anion gap.

Treatment

Treatment of metabolic acidosis is aimed at correcting both acidemia and the underlying disorder. The likelihood that alkali administration is needed and that it will be effective depends on

the blood pH, the compensatory mechanisms, and the underlying condition.

Until the arterial blood pH falls below 7.15 to 7.20, the adverse effects of acidemia are usually compensated for by elevated plasma catecholamines [*see* Diagnosis, *above*]. To maintain adequate buffer reserves, alkali therapy should be considered to keep [HCO_3^-] higher than 10 to 12 mEq/L. Alkali administration is usually unnecessary, however, if the acidosis is likely to resolve spontaneously (as in lactic acidosis after a grand mal seizure). Therapy must take into consideration the underlying cause of metabolic acidosis (see below).

Chronic renal failure Of interest is the finding that the acidemia tends to be more severe in nondiabetic patients with chronic renal failure than in diabetic patients with similar degrees of renal insufficiency.[15] This difference may be the result of more efficient extrarenal bicarbonate generation in diabetic patients.

As long as the metabolic acidosis is mild, many adults with renal failure are not treated with alkali replacement, partly because of a concern that sodium bicarbonate will exacerbate the volume expansion and hypertension that are commonly present.

Some studies, however, have suggested several reasons for the use of alkali replacement therapy in patients with renal failure.[16-18] Among the reasons are the likelihood that acidemia can enhance the breakdown of skeletal muscle, reduce albumin synthesis, and (by activating the complement system) contribute to tubulointerstitial injury and that bone buffering of hydrogen ions can lead to bone resorption.[19] These findings have led some physicians to advocate the early use of alkali therapy to maintain plasma [HCO_3^-] above 22 mEq/L. Definitive studies are still needed, however, to ascertain the benefit of such treatment.

Physicians should be aware that electrolyte studies in hemodialysis patients who use non–hospital-based dialysis units may be performed in central laboratories several hundred miles away. Compared with results of samples obtained locally, samples tested at the central laboratories appear to show consistent and clinically important decreases in serum [HCO_3^-].[20] This in vitro enhancement of metabolic acidosis should be confirmed before treatment is initiated.

Lactic acidosis Correcting the underlying disorder is the primary therapy for lactic acidosis. Reversal of circulatory failure, hypoxemia, or sepsis reduces the rate of lactate production and enhances its removal.

As in chronic renal failure, the use of alkali therapy in lactic acidosis is controversial.[21,22] The principal rationale for bicarbonate administration is the potential maintenance of normal cardiovascular homeostasis. This possible advantage must be weighed against deleterious side effects, such as volume overload, hypernatremia, and alkalosis (when excessive bicarbonate is administered).

Clinical studies also suggest that sodium bicarbonate therapy may not improve either the blood pH or the survival of patients with lactic acidosis. The administration of sodium bicarbonate has been observed to reduce cardiac performance in patients with cardiac disease, congestive heart failure, or acute myocardial infarction.[23] This lack of efficacy possibly results from an associated increase in net lactic acid production, although hyperosmolality of the administered alkali solution also may be important. The finding that dichloroacetate (which promotes the conversion of pyruvate into the Krebs cycle instead of permitting its conversion to lactate) can lower lactate levels and raise the blood pH in patients with lactic acidosis without seeming to improve survival lends further support to the concept that treating the underlying cause of lactic acidosis is more important than treating the acidemia. In view of these observations, a reasonable approach may be to administer bicarbonate to maintain the arterial blood pH at higher than 7.15 and the plasma bicarbonate at higher than 10 mEq/L. If one of the complications of bicarbonate therapy ensues, the benefit of continuing alkali therapy should be reevaluated.

Therapy for D-lactic acidosis must address the two underlying factors that contribute to the overproduction of D-lactic acid: the presence of intestinal bacteria that produce D-lactic acid and the enhanced delivery of carbohydrates to the colon secondary to short bowel syndrome. Treatment usually consists of antibiotic therapy to decrease the number of D-lactate–producing organisms. Alkali therapy has been used but has not been evaluated in a controlled fashion.

Ketoacidosis The trend toward normal-anion-gap metabolic acidosis during recovery from ketoacidosis has an important effect on the rate at which acidemia can be corrected. A maximal rate of 500 ml of fluid an hour appears to be effective replacement therapy for patients with ketoacidosis. Significantly higher rates of fluid administration can result in a decreased anion gap without an increase in the plasma [HCO_3^-]. Once this occurs, correction of the acidosis requires regeneration of bicarbonate by the kidney, a process that may take at least 2 to 3 days[24]; consequently, more vigorous fluid administration (above 500 ml/hr) may delay recovery from acidosis. The rate of fluid administration should be slowed after intravascular volume compromise—manifested by reduced blood pressure or increased plasma creatinine and urea nitrogen concentrations—has been corrected.

Although exceptions occur, the administration of sodium bicarbonate is not usually necessary in ketoacidosis, because there appears to be no difference in mortality between patients treated with sodium bicarbonate and control subjects. Bicarbonate therapy may be a risk factor for the subsequent development of cerebral edema in this setting.[25]

Salicylate, ethylene glycol, and methanol intoxication Salicylate removal is enhanced by urinary alkalinization (to maintain the blood pH between 7.45 and 7.5), which increases urinary excretion even in the setting of dialysis.[26] The usual treatment of ethylene glycol or methanol intoxication is to administer an agent that will reduce conversion of the nontoxic alcohol to its toxic metabolic by-products and to use dialysis in the presence of tissue damage or acidemia. Although ethyl alcohol has been administered historically, fomepizole (4-methylpyrazole) is the only potent inhibitor of alcohol dehydrogenase that has been studied prospectively and that has been approved by the Food and Drug Administration for this condition.[27]

Hyperchloremic acidoses The therapeutic approach to the patient with diarrhea and metabolic acidosis depends upon the severity of the two disturbances. Alkali administration is not necessary with mild to moderate reductions in the plasma [HCO_3^-] if the diarrhea is controlled (thereby minimizing further bicarbonate loss) and renal function is normal (thereby allowing acid excretion to increase). However, some patients will require treatment with bicarbonate.

The acidemia in type 1 RTA can be corrected with bicarbonate

or with a bicarbonate precursor, such as citrate. The usual requirement is 1 to 3 mEq/kg/day. Correcting the acidemia reduces tubular citrate reabsorption, which leads to an increase in urinary excretion and a decrease in the tendency toward nephrolithiasis and nephrocalcinosis. Usually, a potassium salt, such as potassium citrate, is administered because it corrects the potassium deficit as well.

In adults, treatment of type 2 RTA is aimed at the underlying cause (e.g., multiple myeloma). Because the acidemia is typically mild, alkali therapy may not be necessary. Correction of acidemia is appropriate in children because in this age group, acidemia is more likely to impair growth and contribute to metabolic bone disease.

Type 4 RTA, if mild, may not require treatment. Aldosterone replacement with fludrocortisone (0.1 to 1 mg/day) may increase acid secretion by lowering the serum [K^+]; however, many patients cannot tolerate the side effects (e.g., edema and hypertension) associated with this therapy. In these individuals, correction of serum [K^+] may be achieved by administration of a loop diuretic, dietary potassium restriction, or the elimination of drugs that promote hyperkalemia. When fludrocortisone therapy is required, concomitant administration of a loop diuretic may limit the development of high blood pressure and fluid retention.

METABOLIC ALKALOSIS

Primary metabolic alkalosis is characterized by an elevated plasma [HCO_3^-] and an arterial pH greater than 7.42. When there is concomitant metabolic acidosis, however, the blood pH may be increased, decreased, or normal. Furthermore, hyperbicarbonatemia alone is not diagnostic of primary metabolic alkalosis, because it may also represent the appropriate physiologic response to chronic respiratory acidosis. These conditions can usually be easily distinguished by measuring the arterial blood pH, which is reduced in respiratory acidosis.

Causes of Metabolic Alkalosis

Metabolic alkalosis is a relatively common clinical problem that is most often induced by diuretic therapy or the loss of gastric secretions as a result of vomiting or nasogastric suction.[28] Two abnormalities must be present for metabolic alkalosis to develop and to be sustained. First, there must be an initial increase in the plasma [HCO_3^-] caused by hydrogen loss in gastrointestinal secretions or in the urine, hydrogen movement into cells, alkali administration, or volume contraction around a relatively constant amount of extracelluar bicarbonate (called a contraction alkalosis) [*see Table 5*]. Second, one of three factors (in the absence of advanced renal failure) must be present to sustain the high plasma [HCO_3^-] once the initiating event has been terminated: effective circulating volume depletion, chloride depletion, and hypochloremia or hypokalemia [*see* Additional Factors Contributing to Metabolic Alkalosis, *below*].

Gastrointestinal hydrogen loss Gastric juice contains a high concentration of hydrochloric acid and a lesser amount of potassium chloride. Each 1 mEq of hydrogen lost generates 1 mEq of bicarbonate. In normal persons, gastric hydrogen secretion does not lead to metabolic alkalosis, because it is matched by pancreatic bicarbonate secretion that is stimulated as the acid enters the duodenum. There is no stimulus to bicarbonate secretion, however, when vomiting or nasogastric tube drainage prevents the hydrogen ions from reaching the duodenum. Vomiting can be surreptitious in some cases, such as in patients with eating disorders. In some patients, laxative abuse can also lead to a metabolic alkalosis, most likely resulting from a hypokalemia-induced increase in urinary ammonia production, which in turn leads to increased ammonium chloride excretion in the urine.

Table 5 Causes of Metabolic Alkalosis

Disorder	*Cause*
Hydrogen loss	Gastrointestinal losses Removal of gastric secretions (vomiting or nasogastric suction)* Chloride-losing diarrheal states Laxative abuse Renal losses Loop or thiazide diuretics* Mineralocorticoid excess Posthypercapnic alkalosis Hypercalcemia (including milk-alkali syndrome) High-dose intravenous penicillin derivatives Bartter syndrome
Intracellular hydrogen shift	Hypokalemia
Bicarbonate retention	Administration of alkali (as either a bicarbonate or a bicarbonate precursor with massive blood transfusions or with absorbable antacids)†
Contraction alkalosis	Diuretics* Loss of gastrointestinal secretions having high [Cl^-] and low [HCO_3^-] when compared with plasma (usually with vomiting)*

*These are the most common causes.
†For alkalosis to be maintained, renal bicarbonate excretion also must be impaired by either reduced filtration or enhanced reabsorption by the proximal tubule.

Renal hydrogen loss An inappropriate renal acid loss may occur when there is an increase in hydrogen ion secretion by the distal nephrons. Mineralocorticoids, including aldosterone, act here both by directly stimulating the secretory H^+-ATPase pump and by making the tubular lumen more electronegative through the stimulation of sodium reabsorption [*see Figure 6*]. Distal potassium secretion is also enhanced in this setting and results in concurrent hypokalemia.

Metabolic alkalosis associated with loss of renal hydrogen may be caused by mineralocorticoid excess, administration of loop or thiazide diuretics, posthypercapnic alkalosis, or hypercalcemia (e.g., milk-alkali syndrome) [*see Table 5*]. Metabolic alkalosis also occurs in Bartter and Gitelman syndromes. These two disorders produce electrolyte abnormalities similar to those caused by diuretic therapy because they are associated with defects in the transporters in the loop of Henle and the distal tubule, respectively, that inhibit mechanisms also inhibited by loop and thiazide diuretics [*see* Bartter Syndrome and Gitelman Syndrome, *below*]. Any cause of mineralocorticoid excess, such as primary aldosteronism, can result in metabolic alkalosis. Primary aldosteronism is generally accompanied by hypertension and hypokalemia. In contrast, untreated patients with secondary aldosteronism caused by congestive heart failure or cirrhosis usually do not present with metabolic alkalosis or hypokalemia. In such cases, the effect of aldosterone is counteracted by decreased distal sodium delivery (unless diuretics are administered) and reduced urine volume; these factors limit the quantity of acid and potassium secreted into, as well as excreted in, the final urine.

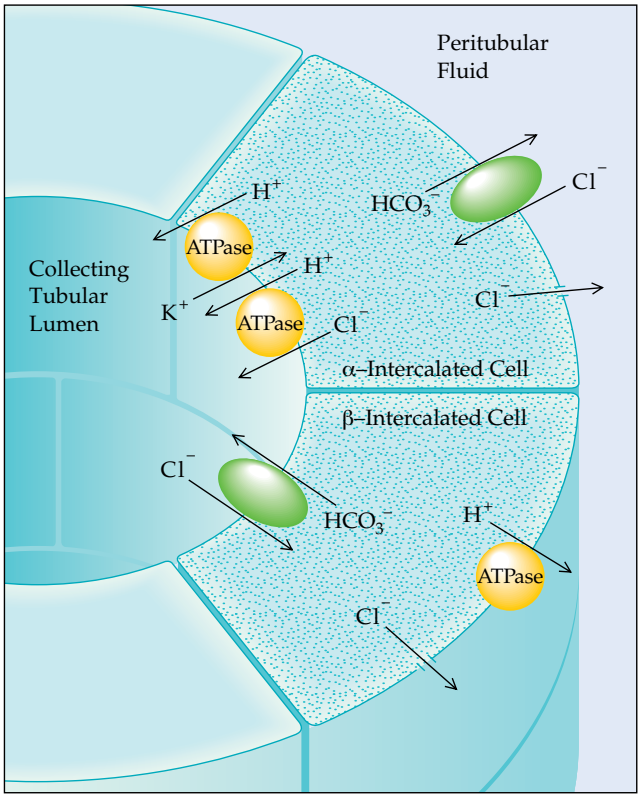

Figure 6 **In metabolic alkalosis, the high ratio of α-intercalated to β-intercalated cells decreases. Unlike α-intercalated cells, which regenerate bicarbonate and add it to the venous blood, β-intercalated cells promote urinary HCO_3^- excretion by exchanging HCO_3^- for Cl^- in the glomerular filtrate. As a result, chloride administration serves an important function in the treatment of most persons with metabolic alkalosis.**

When patients are treated with either thiazide or loop diuretics, adequate distal delivery of sodium chloride and increased secretion of aldosterone occur. The increase in distal hydrogen ion secretion and volume contraction, if the diuresis has been large, contribute to the development of metabolic alkalosis.

Chronic respiratory acidosis brings about an appropriate increase in hydrogen secretion, as the rise in the plasma [HCO_3^-] raises the pH toward normal. Rapid lowering of the P_aCO_2, usually by mechanical ventilation, leads to metabolic alkalosis, as the patient is left with an elevated plasma [HCO_3^-]. This abnormality is called a posthypercapnic metabolic alkalosis.

Hypercalcemia Hypercalcemia increases renal tubular bicarbonate reabsorption. Significant metabolic alkalosis in hypercalcemic patients, however, is more commonly seen in those with milk-alkali syndrome. In milk-alkali syndrome, an increased alkaline load (caused by the ingestion of calcium carbonate) and hypercalcemia-induced renal failure increase bicarbonate production and diminish bicarbonate excretion. Metabolic alkalosis can be observed in any severe hypercalcemic state that is caused by volume contraction and by impaired sodium chloride and potassium chloride absorption resulting from tubular injury.

Intracellular hydrogen shift In addition to being caused by hydrogen loss, metabolic alkalosis can be caused by a shift of hydrogen into the cells. Both vomiting and diuretic therapy directly induce potassium and hydrogen loss. Hypokalemia produces a transcellular shift in which potassium leaves cells to replete extracellular stores; to maintain electroneutrality, hydrogen enters the cells. This shift not only raises the extracellular pH but also decreases the intracellular pH; the latter promotes proximal tubular bicarbonate reabsorption and distal hydrogen ion secretion.

Alkali administration The administration of sodium bicarbonate at a dosage as high as 1,000 mEq/day does not normally induce metabolic alkalosis in normal persons, because the excess bicarbonate is rapidly excreted in the urine. If the ability to excrete bicarbonate is impaired, however, metabolic alkalosis can occur when a very large quantity of bicarbonate or a bicarbonate precursor (e.g., lactate, citrate, or acetate) is administered, as occurs with citrate in large-volume blood transfusions.

Contraction alkalosis Contraction alkalosis develops when loss of relatively large volumes of bicarbonate-free fluid occurs. In this setting, the plasma [HCO_3^-] rises because the extracellular volume contracts around a relatively constant quantity of extracellular bicarbonate.

The most common cause of contraction alkalosis is administration of a loop diuretic to induce rapid fluid removal in a patient with marked edema. Similarly, contraction alkalosis occurs under other conditions in which fluid with a high chloride concentration and a low [HCO_3^-] is lost. Among these causes are receipt of thiazide diuretics; loss of gastric secretions (even in patients with achlorhydria); sweat losses in patients with cystic fibrosis; and diarrhea in some patients with villous adenomas or congenital chloridorrhea.

Additional factors contributing to metabolic alkalosis In the absence of advanced renal failure, one of three factors must be present to sustain high plasma [HCO_3^-]: effective circulating volume depletion, chloride depletion, or hypokalemia.

Both the fall in the glomerular filtration rate (GFR) and the associated sodium avidity seen with hypovolemia limit the excretion of sodium bicarbonate. Most bicarbonate is reabsorbed in the proximal tubule [*see Figure 2*]. An important stimulus for enhanced reabsorption in this nephron segment is increased activity of the Na^+-H^+ antiporter in the tubular cell membranes. Volume contraction promotes Na^+-H^+ exchange in this nephron segment, in part through the release of angiotensin II. The hydrogen ions secreted into the lumen combine with filtered bicarbonate, ultimately leading to a higher rate of transport back into the tubular cells. More bicarbonate is returned to the venous blood at the level of the collecting tubules, partly under the influence of secondary aldosteronism. Volume depletion does not cause metabolic alkalosis without selective chloride losses. For example, blood loss does not increase the [HCO_3^-], because the chloride losses are identical to those in an equal volume of plasma.

Chloride depletion can both promote bicarbonate regeneration and decrease distal bicarbonate secretion. Bicarbonate generation in the α-intercalated cells in the cortical collecting tubule is mediated by hydrogen ion secretion via H^+-ATPase pumps in the luminal membrane [*see Figure 6*]. Passive cosecretion of chloride is required to maintain electroneutrality. Intracellular bicarbonate is returned to the systemic circulation in exchange for chloride.

The β-intercalated cells in the cortical collecting tubule (which increase in number when metabolic alkalosis develops) are able to secrete bicarbonate directly by reversing the location

of the transporters [*see Figure 6*]. Thus, the Cl-HCO_3^- exchangers are located in the luminal membrane, leading to bicarbonate secretion into the tubular lumen; the H^+-ATPase pumps are located in the basolateral membrane. Although the activity of these cells is appropriately enhanced by alkalemia in an attempt to excrete the excess bicarbonate, the associated fall in the tubular fluid [Cl^-] diminishes the favorable inward gradient for chloride, thereby reducing bicarbonate secretion. However, chloride depletion in humans is almost always associated with effective volume depletion.

Hypokalemia directly increases bicarbonate reabsorption by at least two different mechanisms. First, the fall in plasma [K^+] shifts potassium from hydrogen into cells. The ensuing intracellular acidosis stimulates hydrogen secretion and bicarbonate reabsorption in the proximal and collecting tubules. Second, distal hydrogen and potassium secretion is mediated in exchange for luminal sodium [*see Figure 6*]. In states of potassium depletion, the rate of hydrogen secretion in exchange for sodium increases. As a result, hypokalemia and hyperaldosteronism, which stimulate hydrogen ion secretion, can have a potentiating effect on the development and maintenance of metabolic alkalosis.

Diagnosis

Clinical manifestations Some individuals with metabolic alkalosis have severe cramping, paresthesias, or even tetany, but others with similar electrolyte levels do not; the reason for this difference in presentation is unclear. Other clinical findings are the result of the underlying etiology (e.g., hypertension with primary hyperaldosteronism).

The diagnosis of metabolic alkalosis is usually evident from the patient's history of vomiting or receipt of diuretic therapy. In some cases, however, no cause for the metabolic alkalosis is apparent. In such a setting, the most likely diagnosis is surreptitious vomiting caused by an eating disorder, use of diuretics, or one of the causes of mineralocorticoid excess (e.g., primary aldosteronism). The first two factors induce effective volume depletion, whereas primary hyperaldosteronism is usually associated with mild volume expansion as a result of the stimulatory effect of aldosterone on renal sodium reabsorption.

Several findings on physical examination may suggest surreptitious vomiting as the cause, including dental erosion from repeated exposure to acid gastric secretions and the presence of ulcers and calluses on the dorsum of the hand caused by sticking a finger in the back of the throat to induce vomiting.

Laboratory tests Measurement of the [Na^+] in a random urine specimen is used in many conditions to distinguish between volume depletion (urinary [Na^+] usually < 20 mEq/L) and euvolemia (urinary [Na^+] > 40 mEq/L). However, metabolic alkalosis is one of the conditions in which volume depletion may not lead to a low urinary [Na^+]. The capacity to retain sodium in this setting may be antagonized by the need to excrete bicarbonate (as the sodium salt) in an attempt to correct the alkalosis. In such cases, a random urinary [Cl^-] determination is more useful.

Sodium wasting is most likely to occur during the first few days of vomiting, when the plasma [HCO_3^-] and thus the filtered bicarbonate load are increased. Early in the course of vomiting, the ability to enhance bicarbonate reabsorption has not yet occurred. The net effects are a high urinary [Na^+] and urinary [K^+] and a urine pH of greater than 7.0 caused by bicarbonaturia.

As a result, the urinary [Na^+] is not necessarily an accurate reflection of the patient's volume status in metabolic alkalosis. The presence of underlying hypovolemia can be detected more accurately by the finding of a urinary [Cl^-] below 25 mEq/L. The appropriate chloride conservation is caused both by volume depletion and by hypochloremia induced by chloride losses in gastric secretions. The urinary chloride concentration may be inappropriately elevated, however, if a defect in chloride reabsorption is present. Such a defect most commonly occurs in patients who receive diuretic therapy. Thus, in patients with metabolic alkalosis caused by vomiting, the urinary chloride concentration is typically low; it is higher when diuretics are administered. In both circumstances, the urinary [Na^+] may be elevated.

Bartter syndrome and Gitelman syndrome Bartter and Gitelman syndromes are disorders of sodium chloride reabsorption in the loop of Henle and the distal tubule, respectively.[29] Bartter syndrome is a rare disorder that causes hypokalemic metabolic alkalosis. Because the urinary [Na^+] and urinary [Cl^-] are usually higher than 25 mEq/L, surreptitious diuretic use is the major disorder to be considered in the differential diagnosis. Classic Bartter syndrome generally presents in early life and may be associated with delayed growth and mental retardation. The spectrum of findings, including hypercalciuria, is most compatible with a primary defect in sodium chloride reabsorption in the medullary thick ascending limb of the loop of Henle.

Gitelman syndrome is a more benign condition that may be inherited as an autosomal recessive disease; it may not be diagnosed until late childhood or even adulthood. In contrast to patients with Bartter syndrome, who have a defect in urinary concentrating ability (normal function of the loop of Henle is needed to generate a high interstitial osmotic gradient), patients with Gitelman syndrome can demonstrate normal urinary concentrating ability and have hypocalciuria. This finding suggests that the defect resides in the distal tubule, because similar findings are observed in patients treated with thiazide diuretics. Bartter and Gitelman syndromes are diagnosed only after diuretic use—the other, much more common, cause of these findings—has been excluded.

Treatment

In patients with true volume depletion caused by vomiting, nasogastric suction, villous adenomas, or diuretic therapy, metabolic alkalosis can be corrected by the administration of sodium chloride.[30] The administration of potassium chloride to patients with concurrent hypokalemia also contributes to correction of the alkalemia. Measuring the urinary [Cl^-] may be useful in determining when volume depletion has been corrected; once renal perfusion has been restored, this value should be above 40 mEq/L.

Edematous states Therapy is different for edematous patients with metabolic alkalosis usually caused by heart failure, cor pulmonale, or advanced liver disease. In these disorders, sodium chloride is contraindicated because it increases the degree of edema. Administration of the carbonic anhydrase inhibitor acetazolamide (beginning with 250 mg p.o., q.d. or b.i.d., or 125 mg I.V., q.d. or b.i.d.), however, may be particularly effective. This drug preferentially inhibits proximal tubular reabsorption of sodium bicarbonate, thereby correcting both the alkalosis and the fluid overload.

A potential side effect of therapy with a carbonic anhydrase inhibitor is the development or worsening of hypokalemia. Although hypokalemia can be treated with potassium supple-

ments, an alternative approach to therapy is to administer a potassium-sparing diuretic (e.g., spironolactone) instead of a carbonic anhydrase inhibitor. Potassium-sparing diuretics impair sodium reabsorption in the collecting tubules and, as a result, limit further potassium and hydrogen secretion [*see Figure 6*]. In patients with advanced liver disease, the aldosterone antagonist spironolactone or eplerenone may be the most effective diuretic.

On extremely rare occasions, metabolic alkalosis may be so severe that administration of hydrochloric acid is required to correct the problem. The standard 0.1N (decinormal) hydrochloric acid solution contains 100 mEq H^+/L. Because of the corrosive nature of hydrochloric acid solution, administration of hydrochloric acid should be used only when other measures to correct metabolic alkalosis have failed. The hydrochloric acid solution must always be administered into a central vein.

Bartter syndrome and Gitelman syndrome The tubular defect in patients with Bartter syndrome or Gitelman syndrome cannot be corrected. As a result, treatment is directed at minimizing the electrolyte and metabolic abnormalities. The combination of an NSAID, including cyclooxygenase-2 inhibitors (because prostaglandin levels are secondarily increased), and a potassium-sparing diuretic can raise the plasma [K^+] toward normal and largely reverse the metabolic alkalosis. Most patients, however, require continued oral potassium and magnesium supplements because drug therapy is rarely completely effective.

RESPIRATORY ACIDOSIS AND ALKALOSIS

Alveolar ventilation provides the oxygen necessary for oxidative metabolism and eliminates the carbon dioxide produced by these metabolic processes. It is therefore appropriate that the main physiologic stimuli to respiration are a reduced arterial oxygen tension (P_aO_2), termed hypoxemia, and an elevated P_aCO_2. Carbon dioxide stimulates ventilation through its pH effect. In contrast, the initial hypoxemic enhancement of ventilation is mostly mediated by chemoreceptors in the carotid bodies, which are located near the bifurcation of the carotid arteries. A number of disorders can be responsible for acute and chronic respiratory acidosis and alkalosis [*see Tables 6 and 7*].

Table 6 Causes of Respiratory Acidosis

Disorder	*Cause*
Suppression of the medullary respiratory center	Sedative medications Oxygen administration in chronic lung disease Sleep apnea (also caused by extreme obesity) Central nervous system lesions (uncommon) Cardiopulmonary arrest
Reduced respiratory muscle function	Acute Muscle weakness or paralysis (myasthenia gravis, periodic paralysis, intraperitoneal aminoglycosides, Guillain-Barré syndrome, botulism, severe hypokalemia, severe hypophosphatemia) Chronic Muscle weakness: poliomyelitis, amyotrophic lateral sclerosis, myxedema Kyphoscoliosis
Upper airway obstruction	Aspiration of a foreign body or vomitus Obstruction in sleep apnea Laryngospasm
Disorders affecting pulmonary gas exchange	Acute Acute respiratory distress syndrome Acute cardiac pulmonary edema Severe asthma or pneumonia Pneumothorax or hemothorax Chronic Obstructive pulmonary diseases
Inadequate mechanical ventilation	—

Table 7 Causes of Respiratory Alkalosis

Disorder	*Cause*
Hypoxemia	Pulmonary disease: pneumonia, emboli, edema, interstitial fibrosis Congestive heart failure Severe anemia High-altitude exposure
Direct stimulation of the medullary respiratory center	Hyperventilation syndrome Hepatic encephalopathy Sepsis or fever Salicylate intoxication* After rapid correction of metabolic acidosis Pregnancy (i.e., increased progesterone) Neurologic disorders (cerebrovascular accidents, pontine tumors)
Excessive mechanical ventilation	—

*Respiratory alkalosis is the initial disorder observed, although metabolic acidosis develops later if intoxication is severe.

Diagnosis

Clinical manifestations Severe respiratory acidosis can produce a variety of neurologic abnormalities. Initial symptoms include headache, blurred vision, restlessness, and anxiety, which can progress to tremors, asterixis, delirium, and a somnolence termed carbon dioxide narcosis. Some of these signs, including papilledema, appear to be caused by the acidemia-induced increase in cerebral blood flow. Overall, these signs seem to result from the fall in cerebrospinal fluid pH, not from the changes in the arterial pH or P_aCO_2.

The symptoms produced by respiratory alkalosis are related to increased irritability of the central and peripheral nervous systems and include light-headedness, altered consciousness, paresthesias of the extremities and circumoral area, cramps, carpopedal spasm (indistinguishable from that caused by hypocalcemia), and syncope. In critically ill patients, a variety of arrhythmias may also occur. These abnormalities are thought to relate to the ability of alkalosis to reduce cerebral blood flow and to increase membrane excitability; a decrease in ionized calcium or magnesium also contributes to heightened membrane excitability.

Laboratory tests Primary respiratory alkalosis can be diagnosed when the blood pH is greater than 7.42 in the presence of a reduced P_{CO_2}. It can also be identified as a second primary disorder in patients with metabolic acidosis by use of the Winter formula [*see* Metabolic Acidosis, *above*].

Treatment

Usually, respiratory failure causes acute respiratory acidosis. As a result, treatment is normally indicated, and the patient may

require mechanical ventilation [*see 14:VIII Respiratory Failure*]. In contrast, treatment of respiratory alkalosis is generally not necessary; evaluation should be aimed at diagnosing and correcting the underlying disorder.

Plasma Potassium Disorders

Potassium is the major intracellular cation, with much higher concentrations inside cells (123 to 140 mEq/L) than in the extracellular space (3.5 to 5.0 mEq/L). This concentration difference is preserved by the Na^+,K^+-ATPase pump, which actively transports sodium ions out of most cells and potassium ions into most cells. The difference between potassium concentration inside and outside the cell is the major determinant of membrane excitability. Thus, despite the comparatively small quantity of extracellular potassium, slight changes can have dramatic effects on muscle contraction and nerve conduction.

POTASSIUM HOMEOSTASIS

In the United States, the daily dietary potassium intake varies from 40 to 120 mEq (i.e., 1,560 to 4,680 mg). Under normal conditions, about 90% of dietary potassium is excreted in the urine; most of the remainder is eliminated in the stool. Gastrointestinal potassium losses increase in patients with renal failure, but the significance of this adaptation is uncertain.

Only about 50% of an oral or intravenous potassium load appears in the urine during the first 4 hours after administration. Marked and potentially life-threatening hyperkalemia can occur if the remaining potassium is confined to the extracellular fluid; this volume is only about 14 L in a 70 kg male. Transport of most of this potassium into cells before excretion in the urine minimizes the rise in the plasma $[K^+]$.

The most important factors in the transport of dietary potassium into cells are the influences of insulin and $beta_2$-adrenergic receptors. Insulin stimulates the Na^+,K^+-ATPase pump, leading to a more rapid rate of potassium entry. Recent evidence suggests that the rate of disposal of an intravenous potassium load is lower in African Americans than in white Americans.[31] Activation of $beta_2$-adrenergic receptors also promotes potassium movement into cells. Aldosterone is the most important hormone involved in potassium secretion by epithelial surfaces, including epithelial cells of the renal tubule. Aldosterone appears to be less important to the transport of potassium into other cells.

Renal Regulation of Potassium Secretion

Potassium is freely filtered at the glomerulus. The concentration of potassium ions entering the early proximal tubule is approximately 4 mEq/L, which is identical to the plasma $[K^+]$. By the time the glomerular filtrate reaches the distal tubule, 90% of the filtered potassium has been reabsorbed. Thus, renal potassium excretion occurs almost exclusively by secretion in the collecting tubule.

Potassium secretion into the collecting tubule takes place in the principal cells [*see Figure 3*]. Movement of potassium ions from the tubular cells into the lumen is controlled by the rates of (1) dietary potassium intake; (2) sodium reabsorption, which generates a negative electrical gradient that favors potassium movement from the cell interior to the tubule lumen; and (3) distal urine flow, which maintains a high concentration gradient of tubular cell to tubular lumen concentration by washing away secreted potassium.

Aldosterone produced in the adrenal glands enters the principal cells from the antiluminal, or capillary, surface. Once inside, aldosterone binds to receptors that increase the number of open sodium channels on the luminal cell membrane. The number and activity of Na^+,K^+-ATPase pumps in the cell membrane also increase. The ensuing rise in cellular potassium leads to secretion into the collecting tubular lumen down the favorable concentration and electrochemical gradient.

In states of potassium depletion, secretion of potassium ions by the principal cells is reduced (provided the kidney is not the source of potassium wasting) and potassium reabsorption is stimulated. This process occurs in the adjacent intercalated cells [*see Figure 3*].

HYPOKALEMIA

Causes of Hypokalemia

Hypokalemia, which can be defined as a plasma $[K^+]$ lower than 3.5 mEq/L, may be caused by low potassium intake, a shift of potassium into cells, or potassium losses from the body [*see Table 8*]. In most persons, potassium losses occur from the gastrointestinal tract, skin, or kidneys.

Low potassium intake Inadequate potassium intake is uncommon in healthy individuals in developed nations because potassium is abundant in most foods. Furthermore, if intake is diminished, urinary and intestinal losses can be reduced to less than 15 mEq/day.

Altered potassium distribution Even in the presence of normal potassium stores in the body, several conditions can cause transport of potassium into cells and hence reduce the plasma $[K^+]$.

Metabolic and, to a much lesser degree, acute respiratory alkalosis may be associated with hypokalemia. The principal mechanism in this setting is the transfer of hydrogen ions out of cells as part of the buffering response that minimizes the rise in the extracellular pH; electroneutrality is maintained in part by potassium entry into cells. The relation between the degree of hypokalemia and the increase in blood pH varies greatly. Potassium loss from the body also plays an important role in the hypokalemia observed with the metabolic alkalosis caused by vomiting or diuretic use.

A catecholamine surge, which occurs during an acute myocardial infarction or delirium tremens, can result in an acute intracellular shift of potassium caused by stimulation of $beta_2$-adrenergic receptors. This phenomenon, in which epinephrine can convert mild hypokalemia to severe hypokalemia, may contribute to the apparent increase in coronary mortality observed in studies of patients with left ventricular hypertrophy and mild hypertension who have been treated with moderate- to high-dose thiazide diuretics. The plasma $[K^+]$ typically falls during insulin administration in patients with diabetic ketoacidosis, despite a normal or increased level on presentation. This decrease results in part from insulin-stimulated transfer of potassium into cells. A similar problem can occur when intravenous dextrose is given to nondiabetic patients; for example, 5% dextrose in water can temporarily worsen hypokalemia and possibly lead to cardiac arrhythmias.

Rare causes of redistribution-induced hypokalemia include folic acid or vitamin B_{12} administration in the treatment of megaloblastic anemias (in which the rapid production of new cells results in the uptake of potassium from the extracellular fluid) and

Table 8 Causes of Hypokalemia

Disorder	*Cause*
Inadequate potassium intake	Low dietary content
Cellular translocation of potassium	Metabolic and, to a lesser degree, acute respiratory alkalosis $Beta_2$-adrenergic stimulation (myocardial infarction, delirium tremens) Insulin administration (or glucose administration in nondiabetics) Increased cell proliferation during the treatment of megaloblastic anemia Hypokalemic periodic paralysis Hypothermia Barium poisoning Theophylline toxicity (may be caused by catecholamine or insulin-induced shifts)
Losses of potassium from the body	Extrarenal losses Gastrointestinal (i.e., diarrhea) Skin losses Profuse sweating Extensive burns Renal losses Normotensive Diuretics Vomiting or nasogastric suction* Hypomagnesemia Nonreabsorbable anions (high-dose penicillins) Levodopa Tubular disorders: classic type 1 RTA, Bartter and Gitelman syndromes, drugs (cisplatin, aminoglycosides, amphotericin B), and lysozymuria (in leukemia) Hypertensive with high mineralocorticoid activity Low plasma renin activity: primary aldosteronism, licorice ingestion, and Liddle syndrome Normal or high plasma renin activity: renal artery stenosis, malignant hypertension, and Cushing syndrome

*Gastric losses of potassium also contribute but are minor.

poisoning with barium salts (which block cell membrane channels that normally allow potassium to leave the cells). Patients undergoing gastrointestinal radiographic procedures are not at risk for poisoning with barium salts, because barium sulfate, which is used in gastrointestinal studies, is not absorbed into the systemic circulation. Severe theophylline overdoses also may cause hypokalemia resulting from catecholamine-induced potassium shifts or glucose-induced insulin release.

Hypokalemic periodic paralysis is a rare disorder of uncertain cause that is characterized by potentially fatal episodes of muscle weakness or paralysis resulting from the sudden movement of potassium into cells. Acute attacks are often precipitated by rest after exercise, stress, or a carbohydrate meal, events that are often associated with increased release of epinephrine or insulin. Attacks tend to last for 6 to 24 hours but can be longer.

The disorder may be familial, and the abnormal gene in most patients seems to code for the part of the calcium channel in skeletal muscle that is blocked by dihydropyridine calcium channel blockers (e.g., nifedipine). However, some patients with hyperthyroidism, particularly Asian males, acquire the disease[32]; in these patients, excess thyroid hormone may predispose to paralytic episodes by increasing Na^+,K^+-ATPase activity in cells [*see* Treatment, *below*].

Potassium losses from the body The gastrointestinal tract can be an important site of potassium wasting, particularly in patients with vomiting or diarrhea. However, the [K^+] in gastric secretions (5 to 10 mEq/L) is much lower than that in intestinal secretions, where it can reach 75 mEq/L. As a result, the loss of large volumes of gastric secretions would be required to produce substantial potassium depletion. The decreased [K^+] that is seen with vomiting results primarily from increased urinary, rather than gastric, losses (see below). By comparison, oral sodium phosphate administered for preparatoin of the colon for colonoscopy may lead to hypokalemia in elderly individuals.[33]

Two conditions can cause cutaneous potassium losses resulting in hypokalemia: exercise in a hot, humid environment and severe burns. Persons who undergo intense physical exercise may lose more than 10 L of sweat a day. This loss can lead to significant potassium depletion even though the [K^+] in sweat is only about 5 mEq/L. Potassium losses in the urine occur most commonly in patients who are either vomiting or receiving diuretic therapy. Extracellular volume depletion promotes aldosterone release, leading to enhanced Na^+-K^+ exchange in the collecting tubule [*see Figure 3*]. Aldosteronism alone is insufficient to permit increased potassium excretion, however, because distal urine flow must be maintained for secreted potassium to be excreted. Distal urine flow is maintained in the presence of vomiting or diuretic therapy because sodium and water escape reabsorption. Diuretics inhibit reabsorption of water and sodium in either the loop of Henle or the distal tubule. The increased tubular bicarbonate load present during vomiting allows sodium and water to escape reabsorption in the proximal tubule. Direct inhibition of potassium reabsorption also contributes to the hypokalemia observed with the use of loop diuretics.

As many as 40% of hypokalemic persons also have hypomag-

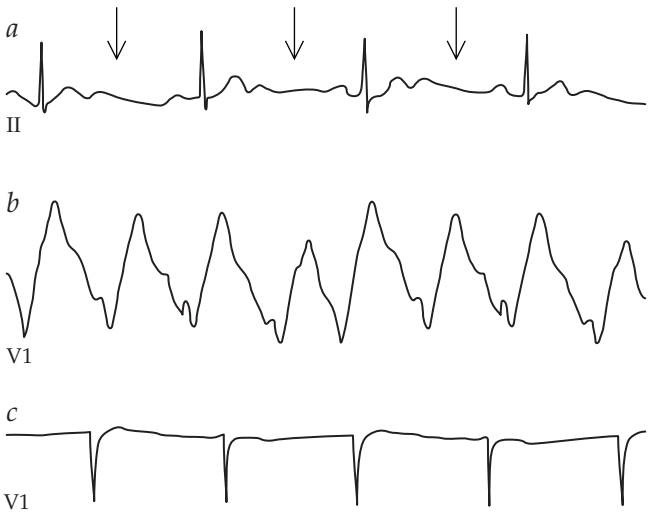

Figure 7 **Both hypokalemia and hyperkalemia can cause changes in the patient's electrocardiogram. (*a*) The ECG from a patient with moderate hypokalemia shows prominent U waves (arrows). (*b*) Marked hyperkalemia results in peaked T waves and widened QRS complexes in this ECG. Ten minutes after the patient receives intravenous calcium, however, all ECG manifestations of hyperkalemia have resolved (*c*).**

nesemia. At times, the cause of potassium wasting, such as diuretic or cisplatin treatment, is also responsible for impaired magnesium reabsorption. However, potassium depletion usually cannot be corrected without restoring magnesium balance. This connection may exist because magnesium can act as a potassium channel blocker. In the loop of Henle, for example, potassium may leak through the cell membrane into the tubular lumen when magnesium levels are low, thereby contributing to ongoing urinary losses.

Several less common causes of tubular dysfunction can also lead to urinary potassium losses. These causes include classic type 1 RTA; drugs (e.g., cisplatin, amphotericin B, and the aminoglycosides); both acute and, less commonly, chronic leukemia; and levodopa administration. Reduced sodium reabsorption, leading to volume depletion, stimulates aldosterone secretion and plays a role in many of these disorders. Primary aldosteronism should be considered, however, whenever unprovoked potassium wasting is detected in a hypertensive person.

Liddle syndrome is a rare cause of hypertension and metabolic alkalosis resulting from a genetic or acquired defect in the epithelial sodium channel, an abnormality that leads to increased sodium reabsorption in the collecting tubule. This disorder is associated with normal or suppressed aldosterone levels. Consequently, it can be treated with potassium-sparing diuretics, such as amiloride, but does not respond to aldosterone antagonists.

Diagnosis

Clinical manifestations In most circumstances, mild hypokalemia (plasma [K^+] 3.0 to 3.5 mEq/L) causes no symptoms. The major disturbances seen with more severe potassium deficiency result from changes in cardiovascular, neuromuscular, and renal function. Cardiac toxicity may be manifested by serious arrhythmias, which occur because hyperpolarization of the myocardial cell membrane leads to a prolonged refractory period and increased susceptibility to reentrant arrhythmias. Other electrocardiographic changes of hypokalemia include T wave depression and prominent U waves [*see Figure 7*].

Hyperpolarization also slows nerve conduction and muscle contraction, which may contribute to muscle weakness, cramps, and paresthesias, although these symptoms are usually not observed until the plasma [K^+] is lower than 2.5 mEq/L. When hypokalemia is severe, it can impair respiratory muscle function, leading to hypoventilation. Because potassium normally permits vasodilatation in response to muscle contraction, severe hypokalemia also predisposes to rhabdomyolysis.

The primary renal manifestations of hypokalemia are polyuria resulting from stimulated thirst and resistance to antidiuretic hormone action. The latter condition is termed nephrogenic diabetes insipidus. Increased thirst is an appropriate response to polyuria, but it is also caused by direct stimulation of the hypothalamic thirst center by hypokalemia. The resistance to antidiuretic hormone is caused by a hypokalemia-induced fall in the number of collecting tubular water channels.[34] Chronic hypokalemia can lead to chronic interstitial nephritis and a decline in glomerular filtration.

When hypokalemia is severe (plasma [K^+] < 2 mEq/L), the ability of the renal tubules to reabsorb sodium and chloride may be impaired. This condition can lead to volume depletion and to the loss of urinary sodium and chloride, even in states of reduced renal perfusion. The mechanism may involve suppressed activity of tubular chloride transporters, many of which also facilitate sodium reabsorption.

Physiologic tests The history and physical examination usually suggest the diagnosis in the hypokalemic patient. Excretion of more than 30 mEq of potassium a day indicates some renal potassium wasting. Patients with extrarenal potassium losses excrete less potassium daily, as do patients who have discontinued diuretic therapy. Once urinary potassium excretion is measured, the following diagnostic possibilities should be considered in the patient with hypokalemia of uncertain origin:

1. In an asymptomatic patient, metabolic acidosis with a low rate of urinary potassium excretion suggests lower gastrointestinal losses because of diarrhea, laxative abuse, or villous adenomas.
2. Metabolic acidosis with renal potassium wasting is most often caused by diabetic ketoacidosis or type 1 RTA.
3. Metabolic alkalosis with potassium wasting and a normal blood pressure is most often caused by surreptitious vomiting (early phase) or diuretic use. In this setting, measurement of the urinary [Cl^-] is often helpful. It is low in patients who have been vomiting, whereas the urinary [Na^+] and urinary potassium excretion may be relatively high. This diagnosis can be determined at the bedside from the urine pH, which should be 7.0 or higher if significant bicarbonaturia is present.
4. Metabolic alkalosis with potassium wasting and hypertension suggests surreptitious diuretic use by a patient with underlying hypertension, renovascular hypertension, malignant hypertension, or primary aldosteronism.
5. In hypokalemic periodic paralysis, a history of exercise or carbohydrate ingestion may be obtained. Urinary potassium is normally conserved during an episode of hypokalemic paralysis.

Treatment

Normalizing the plasma [K^+] is indicated in most cases, although the means of normalization and the quantity and route of potassium administration vary greatly. In the absence of factors that cause transcellular shifts of potassium, a fairly predictable relation exists between the degree of hypokalemia and the extent of total body potassium depletion. For each 1 mEq/L fall in the plasma [K^+], potassium stores fall by 200 to 400 mEq, until the plasma [K^+] drops below 2.0 mEq/L. At that point, the total deficit may exceed 1,000 mEq. With both oral and parenteral replacement, potassium enters the plasma before it is transferred into cells. Consequently, potassium supplementation, particularly when given intravenously, carries the risk of hyperkalemia if the dose is too large or if it is administered too rapidly. Therefore, potassium should be administered orally whenever possible.

Potassium replacement using potassium-rich foods can be effective when metabolic acidosis or renal failure is present. However, dietary potassium is not effective in correcting the potassium deficit that occurs with metabolic alkalosis. In most foods, potassium is bound to poorly reabsorbable anions such as phosphate. Therefore, chloride salts (e.g., potassium chloride, which is used when metabolic alkalosis is caused by diuretics) are usually required to restore potassium losses. An exception to this may be in the preventive treatment of renal calculi with thiazide diuretics, where potassium citrate can maintain a normal serum potassium level.[35]

Potassium can be administered intravenously into a peripheral vein in concentrations as high as 40 mEq/L; higher concentrations can cause phlebitis and thus should be infused only into a

large vein. Except in unusual settings, the rate of administration should probably not exceed 20 to 40 mEq/hr, although dosages as high as 100 mEq/hr have been infused in selected patients with paralysis or life-threatening arrhythmias.[36] Glucose-containing solutions should be avoided because insulin stimulation can drive potassium into cells, thereby exacerbating the hypokalemia.

For patients taking diuretics for high blood pressure, several alternatives are available to correct hypokalemia without use of potassium chloride supplementation. Because patient compliance decreases as the number of medications (including potassium supplements) increases, reducing the diuretic dose (e.g., to 12.5 mg of hydrochlorothiazide) or substituting an alternative agent should be considered first.

Edematous individuals or patients with primary aldosteronism who also experience hypokalemia can be treated with potassium-sparing diuretics (amiloride or spironolactone) until more definitive therapy can be performed (e.g., the surgical removal of an adrenal adenoma in primary aldosteronism).

In patients with hypokalemic periodic paralysis [*see* Altered Potassium Distribution, *above*], administration of potassium chloride can abort acute attacks within minutes; however, long-term potassium chloride supplementation does not usually prevent attacks. Hyperthyroidism should be treated when present, and the administration of a nonselective beta-adrenergic blocker (e.g., propranolol) may prevent episodes in patients with the familial form of the disorder.

HYPERKALEMIA

Hyperkalemia is a common electrolyte disorder. Because a variety of frequently used medications can interfere with normal potassium homeostasis, hyperkalemia is often iatrogenic and therefore preventable. Severe hyperkalemia is associated with altered neuromuscular or cardiac function.

Causes of Hyperkalemia

Hyperkalemia can be caused by excessive potassium intake, increased potassium release from cells, or reduced renal excretion of potassium [*see Table 9*].

Increased potassium intake The increased plasma [K^+] that occurs after an acute oral or intravenous potassium load depends on four factors: (1) the quantity of potassium administered, (2) the ability of some of the excess potassium to enter cells, (3) urinary potassium excretion, and (4) the preceding level of potassium intake—a process called adaptation. The rise in plasma [K^+] is minimized if potassium intake has increased slowly. During a slow increase, renal excretion and, perhaps, cellular entry become more efficient. Increased aldosterone levels and increased Na^+,K^+-ATPase activity in the cortical collecting tubule play important roles in this process. Even in the absence of adaptation, the kidney ultimately excretes the excess potassium, although more slowly. Thus, hyperkalemia resulting from an acute load is transient unless renal potassium excretion is concomitantly reduced.

Increased potassium release from cells Both insulin deficiency and $beta_2$-adrenergic blockade can increase the plasma [K^+]. In patients with end-stage renal disease who are on hemodialysis, for example, propranolol or labetalol, but not the selective $beta_1$-adrenergic blocker atenolol, can raise the plasma [K^+] level by about 1 mEq/L. At higher doses of atenolol, however, this selectivity may be lost.

An elevation in plasma osmolality results in osmotic water movement from the cells into the extracellular fluid. This event is accompanied by the movement of potassium from cells via two mechanisms. First, the increased cellular [K^+] caused by the loss of water creates a favorable gradient for passive exit of potassium through the potassium channels in the cell membrane. Second, friction forces between solvent (water) and solute carry potassium along with water through the water channels (aquaporins) in the cell membrane.

Acute acidemia can also increase the plasma [K^+] by shifting potassium from cells to plasma. This shift is most likely to occur during the infusion of acids; when arginine hydrochloride is infused, for instance, potassium is exchanged for cationic arginine entering the cells. This shift, however, appears to be important in inorganic acidoses only. In comparison, hyperkalemia in lactic acidosis is caused primarily by cell breakdown, and hyperkalemia in ketoacidosis results from insulin deficiency and hyperglycemia.

Massive cell breakdown that occurs during rhabdomyolysis, during abscess formation, with cell necrosis (e.g., bowel infarction), or after chemotherapy for leukemia or lymphoma releases potassium into the plasma. Less common causes of an increased plasma [K^+] include cardiac glycoside intoxication, a result of partial inhibition of the Na^+,K^+-ATPase pump; succinylcholine administration, which depolarizes the cell membrane and thus permits potassium to leave the cells; and the rare disorder hyperkalemic periodic paralysis.

Impaired renal excretion of potassium The kidney, the major site of potassium excretion, has the distinct ability to increase the excretion rate as the plasma [K^+] rises. Thus, sustained hyperkalemia is virtually always associated with some impairment of renal potassium elimination. Distal nephron hydrogen ion secre-

Table 9 Causes of Hyperkalemia

Disorder	*Cause*
Pseudohyperkalemia	Traumatic hemolysis during blood drawing Thrombocytosis Marked leukocytosis
Increased intake of potassium*	Increased dietary potassium Increased intake of potassium-containing medications Increased release of endogenous potassium (as occurs during rhabdomyolysis)
Increased release from cells	Insulin deficiency $Beta_2$-adrenergic blockade Acute metabolic acidosis Cell breakdown Rhabdomyolysis Trauma or infection with abscess formation Tumor lysis syndrome after chemotherapy Marked exercise (transient; resolves with rest) Massive cardiac glycoside intoxication (e.g., digoxin) Succinylcholine Arginine infusion Hyperkalemic periodic paralysis
Impaired renal potassium excretion	Oligoanuric renal failure Marked volume depletion (prerenal diseases) Type 4 RTA Hyperkalemic type 1 RTA [*see Table 3*]

*Sustained hyperkalemia associated with increased intake is always accompanied by impaired renal excretion.

Table 10 Evaluation of the Renal Defect in Hyperkalemia

Disorder	*Urine pH*	*Urinary [Na^+] (mEq/L)*	*Plasma Aldosterone Level*
Renal failure	< 5.3	> 20	Normal or increased
Marked volume depletion	Variable	< 20	Increased
Type 4 RTA	< 5.3	> 20	Low*
Hyperkalemic type 1 RTA	> 5.3	> 20	Normal or increased

*A normal aldosterone level is inappropriate in the presence of hyperkalemia.
Urinary [Na^+]—urinary sodium concentration

tion is frequently impaired as well, leading to a normal-anion-gap metabolic acidosis, because the collecting tubule is the site of both potassium and hydrogen ion secretion. Renal potassium excretion can be impaired by oligoanuric renal failure, reduced effective arterial volume, type 4 RTA, and hyperkalemic type 1 RTA.

Oligoanuric renal failure impairs, but does not halt, potassium excretion. Although renal failure predisposes to potassium retention, excretion of dietary potassium usually continues in chronic renal disease until the GFR is less than 5 to 10 ml/min. Although less efficient in oligoanuric renal failure, renal excretion can still occur because most urinary potassium is derived from tubular secretion, not glomerular filtration.

When the effective arterial volume is reduced, delivery of sodium and water to the collecting tubule is also diminished. Adequate distal delivery of sodium and water is essential to normal potassium excretion. Distal delivery is characteristically reduced, for example, in patients with advanced congestive heart failure or cirrhosis. Both a fall in GFR and a rise in proximal sodium and water reabsorption, mediated in part by angiotensin II, play a role in the reduction of potassium excretion in this setting. Although aldosterone enhances sodium reabsorption and potassium secretion in these conditions, the increase is limited because less sodium is available for reabsorption. Furthermore, secreted potassium may not be eliminated completely if urine flow is markedly decreased.

Aldosterone deficiency or resistance (i.e., type 4 RTA) is responsible for the hyperkalemia in more than 75% to 85% of those cases in which patients have persistent hyperkalemia in the absence of any apparent cause, such as advanced renal failure, an offending drug, or a potassium load.

Type 4 RTA is also associated with diminished hydrogen ion secretion, which is caused in part by impaired ammoniagenesis in the proximal tubule, a possible result of hyperkalemia-induced intracellular alkalosis. The result is a diminished supply of ammonia in the more distal nephron segments. Consequently, an insufficiency of buffer in the urine plays an important role in the limited hydrogen ion secretion and explains why the urine pH is characteristically acidified (< 5.3) in this disorder.

Several conditions cause type 4 RTA [*see Table 4*]. Hyporeninemic type 4 RTA is the most common form of the disorder and occurs most often in patients with mild renal insufficiency. Diabetic nephropathy or chronic interstitial nephritis is often present. Medications such as NSAIDs can also contribute to this disorder.

The pathophysiology of type 4 RTA in hyporeninemic patients is incompletely understood. Decreased angiotensin II production is clearly important, because potassium and angiotensin II are the major physiologic stimuli for aldosterone release. However, at least some patients must also have a concurrent adrenal defect, because observations indicate that the normal adrenal gland can release angiotensin II. It has also been suggested that in some patients, the reduced renin may be secondary. For example, volume expansion, which increases atrial natriuretic peptide, inhibits both renin and aldosterone release.

In other cases of type 4 RTA, the defect in aldosterone synthesis and release seems confined to the adrenal glands. Heparin (or perhaps its preservative, chlorbutol) is a potent inhibitor of aldosterone production, even when given subcutaneously in low doses. Heparin use is not widely associated with hyperkalemia, however, because moderate aldosterone deficiency is not sufficient to cause significant potassium retention in the great majority of patients who still have normal renal function. Hyperkalemia can occur, however, if renal disease is present or if agents that impair the renin-angiotensin-aldosterone system, such as NSAIDs or ACE inhibitors, are concomitantly administered.

The possibility of panadrenal insufficiency (i.e., a deficiency of both aldosterone and cortisol, also termed Addison disease) should be assessed before the diagnosis of selective aldosterone deficiency is made. When panadrenal insufficiency is present, hypoadrenocorticism often impairs water excretion, leading to hyponatremia in addition to the hyperkalemia resulting from aldosterone deficiency.

Although classic type 1 RTA is associated with hypokalemia, some patients with impaired hydrogen ion secretion by the collecting tubule also cannot secrete potassium normally. This condition, hyperkalemic type 1 RTA, is most often seen with urinary tract obstruction but can also be caused by tubulointerstitial damage from such disorders as sickle cell nephropathy, lupus nephritis, or transplant rejection. The hyperkalemia and metabolic acidosis are caused by damage to both the potassium-secreting principal cells and the acid-secreting intercalated cells. Hyperkalemic type 1 RTA can be distinguished from type 4 RTA by the persistently alkaline urine (pH > 5.3) and by a normal or increased plasma aldosterone level [*see Table 10*].

Finally, it is important to remember the effects of medications that can limit potassium secretion directly.[37] Obvious agents are the potassium-sparing diuretics: amiloride, triamterene, and spironolactone. Another, less common agent is trimethoprim-sulfamethoxazole. Trimethoprim in this combination or alone can impair potassium secretion by blocking sodium transport from the tubular lumen into the collecting tubule cell, in a mechanism similar to that of amiloride.

Evidence suggests that aldosterone may be vasculotoxic, cardiotoxic, and nephrotoxic.[38] As a consequence, the combined use of ACE inhibitors or angiotensin receptor blockers (ARBs) with spironolactone has increased. Initial studies of combined ACE and ARB therapy showed very little toxicity from hyperkalemia; however, the risk of hyperkalemia has been found to be associated with combination therapy.[39,40] When multiple medications are administered, each of which can reduce urinary potassium secretion, care must be taken to avoid the morbidity and potential mortality associated with severe hyperkalemia.[41] This is particularly important in patients with impaired renal function.

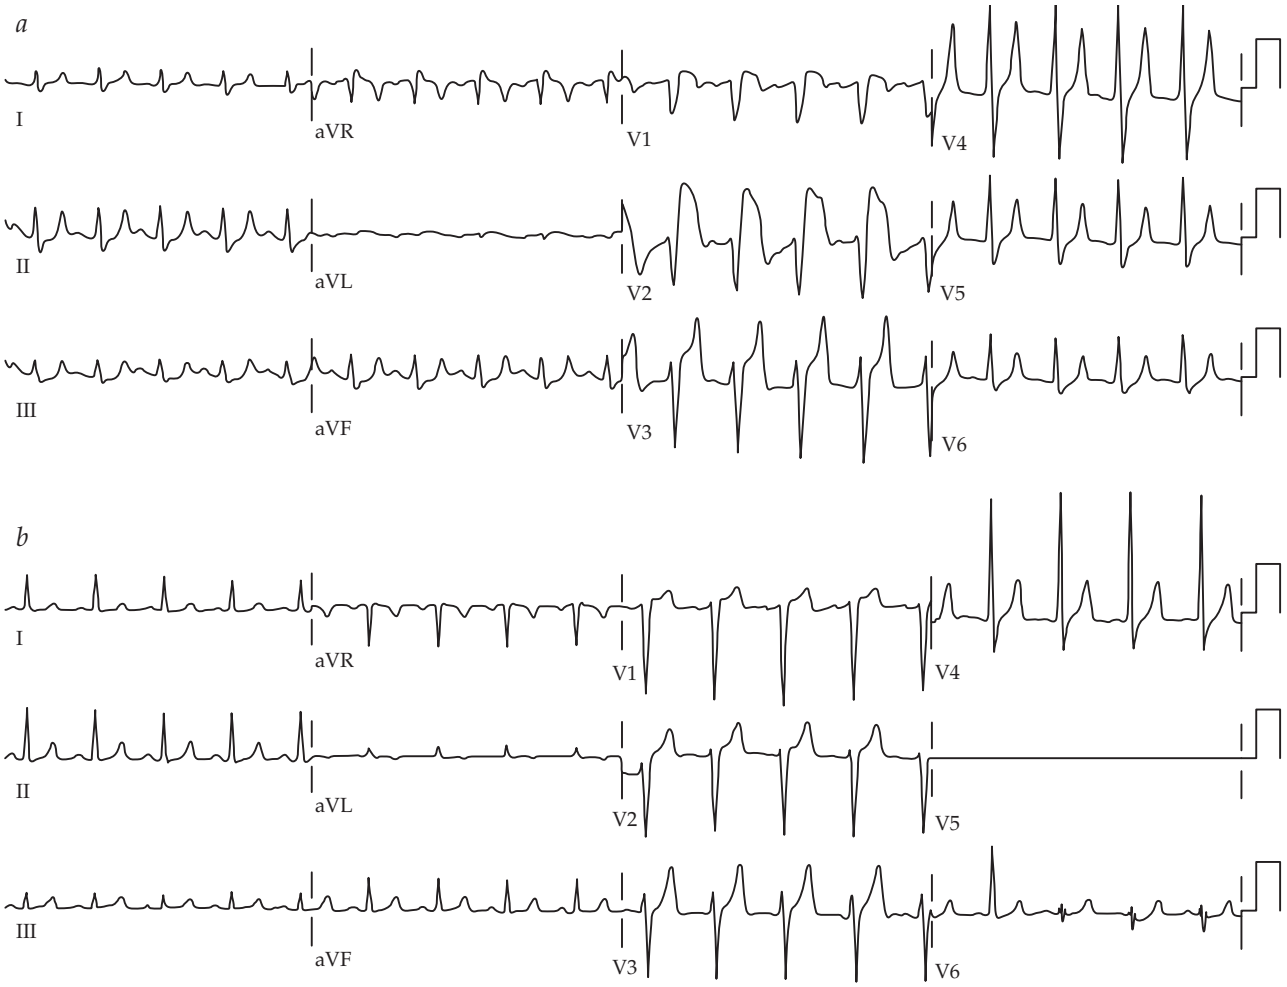

Figure 8 **Pseudoinfarction pattern caused by hyperkalemia. (*a*) ECG from a patient with a serum potassium level of 7.9 mEq/L. The anterior chest leads show ST segment elevation, and there is peaking of the T waves, most notably in leads V3 and V4. (*b*) Resolution of the ECG changes after correction of the serum potassium level.**

Diagnosis

Clinical manifestations The symptoms of hyperkalemia are related to impaired neuromuscular transmission. However, the neuromuscular manifestations are not specific. The earliest findings are paresthesias and weakness, which can progress to paralysis affecting respiratory muscles. These symptoms are similar to those seen with hypokalemia; cranial nerve function, however, characteristically remains unaffected.

The ease of generating an action potential (called membrane excitability) is related both to the magnitude of the resting membrane potential and to the activation state of membrane sodium channels. The opening up of these sodium channels, leading to the passive diffusion of extracellular sodium into the cells, is the primary step in this process.

According to the Nernst equation, the resting membrane potential is related to the ratio of the intracellular [K^+] to the extracellular [K^+]. An elevation in the (extracellular) plasma [K^+] decreases this ratio and therefore partly depolarizes the cell membrane (i.e., it makes the resting membrane potential less electronegative). This change initially increases membrane excitability because less of a depolarizing stimulus is required to generate an action potential. However, persistent depolarization inactivates sodium channels in the cell membrane, thereby producing a net decrease in membrane excitability that may be manifested clinically by impaired cardiac conduction, muscle weakness, or paralysis.

In general, severe symptoms of hyperkalemia do not occur until the plasma [K^+] is higher than 7.5 mEq/L. There is substantial variability among patients, however, because factors such as concomitant hypocalcemia, metabolic acidosis, and the rate at which hyperkalemia develops can increase the toxicity of excess potassium.[42]

Physiologic tests Careful monitoring of the electrocardiogram and muscle strength is necessary to assess the functional consequences of hyperkalemia. At a plasma [K^+] higher than 7.5 to 8.0 mEq/L, severe muscle weakness or marked ECG changes are potentially life threatening and require immediate treatment with almost all of the available modalities [*see* Treatment, *below*].

The earliest ECG abnormality is symmetrical peaking of T waves, which is followed by reduced P wave voltage and widening of the QRS complexes [*see Figure 7*]. If left untreated, severe hyperkalemia may ultimately cause a sinusoidal ECG pattern, with one oscillation representing a wide QRS complex and the complementary oscillation representing an abnormal T wave. ECG changes do not usually occur until the plasma [K^+] exceeds 6.5 mEq/L, and they are more likely to develop when the rise in potassium occurs rapidly. However, there is no absolutely predictive relation between the severity of the elec-

trolyte disturbance and the ECG pattern. In rare cases, the ECG pattern can remain unchanged even in patients with a plasma [K^+] above 9.0 mEq/L. In others, a pseudoinfarction pattern may be observed [*see Figure 8*].[43]

When hyperkalemia is sustained, reduced renal elimination is usually the cause [*see Table 9*]. When type 4 RTA is documented, the plasma cortisol concentration should be measured to determine whether complete adrenal insufficiency is present.

Differential Diagnosis

Pseudohyperkalemia should be considered when there is evidence of hemolysis in the sample or when the platelet or white blood cell count (WBC) is markedly increased. In contrast to true hyperkalemia, which is associated with altered neuromuscular or cardiac function, pseudohyperkalemia does not put patients at risk.

In this condition, the plasma [K^+] measured by the clinical laboratory is increased because potassium is released during clotting that occurs after the blood specimen has been obtained. This condition is most frequently caused by hemolysis resulting from traumatic blood drawing but is also seen with marked thrombocytosis (platelet count > 1,000,000/μl) or leukocytosis (WBC > 100,000/μl). It can also be observed as familial pseudohyperkalemia, in which potassium leaks out of cells at room temperature after clotting, without overt hemolysis.[44]

The diagnosis of pseudohyperkalemia is made by demonstrating that the [K^+] is normal in a nonhemolyzed plasma sample; such a sample is collected by drawing the blood into a heparinized tube, thus preventing clotting. In cases in which no cause for hyperkalemia can be determined (e.g., normal renal function) and the serum [K^+] is over 1 mEq/L higher than the plasma level, the cause of hyperkalemia is an in vitro phenomenon if the patient has a normal serum potassium level after blood is drawn without a tourniquet.[45] Treatment of pseudohyperkalemia is not indicated, because the in vivo (i.e., plasma) [K^+] is normal.

Treatment

In true hyperkalemia, particularly when it is severe (plasma [K^+] > 6.0 mEq/L), discontinuance of all medications that adversely affect potassium balance is mandatory.[46] These medications include nonselective beta blockers, ACE inhibitors, potassium-sparing diuretics, NSAIDs, and trimethoprim. Salt substitutes, which contain potassium chloride, should also be avoided. Persons with mild hyperkalemia (plasma [K^+] < 6.0 mEq/L) can usually be treated conservatively with reduction of daily intake to less than 2 g and, if indicated, with the addition of a loop diuretic.

Active treatment to lower the plasma [K^+] or to antagonize its effects on the cell membrane should be started if the plasma [K^+] has risen acutely to 6.0 mEq/L or higher, particularly if ECG manifestations of hyperkalemia are present; several therapeutic options are available [*see Table 11*].

An infusion of calcium rapidly normalizes the ECG. An increase in the [Ca^+] raises the threshold potential, thereby returning membrane excitability to normal. Calcium should be administered, however, in the presence of only those ECG manifestations of hyperkalemia that may precede ventricular fibrillation. Because calcium can exacerbate or precipitate glycoside-induced cardiac arrhythmias, it should be used only when necessary and with great care in patients receiving digoxin or other digitalis preparations.

Calcium is administered intravenously as the gluconate or chloride salt (10 ml of 10% calcium gluconate over 2 to 3 minutes, with ECG monitoring). Normalization of the ECG may persist for less than 60 minutes; furthermore, this treatment does not alter the plasma [K^+] or total potassium body stores. Consequently, measures that will lower the plasma level and remove potassium from the body should be initiated simultaneously.

Sodium bicarbonate, glucose (with or without insulin), and beta$_2$-adrenergic receptor stimulation lower the plasma [K^+] by promoting the entry of potassium from the extracellular fluid into cells. The administration of sodium bicarbonate reduces the hydrogen ion concentration in the extracellular fluid. Theoretically, if the Na^+-H^+ exchanger were in an active mode, the administration of sodium bicarbonate would favor the movement of H^+ out of cells as Na^+ enters. The subsequent exit of sodium by the Na^+,K^+-ATPase pump would shift potassium into the cell. In the steady state, however, the Na^+-H^+ exchanger appears to be inactive.[47] By comparison, the Na^+-H^+ exchanger is activated by intracellular acidosis.

Several studies have found sodium bicarbonate therapy to be ineffective in the treatment of acute hyperkalemia, despite a rise in the serum [HCO_3^-]. Furthermore, bicarbonate does not appear to potentiate the hypokalemic action of beta$_2$-adrenergic agonists or the combination of glucose and insulin, which are more effective in this setting.[48] Because of these findings, sodium bicarbonate, if used in the treatment of hyperkalemia, should be used in combination with other agents.[47]

Beta$_2$-adrenergic agonists can also transiently lower the serum potassium level. Albuterol can be administered at a dosage of 10 to 20 mg in 4 ml of saline by nasal inhalation over 10 minutes or by a 0.5 mg I.V. infusion. The blood potassium level usually falls by 0.5 to 1.5 mEq/L within 30 minutes after the I.V. infusion, but more than 1 hour is required for a peak effect when albuterol is inhaled.[49]

The hypokalemic effect of insulin is observed within 30 to 60 minutes, and it can be achieved by simply administering 25 g of glucose intravenously, because a glucose infusion rapidly stimulates insulin release. Alternatively, 10 units of regular insulin can be given intravenously with this glucose load to patients with diabetes, although this regimen can cause hypoglycemia in normal persons. Regardless of the method, care must be taken to avoid producing severe hyperglycemia by the glucose infusion, because a high plasma glucose concentration can exacerbate hyperkalemia by causing water, which contains potassium, to shift from the intracellular compartment into the plasma.

Like the administration of calcium, the administration of glucose and insulin, bicarbonate, and beta$_2$-adrenergic agonists is a temporary measure because total body potassium stores are not reduced. Therefore, additional therapy is required to ensure that the plasma [K^+] does not return to pretreatment levels. Furthermore, in some patients, lowering the plasma [K^+] with these

agents shortly before dialysis can lead to reduced dialytic potassium removal, possibly resulting in rebound hyperkalemia after the dialysis treatment has been completed.[49]

Increasing urine flow with diuretics is sometimes useful, but renal insufficiency frequently limits the effectiveness of diuretics. However, the Na^+-K^+ cation exchange resin sodium polystyrene sulfonate can be administered in sorbitol (to promote diarrhea) orally or as a retention enema. The use of sodium polystyrene sulfonate can exchange 4 mEq of Na^+/g for 4 mEq of K^+; therefore, in theory, 30 g of sodium polystyrene sulfonate could remove 120 mEq of potassium. However, because the quantity of gastrointestinal potassium available for exchange may be as little as 5 mEq/day, the effectiveness of sodium polystyrene sulfonate has been questioned.[47] In some studies, sodium polystyrene sulfonate was no more effective than the laxative in which it was administered. Some experts no longer recommend use of sodium polystyrene sulfonate in sorbitol; however, the diarrhea this agent induces may in itself be helpful in reducing the serum [K^+]. I recommend use of sodium polystyrene sulfonate if the urine output is low and if dialysis is not readily available.

Dialysis should be considered in severe or refractory cases of hyperkalemia, particularly when there is advanced renal failure. When available, hemodialysis is preferable in the acute setting because it removes potassium much more quickly than peritoneal dialysis does.

If aldosterone deficiency has been documented in cases of chronic hyperkalemia that are inadequately controlled by diet or diuretics, aldosterone replacement with fludrocortisone acetate may be useful. The combination of fludrocortisone and a loop diuretic may limit the development of hypertension or edema. However, because its onset of action may take several days or longer, this therapy is not sufficiently effective to be used in the treatment of acute, life-threatening hyperkalemia.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III APPROACH TO THE PATIENT WITH RENAL DISEASE

Biff F. Palmer, m.d.

Diseases of the kidney can present as a variety of clinical syndromes. In some cases, the clinical presentation is directly referable to the kidney, as with the finding of proteinuria or an increased serum creatinine concentration. In other instances, the presentation reflects the impact of impaired renal function on other organ systems, such as edema or shortness of breath resulting from renal salt retention. Still other patients are asymptomatic and are simply found to have an abnormal urinalysis result on routine examination. In all of these situations, a systematic approach will promote an efficient and accurate diagnosis.

First, the clinician should determine the duration of the disease. Second, renal function should be measured, to determine whether the patient has suffered a loss in renal function and, if so, to what degree. Third, the specific syndrome should be identified, on the basis of information obtained through the history and physical examination, routine laboratory testing, and imaging of the kidneys. Assessment of volume status deserves particular attention, because volume abnormalities are common in patients with renal disease and offer an important clue not only to the presence of renal failure but also to its management. Approaching the case in this manner will allow the clinician to establish the correct diagnosis and estimate the duration, course, and severity of the renal disease, as well as to institute appropriate therapy.

Determining Disease Duration

Whether renal disease is acute or chronic is important both in asymptomatic patients with normal renal function and in patients with clinical evidence of renal insufficiency. There are two main reasons to differentiate acute from chronic renal disease. First, acute renal disease is more likely to be self-limited and hence to have a better prognosis. Second, the treatment of renal disease may vary, depending on whether the disease is of recent onset or is long-standing. This is particularly true for treatment of acute renal failure versus treatment for chronic renal failure. There are now specific therapies for certain types of acute renal failure that do not apply to chronic renal failure. Moreover, such therapy may conceivably prevent acute renal failure from becoming chronic.

Several tools can help determine disease duration [*see Table 1*]. Use of old medical records is particularly valuable in dating the onset of an increased serum creatinine concentration, proteinuria, or hematuria. In patients with impaired renal function, measurement of kidney size by renal sonography or plain film of the abdomen is quite useful. Small kidneys (i.e., less than 8 cm in total length, in an adult), are an almost certain sign of chronic renal failure. If the kidneys are normal in size, one cannot be certain whether the patient has acute or chronic renal disease. Radiographic evidence of renal osteodystrophy in the distal clavicles, hands, ribs, skull, spine, and pelvis strongly supports the diagnosis of chronic renal disease. However, patients in early stages of chronic renal failure may not have detectable bone lesions even when the kidney size is small. The most precise way to differentiate acute renal disease from chronic renal disease is to perform a renal biopsy; however, this is not practical or necessary in most cases. Renal biopsy is useful in patients who are suspected of having chronic renal failure because of their history and whose kidneys are of normal size on ultrasound or plain films of the abdomen (kidneys, ureters, and bladder [KUB] view).

Assessment of Renal Function

Once renal disease is discovered, the presence or degree of renal dysfunction should be determined. The glomerular filtration rate (GFR) is generally considered the best measure of renal function. Serial assessment of GFR can allow the clinician to determine the course of the underlying disease by demonstrating either rapid or slow rates of decline in renal function. Accurate determination of renal function also helps the clinician to make adjustments in the dosing of pharmacologic agents so as to prevent the accumulation of drugs and metabolites and, thereby, potential toxicities.

Serum Creatinine

Measurement of the serum creatinine concentration is the most commonly used method for determining the level of renal function. The creatinine concentration can be used to estimate GFR because creatinine varies inversely with the level of renal function. Normal creatinine concentrations range from 0.6 to 1.0 mg/dl in women and 0.8 to 1.3 mg/dl in men.

The major limitation of the serum creatinine level is its insensitivity to mild to moderate reductions in renal function. The relationship between creatinine level and GFR is nonlinear. A change in creatinine from 0.6 mg/dl to 1.2 mg/dl reflects a decline in GFR of approximately 50%. If a previous baseline value for creatinine does not exist for comparison, a creatinine of 1.2 would not draw clinical attention to a potential reduction of GFR. On the other hand, nephrologists are often consulted emergently when a patient's creatinine concentration rises from 5 mg/dl to 8 mg/dl, which is far less critical, because GFR has fallen from approximately 20 ml/min to 15 ml/min, a 25% decline. Nevertheless, it is important to detect changes in GFR at relatively low creatinine values, when renal injury may still be reversible.

Changes in the serum creatinine concentration are also slow to reflect acute changes in renal function; accumulation of creatinine in the blood and achievement of a new steady state occur

Table 1 Tools Used to Differentiate Acute from Chronic Renal Disease

Renal biopsy

Note: degree of anemia, if present, and serum phosphate measurement are not useful for this purpose.

gradually. For example, if acute renal failure occurs and the GFR suddenly falls from 100 ml/min to 10 ml/min, the serum creatinine would not rise correspondingly for approximately 7 days.

CREATININE CLEARANCE

A more accurate way to assess the GFR is with a 24-hour urine collection to determine the creatinine clearance. Creatinine is an endogenous marker of filtration that is produced at a relatively constant rate. Creatinine clearance (C_{Cr}) may be calculated by the following equation:

$$C_{Cr}\,(\text{ml/min}) = \frac{\text{urine creatinine (mg/dl)} \times \text{urine volume (ml/min)}}{\text{plasma creatinine (mg/dl)} \times 1{,}440}$$

Normal C_{Cr} is approximately 95 ± 20 ml/min in women and 125 ± 25 ml/min in men. Creatinine is freely filtered and is not reabsorbed; it is thus excreted primarily by filtration. However, 15% to 20% of urinary creatinine is derived from tubular secretion via an organic acid pump in the proximal tubule. Therefore, use of C_{Cr} to assess GFR may be expected to result in an overestimation of the GFR.[1] However, the plasma creatinine (P_{Cr}), as measured by certain picric acid methods (e.g., the Jaffe reaction), is typically inflated because of the presence of noncreatinine chromogens, such as glucose, acetoacetate, pyruvate, uric acid, and proteins in plasma. Thus, the 15% to 20% increase in urine creatinine levels caused by tubular secretion may be counterbalanced by the inflated level of P_{Cr}, resulting in a reasonably close correlation between C_{Cr} and GFR.

The reliability of C_{Cr} assessments, however, is diminished by the variability in tubular secretion of creatinine and by the inability of most patients to accurately collect timed urine samples.[2,3] The accuracy of the urine samples can be estimated on the basis of the normal daily rate of creatinine excretion: 15 to 20 mg/kg lean body weight in women and 20 to 25 mg/kg lean body weight in men. A creatinine excretion rate that is significantly less than the normal daily rate usually indicates an incomplete urine collection. Additionally, tubular secretion of creatinine increases proportionally with declining levels of renal function, resulting in further overestimations of GFR.[4] Prolonged storage of urine can also invalidate urinary creatinine clearance measurements, because high temperatures and low pH promote the conversion of creatine to creatinine in urine.[5]

To avoid the inaccuracies and inconvenience of timed urine collections, the creatinine clearance can be estimated at the bedside by using the patient's age and P_{Cr}, which correlate inversely with GFR, and the patient's ideal body weight (IBW), which correlates directly with GFR:

$$\text{Estimated } C_{Cr} = \frac{(140 - \text{age}) \times (\text{IBW in kg})}{72 \times P_{Cr}}$$

When this equation is used for estimating C_{Cr} in women, the results should be multiplied by 0.85. This equation provides a quick and reasonably accurate estimate of GFR at the bedside and is particularly useful in determining dosage adjustments for pharmacologic agents excreted by the kidney.

Another equation, derived from the Modification of Diet in Renal Disease study, can also be used to more accurately assess renal function[6]:

$$\text{GFR} = 170 \times [\text{Scr}]^{-0.999} \times [\text{age}]^{-0.176} \times [0.762 \text{ if female}] \times [1.180 \text{ if patient is black}] \times [\text{BUN}]^{-0.170} \times [\text{albumin}]^{0.318}$$

This equation estimates GFR rather than creatinine clearance and factors in ethnicity, gender, and serum albumin concentration. The normal GFR is approximately 95 ± 20 ml/min in women and 125 ± 25 ml/min in men.

INULIN CLEARANCE

Inulin is a fructose polymer found in chicory and the Jerusalem artichoke; it is freely filtered by the glomerulus and is neither reabsorbed nor secreted by the tubule. Thus, inulin clearance (C_{In}) is one of the most accurate methods of quantifying renal function. C_{In} can be determined by the following equation:

$$C_{In}\,(\text{ml/min}) = \frac{\text{urine inulin (mg/dl)} \times \text{urine volume (ml/min)}}{\text{plasma inulin (mg/dl)}}$$

Inulin is an exogenous compound and must therefore be administered as a continuous infusion to achieve steady-state concentrations in the blood. The need for continuous infusion and the cost and limited supply of inulin prevent the routine clinical implementation of inulin-clearance testing.

IOHEXOL CLEARANCE

To avoid the aforementioned problems with GFR assessment, investigators use plasma-clearance techniques. Until recently, such measurements depended on radiolabeled markers of GFR, such as technetium-99m–diethylenetriamene pentaacetic acid, chromium-51–ethylenediaminetetraacetic acid, and iodine-125–iothalamate, which are accurate but costly and involve exposure to radioactive material. Plasma clearance of iohexol, a nonionic and nonradiolabeled contrast agent, provides an accurate measurement of GFR.[7,8] Low concentrations of iodine can be measured with x-ray fluorescence techniques in a single blood sample after a bolus injection of iohexol. Because

Table 2 Imaging Studies Used in Evaluating Patients with Renal Disease

Imaging Study	*Use*
Plain radiograph of abdomen (kidneys, ureters, and bladder [KUB])	Determining kidney size and shape; detection of nephrolithiasis (radiopaque) and nephrocalcinosis
Ultrasonography and CT scanning	Determining kidney size and shape, detecting urinary obstruction and radiolucent stones, distinguishing between simple and complex cysts, early evaluation of polycystic kidney disease, evaluation of renal mass
Intravenous pyelogram	Determining kidney size and shape and calyceal anatomy, diagnosis of medullary sponge kidney and papillary necrosis, detection of site and cause of obstruction
Radionuclide studies	Detection of urinary obstruction and urine leak, screening for renal artery stenosis, assessing renal arterial flow
Renal arteriography	Detection of renal artery stenosis, assessing for evidence of vasculitis, distinguishing vascular versus solid masses
Voiding cystourethrogram	Detection of vesicoureteral reflux
Retrograde or antegrade pyelography	Determining site of obstruction, placement of a ureteral stent
Magnetic resonance imaging	Detection of renal mass, detection of renal vein thrombosis

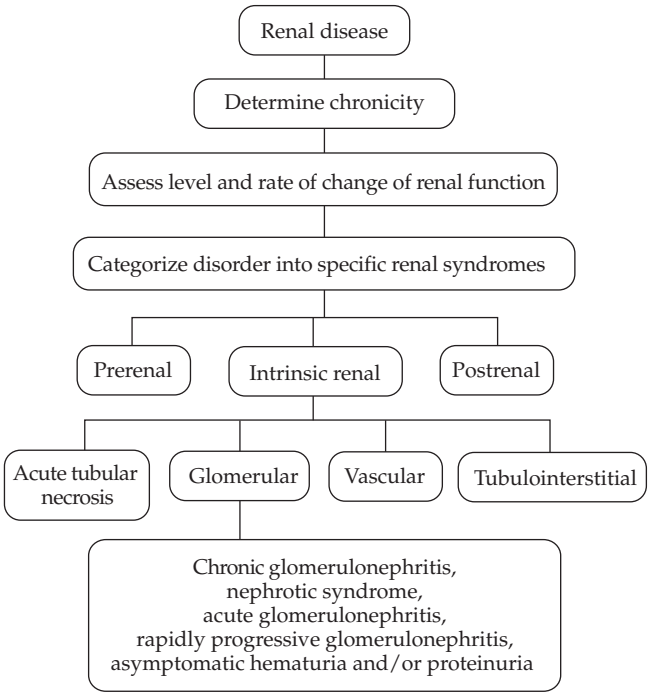

Figure 1 **Approach to the patient with renal disease.**

iohexol is excreted by glomerular filtration, the fall in plasma iodine levels can be converted to a plasma clearance value. Iohexol-derived GFR determinations are accurate over a wide range of values, and iohexol does not appear to be nephrotoxic even at extremely low levels of GFR (< 10 ml/min).[9,10]

Imaging Techniques for the Genitourinary System

Selected use of imaging studies can be an effective tool in the initial evaluation of patients with renal disease [*see Table 2*]. Renal ultrasonography provides information on kidney size, structure, and symmetry; cortical thickness; and the presence of hydronephrosis and nephrolithiasis. At the same time, ultrasound avoids the nephrotoxicity of large-volume radiocontrast procedures, such as the intravenous pyelogram. A plain film of the abdomen (KUB) can be used to assess kidney size and detect calcifications indicative of renal stones or nephrocalcinosis. Magnetic resonance imaging of the genitourinary tract is also a useful, noninvasive imaging modality.[11] In addition to providing a detailed structural image of the kidney, ureters, and bladder, MRI can be used to assess the renal vasculature. Magnetic resonance angiography, in which a gadolinium-based (non–iodine-containing) contrast agent is given intravenously, can be used in the evaluation of renovascular disease. This approach avoids the nephrotoxicity of the iodinated contrast used in conventional angiography. MRI is also an effective tool to detect renal vein thrombosis.

Major Syndromes of Renal Disease

After determining chronicity and current level of renal function, the clinician should attempt to classify the patient's renal disease into one of several syndromes, on the basis of the renal structures most affected [*see Figure 1*]. This classification is based on the information obtained in the history, physical examination, laboratory tests, and selected imaging studies [*see Table 3*]. It is particularly important to identify prerenal and postrenal disorders because they are often readily reversible.

PRERENAL DISEASE

Prerenal disease refers to azotemia that results from a reduction in effective arterial blood volume (EABV). The concept of EABV provides a meaningful way to explain why heart failure (a condition associated with total body volume overload) and severe vomiting (a condition associated with total blood volume depletion) are characterized by a similar renal response. In both of these conditions, the kidney behaves as if renal perfusion is decreased. The kidney is structurally normal and is simply responding to a perceived or actual underfilling in the circu-

Table 3 Urinalysis Findings and Selected Features of Renal Disease Syndromes

Renal Disease	*Urinalysis Findings*	*Other Features*
Prerenal	Specific gravity (SG) 1.020, glucose negative, protein negative, occasional hyaline casts	Signs and symptoms of decreased effective arterial blood volume, heart failure
Postrenal	SG 1.007, protein negative, blood negative, 0–3 erythrocytes/hpf, 0–3 leukocytes/hpf	Decreased urine flow, symptoms of prostatism in men
Acute tubular necrosis	SG 1.010, protein trace, blood negative, 1–3 leukocytes/hpf, many pigmented granular casts, 5–10 renal tubular casts/hpf, occasional renal tubular cells	History of hypotension, sepsis, or administration of nephrotoxins (e.g., radiocontrast, aminoglycosides, cisplatinum)
Nephrotic syndrome	SG 1.015, protein 4+, oval fat bodies, fatty casts	Edema, hypoalbuminemia
Acute tubulointerstitial nephritis	SG 1.012, protein 1+, blood 2+, 20–30 leukocytes/hpf, + stain for eosinophils, few leukocyte casts, 1–15 erythrocytes/hpf	Fever, morbilliform rash, eosinophilia, recent administration of antibiotic
Chronic tubulointerstitial nephritis	SG 1.012, protein 1+, glucose 1+ with normal serum glucose, 10–15 leukocytes/hpf, no bacteria	Type IV renal tubular acidosis, anemia, sodium wasting
Acute glomerulonephritis	SG 1.020, 2+ protein, 3+ blood, 15–20 erythrocytes/hpf, 3–5 erythrocyte casts/hpf, 0–3 leukocytes/hpf	Recent upper respiratory tract infection, nephritic syndrome
Rapidly progressive glomerulonephritis	Same as acute glomerulonephritis	Nephritic syndrome, hemoptysis, rapid loss of renal function

lation. The findings utilized to diagnose prerenal disease are reviewed in detail elsewhere [*see 10:VI Acute Renal Failure*].

POSTRENAL DISEASE

Obstruction of urine flow can occur anywhere along the urinary tract from the renal pelvis to the urethra. Anuria suggests complete urinary obstruction, although anuria can also be a feature of bilateral renal artery thrombosis, acute cortical necrosis, or severe acute tubular necrosis. In the absence of complete obstruction, urine flow may not necessarily be decreased and in fact is often increased. Chronic partial obstruction of the ureters leads to ureteral dilatation, which overcomes the blockage of urine flow. In addition, obstruction impairs the urinary-concentrating ability and thus contributes to a polyuric state. Common causes of urinary obstruction include nephrolithiasis, prostate enlargement, neurogenic bladder in diabetic patients, and an enlarging cervical cancer. The urinalysis result is typically unremarkable in obstructive uropathy. The diagnosis is most often made by demonstrating ureteral dilatation on renal sonography.

INTRINSIC RENAL DISEASE

After excluding prerenal and postrenal disease, the clinician should focus on various causes of intrinsic renal disease. Intrinsic renal disease can be subdivided into acute tubular necrosis, vascular renal disease, tubulointerstitial disease, and glomerular disease [*see Figure 1*].

Acute Tubular Necrosis

Acute tubular necrosis is the most common cause of intrinsic renal disease. This disorder most commonly results from ischemic or nephrotoxic injury to the kidney.[12] Acute ischemic injury is generally the consequence of severe hypotension, as occurs in cardiogenic shock, sepsis, or hemorrhage. Common causes of nephrotoxic injury include aminoglycosides and radiocontrast agents. Characteristic findings on urinalysis include granular and epithelial cell casts [*see Figure 2*]. Free renal tubular cells are also seen. The clinical characteristics of acute tubular necrosis are reviewed in detail elsewhere [*see 10:VI Acute Renal Failure*].

Renal Vascular Disease

Vascular disease of the kidney can involve either the arteries or the veins. Thrombosis of the renal veins is a complication of the nephrotic syndrome. Acute renal vein thrombosis presents as sudden flank pain and hematuria, whereas chronic renal vein thrombosis is often asymptomatic. In some cases, renal vein thrombi may be the source of a pulmonary embolus.

Renal artery diseases may present in one of several ways. Renal artery stenosis can cause secondary hypertension or give rise to ischemic nephropathy and a slow progressive loss of renal function.[13] Administration of an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker can precipitate acute renal failure in the setting of bilateral renal artery stenosis or an obstructed solitary kidney. A comprehensive review of renal vascular disease is provided elsewhere [*see 10:VII Vascular Diseases of the Kidney*].

Tubulointerstitial Renal Disease

Tubulointerstitial renal disease refers to diseases that principally involve the tubules or interstitium, with relative sparing of the glomeruli. These diseases can be primary to the kidney or can be part of a systemic disorder. Tubulointerstitial disease can be further subdivided into acute or chronic, on the basis of the clinical presentation and laboratory findings.

Acute interstitial renal disease most commonly occurs in patients taking a sulfa or β-lactam antibiotic, but this disease can occur with virtually any drug. Clinically, this condition presents as a systemic allergic disorder with fever and rash, beginning 7 to 10 days after the drug is started. Laboratory examination reveals an increased serum creatinine concentration and peripheral eosinophilia. The urinalysis demonstrates white blood cells (WBCs), WBC casts, and eosinophiluria [*see Figure 2*]. Proteinuria tends to be low grade, with no more than 1 to 2 g of protein in a 24-hour specimen. Histologically, there is a marked inflammatory cell infiltrate in the interstitium, with evidence of tubulitis.

Chronic tubulointerstitial renal disease is much more subtle in presentation, often manifested only by a slowly rising creatinine concentration over months to years. The characteristic histologic finding in chronic tubulointerstitial nephritis is interstitial fibrosis. Laboratory tests are characterized by evidence of tubular dysfunction. Characteristic findings include an inability to concentrate the urine, hyperkalemia out of proportion to the reduction in GFR, early development of a hyperchloremic normal-gap metabolic acidosis, and a tendency toward salt wasting. Sterile pyuria is often present on urinalysis. Anemia is common and tends to be more severe than in glomerular disease, because erythropoietin is primarily synthesized by cells in the interstitium. Tubulointerstitial renal disease is discussed in detail elsewhere [*see 10:VIII Tubulointerstitial Diseases*].

GLOMERULAR DISEASE

Diseases of the glomerulus can present as one of five clinical syndromes: chronic glomerulonephritis, nephrotic syndrome, acute glomerulonephritis, rapidly progressive glomerulonephritis, or asymptomatic hematuria or proteinuria [*see Figure 1*]. The clinical characteristics and the urinalysis results are useful for determining which syndrome is present in a patient with suspected glomerular disease [*see Table 3*].

Diseases that cause active inflammation in the glomerulus are typically associated with a constellation of clinical features referred to as the nephritic syndrome. This syndrome is characterized by signs and symptoms suggestive of primary salt retention by the kidney, resulting in volume overload and circulatory congestion. Manifestations include hypertension, congestive heart failure, and peripheral edema. The urinalysis result also reflects active glomerular inflammation and is described as nephritic in nature. A nephritic urinary sediment is characterized by a variable number of red blood cells (RBCs), WBCs, and RBC casts [*see Figure 2*]. The finding of RBC casts is pathognomonic of active glomerulonephritis. Proteinuria is usually modest, ranging from 2 to 6 g in a 24-hour collection, and the GFR is often severely reduced.

The nephrotic syndrome results from diseases that produce little in the way of active glomerular inflammation but, instead, cause massive leakage of protein across the glomerular basement membrane. The development of hypoalbuminemia and subsequent decline in oncotic pressure cause intravascular fluid to translocate into the extravascular compartment, giving rise to a contracted EABV. In turn, the decline in EABV results in secondary renal salt retention. Unlike the nephritic syndrome, hypertension is less prominent and findings of circulatory congestion are absent. Typically, the GFR is only mildly reduced. The urinalysis result also reflects the lack of inflammation in the glomerulus. Characteristic findings include free-fat droplets,

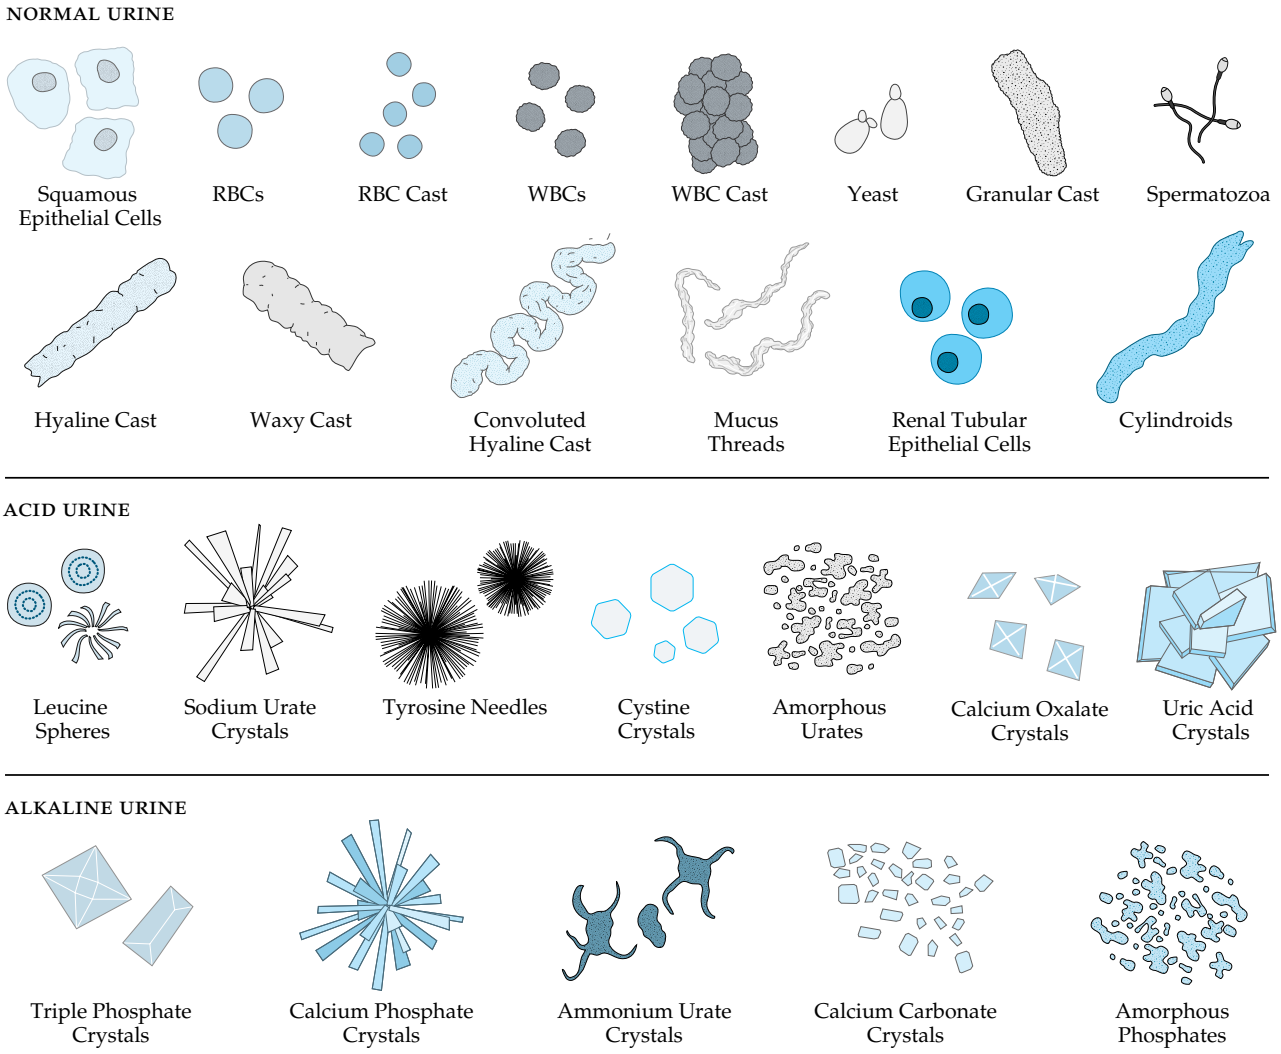

Figure 2 **Components of urinary sediment.**

oval fat bodies, fatty casts, and only minimal amounts of cellularity. These findings, along with large amounts of protein in the urine, constitute a nephrotic urinary sediment.

Chronic Glomerulonephritis

Chronic glomerulonephritis describes a patient with evidence of chronic renal failure who shows characteristics of glomerular disease. The urinalysis demonstrates a few RBCs and WBCs but is mostly nonspecific. A variable amount of proteinuria is present. Kidney size is typically small, reflecting the presence of advanced fibrosis and glomerulosclerosis. Patients with this syndrome presumably have a glomerular disease that has progressed to end stage, leaving the kidneys irreversibly damaged.

Nephrotic Syndrome

The nephrotic syndrome describes a patient who presents with a nephrotic clinical picture and a nephrotic urinary sediment. In addition to edema, hypoalbuminemia, and large amounts of protein in the urine, a number of other findings are typical of the nephrotic syndrome. These include hyperlipidemia, hypercoagulability, and a predisposition to infection with encapsulated gram-positive organisms because of hypogammaglobulinemia. As with other clinical syndromes, the underlying cause of the nephrotic syndrome can be a primary renal disease or secondary kidney involvement as part of a systemic disorder. Because the kidney can respond to injury in only a few ways, systemic disorders often cause the same histologic picture as primary renal disease. For example, membranous glomerulopathy is a primary renal disease, but this same histologic pattern can develop as a result of systemic lupus erythematosus or exposure to gold in the treatment of rheumatoid arthritis.

The approach to the patient with nephrotic syndrome is directed toward distinguishing primary from secondary glomerular diseases. Routine clinical evaluation may be sufficient to make this distinction, but in many cases, additional laboratory tests are required [*see 10:V Glomerular Diseases*].

Acute Glomerulonephritis

Acute glomerulonephritis describes a patient who presents with the abrupt onset of a nephritic clinical syndrome accompanied by a nephritic urinary sediment. There is evidence of circulatory congestion, manifested by hypertension and occasionally

by pulmonary congestion. Examination of the urine demonstrates RBCs, WBCs, and RBC casts. The GFR is relatively stable, in contrast to the rapid fall in GFR seen with the syndrome of rapidly progressive glomerulonephritis. Acute glomerulonephritis is often associated with a preceding infection and can resolve spontaneously. The workup is designed to determine whether the underlying disorder is a primary renal disease or a systemic disorder affecting the kidney [*see 10:V Glomerular Diseases*].

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis should be considered in patients who present with a nephritic clinical picture and who have a nephritic urinary sediment. This condition is distinguished from acute glomerulonephritis by the rapid loss of renal function, which is defined as a rise in the serum creatinine concentration of more than 2 mg/dl over a 3-month period. This syndrome has a much less consistent temporal relationship with infection, and there is little tendency for spontaneous recovery.

This syndrome needs to be recognized early so that renal biopsy can be done and therapy instituted immediately, if indicated. With patients in whom renal biopsy shows a crescentic glomerulonephritis, immunofluorescent studies provide a useful classification of the diseases that most commonly give rise to this clinical syndrome.

Asymptomatic Hematuria or Proteinuria

Asymptomatic hematuria or proteinuria describes a patient who has hematuria or proteinuria, or both, but who is otherwise without clinical symptoms. The approach to these patients is described below.

Asymptomatic Urinary Sediment Abnormalities

PROTEINURIA

Proteinuria is relatively common, with 5% to 10% of urine dipstick tests showing positive results in adults during screening examinations.[14] Because many disease states and mechanisms can underlie proteinuria, it is important to review renal handling of protein under normal conditions to formulate a differential diagnosis on the basis of structural-functional abnormalities.

Transient and Orthostatic Proteinuria

Two types of asymptomatic, isolated proteinuria warrant consideration: transient or functional proteinuria and orthostatic proteinuria. The underlying mechanism for transient proteinuria is not yet understood. Common factors such as fever, heart failure, seizure activity, pancreatitis, and exercise are frequently associated with transient proteinuria.[15] The proteinuria resolves with treatment of the underlying cause. Orthostatic proteinuria occurs in up to 5% of adolescents but is uncommon in older age groups.[16] Typically, such patients demonstrate proteinuria while in the upright position, which then resolves when the recumbent position is assumed. Long-term follow-up studies demonstrate no deterioration in renal function over time. Generally, orthostatic proteinuria resolves spontaneously.[16]

Persistent Proteinuria

Persistent proteinuria generally connotes significant renal pathophysiology. Renal protein excretion is determined primarily by three factors: the characteristics of the protein (its size and charge, as well as its concentration in the blood); the permeability of the glomerular capillary wall; and tubular reabsorption of filtered protein. Smaller and more positively charged proteins have greater rates of filtration into the urinary space than do larger and more negatively charged proteins. Normally, 1 to 3 g of protein (approximately two thirds globulin and one third albumin) are filtered daily. Over 90% of the filtered load is reabsorbed by the tubule, so that 150 mg of protein is maximally excreted each day.

There are three categories of persistent proteinuria: overflow, glomerular, and tubulointerstitial. In overflow proteinuria, proteins that are normally filtered are produced in such high quantities that they overwhelm the reabsorptive capacity of the tubule and are spilled into the urine. The glomerular filtration barrier is intact and functions normally. Paraprotein disorders such as multiple myeloma, in which excess immunoglobulin light chains are produced, result in Bence-Jones proteins in the urine. Lysozymuria, which occurs in patients with myelogenous leukemia, and myoglobinuria caused by rhabdomyolysis are two additional examples of overflow proteinuria. Standard urine dipsticks will react positively only with albumin (and other negatively charged proteins) and thus will be negative in dysproteinemic states when paraproteins (positively charged proteins) appear in the urine. When such disorders are suspected, sulfosalicylic acid or heat acetic precipitation methods should be used to detect nonalbumin species.

In glomerular proteinuria, the glomerular filtration barrier is structurally abnormal (as in diabetic nephropathy, amyloidosis, and membranous lesions) or loses its fixed negative charge (as in minimal change disease). Both the filtration barrier of the glomerular basement membrane and the reabsorptive capacity of the tubule are exceeded. As a result, proteinuria is often heavy, with albumin being the most prevalent protein. When urinary protein excretion exceeds 3.5 g in a 24-hour collection, nephrotic-range proteinuria is said to be present.

Tubulointerstitial proteinuria occurs when tubular dysfunction and injury preclude normal reabsorptive pathways for filtered proteins, primarily low-molecular-weight globulins. Additionally, damaged tubules may secrete excess proteinaceous material into the urinary space (Tamm-Horsfall mucoprotein). Typically, protein excretion amounts to 1 to 2 g/24 hr but can exceed 3 g/24 hr as tubulointerstitial disease progresses, causing secondary glomerular injury. Acute tubulointerstitial nephritis, tubular toxins such as aminoglycosides, and Fanconi syndrome can underlie this type of proteinuria. So-called indeterminate proteinuria (0.3 to 3.0 g/24 hr, primarily albumin) can be seen in diseases such as hypertensive nephrosclerosis, obstructive uropathy, and chronic tubulointerstitial nephritis.

Diagnosis of Proteinuria

Quantifying the amount of protein excreted by a patient is conventionally done with a 24-hour urine collection. An efficient and accurate alternative is measurement of the protein-to-creatinine ratio in a spot urine specimen.[17] The numerical value of this ratio represents the amount of urinary protein excreted in grams per day. For example, if a patient has 150 mg/dl of protein and 50 mg/dl of creatinine in a spot urine specimen, a total protein excretion rate of 3 g/24 hr would be expected. This simple procedure is accurate and independent of the amount of proteinuria, degree of renal insufficiency, or underlying disease state.

The urine dipstick test for protein can give false positive results when various pharmacologic agents and gross hematuria

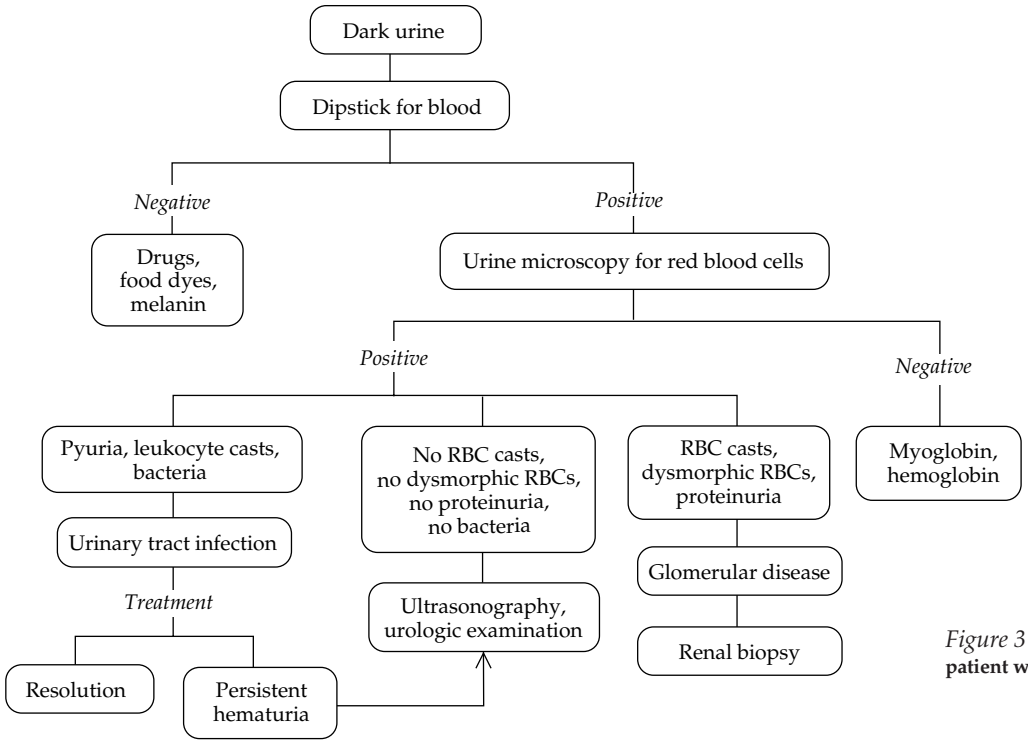

Figure 3 **Approach to the patient with hematuria.**

are present or when urine pH is high (> 7.0). False negative results highlight the fact that dipstick testing primarily detects albumin but misses positively charged proteins such as paraproteins (e.g., Bence-Jones immunoglobulin light chains).

HEMATURIA

Hematuria is defined as an RBC count greater than 1 RBC per high-power field for men and a count greater than 3 RBCs per high-power field for women. Alternatively, urinary tract blood loss that is greater than 8,000 to 15,000 RBCs/ml of urine is considered abnormal. Hematuria can be microscopic or gross, but the degree of hematuria is generally of little diagnostic or prognostic value. As little as 1 ml of blood per liter of urine can cause a visible color change. Not all reddish-brown urine is the result of hematuria. Hemoglobinuria and myoglobinuria can cause similar discoloration, but only the supernatant of a spun urine sample is discolored; RBCs are absent on urine microscopy in these conditions. Drugs such as rifampin, sulfasalazine, and the phenothiazines can also cause red discoloration of urine [*see Figure 3*].

Hematuria is a relatively common clinical finding. Froom and colleagues reported a 40% incidence on routine urinalysis in 1,000 men between 18 and 33 years of age; 13% of postmenopausal women were reported to have hematuria on routine screening.[18,19] Crystalluria caused by hypercalciuria or hyperuricosuria may often account for so-called idiopathic hematuria in asymptomatic persons. Crystal aggregates or microcalculi are thought to injure tubular epithelium, resulting in hematuria. Andres and colleagues found that more than 30% of children with isolated hematuria had hypercalciuria and a positive family history of nephrolithiasis.[20] If left untreated, these children have an increased risk of kidney stones later in life. Similar patterns have been observed in adults; correction of hypercalciuria or hyperuricosuria leads to resolution of hematuria in most cases.

Differential Diagnosis

The differential diagnosis of hematuria is extensive but can be divided into two broad categories: renal, or so-called upper tract, sources; and nonrenal, or so-called lower tract, sources.[21] In most cases, hematuria is nonrenal in origin. Mariani and colleagues determined the etiology for asymptomatic, isolated hematuria in adults in 1,000 consecutive cases.[22] Of 883 cases in which causes were identified, only 13 (1.5%) were glomerular in origin, whereas urethritis, prostate disease, bladder carcinoma, and cystitis accounted for more than 75% of cases.

RBCs originating from the glomerulus have a distinctive dysmorphic appearance when viewed on phase-contrast microscopy, whereas hematuria originating from the lower urinary tract (nonglomerular hematuria) is characterized by uniform, intact RBCs similar to those seen on a peripheral smear. Diagnostically, the use of RBC dysmorphism is somewhat limited by the need for phase-contrast microscopy and a trained urine microscopist.

If glomerulonephritis appears to be an unlikely diagnosis on the basis of clinical findings, serial urinalyses should be done to determine whether hematuria is transient or persistent. Transient hematuria, particularly in young persons, is quite common and rarely indicative of significant pathology.[23] When present in patients older than 50 years, however, transient hematuria warrants a comprehensive evaluation to rule out malignancy. Persistent hematuria in patients of any age mandates a thorough diagnostic workup.

Historical clues can provide key diagnostic information in the evaluation of patients with hematuria. For example, inherited forms of renal disease are likely if a patient has a family history of autosomal dominant polycystic kidney disease, deafness (Alport disease), or sickle cell trait or disease. Flank pain radiating to the groin may indicate urinary tract obstruction caused by stones or blood clots. Dysuria, urinary frequency, and urgency are consistent with an infectious source. A recent upper respiratory tract infection may have triggered IgA nephropathy or postinfectious glomerulonephritis. Hematuria may develop spontaneously in patients receiving anticoagulants. Finally, in-

tense exercise, such as long-distance running, can precipitate hematuria, as can prostate enlargement.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

IV MANAGEMENT OF CHRONIC KIDNEY DISEASE

Biff F. Palmer, m.d., f.a.c.p.
Michael K. Hise, m.d.

End-stage renal disease (ESRD) is an important source of long-term morbidity and mortality. Efforts to reduce or prevent the development of this disorder are of paramount importance. One of the problems that nephrologists often encounter is that patients are referred late in the course of disease, when treatments are largely ineffective. Thus, it is imperative to identify patients early and to treat them aggressively. Recently published clinical practice guidelines are aimed at accomplishing this goal. This chapter reviews the management of patients with chronic kidney disease (CKD), giving particular emphasis to the following: (1) methods that can be clinically used to accurately stage and monitor the level of renal function; (2) identification of common comorbidites of CKD; (3) the pathophysiology of CKD; (4) therapies designed to slow the progression of CKD; (5) management of common complications of CKD (e.g., anemia, fluid and electrolyte disturbances, and renal osteodystrophy); and (6) timely referral to a nephrologist so as to ensure a smooth transition to renal replacement therapy when indicated. Information on the causes and manifestations of CKD are covered elsewhere [*see 10:X Chronic Renal Failure and Dialysis*].

Overview of Clinical Practice Guidelines for Chronic Kidney Disease

It is estimated that 20 million persons in the United States population have chronic kidney disease. The typical course of patients with CKD is progression to kidney failure and development of cardiovascular disease. Increasing evidence suggests that treatment strategies initiated at earlier stages of CKD are effective in slowing the progression toward kidney failure. In addition, addressing cardiovascular risk factors at earlier stages of CKD should be effective in reducing cardiovascular events and mortality, both before and after the onset of kidney failure.

To date, implementation of measures designed to detect and treat CKD at an early stage have been hampered, in part by lack of agreement on a definition and classification of stages in the progression of chronic kidney disease. In addition, there has not been a uniform application of tests for detection and evaluation of such patients. In February 2002, the Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines were published in an attempt to address the growing burden of CKD in the United States.[1] These guidelines emphasize the need for prevention, early diagnosis, and aggressive treatment of CKD.

definition and staging of chronic kidney disease

CKD is defined as either kidney damage or a glomerular filtration rate (GFR) of less than 60 ml/min/1.73 m^2 for more than 3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormal findings in blood or urine tests or imaging studies. In patients with CKD, the stage is defined by the level of the GFR. The level of GFR is considered to be the best measure of overall kidney function in health and disease.

Inulin or iothalamate clearance is regarded as the gold standard for measuring GFR. However, these methods are cumbersome and expensive and are not available to many practicing physicians. By contrast, the GFR can be easily estimated by formulas that take into account the patient's age, gender, ethnicity, and serum creatinine concentration [*see Table 1*]. The Modification of Diet in Renal Disease (MDRD) and Cockcroft-Gault equations are two such formulas that provide useful estimates of GFR in adults. Of these, the MDRD equation is more accurate and precise for persons with a GFR of less than 90 ml/min/1.73 m^2. The equation was based on a large database encompassing persons with various diseases and including both European Americans and African Americans. The K/DOQI clinical practice guidelines state that clinicians should not use serum creatinine concentration as the sole means to assess the level of kidney function. In addition, measurement of the 24-hour creatinine clearance level to assess GFR is no more accurate than estimating GFR from the MDRD equation. Certain clinical conditions, however, may necessitate use of creatinine clearance as a way to better assess the GFR [*see Table 2*].

Evaluation of all patients with CKD should include testing for proteinuria. Persistent proteinuria is usually a marker of kidney damage, and in the setting of a normal or increased GFR, it signifies the presence of stage 1 CKD. Proteinuria is also a strong and independent predictor of increased risk for cardiovascular morbidity and mortality, particularly in high-risk groups such as diabetics, hypertensives, the elderly, and those with CKD.

The preferred method for measuring proteinuria is the ratio of protein or albumin to creatinine (mg/g) in an untimed urine specimen. Timed urine collections are inconvenient to obtain and may be associated with errors; therefore, they are usually not necessary for measuring proteinuria. In addition to being utilized for the detection of CKD, measurement of the protein- or albumin-to-creatinine ratio is a useful way to monitor proteinuria in patients with known CKD. Changes in the degree of proteinuria are directly associated with the risk of loss of kidney function.

evaluation and treatment

Once a patient is identified as having CKD, a clinical action plan is implemented on the basis of the patient's stage of disease [*see Table 3*]. Although specific therapies vary according to the underlying cause of kidney disease, many aspects of treatment are common to all types of CKD. Treatment of comorbid conditions, interventions to slow the progression of kidney disease, and measures to reduce cardiovascular disease should begin during stages 1 and 2. Particular attention needs to be given in

Table 1 Equations to Estimate Glomerular Filtration Rate

Abbreviated MDRD (Modification of Diet in Renal Disease Study) equation:

GFR (ml/min/1.73 m^2) = $186 \times (Scr)^{-1.154} \times (age)^{-0.203} \times 0.742$ (if female) $\times$ 1.210 (if African American)

Cockcroft-Gault equation:

Creatinine clearance (ml/min) = [140 – age $\times$ weight (kg) / 72 $\times$ serum creatinine] $\times$ 0.85 (if female)

Table 2 Clinical Conditions That May Require Measurement of GFR Using Clearance Methods

- Extremes of age and body size
- Severe malnutrition or obesity
- Diseases of skeletal muscle
- Paraplegia or quadriplegia
- Vegetarian diet
- Rapidly changing kidney function
- Calculation that potentially toxic drugs may be excreted by the kidney

stages 1 and 2 to aggressively control blood pressure. Evaluation and treatment of anemia, malnutrition, bone disease, neuropathy, and decreased quality of life should be undertaken in patients with stage 3 CKD. Preparations for renal replacement therapy should begin as patients enter stage 4. Kidney failure (stage 5) is defined either as a GFR of less than 15 ml/min/1.73 m^2 or as complications of decreased GFR severe enough to increase the risk of mortality and morbidity unless initiation of kidney replacement is undertaken. Some patients who have symptoms of uremia may require kidney-replacement therapy although their GFR is greater than 15 ml/min/1.73 m^2.

The K/DOQI guidelines recommend that all routine health encounters include an assessment to determine whether an individual is at increased risk for developing kidney disease. Persons deemed to be at increased risk should undergo testing for proteinuria. Detection of proteinuria in patients at increased risk would allow for early implementation of measures designed to reduce proteinuria, slow the progression of kidney disease, and reduce the risk of cardiovascular mortality and morbidity. Numerous clinical factors are identified with increased risk of developing kidney disease [*see Table 4*]. Some of these factors are discussed in more detail below.

Comorbidites of Chronic Kidney Disease

In the United States, millions of patients have an increased serum creatinine concentration.[2,3] In many of these patients, the renal insufficiency is advanced. Diabetes and hypertension are the underlying causes of renal disease in the majority of these patients. The remaining cases can be accounted for by a variety of primary glomerular diseases, cystic renal diseases, obstruction uropathy, and renal diseases related to infections.

Regardless of the underlying cause, it should be appreciated that CKD carries with it the burden of other comorbidities that directly influence patient outcome. In addition, abnormal renal function confers its own inherent risk. In the Hypertension Detection and Follow-up Program, cardiovascular disease was strongly associated with a serum creatinine level of 1.7 mg/dl or more, and this risk was independent of other factors.[4] In the 10,768 participants in this program, the risk of death increased progressively with increasing creatinine concentration. There was an almost fivefold increase in the 8-year mortality between patients in the lowest stratum of creatinine concentration and those in the highest. Similar findings were reported in the Heart Outcomes and Prevention Evaluation.[5] In this study, the incidence of cardiovascular death, myocardial infarction, and stroke increased with each quartile of serum creatinine concentration. This association between renal function and mortality is particularly strong in the elderly.[6]

STROKE

The prospective British Regional Heart Study, comprising 7,690 men 40 to 59 years of age, demonstrated that the risk of stroke was significantly increased when the creatinine concentration was above the 90th percentile—a serum creatinine concentration of 116 mmol/L—whereas all-cause mortality and cardiovascular mortality were significantly increased when the serum creatinine concentration was only above the 97.5 percentile.[7] In elderly persons admitted to an acute care hospital with stroke, the serum creatinine concentration was a highly significant predictor of survival.[8]

CARDIAC DISEASE

The relationship between renal function and myocardial infarction (MI) was studied in 417 patients.[9] These individuals did not have diabetes, and their baseline creatinine values ranged from 0.7 to 1.9 mg/dl. Each 0.1 mg/dl increase in baseline creatinine concentration was associated with a 36% increase in the relative risk of subsequent overall mortality and a 47% increase in the relative risk of subsequent mortality from coronary artery dis-

Table 3 Stages of CKD and Clinical Action Plans

Stage	*Description*	*GFR (ml/min/1.73 m^2)*	*Action*
0	At increased risk	≥ 90 (with CKD risk factors)	Estimate GFR and determine presence or absence of proteinuria; institute steps to reduce CKD risk
1	Kidney damage with normal or ↑ GFR	≥ 90	Diagnosis and treatment, treatment of comorbid conditions, slow progression, CKD risk reduction
2	Kidney damage with mild ↓ GFR	60–89	Estimate progression
3	Moderate ↓ GFR	30–59	Evaluate and treat complications
4	Severe ↓ GFR	15–29	Prepare for kidney replacement therapy
5	Kidney failure	< 15	Kidney replacement (if uremia present)

CKD—chronic kidney disease ↑ GFR—increased glomerular filtration rate ↓ GFR—decreased glomerular filtration rate

Table 4 Risk Factors for CKD Requiring Testing for Proteinuria and Determination of an Estimated GFR

Clinical factors	Diabetes Hypertension Autoimmune diseases Urinary tract infection Nephrolithiasis Urinary tract obstruction Cancer Family history of CKD Reduction in kidney mass Exposure to nephrotoxins Low birth weight
Sociodemographic factors	Elderly Ethnic minority status (African American, Native American, Hispanic) Exposure to chemical or environmental hazard Low income or education

CKD—chronic kidney disease GFR—glomerular filtration rate

ease. A similar trend between mortality and serum creatinine levels was observed in another study of post-MI patients.[10] Nearly 75% of individuals starting dialysis have left ventricular hypertrophy (LVH), and there is an inverse relationship between renal function and the incidence of LVH in patients before undergoing dialysis.[11] There is also a high prevalence of congestive heart failure. The incidence of coronary artery disease is approximately 40% in patients receiving dialysis, and there also appears to be an increased incidence of peripheral vascular disease in patients with abnormal renal function.

Risk Factors for Progression of Kidney Disease

Most patients with established CKD continue to experience a decrease in renal function over time.[3] This section reviews various factors known to contribute to loss of renal function. In addition, therapies that can slow the progression of CKD are discussed.

DIABETES MELLITUS

Animal models have provided a clear picture of the mechanisms underlying diabetic glomerular destruction. What is not known is why only approximately 40% of patients with type 1 (insulin-dependent) diabetes mellitus are at risk. Obviously, genetics plays an important role, but other potentially manageable factors are also important. Hyperglycemia through nonenzymatic glycosylation, production of oxidants, or stimulation of the production of diacylglycerol may activate protein kinase C (PKC). It has been shown that levels of PKC are increased in the diabetic kidney.[12,13] PKC causes an increase in production of transforming growth factor–β (TGF-β), which is a potent stimulator of collagen formation and basement membrane thickening. A variety of other alterations, including permeability changes, altered fibrinolysis, changes in gene expression, and vascular contractility, may also be stimulated by PKC.[14] Interestingly, inhibition of PKC in the kidney and retina reduces diabetes-related abnormalities.[15] Micropuncture studies in diabetic animals showed that glomerular intracapillary pressures were increased.[16] These changes may lead to structural alterations that are important in the pathogenesis of diabetes-related complications.

Type 1 Diabetes Mellitus

The most important study regarding the treatment of type 1 diabetes is the Diabetes Control and Complications Trial (DCCT).[17] This study examined 1,441 patients with type 1 diabetes. Of these patients, 726 had no retinopathy at baseline; 715 had mild retinopathy. After a mean follow-up period of nearly $6\frac{1}{2}$ years, intensive insulin therapy reduced the occurrence of microalbuminuria by 39% and the occurrence of macroalbuminuria (> 300 mg/24 hr) by 54% in the combined groups. Improvement in nephropathy was mirrored by a slowing in the progression of retinopathy and neuropathy. A follow-up to this study indicated that the effects of intensive treatment are long lasting.[18]

Type 2 Diabetes Mellitus

Although type 1 diabetes has received a great deal of attention, the incidence of type 2 (non–insulin-dependent) diabetes continues to rise at a rapid pace, particularly in members of minority groups, including African Americans and Native Americans. In patients with nephropathy and type 2 diabetes, familial clustering has been observed. Polymorphism of the angiotensin-converting enzyme (ACE) gene may influence the rate of renal disease progression, and several genes have been linked to renal disease in specific populations.[19] Although the renal lesions in type 2 diabetes are similar to those in type 1, a greater proportion of patients with type 2 diabetes have nonspecific lesions, including ischemic changes.[20] Control of hyperglycemia in patients with type 2 diabetes is a controversial issue. Some studies have failed to show an association between good glucose control and the maintenance of functional nephron mass. On the other hand, Hsu and colleagues demonstrated that hemoglobin A_{1c} (HbA_{1c}) levels were independent predictors of a decline in renal function.[21]

Treatment of Diabetes Mellitus in Patients with CKD

Treatment of type 1 diabetes mellitus Treatment of type 1 diabetes in patients with CKD requires the use of insulin therapy [*see 9:VI Diabetes Mellitus*]. Management should include a carefully structured diet and exercise. Care must be taken to avoid malnutrition with advancing renal insufficiency because anorexia is part of the uremic syndrome. Continuing podiatric care is an important part of the exercise program. The use of insulin requires special care in patients with renal insufficiency because of the prolonged half-life of insulin. Furthermore, CRF patients with type 1 diabetes frequently have long-standing disease, and there may be few warning signs of hypoglycemia. Gastroparesis with erratic food absorption further increases the risk of hypoglycemia. Home glucose monitoring is an invaluable element in the care of these patients, as is careful follow-up by providers skilled in diabetes management. Symptomatic hypoglycemia is much more common with tight glucose control, and it is difficult to maintain proper glucose levels within the framework of traditional practice. This is clearly evident in the follow-up of the patients in the DCCT trial.[17,18] In the patients assigned to receive tight control of glucose levels, HBA_{1c} increased from 7.2% to 7.9% in the 4-year interval after the conclusion of the original study. Transplantation is gaining increasing favor as a method of treating patients with type 1 diabetes, especially those with advancing renal disease, because of the use of simultaneous kidney and pancreas transplantation.

Treatment of type 2 diabetes mellitus Treatment of patients with type 2 diabetes who have renal insufficiency should

also begin with a carefully designed diet and exercise program. Weight loss plays an important role in improving insulin resistance and should be employed as well. It should be kept in mind that there are a number of drugs that are associated with worsening of insulin resistance [*see Table 2 and 9:VI Diabetes Mellitus*]. One should consider altering the drugs in patients with type 2 diabetes whose glucose levels are difficult to control. Early in the course of disease, when the patient has some pancreatic insulin reserves, hypoglycemic agents can be considered. Their use, however, is complicated in patients with renal disease. Metformin and other biguanides may cause lactic acidosis and should not be used in patients with even mild degrees of renal dysfunction. Troglitazone may be used in this situation because of its hepatic excretion; however, there is a high risk of acute hepatitis with this agent, necessitating monthly monitoring of liver function. One should avoid the older sulfonylureas, such as chlorpropamide, because of their reduced renal excretion. Glipizide is inactivated by the liver and may be a better choice. Acarbose, which reduces carbohydrate absorption, should be avoided. Unfortunately, the majority of patients with type 2 diabetes require insulin therapy. These individuals frequently gain weight with therapy. Other complications include hypoglycemia and hyperinsulinemia. The latter is of concern because of its association with cardiovascular complications. Patients whose glucose levels cannot be controlled within an acceptable range should be referred to specialized clinics. Investigations are needed to understand and reverse the trend toward increasing obesity in the United States, as it is a contributing factor in the development of type 2 diabetes, particularly in susceptible minority populations.

HYPERTENSION

The mechanisms of renal injury in hypertension were presumed to be ischemic in nature, but these mechanisms remained largely unexplained until the work of Brenner and colleagues provided detailed studies of the glomerular alterations in hypertensive rats with reduced renal mass.[22,23] These studies demonstrated that afferent arteriolar vasodilatation accompanied by similar but relatively less efferent arteriolar changes increased transcapillary filtration pressures. Although these changes were associated with improving glomerular filtration rates in the short term, they were eventually seen to be detrimental, leading to progressive glomerular sclerosis. In a direct test of this hypothesis in patients, a collaborative study demonstrated that the ACE inhibitor captopril was effective in reducing the development of nephropathy in patients with type 1 diabetes and in retarding the progression of established renal dysfunction over and above its effects in lowering blood pressure.[24] A similar benefit was recently shown with use of angiotensin receptor blockers in patients with type 2 diabetes and established nephropathy.[25,26]

The United Kingdom Prospective Diabetes Study demonstrated that moderate reductions in blood pressure were effective in reducing renal abnormalities; in this study, there were no apparent differences in effectiveness between the beta blocker atenolol and captopril. However, the target blood pressure values may have been too high to substantiate the beneficial effects of the ACE inhibitor.[27,28] The Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) study comprised 1,513 participants who were followed for an average of 3.4 years. It demonstrated that an antihypertensive program containing the drug, compared with placebo, significantly decreased the risk of the doubling of serum creatinine, ESRD, and death.[26] A repeat analysis of these data was performed to look specifically at systolic blood pressure and pulse pressure; every 10 mm Hg rise in baseline systolic blood pressure increased the risk for ESRD or death by 6.7%; a similar rise in diastolic blood pressure decreased the risk by 10.9%. Pulse pressure was a significant risk factor that was dramatically improved by losartan.[29]

Hypertension in Diabetic Patients

Although there is a great deal of focus on negative outcomes in patients with CRF, the Heart Outcomes and Prevention Evaluation (HOPE) trial provides some reasons for optimism. This study followed 3,577 individuals with diabetes for a median of 4.5 years. This group included 1,139 patients with microalbuminuria and 333 patients with renal insufficiency (i.e., serum creatinine level less than 2.3 mg/dl). During the follow-up period, serum creatinine values remained stable in those persons without overt proteinuria, as well as in those persons with renal insufficiency, microalbuminuria, or both. It should be noted that the patients were treated aggressively with lipid-lowering agents and antihypertensives. In addition, the study included only a few smokers.[30]

Hypertension in Nondiabetic Patients

Blood pressure control is equally important in nondiabetic patients with CKD. In the Seventh Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII), a blood pressure goal of less than 130/85 mm Hg is recommended.[31] It should be anticipated that multiple medications will be required to achieve these levels of control in most CKD patients.

Treatment of Hypertension in Patients with CKD

The MDRD study helped define the target levels of blood pressure in persons with renal disease. The results suggest that in patients with less than 1 g of protein in a 24-hour urine collection, the target blood pressure should be 130/80 mm Hg or less.[32] For those with findings of more than 1 g of protein, a target blood pressure value of 125/75 mm Hg should be sought. A recent consensus group sponsored by the National Kidney Foundation has suggested that the target blood pressure value for adults with hypertension and diabetes should be 130/80 mm Hg.[33] In most cases, these lower blood pressure goals can be obtained without significantly increasing side effects [*see 1:III High Blood Pressure*]. The findings of the African American Study of Kidney Disease and Hypertension (AASK) trial provides evidence that factors other than blood pressure play important roles in the functional decline in CKD. A low blood pressure, (e.g., average of 128/78, compared with 141/85) did not improve protection in the participants. However, an ACE inhibitor proved superior to a dihydropyridine calcium channel blocker in retarding progression of hypertensive kidney disease.[34]

PROTEINURIA

In a study of elderly persons, urinary albumin excretion was found to be associated with cardiovascular disease.[6] In this study, prognostic factors were male sex, serum creatinine concentration, and hypertension. In a study of 11,343 German patients, the presence of microalbuminuria served to identify hypertensive patients with cardiovascular risks.[35] In diabetic patients, microalbuminuria is a well-known risk factor for progression to ESRD. A study from the Royal Infirmary in Edinburgh, United Kingdom, examined the course of 190 patients with type I diabetes who had had the disease for least 30 years'

duration; the study followed the participants for at least 5 years. Microalbuminuria was absent in 66% of participants at baseline; 11% of these individuals died during the follow-up period. Individuals with microalbuminuria at baseline were 22% of the total; of these, 26% died during the follow-up period. Of the 8% of patients who had macroalbuminuria at baseline, 44% died during the follow-up period. These data provide strong evidence for the influence of albuminuria on overall mortality.[36]

Interestingly, microalbuminuria is also a predictor of renal disease in patients who do not have diabetes.[37] The association between proteinuria and a decline in renal function is particularly strong in patients with a finding of more than 1 g of protein in a 24-hour urine collection. The mechanism behind the association between proteinuria and a decline in renal function appears to be in part related to the fact that high levels of urinary protein stimulate interstitial inflammation and fibrosis.[38] For these reasons, drug therapy that minimizes urinary protein loss seems prudent. Because angiotensin II stimulates *TGF-β1* gene expression and type IV collagen production, treatment with agents that block the effects of angiotensin are likely to be effective.

SMOKING

Smoking is a well-known risk factor for the development of cardiovascular disease. The World Health Organization estimates that as many as three million deaths a year worldwide are related to tobacco use. This number of deaths will likely increase substantially in the future. Smoking is an independent risk factor for microalbuminuria in both hypertensive and nonhypertensive patients.[39] The relationship between smoking and progression of renal disease is not widely appreciated; however, the risk of the progression of diabetic nephropathy has been known for over 20 years. A multicenter case-control European study of 582 patients with either IgA nephropathy or polycystic kidney disease demonstrated an increase in the risk of progression to ESRD with increased levels of smoking, as measured in pack-years; this risk was mitigated by the use of ACE inhibitors.[40] Bleyer and colleagues analyzed data from the Cardiovascular Health Study Cohort. In 4,142 nondiabetic patients who were at least 65 years of age, the number of cigarettes smoked per day was found to correlate with an increase in creatinine concentration of at least 0.3 mg/dl. In general, these patients had a relatively low incidence of progressive renal deterioration.[41] The mechanisms of smoking-related renal injury are complex. Possible alterations include changes in intrarenal hemodynamics, altered sympathetic activity, direct tubular damage, changes in intrarenal hormones, and oxidative stress. Physicians should be aware of the specific data regarding the overall risk of smoking to health. The renal risks of smoking should not be underestimated, and smoking should trigger an aggressive approach by the health care provider [*see Clinical Essentials: III Reducing Risk of Injury and Disease*].

PROTEIN INTAKE

Protein intake has long been considered a potential risk factor for the progression of renal disease; protein restriction, however, remains a controversial topic in the treatment of chronic kidney disease. Interest in protein restriction in patients with renal disease has been fueled by animal studies conducted over several decades that demonstrate that diets high in protein lead to histologic abnormalities in the kidney and to proteinuria and that such diets are associated with high death rates. These effects have been shown to be reduced or eliminated by protein or calorie restriction. The fact that the controversy still exists suggests that the effects of protein restriction are likely to be small and difficult to achieve. A meta-analysis of 890 nondiabetic patients reported in 46 studies suggested that protein restriction was beneficial in reducing ESRD.[42] There was a 46% decrease in the number of patients requiring replacement therapy. Another meta-analysis, of 1,413 patients, demonstrated a reduction of ESRD or mortality in both diabetic patients and nondiabetic patients who were assigned to receive a low-protein diet.[43] A third meta-analysis, of 1,919 randomized patients and 2,248 nonrandomized patients, found that a reduction in dietary protein had only a weak effect on the development of ESRD, with diabetic patients tending to benefit the most and with more benefit being associated with longer follow-up.[44]

The most ambitious test of the low-protein-diet hypothesis was the MDRD study, in which 585 patients with GFRs of 25 to 55 ml/min were randomized to receive either 1.3 or 0.58 g protein/kg/day. A second group, with GFRs of 13 to 24 ml/min, were randomized to receive either 0.58 or 0.29 g protein/kg/day.[45] The diets of patients in the latter group were supplemented with an amino acid–keto acid mixture that equalized the protein intake. Nuclear clearances with iodine-125–iothalamate were employed; the follow-up period was slightly longer than 2 years. During the initial 4 months of the study, renal function worsened more rapidly in the low-protein group; after that initial 4-month period, the rate of decline in GFR was lower. The decline in renal function seen at the end of the study did not differ between the two patient groups. Similarly, there was no clear difference in renal function in the group receiving a very low protein diet, but there was a trend toward better outcomes in the group receiving the lowest amount of protein. A more recent review of the data indicates that individuals in the lowest GFR category whose diets contained the lowest amount of protein may have benefited from the intervention. A multicenter trial in Europe assigned 456 adults with renal disease to either a low-protein diet (0.6 g/kg/day) or a normal-protein diet (1 g/kg/day).[46] The end point of the study was a doubling of the baseline creatinine level or a need for dialysis. The difference between the groups in cumulative renal survival was of borderline significance ($P < 0.06$). Compliance was good in the group receiving the higher amount of protein and poor in the low-protein group. Protein restriction is of particular concern in children because of the added complication of growth. During a 3-year study, a low-protein diet did not affect renal outcome in children from 2 to 18 years of age.[47]

Several caveats are important when one considers diet therapy in patients with CKD. First, one must ensure an adequate caloric intake of approximately 35 kcal/kg/day. Second, physicians caring for these patients should understand the techniques used to monitor overall nutrition, including anthropometric measurements and use of serum transferrin and serum albumin levels. Protein intake can be estimated through the use of 24-hour urine urea nitrogen measurements plus an estimate of nonurea nitrogen losses. Third, physicians should understand that uremic symptoms respond to diets low in protein. These diets normally entail reduced intake of sodium, potassium, phosphate, and acid. Thus, renal osteodystrophy, hypertension, and metabolic acidosis are improved. Fourth, low-protein diets can be used without provoking malnutrition; however, patients should be closely monitored. A low-protein diet of 0.6 to 0.7 g/kg/day can be safely used as adjunctive therapy in individuals with CKD to ameliorate symptoms and to reduce complications of uremia. In certain patients, particularly those

with diabetes, such diets may slow the rate of renal disease progression.

HYPERLIPIDEMIA

A substantial number of patients with nephrotic syndrome without impaired renal function will have lipid abnormalities, including patients with diabetes and heavy proteinuria. The etiology appears to be related to an increase in hepatic synthesis of lipids. In an elegant study, Appel and colleagues demonstrated an inverse correlation between the total plasma cholesterol level and serum albumin level.[48] There was also an inverse relationship between cholesterol level and plasma oncotic pressure. On the other hand, there was no correlation between cholesterol level and plasma viscosity. The incidence of hyperlipidemia is also increased in patients with CRF. Kasiske has estimated that approximately 30% of patients with CKD and proteinuria in the nonnephrotic range have total cholesterol values higher than 240 mg/dl. Levels of triglycerides and lipoprotein(a) are estimated to be higher than 200 mg/dl and 30 mg/dl, respectively, in approximately 60% of patients. High-density lipoprotein (HDL) cholesterol levels tend to be low, whereas only approximately 10% will have elevated low-density lipoprotein (LDL) values.[49] One issue that must be considered is the relationship between lipid abnormalities and the deterioration of renal function. In a study by Bleyer and coworkers, there was no association between cholesterol level and a rise of 0.3 mg/dl in creatinine level, with measurements made at least 3 years apart.[41] On the other hand, there are several studies, including studies with diabetic patients, that do demonstrate a relationship between lipid abnormalities and the progression of CRF. Because of the high incidence of cardiovascular disease, all patients with CRF should be screened. Recently, the guidelines for treatment were revised by the National Cholesterol Education Program.[50] Diet should be the first line of therapy, but the addition of lipid-lowering drugs is almost always necessary. Newer HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors lower both LDL and triglyceride levels. Fibric acid analogues are effective in reducing triglyceride levels; however, myositis and rhabdomyolysis limit use of these agents. The dose of the fibric acid analogues should be adjusted appropriately for the degree of renal function.

Management of Complications of Chronic Kidney Disease

SODIUM AND WATER IMBALANCE

As renal mass becomes progressively reduced, the fractional excretion of salt and water increases in the remaining nephrons. The solute diuresis that occurs in the remaining nephrons results in a relatively fixed level of salt and water excretion. Thus, in patients with CKD, renal salt and water excretion is limited to a range that is quite a bit narrower than that of healthy persons.

The optimal salt intake will differ from patient to patient; once a level has been prescribed, salt intake will need to be constantly monitored, because requirements will vary as renal function changes. The goal should be a salt intake that results in the patient's being normotensive and maintaining a constant weight, with only trace edema present. A diet that restricts the amount of salt to 6 to 8 g/day is a useful starting point [*see Table 5*]. If the patient's weight begins to decrease over a period of several days and the patient becomes more azotemic, a higher salt intake is required. In addition, during intercurrent illness, supplemental salt can be given in the form of bouillon cubes if a deficit in extracellular fluid volume develops. By contrast, if the patient's weight increases over time and is accompanied by increasing edema and worsening hypertension, further salt restriction is indicated. Once the estimated GFR falls below 20 ml/min, even salt-restricted diets may exceed the excretory capacity of the kidney, and diuretic therapy will have to be utilized to prevent progressive expansion of the extracellular fluid volume.

Table 5 Typical Diet for Patients with Renal Insufficiency

0.8 protein/kg body weight	800–1,000 mg phosphate
6–8 g sodium	1,000–1,500 mg elemental calcium
70 mEq potassium	1,000–1,500 ml free water in excess of urine output

The ability to maximally concentrate or dilute the urine becomes progressively impaired as renal function declines. As a result, patients with CKD are at risk of developing positive water balance and resultant hyponatremia, as well as negative water balance and hypernatremia. In general, fluid intake should be equal to urine output plus an additional 1,000 to 1,500 ml/day to account for insensible losses. The treatment of hyponatremia depends on the existing extracellular fluid balance. In volume-overloaded patients, further water restriction is indicated. In hypovolemic patients, water restriction with judicious administration of salt and the withdrawing of diuretic therapy is the appropriate treatment.

POTASSIUM IMBALANCE

Potassium balance is generally maintained within normal limits until the GFR falls to less than 10 ml/min. This balance is achieved by an increased potassium excretion rate per remaining nephron and by an increase in extrarenal potassium excretion, primarily effected via the colon. The development of hyperkalemia at higher levels of renal function suggests the presence of tubulointerstitial disease or disturbances in the renin-angiotensin-aldosterone axis. In addition, there are several commonly used medications that can predispose to hyperkalemia in the patient with renal failure [*see Figure 1*].

The initial approach to the treatment of hyperkalemia is the institution of a low-potassium diet (50 to 70 mEq/day). Should hyperkalemia persist, administration of a loop diuretic is a reasonable second step, especially if the patient has demonstrable edema or is hypertensive. Loop diuretics increase distal sodium delivery and thus serve to increase potassium secretion from the distal tubule. If the patient is acidotic, sodium bicarbonate administration is an effective way to lower the serum potassium concentration. This agent also increases distal sodium delivery and, therefore, potassium secretion from the distal tubule. In addition, correction of the underlying acidotic state causes a shift of potassium into cells. Some patients continue to remain hyperkalemic despite this therapy. In these patients, a potassium-binding resin such as sodium polystyrene sulfonate (Kayexalate) may have to be given daily or every other day. This agent should be given with a bowel cathartic such as sorbitol to prevent constipation. Constipation can actually worsen hyperkalemia because potassium secretion by the colon is substantial in patients

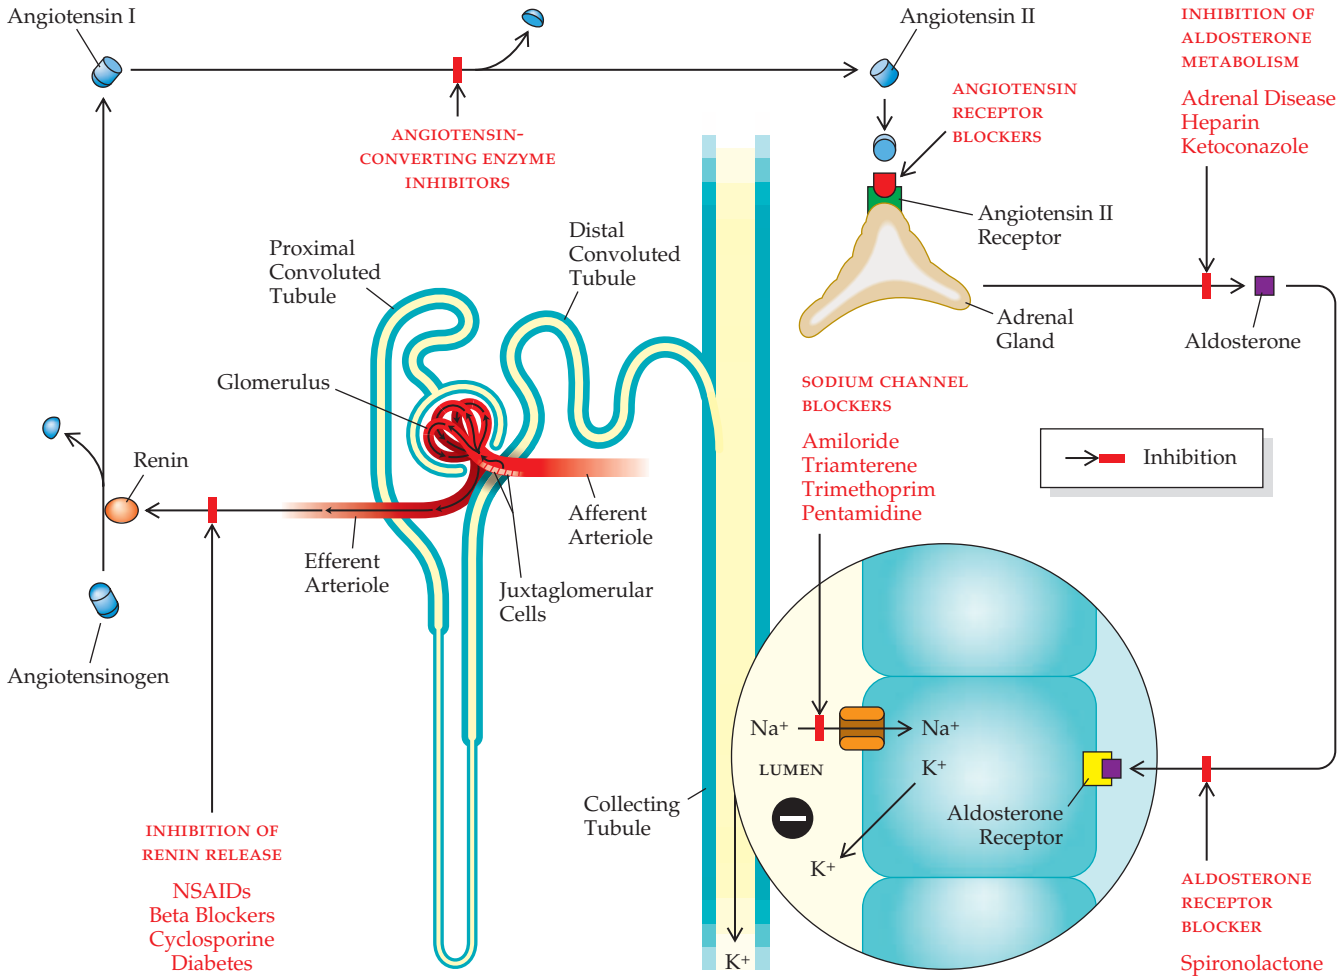

Figure 1 **This diagram depicts the renin-angiotensin-aldosterone cascade. Aldosterone stimulates sodium reabsorption in the collecting duct, which in turn generates a lumen-negative potential. The luminal electronegativity serves as a driving force for potassium excretion. Drugs that interfere with this process are depicted according to mechanism of action. Use of these agents in the setting of chronic renal insufficiency can predispose to the development of hyperkalemia. (AI—angiotensin I; AII—angiotensin II; K—potassium; Na—sodium; NSAIDs—nonsteroidal anti-inflammatory drugs)**

with advanced renal insufficiency. Cathartics that contain magnesium should be avoided because of the risk of inducing hypermagnesemia in the setting of renal insufficiency.

METABOLIC ACIDOSIS

Under normal conditions, the kidney is responsible for regenerating consumed bicarbonate as a result of the buffering of daily net acid production. As renal insufficiency progresses, patients typically become acidotic. Initially, the acidosis is of the non–anion gap type, but as renal insufficiency becomes far advanced, an anion gap acidosis supervenes. If left untreated, acidosis leads to bone resorption; in addition, it may contribute to protein catabolism and can result in malaise and dyspnea.[51]

Measurement and monitoring of the serum bicarbonate should be part of the routine electrolyte analysis in patients with CKD. In patients with stage 3 CKD, the bicarbonate should be measured at least every 12 months; in patients with stage 4 or 5 CKD, it should be measured every 3 months. Every effort should be made to keep the bicarbonate concentration above 22 mEq/L to avoid adverse effects on bone histology and protein catabolism.

Alkali therapy can be administered in the form of sodium bicarbonate tablets. Each 650 mg tablet contributes 8 mEq of bicarbonate. A useful starting dosage is one tablet three times a day. Alternatively, a sodium citrate solution (Bicitra) can be given; this solution contributes 1 mEq of bicarbonate per millimeter of solution. Citrate-containing alkali should not be administered to patients receiving aluminum-containing phosphate binders, because citrate is known to enhance the GI absorption of aluminum. Alkali therapy contains a substantial sodium load, and therefore, the patient needs to be monitored closely for the development of volume overload.

CALCIUM AND PHOSPHORUS IMBALANCE

Disturbances in calcium and phosphate metabolism regularly accompany CKD and contribute to many of the manifestations of uremia. As GFR declines, the serum phosphate level begins to increase, causing a reciprocal decrease in the serum calcium concentration. In response, parathyroid hormone (PTH) is released, resulting in increased phosphate excretion in each of the remaining nephrons; thus, calcium and phosphorus levels return to

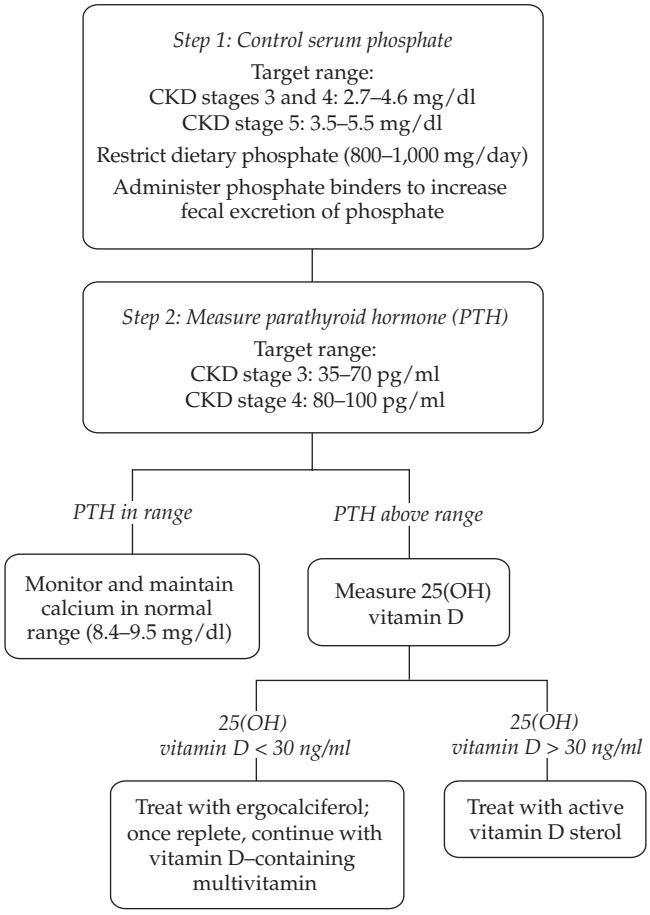

Figure 2 **Steps to manage calcium and phosphorus abnormalities that accompany chronic kidney disease.**

normal. As renal function continues to decline, calcium and phosphorus levels remain within the normal range but at the expense of an ever increasing level of PTH. Patients with stage 3 CKD commonly have elevated PTH levels and may already demonstrate evidence of osteitis fibrosa cystica on bone biopsy. Ultimately, loss of renal mass is so great that hyperphosphaturia per nephron is insufficient to prevent phosphate retention, so that hyperphosphatemia becomes sustained.

As renal mass declines, the circulating level of 1,25-dihydroxyvitamin D [1,25-(OH_2)D] also begins to fall. 25-Hydroxyvitamin D [25-(OH)D] undergoes 1α-hydroxylation in the kidney to form 1,25-(OH_2)D. Lack of 1,25-(OH_2)D contributes to the development of hypocalcemia because this hormone normally serves to increase calcium absorption from the GI tract and enhances the ability of PTH to mobilize calcium from bone. Decreased absorption of calcium from the intestine is further compounded by the low calcium content in the diet of patients with CKD. Low levels of active vitamin D also contribute to the development of secondary hyperparathyroidism, because this hormone normally exerts a direct inhibitory effect on the release of PTH from the parathyroid gland. Finally, during the course of advancing renal insufficiency, the set point at which calcium suppresses PTH release becomes higher, leading to further elevations in the level of PTH.

Clinical practice guidelines regarding the management of calcium and phosphorus disturbances in CKD patients are now available.[52] The primary goal in the management of patients with CKD is to maintain the serum phosphorus level within normal limits [*see Figure 2*]. The serum level of phosphorus should be maintained between 2.7 and 4.6 mg/dl in patients with stage 3 or 4 CKD. In patients with stage 5 disease, the serum level of phosphorus should be maintained between 3.5 and 5.5 mg/dl. To achieve these levels, the patient should initially be placed on a phosphate-restricted diet (800 to 1,000 mg/day); the serum phosphorus level should be monitored monthly.[52] Dietary sources particularly rich in phosphate must be restricted; these include eggs, dairy products (e.g., cream, milk, and cheese), and meat products. Although a few patients may be able to maintain the serum phosphate level within normal limits on a restricted diet alone, most patients with advanced CKD will require treatment with a phosphate binder to increase fecal excretion of phosphate.

Oral phosphate binders are available as either calcium- or non–calcium-containing drugs. In patients with stage 3 or 4 CKD, calcium-containing phosphate binders are usually effective in controlling the serum phosphorus. In patients with stage 5 disease, control of the serum phosphorus level may require a combination of both calcium- and non–calcium-containing binders.

The decision as to which class of binder to use should be based on the starting phosphate level and the calcium-times-phosphorus product. Every effort should be made to keep the calcium-phosphorus product lower than 55. In patients with a serum phosphorus level higher than 7 mg/dl or a calcium-phosphorus product greater than 63, a non–calcium-containing binder is the appropriate choice. Sustained use of calcium-containing binders in patients with a high product will result in the development of metastatic calcification; therefore, these binders should be avoided in such patients.

Sevelamer (RenaGel) is a calcium- and aluminum-free phosphate binder that is increasingly being used in the care of patients with ESRD. It has been shown to control serum phosphorus levels and to reduce PTH levels without inducing hypercalcemia.[53] In addition, this agent lowers serum cholesterol levels. Several trials are comparing the degree of major artery calcifications associated with calcium-containing and calcium-free phosphate binders. Lanthanum carbonate is another non–calcium-containing binder that may soon become available for clinical use.

Because of concerns about long-term toxicity, aluminum-containing binders have largely fallen from favor. Aluminum-containing compounds such as aluminum hydroxide and aluminum carbonate may be used as a short-term therapy (1 month) but should be replaced thereafter by other non–calcium- containing phosphate binders, such as sevelamer. As soon as the serum phosphate level is reduced to less than 7 mg/dl and the calcium-phosphorus product is less than 63, calcium-containing binders can be utilized.

The calcium-containing phosphate binders are available as the calcium salts of carbonate, acetate, and citrate. Recent evidence suggests that calcium acetate is the most potent phosphate binder in this class. To be most effective, all the phosphate binders should be given with meals. The effectiveness can be further enhanced by varying the dose of the binder in proportion to the phosphate content of each meal.

As previously discussed, patients with advancing renal insufficiency tend to develop negative calcium balance because of decreased GI absorption of calcium and decreased calcium content in the diet. To remain in calcium balance, most patients with CKD require 1,000 to 1,500 mg/day of elemental calcium. This level is difficult to achieve with diet alone because many foods that are high in calcium are also high in phosphorus and are

therefore restricted. To overcome this problem, supplemental calcium needs to be administered; supplemental calcium can be given as calcium carbonate or calcium acetate. When administered for this indication, calcium should be given between meals. Once again, to prevent calcium phosphate deposition in the tissues, calcium should not be given until the serum phosphate level is normalized.

Although calcium-containing binders provide an effective means of controlling phosphorus, their use may not be without risk. Calcium excess induced by the prescription of large doses of calcium-containing phosphate binders has been associated with calcifications of the aorta and the carotid and coronary arteries.[54] Use of these drugs has also been implicated in the development of calciphylaxis. Given these concerns, the total dose of elemental calcium provided by calcium-based phosphate binders should not exceed 1,500 mg/day, and the total intake of elemental calcium, including that derived from dietary sources, should not exceed 2,000 mg/day.

Chronic kidney disease is associated with the development of secondary hyperparathyroidism. Monitoring of plasma levels of intact PTH may help prevent the development of secondary hyperparathyroidism. In patients with stage 3 CKD, the target plasma level of intact PTH is 35 to 70 pg/ml; in patients with stage 4 disease, it is 80 to 100 pg/ml. For patients with values above the target range, 25-(OH)D levels should be obtained at first encounter; if the serum level is normal, the test should be repeated annually. If the serum level of 25-(OH)D is less than 30 ng/ml, supplementation with vitamin D_2 (ergocalciferol) should be initiated. Once vitamin D levels are replenished, the patient should be maintained on a multivitamin containing vitamin D.

Serum levels of 25-(OH)D are considered the measure of body stores of vitamin D. In patients with a GFR of 20 to 60 ml/min, levels of 25-(OH)D below 30 ng/ml are common. The prevention and treatment of vitamin D deficiency in patients with stage 3 or 4 CKD is believed to decrease the frequency and severity of secondary hyperparathyroidism.

Serum levels of calcium and phosphorus need to be monitored every 3 months after starting therapy with ergocalciferol. If the total corrected serum calcium level exceeds 10.2 mg/dl, vitamin D therapy should be discontinued. If the serum phosphorus level exceeds 4.6 mg/dl, phosphate binders should be initiated or the dose increased. Persistently increased serum phosphorus levels should prompt the discontinuance of vitamin D.

In patients who have stage 3 or 4 CKD, serum 25-(OH)D levels greater than 30 ng/ml, and plasma levels of PTH above the target range, therapy with an active form of vitamin D (calcitriol, alfacalcidol, or doxercalciferol) is indicated. There were early concerns that administration of the active form of vitamin D would hasten the loss of renal function by causing hypercalcemia, hyperphosphatemia, and hypercalciuria. Reports to date have generally shown no change in renal function in association with vitamin D therapy, provided that prolonged hypercalcemia is avoided. As a result, close monitoring of both the serum calcium level and the phosphate concentration are required, because vitamin D enhances the GI absorption of these electrolytes. Treatment should be initiated only if the total corrected serum calcium level is less than 9.5 mg/dl and the serum phosphorus level is less than 4.6 mg/dl. The serum levels of calcium and phosphorus should be monitored monthly for the first 3 months after initiation of therapy and every 3 months thereafter. The active vitamin D sterol should be held for calcium values that exceed 9.5 mg/dl or serum levels of phosphorus greater than 4.6 mg/dl.

Plasma levels of PTH also need to be monitored during therapy when the active form of vitamin D is being used. The target values for PTH in patients with CKD are higher than normal because of evidence that higher levels are required for normal bone remodeling, presumably as a result of the end-organ resistance to PTH in patients with uremia. Suppression of PTH to normal nonuremic values is not desirable, because such PTH levels are associated with a higher prevalence of a dynamic bone disease. After the initiation of therapy with vitamin D, plasma PTH levels should be measured every 3 months. Vitamin D should be withheld when PTH values fall below the target range.

Once patients reach stage 5 CKD, levels of PTH are almost always elevated. A plasma level of intact PTH of 300 pg/ml should prompt the initiation of active vitamin D therapy, with the goal of reducing PTH levels to a target range of 150 to 300 pg/dl. As with earlier stages of CKD, close monitoring of serum calcium and phosphorus levels is required. In these patients, treatment with ergocalciferol is not indicated, because there is inadequate renal mass to convert 25–(OH)D to the active vitamin D sterol.

ANEMIA

Patients with CKD almost uniformly develop a normocytic, normochromic anemia that tends to worsen in parallel with advancing azotemia. Anemia can develop in CKD patients who have a serum creatinine level as low as 2 mg/dl (occasionally lower), particularly in individuals with reduced muscle mass. The anemia seen in CKD patients is primarily caused by a decrease in the biosynthesis of erythropoietin from the kidney. Recombinant human erythropoietin is now the most definitive treatment of the anemia of CKD. In addition to freeing the patient from repetitive exposures to blood-borne pathogens, iron overload, and sensitization, the use of erythropoietin has been demonstrated to improve cardiovascular and cognitive function and the overall quality of life of patients with CRF. Although transfusions are clearly indicated for the treatment of acute hemorrhage and cardiovascular instability, this form of therapy should no longer be considered routine in the management of anemia of patients undergoing peritoneal dialysis or hemodialysis.

Clinical practice guidelines are now available for the management of anemia in patients with CKD.[1] Before the initiation of erythropoietin therapy, the patient should undergo a workup to exclude causes of anemia other than CKD. The evaluation should at least include hemoglobin levels, red blood cell indices, iron parameters, and testing for occult blood in the stool. Monitoring of iron levels should include testing for serum iron, total iron-binding capacity, percent transferrin saturation, and serum ferritin. If it is concluded that the anemia is the result of CKD, erythropoietin therapy can be initiated. Measurement of erythropoietin levels is usually not indicated.

Erythropoietin is administered subcutaneously in doses of 50 to 150 U/kg up to three times a week. The target range for hemoglobin (hematocrit) is Hgb 11 to 12 g/dl (33% to 36%). The need to administer erythropoietin two to three times a week can be bothersome to the patient with early CKD who is largely asymptomatic and ambulatory. Darbepoetin alfa, an erythropoiesis-stimulating protein, offers the advantage of less frequent administration. Darbepoetin alfa has a much longer half-life than recombinant human erythropoietin. Dosing once or twice weekly can often maintain hemoglobin concentrations in the target range. The optimum starting dose is 0.45 μg/kg once or twice weekly administered subcutaneously.

Failure to respond to erythropoietin therapy is most commonly the result of iron deficiency. A transferrin saturation of less than 25% or a serum ferritin level of less than 100 mg/L indicates inadequate iron stores; such a condition requires iron supplementation, usually given as ferrous sulfate, 325 mg twice or three times a day. Oral iron is best absorbed when it is ingested without food or medications. Intravenous iron is usually reserved for patients who are already receiving hemodialysis or peritoneal dialysis. The occasional patient with early CKD who requires intravenous iron supplementation can be given 500 to 1,000 mg of iron dextran administered intravenously in a single infusion. An initial test dose of 25 mg should precede an infusion of 1,000 mg. During the course of therapy, the transferrin saturation and serum ferritin level should be monitored frequently to ensure that iron deficiency does not develop. Other causes of a suboptimal response include the presence of an underlying inflammatory illness, aluminum intoxication, and the presence of marrow fibrosis due to long-standing hyperparathyroidism.

Patients with advanced CKD typically develop a qualitative defect in platelet function. In patients at risk for bleeding complications, three forms of therapy have been shown to be effective in lowering the prolonged bleeding time associated with uremia. First, one can administer desmopressin intravenously at a dose of 0.3 mg/kg in 50 ml of normal saline solution infused over 30 minutes. Alternatively, one can administer cryoprecipitate (10 bags) infused intravenously over 30 minutes. Finally, conjugated estrogens given at a dosage of 0.6 mg/kg I.V. daily for 5 consecutive days have also been shown to be effective.

The Case for Early Referral to a Nephrologist

Optimal care of the patient with CKD involves a multifaceted treatment approach that includes close monitoring of renal function and aggressive institution of measures designed to slow the progression of loss of renal function. Interventions to reduce the comorbidities that accompany CKD should be initiated early. Metabolic and hematologic complications of uremia should be prevented; if already present, they should be treated judiciously. Patients with advanced CKD should be adequately prepared so that referral for renal replacement therapy is smooth and timely.

Disturbingly, recent reports indicate that pre-ESRD care in the United States is suboptimal for a substantially large number of patients.[55-58] Evidence suggests that less than ideal management of the pre-ESRD patient may be an important factor contributing to the high morbidity and mortality of patients receiving dialysis. For example, many patients are significantly anemic and have not been treated with erythropoietin before initiation of dialysis. Severe anemia contributes to the development of left ventricular hypertrophy, which in turn is an important predictor of subsequent cardiac morbidity and mortality in patients receiving dialysis. Hypoalbuminemia is also a common finding at the time dialysis is initiated. Hypoalbuminemia is a strong predictor of subsequent morbidity and mortality in dialysis patients. Although the cause of hypoalbuminemia is multifactorial in this setting, it is likely that lack of supervision by a qualified dietitian early in the course of the disease is a contributing factor.

There is also evidence that many patients are not adequately prepared for initiation of dialysis. Optimal preparation for initiation of dialysis involves educating the patient and family about the various forms of renal replacement therapy. In those who choose hemodialysis, a vascular-access device needs to be placed several months before initiation so that it can be used for the first treatment. Because of the time commitment required to be trained for peritoneal dialysis, patients referred late are more likely to be started on hemodialysis, effectively limiting patient choice. The lack of a permanent access device at the time of initiation necessitates placement of a temporary catheter and increases the likelihood that the patient will receive an arteriovenous graft rather than an arteriovenous fistula. Finally, evidence is accumulating that early initiation of dialysis is associated with improved patient outcome.

Given the complexities involved in management, patients with CKD should be referred to a specialist for consultation and comanagement if the primary care provider cannot adequately evaluate and treat the patient. A nephrologist should participate in the care of patients who have an estimated GFR of less than 30 ml/min/1.73 m^2. To achieve optimal management of all CKD patients, education targeting patients, generalists, and nephrologists is required.

V GLOMERULAR DISEASES

Raimund H. Pichler, m.d.
Stuart J. Shankland, m.d

Clinical Classification of Glomerular Disease

A number of inflammatory and noninflammatory diseases can affect glomerular integrity and function. In general, nephrologists use the term glomerulonephritis to denote glomerular diseases that result from an inflammatory process; these diseases also usually have an immunologic component. Important examples of glomerular diseases that are not caused by an inflammatory process include diabetic nephropathy [*see 9:VI Diabetes Mellitus*], hypertensive nephrosclerosis [*see 1:III Hypertension*], amyloidosis, and hereditary nephropathies (e.g., Alport syndrome). Diabetic nephropathy and hypertensive nephrosclerosis are the most common causes of chronic renal failure and end-stage renal disease in North America.

The clinical approach to glomerular disease often appears more complicated than it perhaps should be. This stems in part from the variety of classification systems used for glomerular disease, which categorize these disorders on the basis of different criteria—clinical syndromes, underlying renal pathology (including the percentage of glomeruli involved), molecular and cellular mechanisms underlying the injury,[1] the localization of immune deposits,[2] levels of serum complement,[3] and specific antibodies involved.[4] Moreover, although glomerular diseases may be named according to descriptive histologic findings, such as proliferative glomerulonephritis, these classic names do not distinguish between primary renal disease (i.e., disease limited to the kidneys) and glomerular involvement that is secondary to a multisystem disease.

To simplify matters, this chapter classifies glomerular disease into two main groups, on the basis of the clinical presentation: nephritic syndrome (caused by glomerulonephritis) and nephrotic syndrome [*see Table 1 and Figure 1*]. Occasionally, a patient presents with features of both syndromes (nephritic-nephrotic syndrome). Two additional points should be noted. First, although patients typically present with nephritic or nephrotic syndrome, they may manifest an underlying systemic disease, such as systemic lupus erythematosus (SLE) or systemic vasculitis. Also, in early stages of glomerular diseases, patients may present with only hematuria or low-grade proteinuria before developing full-blown nephritic or nephrotic syndrome. Early recognition of the underlying disease process—with referral to a nephrologist—renal biopsy if indicated, and initiation of appropriate therapy are essential in preventing progressive renal injury. Second, patients may present with complications of glomerular disease, such as hypertension, electrolyte and acid-base disturbances, and edema. Regardless of the clinical presentation, the physician should correlate the clinical syndrome with the underlying pathophysiologic events.

Epidemiology

Diseases of the glomerulus are the most common causes of end-stage renal disease worldwide. In the United States, the major glomerular diseases causing end-stage renal disease include diabetes mellitus (43%), hypertension (26%), and glomerulonephritis (9%). Worldwide, by far the leading cause of end-stage renal disease is glomerulonephritis, probably because of the prevalence of infectious diseases in developing countries. It is estimated that only 10% to 20% of patients with glomerulonephritis show clinical symptoms; thus, the prevalence of glomerular diseases may be underestimated.

Pathogenesis

Each kidney contains approximately one million glomeruli. The glomerulus is a complex structure comprising a series of capillary loops that derive from the afferent arteriole and drain into the efferent arteriole. There are four glomerular cell types: mesangial cells, glomerular endothelial cells, podocytes (also called visceral epithelial cells), and parietal epithelial cells [*see Figure 1a*]. Each glomerular cell type serves distinct functions, and injury to each cell type results in a different renal histologic pattern and clinical picture [*see Figure 1b*].

The normal glomerular filtration rate (GFR) is about 80 to 120 ml/min. Approximately 30% of the plasma flow is filtered at the level of the glomerulus. The major barrier to filtration of plasma constituents is the glomerular capillary wall, which consists of glomerular endothelial cells, glomerular basement membrane

Table 1 Clinical Presentation and Common Causes of Glomerular Disease

	Nephritic Syndrome	*Nephrotic Syndrome*
Clinical findings	Hypertension Edema Reduced glomerular filtration rate Active urinary sediment (red cell casts) Proteinuria < 3.5 g/24 hr	Hypoalbuminemia Edema Hyperlipidemia Oval fat bodies in urine Proteinuria > 3.5 g/24 hr
Primary renal disease	IgA nephropathy Poststreptococcal GN*† Idiopathic necrotizing GN Anti-GBM disease	Focal segmental glomerulosclerosis Membranous nephropathy Minimal change disease Membranoproliferative GN*‡
Systemic disease	Systemic lupus erythematosus*† Vasculitis (ANCA-related): Wegener granulomatosis Microscopic polyarteritis Hypersensitivity vasculitis Henoch-Schönlein purpura Goodpasture syndrome Cryoglobulinemia	Diabetes mellitus Amyloidosis

*Low complement.
†May present with the nephrotic syndrome.
‡May present with the nephritic syndrome.
ANCA—antineutrophil cytoplasmic antibody GBM—glomerular basement membrane GN—glomerulonephritis

(GBM), and podocytes.[5] The normal rate of urinary protein excretion is less than 150 mg/day, of which less than 20 mg is albumin. The normal filtration barrier limits passage of molecules by size and charge selectivity.[6] The negative charge of the glomerular endothelial cells, GBM, and podocytes limits the passage of anionic substances, such as albumin.[7] Most glomerular diseases cause an alteration in both size and charge selectivity, which leads to proteinuria.

Glomerular diseases can be caused by a variety of mechanisms, including immune mediated, hemodynamic (e.g., hypertension, reduced renal mass), metabolic (e.g., diabetes, metabolic syndrome), and hereditary (e.g., defects of the GBM in Alport syndrome). The most common cause of glomerulonephritis is immune-mediated injury.[8]

Two mechanisms underlie antibody-mediated glomerular disease. One is the deposition of circulating antibodies directed against specific antigens in the glomerulus. The major example is Goodpasture syndrome, in which an antibody is directed against the noncollagenous portion of the α3 chain of type IV collagen in the GBM.[9,10] Antibodies may be directed against an intrinsic glomerular antigen; for example, in idiopathic membranous nephropathy, the antibody is directed against an antigen on the podocyte.[11] Alternatively, glomerular disease may result when antibody-antigen complexes circulating in the bloodstream are deposited in the subendothelial space or mesangium during the normal filtration process. Examples of such immune complex deposition include poststreptococcal glomerulonephritis (PSGN) and membranoproliferative glomerulonephritis (MPGN) from hepatitis C.[12]

Immune complexes generally activate either the alternative or the classical pathway of the complement cascade, thereby initiating injury.[13] The site of the immune complex deposition determines which glomerular cell is injured and, therefore, which clinical manifestations develop.

In contrast to immune-complex mechanisms, certain glomerular diseases develop primarily from cell-mediated immunity.[14] It is postulated that T cells sensitized to exogenous or endogenous antigens in the glomerulus recruit macrophages into the glomerulus, leading to a delayed-type hypersensitivity reaction. A classic example is minimal change disease, which has been postulated to occur when a T cell product injures podocytes and induces a permeability defect.

Diagnosis

Although renal biopsy remains the definitive diagnostic tool in glomerular disease, a thorough clinical evaluation is essential in determining the etiology and nature of these cases.

HISTORY

A carefully obtained history may help define a possible cause of glomerular disease. A family history of renal disease may suggest Alport syndrome, especially if affected individuals have hearing loss or another of the manifestations that are characteristic of this syndrome; there are also familial forms of IgA nephropathy, focal segmental glomerulosclerosis (FSGS), and hemolytic-uremic syndrome.

A number of glomerular diseases may be caused by drugs or toxins. For example, minimal change disease has been associated with the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and interferon. Gold, penicillamine, NSAIDs, and mercury have been shown to cause membranous nephropathy. Thrombotic microangiopathy has been associated with the use of cyclosporine, tacrolimus, mitomycin C, and oral contraceptives.

Certain glomerular disorders are associated with malignancies. These include membranous nephropathy, which is associated with lung, breast, and gastrointestinal cancers; minimal change disease with Hodgkin disease; MPGN with non-Hodgkin lymphoma; and amyloid with renal cell carcinoma.

SIGNS AND SYMPTOMS

Patients with glomerular disease may be asymptomatic or may present with manifestations ranging from minimal findings to full-blown nephritic or nephrotic syndrome. Many patients have only mild to moderate proteinuria (150 mg to 3 g/24 hr) or microscopic hematuria (> two red blood cells [RBCs] per high-power field). Others present with painless gross hematuria. The classic example is hematuria immediately following an intercurrent infection, which occurs in IgA nephropathy; onset of hematuria 2 to 3 weeks after infection is typical of postinfectious glomerulonephritis. Patients with rapidly progressive glomerulonephritis (RPGN) present with rapid onset of renal failure over days or weeks with hematuria (from RBC casts) and proteinuria.

Patients with chronic glomerulonephritis generally have hypertension, renal insufficiency, and proteinuria. On renal ultrasonography, the kidneys are somewhat smaller than normal and display increased echogenicity.

RENAL BIOPSY

The ultimate diagnostic tool in many renal diseases is a renal biopsy, which is performed percutaneously with a spring-loaded biopsy needle, using local anesthesia, or surgically as an open biopsy with the patient under general anesthesia. Renal biopsies should be performed only after the patient has been evaluated by a nephrologist, but they also should be performed in a timely fashion, because early initiation of therapy is essential in preserving renal function and preventing further, potentially irreversible, injury to the kidney.

Although renal biopsy is generally a safe procedure, complications include hematoma, gross hematuria, arteriovenous fistula, and infection. In rare cases, renal biopsy leads to complications requiring surgical intervention.

Four situations mandate consideration of renal biopsy: (1) nephrotic syndrome (except in children, who may be assumed to have minimal change syndrome, and in diabetics, who are likely to have diabetic nephropathy); (2) renal disease in the setting of a systemic disorder (e.g., SLE, myeloma, amyloid, or vasculitis); (3) acute renal failure in the setting of glomerular disease; and (4) renal abnormalities in renal transplant recipients (when there is a possibility of rejection or of recurrent or de novo glomerular disease). Some patients with nonnephrotic proteinuria, hematuria, and chronic renal failure may also benefit from a renal biopsy for diagnostic and prognostic purposes.

The renal biopsy establishes a diagnosis, determines whether disease is mediated by antibody or by complement, and assists in determining disease-specific therapy. The biopsy also provides important information on the degree of glomerular and interstitial fibrosis. The latter is particularly important as a prognostic index. The renal pathology report includes a description of the kidney by light microscopy, immunofluorescence, and electron microscopy.

†Often presents with the nephrotic syndrome.

Light Microscopy

Light microscopy describes glomerular cellularity—that is, whether the number of glomerular cells is normal or increased (hypercellularity). Often, light microscopy can distinguish which cell type (resident glomerular cells or infiltrating cells such as neutrophils) is increased; whether the GBMs are thickened and whether the capillary loops are patent, collapsed, or filled with material such as hyaline; and the presence or absence of glomerulosclerosis (scarring). Although the glomerulus is the primary site of injury in glomerular disease, the tubules and the interstitium must be carefully inspected because the degree of tubulointerstitial fibrosis is the best predictor of the prognosis in renal disease.

Light microscopy is also used to classify glomerular disease as focal or diffuse. If less than 50% of glomeruli are involved by the disease process, the disease is termed focal; if 50% or more glomeruli are involved, the disease is called diffuse. If a small portion (or segment) of an individual glomerulus is involved,

the disease is described as segmental; if most of an individual glomerulus is involved, it is called global.

The presence of glomerular crescents can also be detected on light microscopy. Crescents are layers of cells (parietal epithelial cells, podocytes, lymphocytes, and macrophages) in the Bowman space, and their presence signifies severe disease.

Immunofluorescence

Immunofluorescent immunostaining determines the presence or absence of any underlying immune processes. Staining is directed against specific antibodies (e.g., IgG, IgA, and anti-GBM) and individual complement components (e.g., C3, C4, and C5b-9). The pattern of the immune components is also diagnostic. A granular pattern is typical of antigen-antibody complexes, such as in membranous nephropathy, whereas a linear pattern occurs in anti-GBM disease. The location of antibody or complement (e.g., in the mesangium in IgA nephropathy) also provides clues to the diagnosis. Immunostaining can determine the presence of matrix proteins (silver stain), amyloid fibrils (Congo red), and viral inclusions.

Electron Microscopy

Electron microscopy provides information about the presence and subcellular location of immune complexes (which are seen as electron-dense deposits), the degree of injury to glomerular cells, and the consistency of the basement membrane. Electron microscopy also detects fibrils and provides information on the ultrastructure of the kidney, such as podocyte effacement and flattening, which cannot be readily detected by light microscopy.

General Management

THERAPEUTIC PRINCIPLES

Four principles govern the treatment of glomerular disease. First, treat any acute complications of renal failure such as pericarditis; hyperkalemia; acidosis; hypertension with or without myocardial, cerebral, or other vascular bed crisis; and volume overload causing pulmonary edema. Second, use disease-specific therapeutic agents to treat any underlying primary and secondary glomerular disease. Third, to reduce the risk of further glomerular damage, use nonspecific strategies to lower the intraglomerular capillary pressure, reduce systemic blood pressure, and decrease elevated serum cholesterol levels. Fourth, anticipate and treat potential complications of nephrotic syndrome, such as hypercoagulability, infection, and skeletal abnormalities.

NONSPECIFIC TREATMENT

To reduce glomerular filtration pressure and proteinuria, give angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), or both. The treatment goal is to reduce proteinuria to less than 1 g/24 hr. A 24-hour urine collection remains the gold standard for assessing proteinuria, but for patient convenience, measurement of the protein-to-creatinine ratio in a spot urine specimen can be used to follow proteinuria. In such cases, both protein and creatinine concentration are measured in mg/dl. Dividing the protein concentration by the creatinine concentration yields an estimate of the amount of protein excreted in grams per 24 hours.

Hypertension requires aggressive treatment. The goal is a blood pressure of less than 130/80 mm Hg. Hyperlipidemia is treated with a statin drug. The goal is a low-density lipoprotein (LDL) cholesterol level of less than 100 mg/dl. In addition to lowering lipid levels, statins have been shown to reduce proteinuria and to help prevent progression of glomerular disease by lipid-independent mechanisms.

Specific Glomerular Diseases

DISEASES PRESENTING AS NEPHRITIC SYNDROME

The clinical features of nephritic syndrome are caused by a severe and typically acute inflammatory injury to the glomeruli, which leads to decreased renal function. The clinical characteristics include hematuria, proteinuria, hypertension, and increased creatinine levels. Hematuria in nephritic syndrome may be macroscopic or microscopic.[15] RBCs and RBC casts in the urine, which represent an active urinary sediment, are pathognomonic for glomerulonephritis. Proteinuria in nephritic syndrome is generally less than 3.5 g/24 hr. In contrast, nephrotic syndrome is distinguished by a marked increase in glomerular permeability and more marked proteinuria (> 3.5 g/24 hr).

The major complications of nephritic syndrome are hypertension, volume overload, hyperkalemia, and metabolic acidosis; patients may present with one or more of these. The decrease in glomerular filtration in nephritic syndrome causes marked salt and water retention, leading to hypertension and edema. Acute hypertensive crisis with congestive heart failure, cerebral failure, and pulmonary edema may occur. An acute decrease in GFR can also cause hyperkalemia and metabolic acidosis.

The more common forms of glomerulonephritis that present as nephritic syndrome can be classified on the basis of their underlying disease mechanisms into three categories: immune complex mediated (e.g., postinfectious glomerulonephritis, IgA nephropathy), antibody induced (e.g., anti-GBM disease), and pauci-immune (i.e., with no immune complexes detected by immunofluorescence; for example., vasculitis associated with antineutrophil cytoplasmic antibodies [ANCAs]). The clinical course of individual glomerular diseases may vary. For example, PSGN is usually acute and self-limiting, IgA nephropathy is intermittent and chronic, and anti-GBM disease and ANCA-associated vasculitis have a rapid onset and are progressive, leading to end-stage renal failure within a short period if not treated.

Glomerular Diseases Associated with Infection

Acute glomerulonephritis can result from bacterial infections (*Streptococcus, Staphylococcus aureus, Salmonella, Escherichia coli, Legionella,* and *Mycoplasma*), viral infections (hepatitis B, hepatitis C, HIV, and cytomegalovirus), parasitic infections (*Schistosoma*, *Plasmodium*, *Trypanosoma*), and fungal infections (*Aspergillus, Histoplasma, Candida*). Renal disease associated with infection is typically immune complex related; the complexes comprise antigens from the infectious agent and host antibodies directed against the antigens.

The classic glomerular disease associated with infection is PSGN, which produces a different glomerular histologic picture than most other postinfectious forms of glomerulonephritis.[16] At present, hepatitis C[17] and HIV[18,19] are the leading causes of infection-associated glomerulonephritis in developed countries, whereas PSGN remains common in other parts of the world. Hepatitis C–associated glomerulonephritis and PSGN typically present as nephritic syndrome, whereas HIV causes nephrotic syndrome.

Hepatitis C virus–associated glomerulonephritis Glomerular disease is a common extrahepatic manifestation of chronic hepatitis C infection. Hepatitis C infection is now the major cause of essential mixed cryoglobulinemia. Patients can present with different histologic and clinical syndromes,[20] with renal disease carrying the worst prognosis. About 40% to 50% of patients with renal disease have systemic indications of cryoglobulinemia, manifesting as the triad of arthralgias, purpura, and weakness; 50% of patients have renal manifestations only, in the form of proteinuria, microhematuria, or renal dysfunction. The proteinuria may be nephrotic (> 3.5 g /24 hr) or nonnephrotic (< 3.5 g/24 hr). The majority of patients have hypocomplementemia (low C3 and C4 levels) and elevated rheumatoid factor levels (indicative of cryoglobulins). Occasionally, patients present with signs of severe vasculitis and a rapid decline in renal function. Overt liver disease is unusual, however.

The most common histologic finding in patients with hepatitis C–associated glomerulonephritis is MPGN type I with mixed cryglobulinemia, but there are also reports of MPGN type I without cryoglobulinemia in these patients [*see* Membranoproliferative Glomerulonephritis, *below*]. MPGN is characterized by deposits of preformed hepatitis C antigen-antibody complexes that are trapped in the glomerular subendothelial space and mesangial cells, which causes glomerular cell proliferation. The mesangium increases in size and interposes into the GBM, causing basement membrane splitting (hence the term membranoproliferative). Less frequently, hepatitis C causes membranous nephropathy, fibrillary glomerulonephritis, FSGS (in African Americans) and thrombotic microangiopathy (in renal transplant recipients).

Treatment of hepatitis C–associated MPGN is directed against the virus and consists of polyethylene glycol (PEG) interferon alpha-2b and ribavirin (if renal function allows) to reduce the viral burden. Severe acute disease is treated with plasmapheresis to remove cryoglobulins, plus immunosuppressive therapy with corticosteroids and cyclophosphamide, followed by initiation of antiviral therapy.

Poststreptococcal glomerulonephritis PSGN is typically a self-limiting disease that develops after a pharyngeal infection or skin infection (e.g., impetigo or pyoderma) with so-called nephritogenic strains of group A streptococci. Occasionally, cases have been associated with group C streptococci. PSGN most often affects children 2 to 10 years of age and is twice as common in males as in females. The disease is usually sporadic but can occur in epidemics.

PSGN is a classic immune complex–mediated form of glomerulonephritis.[21] The glomerular injury is induced when circulating preformed immune complexes (comprising the streptococcal antigen and an antibody directed against it) are deposited in the mesangium and subendothelium. Two streptococcal antigens are most likely involved in the pathogenesis of PSGN: plasmin receptor protein (related to preabsorbing antigen and endostreptosin) and streptococcal zymogen (exotoxin B). Antibodies to these antigens correlate with clinical disease; both antigens have been localized in glomeruli in a large percentage of patients. The formation of immune complexes explains the typical 2- to 3-week delay between streptococcal infection and the onset of PSGN.

On light microscopy, PSGN is characterized by diffuse glomerular involvement [*see Figure 2*]. The histologic hallmark of PSGN is glomerular hypercellularity, which is caused by the proliferation of resident mesangial and endothelial cells and an influx of infiltrating cells such as neutrophils. Severe PSGN, which occurs in less than 5% of patients, is marked by crescent formation in the Bowman space. The clinical presentation of patients with crescents on renal biopsy is typically that of RPGN (see below).

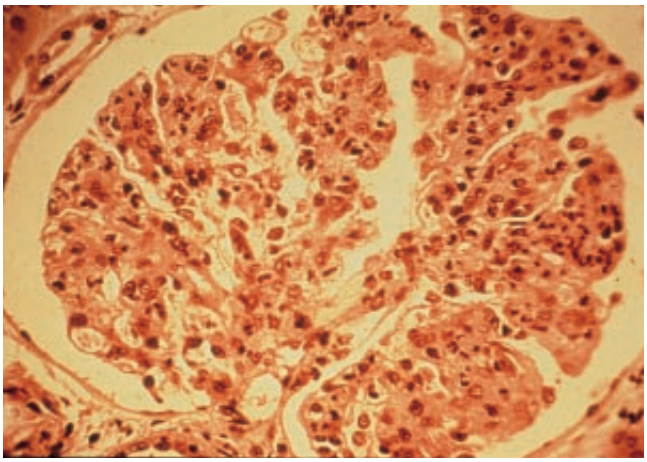

Figure 2 **Light micrograph of poststreptococcal glomerulonephritis showing increased glomerular hypercellularity.**

There are three patterns of immunofluorescent staining in PSGN; these are termed starry sky, garland, and mesangial. The classic starry-sky pattern of immune deposition is seen in about 30% of PSGN cases and occurs early in the disease. It consists of fine granular deposits of IgG and C3, without C1q and C4, on all capillary walls and the mesangium. The garland pattern, which consists of coarse granular deposits of large amounts of IgG and C3 along the capillary loops, with relatively few mesangial deposits, also is found in about 30% of patients. The mesangial pattern of IgG deposition, which is often associated with mesangial cell proliferation, occurs in about 40% of patients.

Electron microscopy in PSGN shows multiple large, dome-shaped, immune complex deposits that are referred to as subepithelial humps because of their location at the base of the podocyte [*see Figure 3*].[22] The differential diagnosis of subepithelial immune deposits includes membranous nephropathy, lupus nephritis, and MPGN type III [*see* Membranoproliferative Glomerulonephritis, *below*]. Biopsies taken early in the course of PSGN may show immune complex deposits in the mesangium and subendothelium.

Although PSGN presents as an acute disease, there is a latent phase between the initiating pharyngitis (mean, 10 days) or skin infection (mean, 21 days) and the onset of the nephritic syndrome.[16] Patients present with pronounced edema, often of the upper body; diminished urine output; dark or smoky urine containing RBCs and RBC casts; and signs and symptoms of hypertension.

The serum creatinine level is often normal; a rise in creatinine reflects underlying acute renal failure. Proteinuria is typically less than 500 mg/day during the acute illness. Throat and skin cultures are usually negative, but serologic measures of recent streptococcal infection, such as antistreptolysin O, are elevated and remain so for 3 to 6 months. Antistreptolysin O titers may be blunted by recent antibiotic usage and are less marked after skin infections. Because PSGN is induced by immune complexes via the alternative pathway, patients demonstrate marked decreases

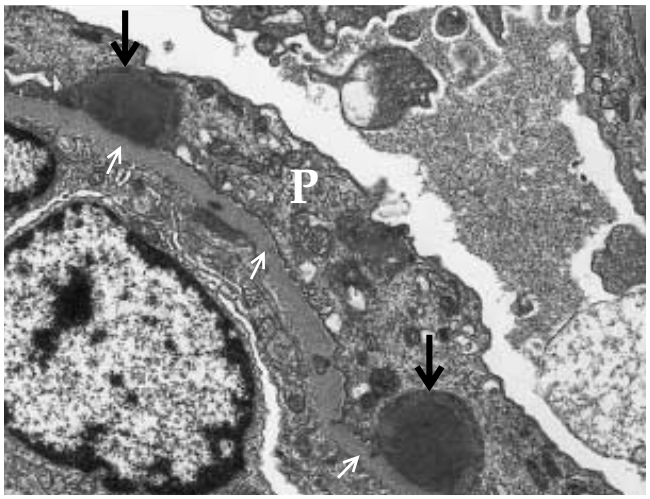

Figure 3 **Transmission electron micrograph (magnification: × 10,500) showing characteristic subepithelial hump-shaped deposits (illustrated by thick arrows) in postinfectious glomerulonephritis lying below the podocytes (P); small arrows indicate the glomerular basement membrane.**

in levels of CH50 and C3, but not of C1q, C2, or C4, which are activated by the classical complement pathway [*see 6:II Innate Immunity*]. Depression of the C3 level that lasts longer than 8 weeks should suggest another cause.

There is no role for antibiotic therapy in PSGN, because the inciting infection has typically occurred weeks earlier and the antigen-antibody complexes have already formed. Treatment is therefore supportive. The majority (> 95%) of patients recover normal renal function; the remainder, however, develop end-stage renal failure. Although macroscopic hematuria and edema usually resolve within 2 weeks, microscopic hematuria may persist for a year; 20% of patients develop nephrotic-range proteinuria, typically during the recovery phase of the disease, that resolves spontaneously. However, proteinuria in the nonnephrotic range can last as long as 2 years. Recurrent PSGN is exceedingly rare.

Other forms of postinfectious glomerulonephritis Bacterial infections (e.g., infective endocarditis,[23] infected shunts,[24] and visceral abscesses[25]), as well as certain viral infections (e.g., hepatitis B and hepatitis C[26]), can cause MPGN, which is associated with alternative-pathway hypocomplementemia characterized by low C3 and normal C4 levels. Antibiotic therapy eliminates infection in endocarditis and allows for resolution of the immune response. A persistently low C3 level suggests that infection is not cleared.

IgA Nephropathy

IgA nephropathy derives its name from the glomerular deposition of IgA, which causes an injurious inflammatory response.[27] IgA nephropathy is the most prevalent pattern of glomerulonephritis found in countries where renal biopsy is widely used as an investigative tool.[28] IgA nephropathy is particularly prevalent in Asia and southern Europe but is less common in the United States and Canada, which suggests a possible genetic predisposition to the disease. IgA nephropathy affects more males than females (3-to-1 ratio) and occurs most commonly in children and young adults. Although most cases of IgA nephropathy are idiopathic, a number of diseases have been associated with secondary IgA nephropathy [*see Table 2*], and hereditary forms have also been described.

Pathogenesis and histology Mesangial cell injury in IgA nephropathy results from the deposition of IgA on mesangial cells [*see Figure 4*].[29] The tendency for flares of macroscopic or microscopic hematuria to occur within 24 hours after a mucosal infection (e.g., upper respiratory tract or bowel) indicates that the glomerular disease may be initiated by an impaired mucosal IgA response to infection. However, studies have suggested that IgA derived from bone marrow may be increased in these patients and that hepatic clearance of IgA may be decreased, which may in part reflect abnormal glycosylation.[30]

The glomerular lesions that follow mesangial cell IgA deposition are variable.[29] The characteristic lesion is mesangial cell proliferation [*see Figure 5*], which appears on light microscopy as mesangial cell hypercellularity [*see Figure 6*]. Glomerular involvement may be focal or diffuse. In severe cases that progress to end-stage renal failure, mesangial scarring is noted. Glomerular crescents form occasionally, and as in most forms of glomerular disease, tubulointerstitial fibrosis is present in those patients with renal failure.

Immunofluorescent staining reveals IgA [*see Figure 4*] and, occasionally, IgG and IgM in the mesangium; C3 is often detected without C1q and C4, suggesting activation of the alternative complement pathway. Mesangial immune deposits can occasionally be seen as electron densities on electron microscopy.

Clinical and laboratory findings IgA nephropathy has six different clinical-presentation patterns[31]: episodic macroscopic hematuria, asymptomatic microscopic hematuria and nonnephrotic-range proteinuria, nephrotic syndrome, acute renal failure, chronic renal failure and hypertension, and concomitant systemic disease.

Episodic macroscopic hematuria is the classic presentation of IgA nephropathy. It occurs in 40% to 50% of patients. The hematuria is often characterized by RBC casts and occurs within 24 hours after a mucosal infection, commonly of the upper respiratory tract. This presentation is also called synpharyngitic hematuria. Episodic macroscopic hematuria differs from the delayed-onset hematuria that appears 2 to 3 weeks after pharyngitis in PSGN. Macroscopic hematuria usually resolves spontaneously

within days, and microscopic hematuria often occurs between mucosal infections.

Asymptomatic microscopic hematuria and nonnephrotic-range proteinuria constitute 30% to 40% of IgA nephropathy; nephrotic syndrome constitute approximately 5%. Acute renal failure, which constitutes less than 5%, can occur in association with crescents (i.e., crescentic IgA nephropathy) or, possibly, as a result of acute tubular necrosis from excessive hematuria. In rare instances, IgA nephropathy presents as part of a systemic disease [*see Table 2*].

Laboratory investigations are usually not helpful in diagnosing IgA nephropathy. Serum IgA levels are increased in about a third of patients, and IgA-fibronectin aggregates are increased in about half. Mesangial deposition of C3 is found in more than half of patients. Serum complement levels are usually normal. Taken together, the diagnosis is clinical, supported by a renal biopsy.

The differential diagnosis of persistent isolated microscopic glomerular hematuria includes hereditary glomerulonephritis (Alport syndrome), postinfectious glomerulonephritis, thin basement membrane disease, SLE, FSGS, and minimal change disease. A major consideration in the differential diagnosis of IgA nephropathy is Henoch-Schönlein purpura (HSP). HSP is a systemic vasculitis that is characterized by deposition of IgA-containing immune complexes in tissues, including mesangial cells, and thus shares many features with IgA nephropathy.[32] HSP is manifested clinically by a classic tetrad of purpuric rash (typically over the extremities), arthralgias (in knees and ankles), abdominal pain, and renal disease. Although HSP is more common in children younger than 5 years, renal involvement is more common in older children and adults. Like IgA nephropathy, HSP often follows an upper respiratory tract infection. A typical urinary finding is mild proteinuria and an active urinary sediment (containing RBCs and RBC casts), which is often transient. Most patients are asymptomatic, with a normal or slightly elevated serum creatinine level, but nephrotic syndrome develops in 20% of cases. The diagnosis of HSP can often be made clinically. Confirmation requires evidence of tissue deposition of IgA on either a skin biopsy (which shows a leukocytoclastic vasculitis) or renal biopsy (which shows an IgA immunostaining in a typical mesangial distribution). HSP is discussed in detail elsewhere [*see 10:VII Vascular Diseases of the Kidney*].

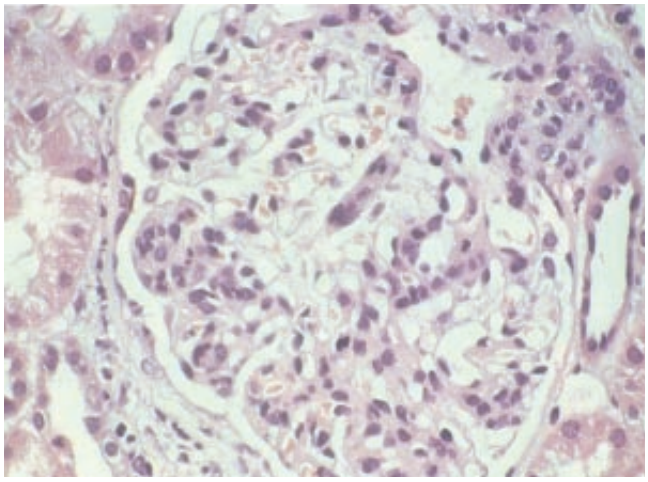

Figure 5 **Light micrograph from a patient with IgA nephropathy showing the characteristic glomerular hypercellularity.**

Treatment Although a variety of treatment strategies have been tried, therapy for IgA nephropathy remains disappointing.[33] Several studies suggest that the use of ACE inhibitors, even in normotensive patients, may slow progression by lowering glomerular filtration pressure and reducing proteinuria.[34-36] Combining ACE inhibitors with ARBs may enhance the antiproteinuric effect and further slow the progression of renal disease.[37] In patients with aggressive or progressive IgA nephropathy, slowing or arresting of disease progression may be accomplished with the combination of cytotoxic agents (oral cyclophosphamide, 1.5 mg/kg daily for 3 months, then converted to azathioprine) and prednisolone.[38] Clinical trials evaluating the efficacy of fish oil have produced conflicting results, and a meta-analysis concluded that a minor benefit was likely.[39]

All patients with IgA nephropathy should receive treatment with an ACE inhibitor, an ARB, or both. Corticosteroid therapy for 18 to 36 months may be associated with less proteinuria and better outcome.[40-43] However, studies showing a benefit from corticosteroid therapy were performed before the current aggressive use of angiotensin antagonists. A subset of proteinuric patients without hematuria (usually with nephritic syndrome and minimal glomerular changes on light microscopy and effacement of the foot processes on electron microscopy) seem to respond very well to steroid treatment. Some experts recommend steroid treatment only for patients with nephrotic syndrome and minimal apparent changes on histology; progressive active disease despite the use of ACE inhibitors, ARBs, or both; or severe disease on biopsy.[44]

Prognosis Most patients with IgA nephropathy have an indolent course, with chronic intermittent hematuria. Risk factors for disease progression include an elevated serum creatinine level and elevated blood pressure on presentation (although these may instead reflect severe disease), persistent proteinuria (> 1 g/day), older age, and interstitial fibrosis on renal biopsy. For reasons that are still unclear, recurrent macroscopic hematuria is often associated with a better prognosis than persistent microscopic hematuria and proteinuria. Serum IgA levels and gender are not prognostic factors. IgA nephropathy is a significant cause of end-stage renal failure, with 20% of patients requiring renal replacement therapy within 20 years of presentation.

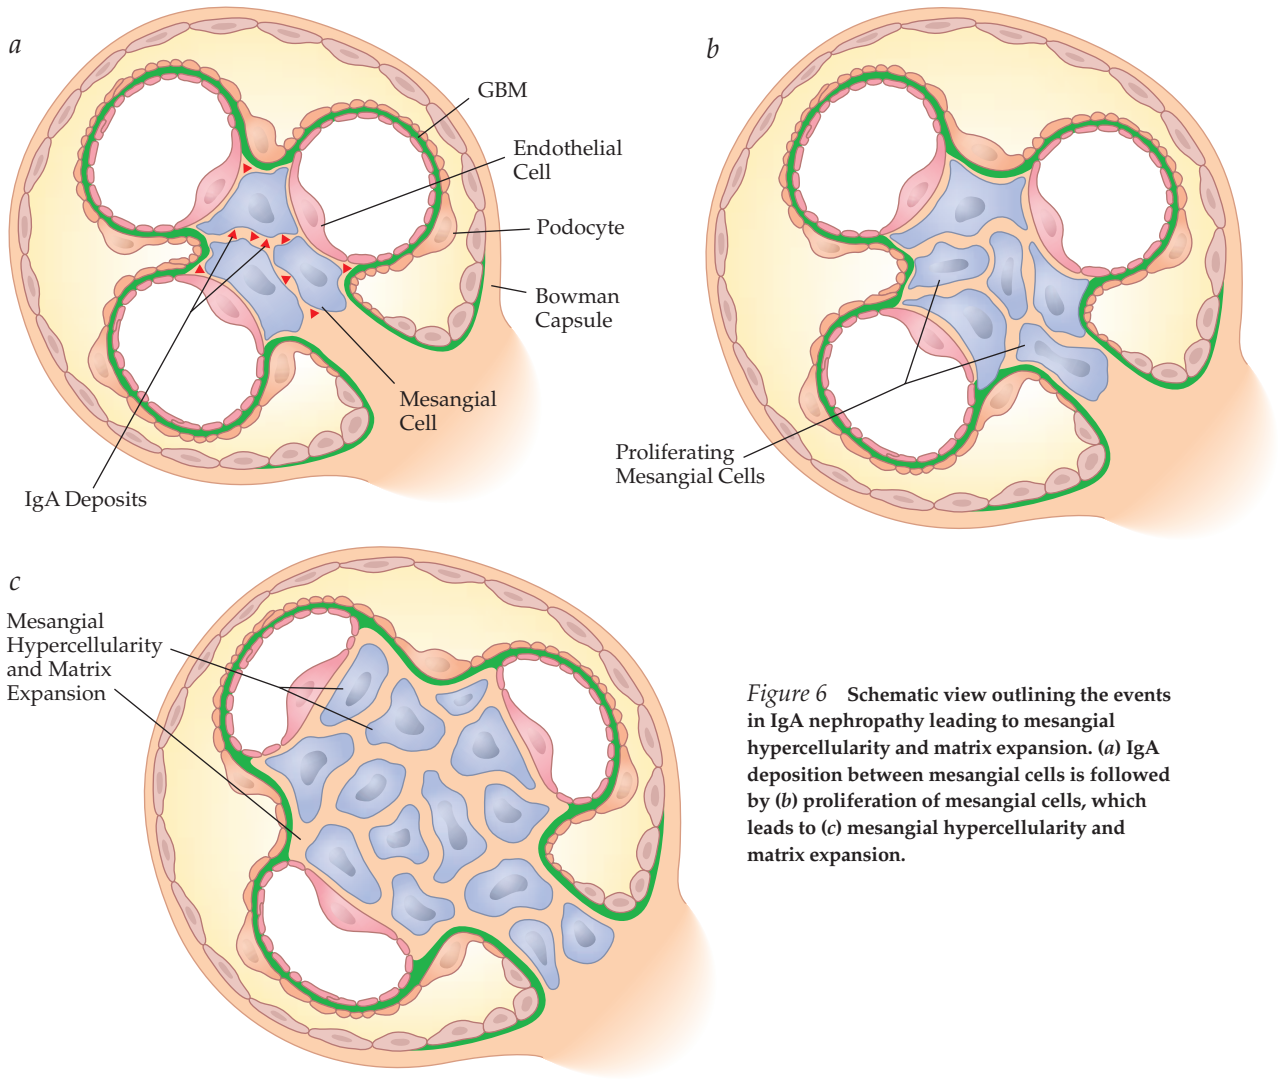

Figure 6 **Schematic view outlining the events in IgA nephropathy leading to mesangial hypercellularity and matrix expansion. (*a*) IgA deposition between mesangial cells is followed by (*b*) proliferation of mesangial cells, which leads to (*c*) mesangial hypercellularity and matrix expansion.**

Anti–Glomerular Basement Membrane Disease

Epidemiology Anti-GBM disease is rare, with an estimated annual incidence of 0.5 to 0.9 cases per million population in whites and an even lower incidence in other races. Most patients are male and in either the second to third or the sixth to seventh decades of life, but the disease has been reported in both men and women and at all ages. Exposure to pulmonary toxins, such as hydrocarbons, increases the incidence of anti-GBM disease.

Pathogenesis and histology Anti-GBM disease is caused by a nephritogenic antibody directed against a specific epitope on the noncollagenous (NC1) domain of the α3 chain of type IV collagen in the GBM.[9,45] Type IV collagen also occurs in the alveolar basement membrane, so these antibodies may also result in pulmonary involvement. Anti-GBM disease is the term used if the disorder is restricted to the kidney (primary renal disease); Goodpasture syndrome refers to the constellation of glomerulonephritis, pulmonary hemorrhage, and anti-GBM antibodies[46] [*see 10:VII Vascular Diseases of the Kidney*].

The characteristic finding on renal biopsy is a diffuse necrotizing proliferative lesion (with increased cellularity because of proliferation) and crescents (layers of cells in the Bowman space comprising parietal epithelial cells, podocytes, macrophages, and leukocytes) in more than 50% of glomeruli [*see Figure 7*]. Although the initial injury occurs within the glomerular tuft, breaks in the GBM allow plasma products to leak from the capillaries into the Bowman space [*see Figure 8*]. The early cellular and later fibrocellular crescents compress the glomerular tuft [*see Fig-*

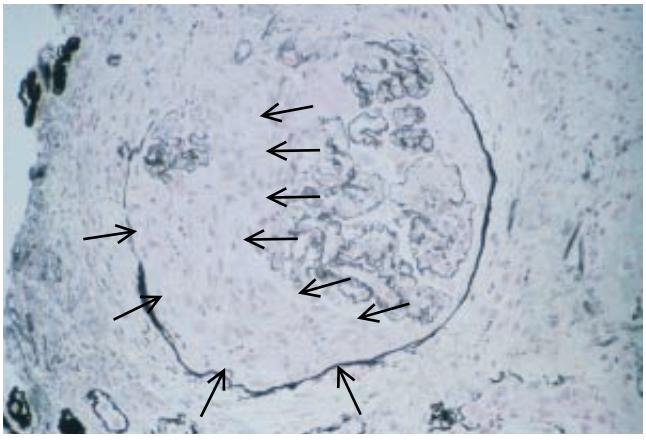

Figure 7 **A large multilayer of cells in the Bowman space (arrows) represents a typical crescent in anti–glomerular basement membrane disease.**

ure 8], so disease severity is related in part to the extent of crescents. Pathognomonic findings on renal biopsy in both anti-GBM disease and Goodpasture syndrome are linear deposition of IgG and C3 along the GBM [*see Figure 9*]. These findings are in contrast with the granular pattern of IgG immunostaining in immune complex glomerulonephritis (i.e., PSGN, IgA nephropathy, MPGN, and lupus nephritis).

Clinical and laboratory findings The typical presentation of anti-GBM disease consists of a rapid decline in renal function in a patient with a so-called active urinary sediment (i.e., containing RBCs and RBC casts and, occasionally, white blood cell [WBC] casts) and mild proteinuria, with or without the complications of pulmonary hemorrhage. There is a direct correlation between the initial plasma creatinine concentration and the percentage of glomeruli with crescents; crescents are present in more than 75% of glomeruli when plasma creatinine concentration is above 5 mg/dl.

Patients with pulmonary-renal syndrome (exemplified by Goodpasture syndrome) present with pulmonary hemorrhage, acute renal failure, and anemia; these patients may have a history of viral infection or exposure to pulmonary toxins such as cigarette smoke or hydrocarbons.[47] Blood loss from pulmonary hemorrhage often leads to iron deficiency anemia.

The diagnosis is confirmed by an increase in serum anti-GBM antibody titers. Serum complement levels are normal, and ANCA assays are positive in 20% to 30% of patients. Despite the presence of ANCAs in some patients, anti-GBM disease is not classified as a renal vasculitis.

Treatment and prognosis Patients with anti-GBM disease require urgent therapy to prevent a progressive decline in renal

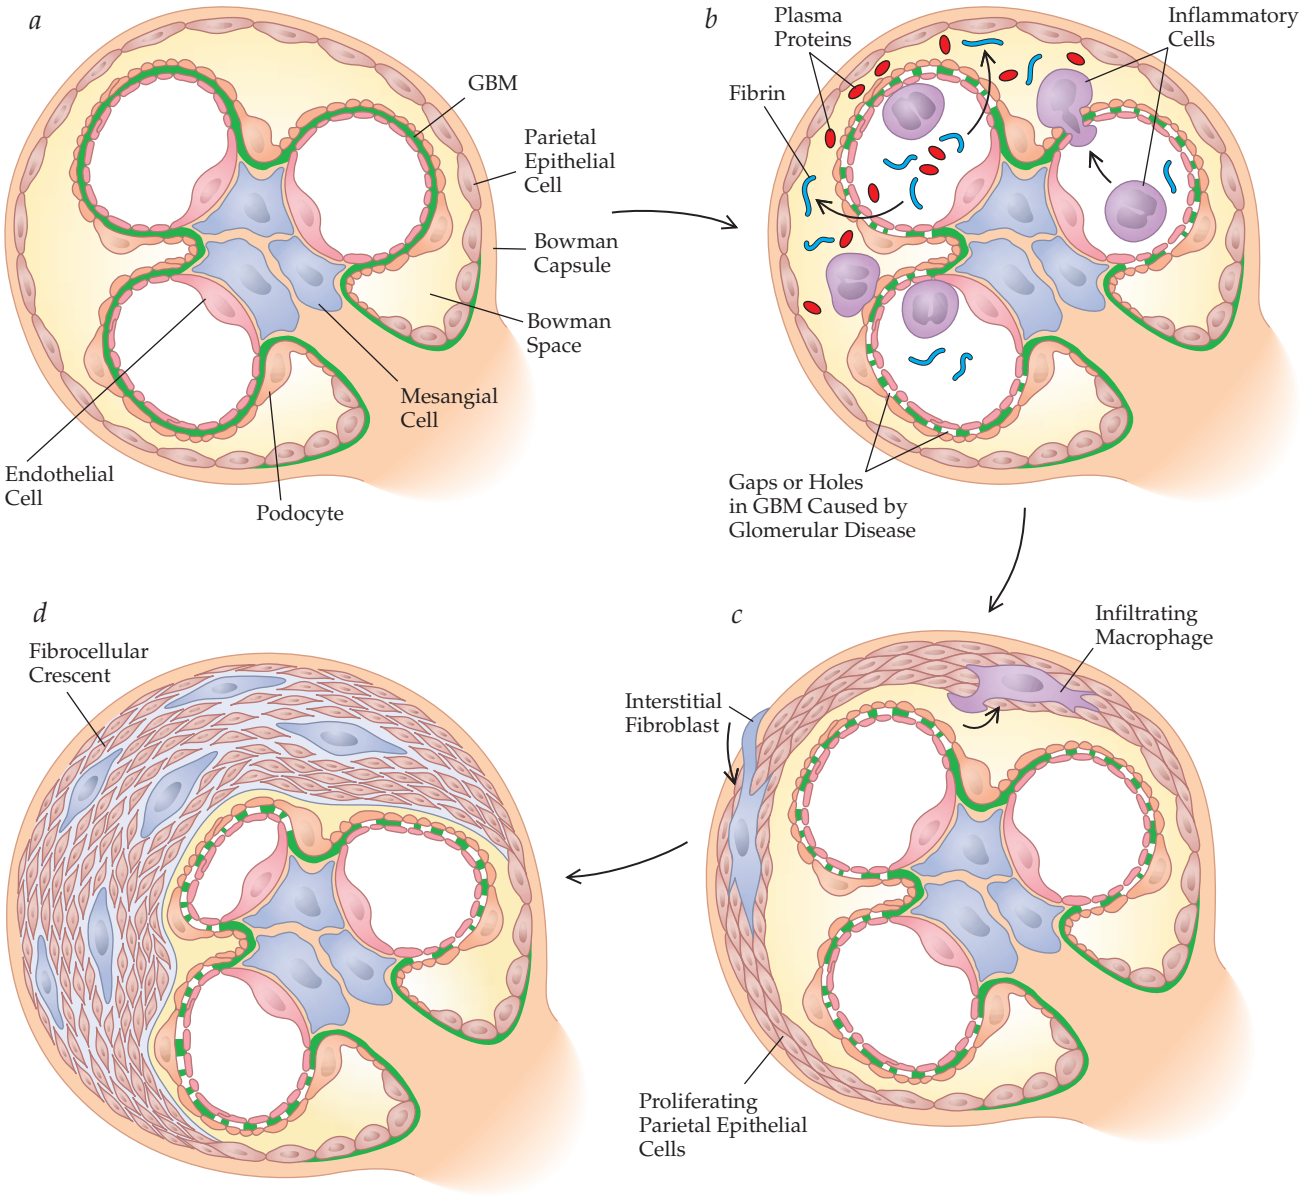

Figure 8 **Schematic view illustrating the events leading to crescent formation. (*a*) Normal glomerulus. (*b*) Glomerular disease leads to gaps or holes in the glomerular basement membrane (GBM), resulting in (*c*) proliferation of parietal epithelial cells and ultimately (*d*) fibrocellular crescent formation.**

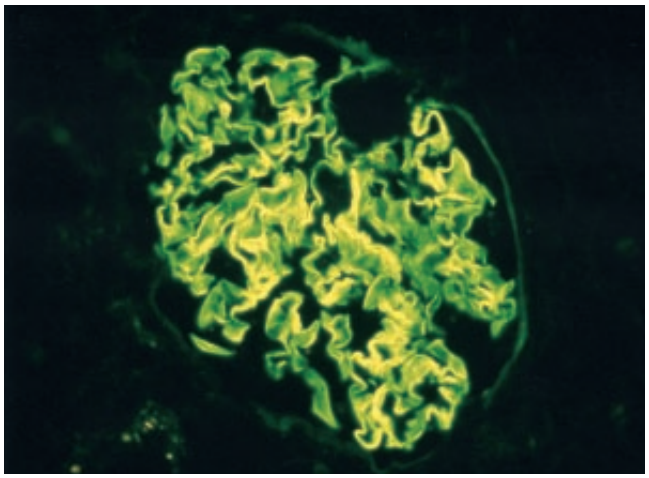

Figure 9 **Linear pattern of IgG immunostaining along the GBM in a patient with anti-GBM disease.**

function. The treatment of choice is triple therapy, consisting of plasmapheresis plus prednisone and cyclophosphamide. The rationale is that plasmapheresis removes circulating anti-GBM antibodies and other mediators of inflammation, whereas prednisone and cyclophosphamide minimize new antibody formation. Pulse steroids (methylprednisone, 30 mg/kg or 1,000 mg I.V.) are given for 3 days, followed by high-dose oral prednisone (1 mg/kg/day) given for several months, with plasma exchanges (4 L/day) given daily or on alternate days until the anti-GBM antibody is undetectable.[48,49] Cyclophosphamide is given orally at a dosage of 2 mg/kg/day. Therapy is generally continued for 9 to 12 months.

More than 70% of treated patients with anti-GBM disease recover renal function. Oliguria and a serum creatinine level greater than 6 mg/dl are poor prognostic findings; patients with this high a creatinine level are generally considered not to be candidates for triple therapy. Renal transplantation should be avoided until the anti-GBM antibody has been undetectable for 12 months.

Renal and Systemic Vasculitis

The kidney is often involved in systemic vasculitis; examples include microscopic polyangiitis, Wegener granulomatosis, Churg-Strauss syndrome, and isolated pauci-immune crescentic glomerulonephritis. These diseases are discussed in detail elsewhere [*see 10:VII Vascular Diseases of the Kidney and 15:VIII Systemic Vasculitis Syndromes*].

Rapidly Progressive Glomerulonephritis

RPGN, an acute nephritic syndrome, is distinguished from other forms of nephritic syndrome by its clinical presentation, glomerular histology, and etiology [*see Figure 10*].[50] RPGN is diagnosed clinically as a doubling in serum creatinine level over 3 months because of an underlying glomerulonephritis.[50] Frequently, renal function deteriorates over as little as days or weeks. Most authorities also require the presence of glomerular crescents on renal biopsy to confirm the diagnosis. Typically, if more than 50% of glomeruli contain crescents, renal function decreases acutely (i.e., over days to weeks). RPGN constitutes a medical emergency.

RPGN can occur as a primary renal disorder or as a consequence of systemic disease. Conventionally, RPGN is classified according to the underlying disease mechanism into one of three categories: 50% of cases are from pauci-immune disease, which is often associated with ANCAs; 30% are from immune complex disease (e.g., postinfectious glomerulonephritis, lupus nephritis, IgA nephropathy, and MPGN); and 20% of cases are from anti-GBM.[51]

DISEASES PRESENTING AS NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by heavy proteinuria (> 3.5 g/24 hr), hypoalbuminemia (< 3 g/dl), peripheral edema, hyperlipidemia (elevated total and LDL cholesterol levels) and lipiduria (oval fat bodies in urinary sediment). Nephrotic syndrome results from a marked increase in glomerular permeability to protein and other macromolecules. Although glomerular injury is often severe in diseases causing nephrotic syndrome, it is unusual for patients to present with a decrease in renal function early in the course of disease. A rise in the serum creatinine level is usually a feature of more advanced disease. The urinary sediment is typically devoid of red and white cells or casts and is termed an inactive urinary sediment. This contrasts with the active urinary sediment in nephritic syndrome. However, some patients who present with a combined nephritic-nephrotic picture will have an active urinary sediment. In nephrotic patients with a marked increase in serum lipid levels, fat and cholesterol casts can be seen in the urine because of markedly increased glomerular permeability.

The hallmark of the nephrotic syndrome is proteinuria greater than 3.5 g/24 hr. It is very unusual for proteinuria of this magnitude to be caused by conditions other than glomerular disease. In the absence of a 24-hour urine collection, a spot urine collection can be used to estimate the degree of proteinuria.[52] A normal urinary protein-to-creatinine ratio (mg/mg) is less than 0.15, which indicates a protein excretion of less than 150 mg/day; a ratio greater than 3.5 is consistent with excretion of more than 3.5 g of protein, which defines nephrotic syndrome. A urine dipstick detects only albumin, not other proteins, and is positive only when protein excretion exceeds 300 to 500 mg/day. Caution must also be used when interpreting dipstick units, however, because urine tonicity or specific gravity affects the measurement. In certain circumstances (e.g., Bence Jones proteinuria in multiple myeloma), the dipstick will be negative for protein.

Lesser degrees of proteinuria (< 3.5 g/24 hr) may result from glomerular or nonglomerular causes. These include heart failure; renal vascular disease; increased GFR from exercise, pregnancy, diabetes, or fever; tubulointerstitial disorders; increased protein delivery from myeloma; and orthostatic proteinuria (a benign condition in which low-grade proteinuria occurs only when the patient is not recumbent).

Although nephrotic syndrome is caused by an underlying glomerular disease, progressive renal failure is caused by tubulointerstitial inflammation and scarring that results from ongoing proteinuria. Thus, the renal biopsy must also be evaluated for the presence of tubulointerstitial fibrosis.

The etiology of nephrotic syndrome is separated into primary and secondary causes. The most common primary glomerular diseases that cause nephrotic syndrome in adults are FSGS, membranous nephropathy, minimal change disease, and MPGN [*see Table 1*]. Although these disease entities are usually primary (and idiopathic), each can also be secondary to an underlying systemic disease. However, the glomerular histology is indistinguishable in primary and secondary forms. Diabetes mellitus and amyloidosis are the leading causes of secondary nephrotic syndrome.

The target of injury in FSGS, membranous nephropathy, minimal change disease, and even diabetes is the podocyte [*see Figure 1b*]. A critical function of the podocyte, which sits on the outer aspect of the GBM, is to prevent proteinuria. Thus, the characteristic clinical consequence of podocyte damage is massive proteinuria. Moreover, because podocytes are located on the outer aspect of the GBM and therefore not in close proximity to the capillary loops, podocyte injury in nephrotic syndrome is typically not associated with red or white cells or cell casts in the urine.

Therapeutic Principles in Nephrotic Syndrome

Four principles guide the management of the nephrotic syndrome. First, treat any complications: reduce fluid overload with diuretics, provide anticoagulation therapy for patients at high risk for venous thrombosis (e.g., those with a serum albumin level < 2.0 g), aggressively treat hypertension (blood pressure goal < 130/80 mm Hg), and decrease hyperlipidemia with statins. Second, lower proteinuria to less than 1 g/24 hr, ideally through combination therapy with ACE inhibitors and ARBs. Third, use disease-specific therapy when possible. Fourth, treat the underlying secondary cause if one is present.

Complications of Nephrotic Syndrome

Major complications of nephrotic syndrome include hypoalbuminemia, edema, hypercholesterolemia, and hypercoagulability. Although the liver is capable of synthesizing large amounts of albumin, proteinuria is associated with increased tubular uptake of protein. In the tubules, protein is catabolized rather than recycled for further use.[53] As a result, serum albumin levels decrease. Hypoalbuminemia decreases the plasma oncotic pressure, resulting in a decrease in effective circulating volume. This is followed by an increased proximal tubular sodium resorption because of increased angiotensin II, aldosterone, and epinephrine. A concomitant increase in antidiuretic hormone levels results in fluid retention, which manifests clinically as edema and hypertension. Hypoalbuminemic nephrotic patients are often resistant to loop diuretics such as furosemide, because loop diuretics are inactivated by binding to albumin in the tubular lumen. Edema also appears to result from a primary defect in sodium excretion that leads to an expanded plasma volume, followed by transudation of fluid.

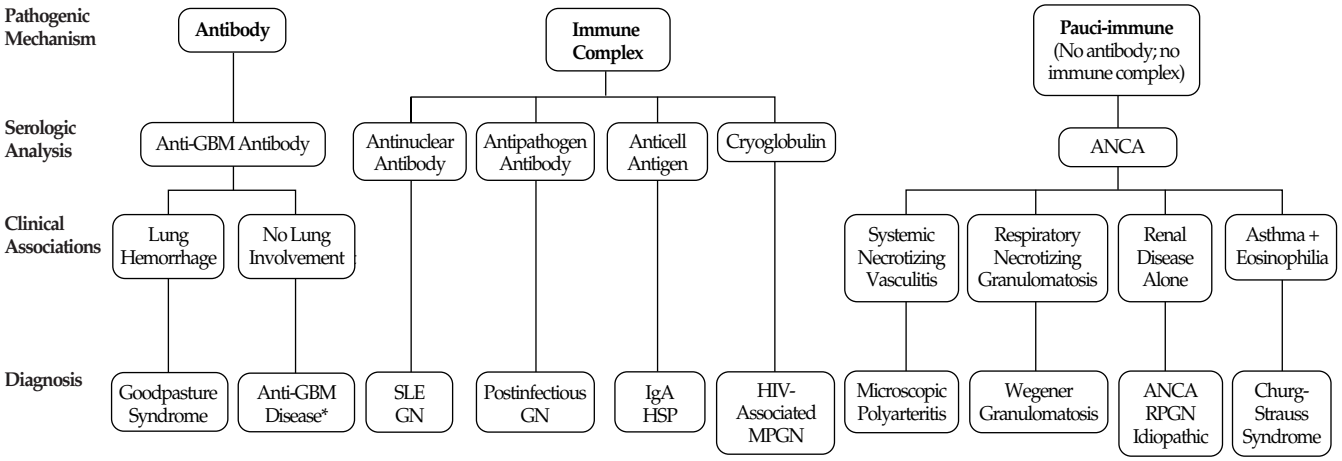
Hepatic cholesterol and lipid synthesis are increased in nephrotic patients, probably in response to decreased oncotic pressure.[54] Moreover, there is decreased catabolism, which explains in part the increase in levels of very low density lipoprotein. Hyperlipidemia is a major risk factor for cardiovascular disease in nephrotic patients. It may also contribute to the progression of glomerular diseases. Treatment of hyperlipidemia should be aggressive and includes cholesterol-lowering agents such as statin drugs [*see 9:II Diagnosis and Treatment of Dyslipidemia*].

Patients with nephrotic syndrome are in a hypercoagulable state: 10% to 40% will experience arterial or venous thromboembolism.[55] Factors that underlie increased coagulation include urinary losses of the anticoagulant antithrombin, increased platelet activation, and alterations in the fibrinolytic system. Patients may present with lower extremity, pulmonary, or renal vein thrombosis. Renal vein thrombosis complicates all forms of the nephrotic syndrome—especially membranous nephropathy—and may present acutely as a sudden decrease in renal function, loin pain, hematuria, or even systemic emboli. However, thrombosis of the renal vein may also be asymptomatic, especially if collateral veins have been established. Diagnosis is made by renal vein Doppler sonography, CT angiography, or MR angiography. Treatment includes anticoagulation therapy with heparin followed by warfarin. Many authorities use prophylactic low-dose warfarin when the plasma albumin concentration is less than 2 g/dl [*see 5:XIV Thrombotic Disorders*].

Other complications of the nephrotic syndrome include an increased susceptibility to infection (caused by urinary losses of IgG), bone disease (caused by loss of vitamin D), and loss of trace elements.

Focal Segmental Glomerulosclerosis

FSGS is the leading cause of nephrotic syndrome in adults, responsible for 35% of all cases and more than 50% of cases in



* May be associated with ANCA (~30% of cases).

ANCA—antineutrophil cytoplasmic antibody GBM—glomerular basement membrane GN—glomerulonephritis HSP—Henoch-Schönlein purpura MPGN—membranoproliferative GN RPGN—rapidly progressive GN SLE—systemic lupus erythematosus

Figure 10 **Rapidly progressive glomerulonephritis (RPGN) is classified by the underlying disease mechanism. Specific serologic tests determine whether RPGN is caused by an antineutrophil cytoplasmic antibody (ANCA)–negative or ANCA-positive glomerular disease. Clinical findings further differentiate each disease entity.**

Table 3 Causes of Focal Segmental Glomerulosclerosis (FSGS)

Primary
Idiopathic
Minimal change disease
Collapsing FSGS
Hereditary
Secondary
Infection (e.g., HIV)

Obesity
Reduced nephron number (e.g., reflux nephropathy, unilateral renal agenesis/congenital renal dysplasia, surgical reduction, sickle cell disease, or any advanced renal disease causing reduced nephron number)
Collapsing FSGS

African Americans. The name derives from the histologic findings: less than 50% of glomeruli are involved (focal); and within the involved glomeruli, a segment is scarred (sclerotic).

Pathogenesis and histology FSGS may be primary, hereditary, or secondary [*see Table 3*]. Except in so-called collapsing FSGS (see below), the histologic findings are the same regardless of the cause. Because FSGS typically begins at the corticomedullary junction and progresses to the outer cortex, an inadequate renal biopsy may miss the lesion. Although sclerosis is visible only in segments of a minority of glomeruli, all glomeruli leak protein and have foot process fusion (a primary alteration in the podocyte).

The mechanisms of FSGS depend on the underlying cause. Hereditary FSGS results from mutations in the genes that code for podocyte proteins. The structure and function of several podocyte proteins have been identified and characterized. The slit diaphragm, the major size barrier to molecules on the outer side of the GBM, comprises a complex and active network of proteins called nephrin, podocin, and CD2AP. These proteins signal and communicate with the rich actin cytoskeleton of the podocyte, which is also regulated by the actin-binding protein, α-actinin 4. Abnormalities of any of these proteins can lead to abnormal function and, therefore, to nephrotic syndrome, which is usually characterized by the histologic lesion of FSGS.

In idiopathic and hereditary FSGS, the primary target of injury is the podocyte, and the histologic findings are secondary to this injury. There is evidence that a circulating glomerular permeability factor plays a role in the genesis of the podocyte injury in idiopathic FSGS, but the exact nature of this role needs to be determined.[56] In contrast, in secondary forms of FSGS, podocyte injury is a consequence of the underlying disease. For example, secondary injury to podocytes from increased intraglomerular pressure [*see Figure 11*] leads to progressive podocyte dysfunction and ultimately to cell loss. Obesity is an increasing cause of FSGS, but it is usually not associated with proteinuria in the nephrotic range.

Light microscopy in glomerulosclerosis shows collapse of the glomerular capillaries [*see Figure 12*], which are filled with proteinaceous material. It is hypothesized that injured podocytes detach from the GBM, which results in denudation of the underlying GBM.[57] This promotes the formation of adhesions and synechial attachments between the glomerular tuft and the Bowman capsule, which may be accompanied by mesangial hypercellularity and, in severe cases, by tubulointerstitial fibrosis.

Because FSGS is not an immune-mediated disease, immunofluorescent staining is typically negative for IgG and complement components. However, some IgM and C3 may be found in the sclerotic areas as a consequence of passive trapping.

Electron microscopy shows fused, effaced, and flattened foot processes. One distinguishing feature between idiopathic and secondary FSGS is that foot process fusion is diffuse in the former but localized to the site of injury in the latter.

In addition to the classic histologic findings, there is a histologic variant known as collapsing or cellular FSGS.[58] This entity occurs in HIV infection, but it also has been described with the use of bisphosphonates.[59] In contrast to classic FSGS, collapsing FSGS is associated with podocyte proliferation and a marked collapse of the glomerular tuft. The decline in renal function in patients with collapsing FSGS occurs more rapidly than in patients with classic FSGS.

Clinical and laboratory findings Approximately 90% of children and 70% of adults with FSGS present with clinical and laboratory findings of the nephrotic syndrome. It is unclear why the incidence and severity of FSGS is increased in African Americans. Approximately 50% of adults present with hypertension and hematuria and 30% present with renal insufficiency.[60] As in most diseases involving the podocyte, urinalysis in FSGS typically shows no red, white, or tubular cell casts; however, hematuria is present in some patients. There are no laboratory findings specific for the diagnosis of idiopathic FSGS. Specific tests, such as those for HIV infection, may assist in ruling out secondary causes. Although studies have shown that a permeability factor is increased in many patients, an assay for this factor is not available commercially.[61]

Treatment and prognosis As in all glomerular diseases, treatment of FSGS is directed toward any underlying diseases and toward the complications of the nephrotic syndrome [*see Figure 13*]. Disease-specific therapy should be offered to patients with nephrotic-range proteinuria and to those whose serum creatinine level is below 3 mg/dl.[62] No disease-specific therapy is indicated for patients with nonnephrotic-range proteinuria. It is important to stress that FSGS caused by mutations in podocyte-specific proteins is steroid resistant. However, the tests for diagnosing these mutations are not widely available.

The first line of disease-specific therapy in adults with primary FSGS is prednisone (1 mg/kg/day) for 3 to 4 months. To minimize toxicity, many authors now recommend 2 mg/kg of prednisone every other day. In the 55% of patients who respond, prednisone should then be changed to 0.5 mg/kg/day for 8 weeks (or 1 mg/kg on alternate days) and tapered over the next 6 weeks. The duration of therapy is critical in preventing relapses. In the 45% of patients who are steroid resistant and in steroid-responsive patients who encounter relapses, the next line of therapy includes cyclosporine at a dosage of 7 mg/kg/day in divided doses, aiming for trough levels between 125 and 225 μg/L.[63] Patients who experience frequent relapses and those who are steroid dependent may benefit from cyclophosphamide (2 mg/kg/day) for 3 months and high-dose prednisone (1 mg/kg/day) for 1 month, followed by a steroid taper. Initiating therapy with cytotoxic agents and prednisone has no added benefit over therapy with prednisone alone.

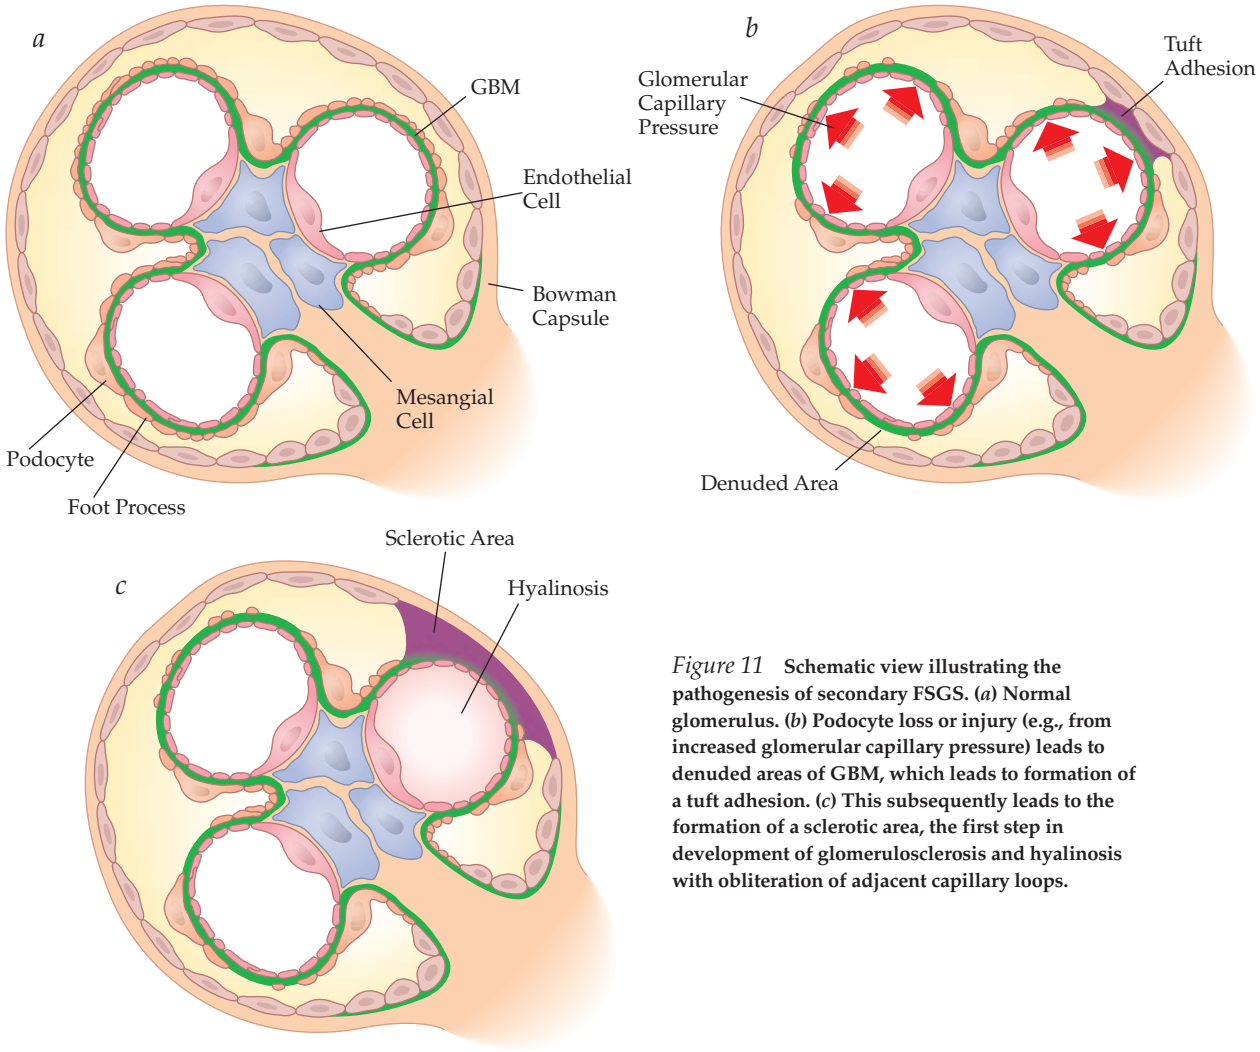

Figure 11 **Schematic view illustrating the pathogenesis of secondary FSGS. (*a*) Normal glomerulus. (*b*) Podocyte loss or injury (e.g., from increased glomerular capillary pressure) leads to denuded areas of GBM, which leads to formation of a tuft adhesion. (*c*) This subsequently leads to the formation of a sclerotic area, the first step in development of glomerulosclerosis and hyalinosis with obliteration of adjacent capillary loops.**

An increased serum creatinine level at presentation and heavy proteinuria are poor prognostic indicators in FSGS. Control of proteinuria is associated with greater renal survival than the persistence of proteinuria in the nephrotic range. Surprisingly, the number of scarred glomeruli is not a prognostic factor. However, the presence of diffuse mesangial hypercellularity does correlate with a poor prognosis. Progression to renal failure in FSGS has no significant correlation with age or gender or the presence of hematuria or hypertension on presentation.

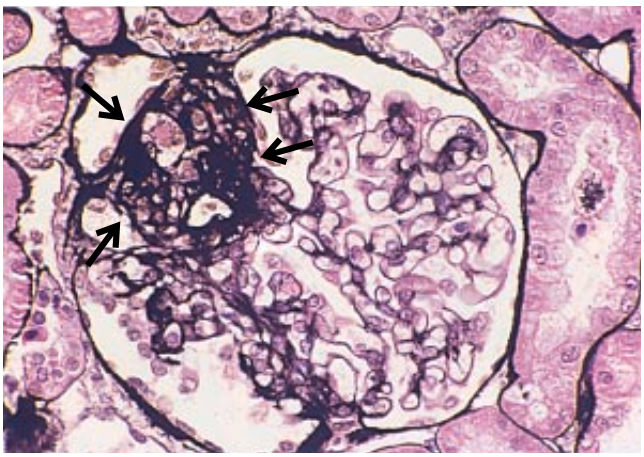

Figure 12 **Light micrograph showing the characteristic features of focal segmental glomerulosclerosis, with collapse of capillaries, hyalinosis, and adhesion (area highlighted by arrows).**

Patients with end-stage renal failure from FSGS are excellent transplant candidates. However, the disease subsequently occurs in the transplanted kidney in 20% to 30% of patients. Plasmapheresis has proved helpful in some patients with recurrent FSGS after transplantation, who likely have a circulating factor causing their disease.[64]

HIV-Associated Nephropathy

HIV infection can cause glomerular lesions.[65] The most common presentation is nephrotic syndrome caused by FSGS (see above). HIV infection typically is associated with the collapsing form of FSGS, also known as HIV-associated nephropathy (HIVAN). HIVAN occurs predominantly in African Americans. Histologically, HIVAN is characterized by proliferation of podocytes and collapse of the glomerular tuft. HIV infection can also cause hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura, IgA nephropathy, mesangial proliferative glomerulonephritis, and MPGN.

Patients with HIVAN usually have advanced HIV infection, with $CD4^+$ T cell counts below 200 cells/μl. In about 30% of pa-

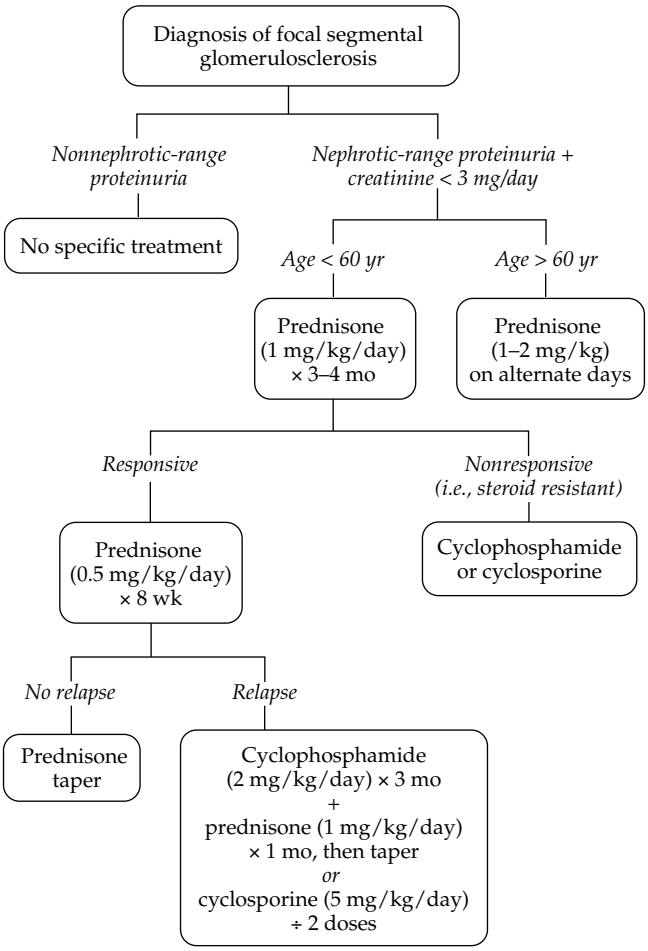

Figure 13 **Treatment algorithm for patients with focal segmental glomerulosclerosis.**

tients, HIVAN may be the presenting symptom that prompts a workup for HIV infection. Steroids, antiretroviral therapy, and ACE inhibitors have been found to be helpful in the treatment of HIVAN.

In the past, HIVAN was characterized by progression to end-stage renal disease within months. With current antiretroviral therapy, however, many patients can avoid dialysis for years. In contrast to the small kidney size that characterizes most forms of end-stage renal disease, HIV-associated nephropathy is associated with an enlarged kidney.

Membranous Nephropathy

Although membranous nephropathy derives its name from the characteristic thickening of the GBM seen on light microscopy, the primary site of injury is the podocyte. In turn, podocyte dysfunction results in increased extracellular matrix protein accumulation, causing the basement membrane thickening that is the hallmark of the disease.

Membranous nephropathy is the most common cause of the nephrotic syndrome in white adults and is the leading cause of nephrotic syndrome in persons older than 60 years. In adults, 80% of cases are idiopathic; the remaining 20% are from secondary causes [*see Table 4*]. The most common secondary causes are SLE; hepatitis B infection[66]; drugs (e.g., gold, penicillamine); and, in the elderly, solid tumors—malignancy underlies 20% of cases in patients older than 50 years.[67] Membranous nephropathy is typically a disease of men (the male-to-female ratio is 2:1 to 3:1) and has a biphasic age distribution of 30 to 40 years and 50 to 60 years.

Pathogenesis and histology Although thickening of the GBM characterizes membranous nephropathy, it occurs late in the course of disease. The pathognomonic finding is diffuse deposition of finely granular immune deposits at the base of the podocytes on the outer surface of the GBM, which are referred to as subepithelial or subpodocyte immune deposits [*see Figure 14*]. The location of the immune deposits and evidence from experimental models of disease suggest that the target of disease is one or more antigens on the podocytes.[68] The inciting antigen (or antigens) remains to be identified in humans. However, the concurrent presence of subendothelial and mesangial deposits is more suggestive of circulating antigens or antigen-antibody complexes. Antibodies such as antineuroendopeptidase have been linked with the onset of membranous nephropathy. Membranous nephropathy is mediated by a humoral immune response, leading to deposition of IgG and C3, but not C4, indicating activation of the alternative complement pathway. Immunostaining for C5b-9 (the membrane attack complex) occurs in a pattern similar to that for IgG [*see Figure 15*]. Consequences of C5b-9 injury to podocytes include production of oxidants, cytokines, proteases, and growth factors that further damage the podocyte and the underlying GBM. The presence of C1q on the biopsy suggests lupus nephritis class V as the secondary cause.

Later in the course of disease, thickening of the GBM is evident on light microscopy. Silver immunostaining, which is used to detect organized matrix, shows the characteristic spike pattern of membrane thickening forming around the subepithelial deposits. Electron microscopy shows flattening, fusion, and effacement of the podocytes, which augments proteinuria. As in most forms of progressive glomerular disease, further deterioration in renal function is caused by progressive tubulointerstitial fibrosis.

Clinical and laboratory findings Patients with membranous nephropathy present with the complications of marked nephrotic-range proteinuria (> 3.5 g/day), including edema and fluid retention. The proteinuria is nonselective (i.e., including not only albumin but also larger proteins) and is usually in the range of 5 to 15 g/day. However, 20% of patients with membranous

Table 4 Conditions Associated with Membranous Nephropathy

Tumors (e.g., bowel, breast, lung)
Infections (e.g., hepatitis B, hepatitis C, syphilis, filariasis, hydatid disease, schistosomiasis, malaria, leprosy)
Drugs and toxins (e.g., gold, penicillamine, nonsteroidal anti-inflammatory drugs, mercury, captopril, formaldehyde, hydrocarbons)
Immune diseases (e.g., systemic lupus erythematosus, diabetes mellitus, rheumatoid arthritis, Hashimoto disease, Graves disease, mixed connective tissue disease, Sjögren syndrome, primary biliary cirrhosis, bullous pemphigoid, small bowel enteropathy syndrome, dermatitis herpetiformis, ankylosing spondylitis, graft versus host disease, Guillain-Barré syndrome)
Miscellaneous conditions (e.g., sarcoidosis, Kimura disease [angiolymphoid hyperplasia with eosinophilia], angiofollicular lymph node hyperplasia)

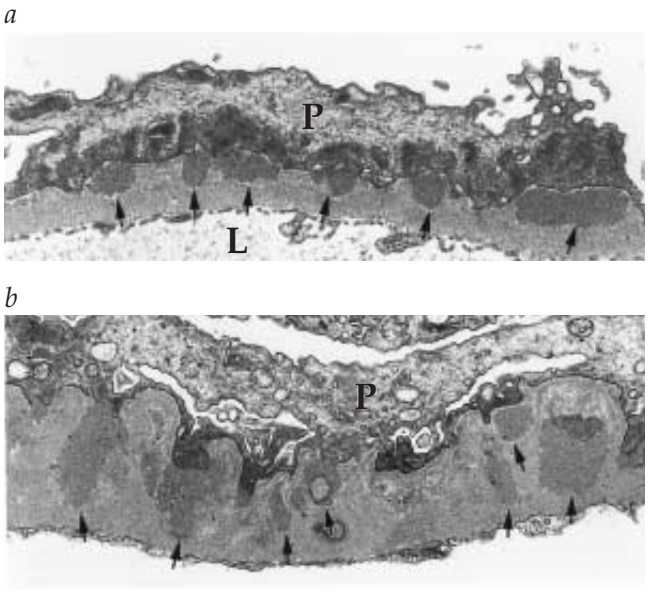

Figure 14 **Transmission electron micrograph showing characteristic subepithelial cell deposits (arrows) in (*a*) early and (*b*) late membranous nephropathy; P illustrates podocytes, and L shows the capillary lumen.**

nephropathy have non–nephrotic-range proteinuria and therefore may be asymptomatic. Clinical clues to secondary causes may be evident at presentation in patients who have systemic symptoms (e.g., a rash in patients with SLE). Microscopic hematuria is noted in 50% of patients, yet the urine is devoid of RBC casts and WBCs. Because the decline in GFR occurs slowly in membranous nephropathy, renal function is normal in 80% of patients at presentation. Hypertension occurs in 30% of cases.

Positive laboratory studies in membranous nephropathy include those providing evidence of nephrotic syndrome (i.e., hypoalbuminemia, hypercholesterolemia, and proteinuria). Although hypercoagulability can complicate any form of the nephrotic syndrome, renal vein thrombosis is most commonly found in membranous nephropathy and may occur in up to 50% of patients. Despite the local activation of complement in the glomerulus, serum total complement and individual complement components are normal in idiopathic membranous nephropathy. In contrast, low complement levels support secondary causes, such as SLE, hepatitis B, and hepatitis C. Investigations for specific secondary causes should be sought, especially in patients older than 50 years.

Treatment and prognosis Management of membranous nephropathy includes the treatment of the underlying disease in secondary forms of membranous nephropathy and prevention or reduction of complications of nephrotic syndrome. The prognosis of idiopathic membranous nephropathy has traditionally been known by the rule of thirds[69]: about one third of patients have a spontaneous, complete remission within 3 to 5 years, with resolution of proteinuria and normalization of the GFR; one third have partial remission, with persistent proteinuria of less than 2 g/day but a normal GFR; and one third progress to end-stage renal disease. Some studies have shown that closer to 50% of patients progress to end stage. In these patients, GFR drops 50% over 3 to 4 years. Poor prognostic markers include male sex, age over 60 years, hypertension, proteinuria that is massive in both quantity and duration (e.g., > 8 g for 6 months, > 6 g for 9 months, or > 4 g for 12 months), and a decrease in GFR.

Renal injury can be reduced by controlling hypertension and lowering proteinuria or by the judicious use of ACE inhibitors, ARBs, or both. In patients who are at high risk for progressive re-

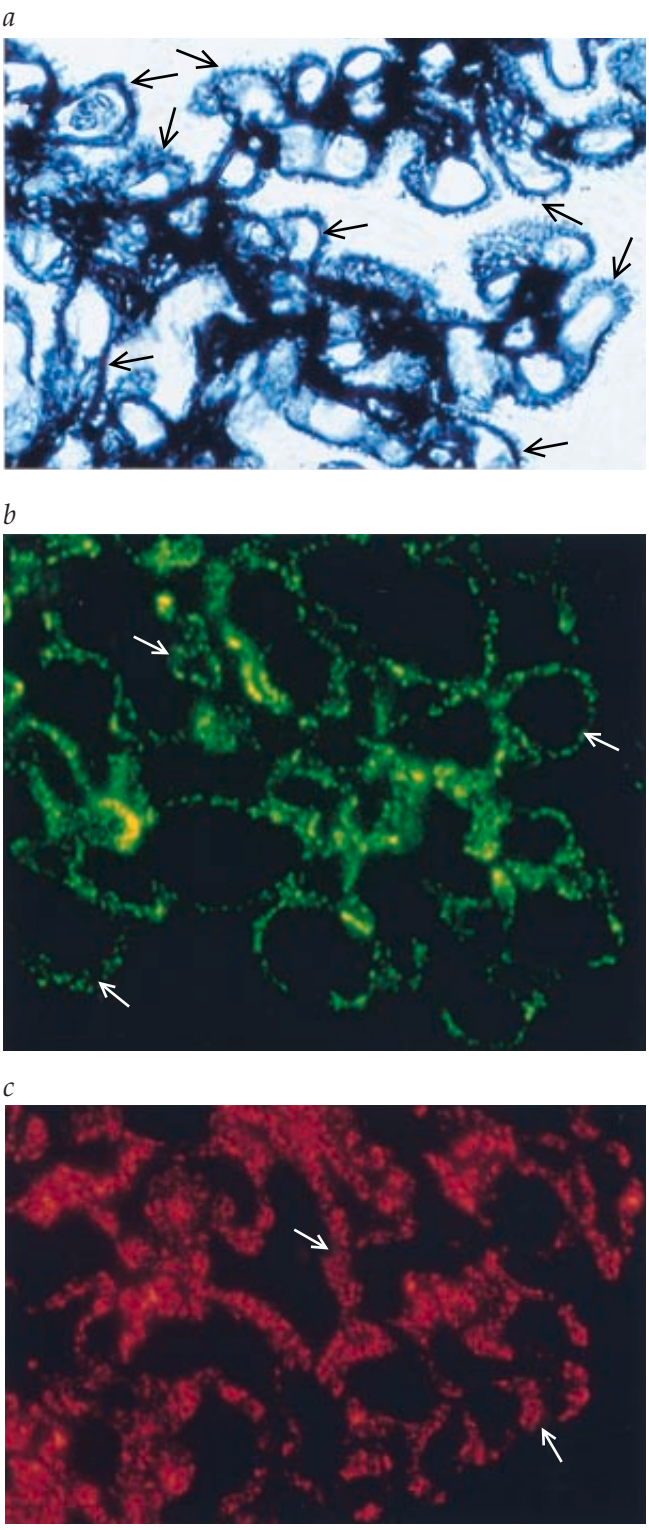

Figure 15 **(*a*) Silver staining showing thickened GBM and spike formation in membranous nephropathy. (*b*) Immunofluorescent staining showing the typical granular pattern of IgG in membranous nephropathy. (*c*) C5b-9 immunostaining in a pattern similar to that of IgG.**

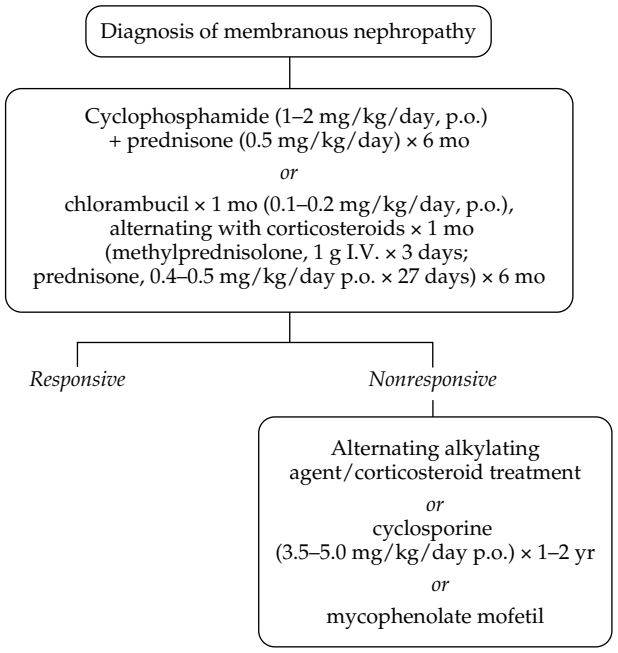

Figure 16 **Treatment algorithm for high-risk patients with membranous nephropathy.**

nal failure, disease-specific treatment should be implemented in addition to these nonspecific measures [*see Figure 16*].[70]

In contrast to idiopathic FSGS and minimal change disease, membranous nephropathy cannot be adequately treated with corticosteroids alone; instead, disease-specific therapy includes both alkylating agents and steroids. Two regimens are used. The first is oral cyclophosphamide (1 to 2 mg/kg/day) with prednisone (0.5 mg/kg/day) for 6 months.[71-73] A second, proposed protocol involves alternating cycles of oral chlorambucil (0.1 to 0.2 mg/kg/day) for 1 month and steroids for 1 month (methylprednisolone, 1g I.V., followed by 0.4 to 0.5 mg/kg/day of oral prednisone for 27 days).[74]

If alkylating agents are contraindicated or if the patient experiences relapses, the second line of therapy is oral cyclosporine (3.5 to 5.0 mg/kg/day) for 1 to 2 years.[75] Alternative and experimental therapies include intravenous immunoglobulin and mycophenolate mofetil and, more recently, rituximab. These therapies should be administered by a nephrologist. Renal transplantation for patients with end-stage renal failure from membranous nephropathy is encouraged, although there is a slight (5%) risk of subsequent occurrence in the donor kidney.

Minimal Change Disease

Minimal change disease derives its name from the lack of clear-cut histologic abnormalities visible on light microscopy of renal biopsy specimens.[76] Minimal change disease is the most common form of primary glomerular disease causing nephrotic syndrome in children and is the third most common cause of nephrotic syndrome in adults.[77] There is no gender predilection in adults, whereas twice as many boys as girls are affected.

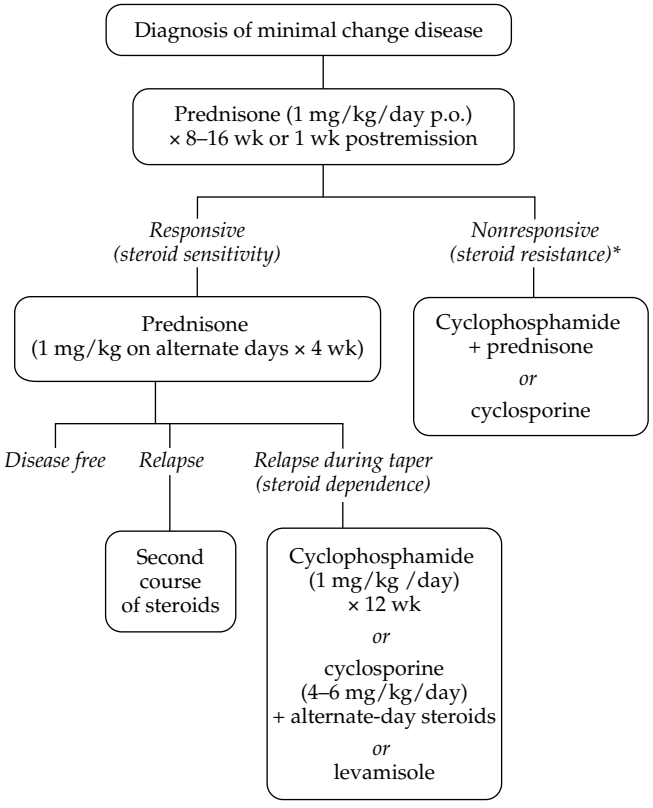
Although most forms of minimal change disease are idiopathic, secondary causes need to be ruled out [*see Table 5*]. A combination of the nephrotic syndrome and renal failure should alert the clinician to NSAID-induced minimal change disease complicated by interstitial nephritis.[78,79]

Table 5 Causes of Minimal Change Disease

Drugs (e.g., nonsteroidal anti-inflammatory drugs, interferon alfa, lithium, gold)
Allergies (e.g., pollen, house dust, insect stings, immunizations)
Malignancies (e.g., Hodgkin lymphoma, leukemia)

Pathogenesis and histology Minimal change disease is probably caused by a defect in cell-mediated immunity, particularly T cells. Podocytes are the target of injury. However, no abnormalities are seen on light microscopy, and immunofluorescent staining is negative for immunoglobulins and complement factors. On electron microscopy, the classic finding is flattening, effacement, and fusion of the foot processes.[80] Podocyte injury leads to a decrease in production of negatively charged proteoglycans in the underlying basement membrane and foot processes, which underlies the development of proteinuria.

Clinical and laboratory findings Because the onset of proteinuria is typically abrupt in minimal change disease, patients present with acute clinical findings of the nephrotic syndrome. The laboratory abnormalities usually reflect the severity of the nephrotic syndrome. Hypertension and a decline in renal function occur in fewer than 20% of affected adults. Proteinuria is typically massive (> 6 g/day), urine sediment is unremarkable, and hematuria is rare.



*Heavy proteinuria for more than 12–16 wk.

Figure 17 **Treatment algorithm for patients with minimal change disease.**

Table 6 Causes of Membranoproliferative Glomerulonephritis Types I–III

Type	*Causes*
I	Idiopathic Collagen vascular diseases (e.g., rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus) Complement deficiencies Acquired (e.g., C4 nephritic factor) Hereditary (e.g., C1q, C2, C3, C4) Cryoglobulinemia (types 2 and 3) Infections Viral (e.g., hepatitis C, chronic hepatitis B, HIV) Bacterial (e.g., infective endocarditis, visceral abscess, infected shunt) Other (e.g., *Plasmodium malariae, Schistosoma, Mycoplasma*) Malignancies (e.g., chronic lymphocytic leukemia, lymphoma, renal cell carcinoma) Other (e.g., α_1-antitrypsin deficiency, other chronic liver diseases, hypocomplementemic urticaria vasculitis)
II	Idiopathic Associated with C3 nephritic factor Associated with factor H defect Partial lipodystrophy
III	Idiopathic Associated with terminal complement nephritic factor Same causes listed for type I (see above)

Treatment and prognosis Corticosteroids are the treatment of choice for minimal change disease [*see Figure 17*]. In adults, prednisone (1 mg/kg/day) should be given for 8 to 16 weeks. In those patients who respond (> 95%), prednisone is then switched to alternate days at a dosage of 1 mg/kg for 4 weeks, followed by tapering over the next few months.[80] A first relapse should be treated with another course of steroids. In patients who have relapses more than twice after completion of the steroid course and in patients who have a relapse during the taper (i.e., steroid-dependent patients), cyclophosphamide (2 mg/kg/day) should be given for 8 to 12 weeks, combined with prednisone at an increased dosage. Alternatives to cytotoxic therapy include cyclosporine (4 to 6 mg/kg/day) along with alternate-day prednisone. Limited published experience with mycophenolate mofetil suggests some benefit in patients with refractory or relapsing disease.[81-83] In patients who do not respond to prednisone within 12 to 16 weeks (i.e., steroid-resistant patients), cyclophosphamide or cyclosporine may be used. Levamasole, an immune stimulant, has also been used with some success in steroid-dependent children with nephritic syndrome from minimal change disease.[84] In children who have frequent relapses after treatment with alkylating agents, levamisole may serve as an alternative.[85]

DISEASES PRESENTING AS MIXED NEPHRITIC-NEPHROTIC SYNDROME

Membranoproliferative Glomerulonephritis

MPGN, which is also known as mesangiocapillary glomerulonephritis, is an immune complex–mediated glomerular disease.[86] It can present as nephritic, nephrotic, or nephritic-nephrotic syndrome. The name derives from the classic finding of splitting of the basement membrane and proliferation of mesangial and endothelial cells. MPGN accounts for 5% to 20% of all primary nephrotic syndromes. The incidence of the disease is highest in South America and Africa, and it occurs equally in males and females. MPGN is mostly idiopathic, but the histologic diagnosis should always prompt a search for secondary causes [*see Table 6*].[87]

Pathogenesis and histology MPGN is classified into types I, II, and III, according to the sites of deposition of glomerular immune complexes (IgG and C3). These are preformed immune complexes, such as hepatitis C antigen and anti–hepatitis C antibody. Each type of MPGN has a different cause and involves activation of different components of the complement pathway, giving rise to differences in serum complement levels.

MPGN type I refers to immune complex deposits that are subendothelial and mesangial and result from diseases characterized by chronic immune complex formation that activates the classic complement pathway [*see Figure 18*].[88] The most common cause of MPGN type I is hepatitis C, with or without mixed cryoglobulinemia.[26] Less frequent causes include mixed cryoglobulinemia that does not result from hepatitis C infection, hepatitis B infection, or subacute bacterial endocarditis. The classic double contouring (so-called tram tracks) seen on histology is a result of interposition of mesangial cells, leukocytes, or endothelial cells in the capillary wall, with the synthesis of new basement membrane material. Resident mesangial and endothelial cells and infiltrating cells proliferate in MPGN. Immunofluorescent staining is positive for IgG, IgM, and C3 along the capillary wall; these immune complexes take on a granular pattern, which is distinct from the linear pattern in anti-GBM disease.

MPGN type II occurs primarily in young adults and children. It is caused by activation of the alternative complement pathway and is associated with the presence of dense deposits in the basement membrane itself that are positive for C3 but negative for IgG and for the classic complement components C1q and C4.[89] Accordingly, type II MPGN is also called dense-deposit disease. Its etiology is unknown, but possible causes include the absence of a constitutive inhibitor of the alternative complement pathway (factor H) or the presence of a circulating autoantibody (C3 nephritic factor) that binds to and prevents inactivation of the alternative pathway C3 convertase.[90]

MPGN type III has lesions that are similar to those of type I but have additional subepithelial deposits. Occasionally, intramembranous deposits are also present.[91]

Clinical and laboratory findings MPGN has four clinical presentations: microscopic hematuria and nonnephrotic proteinuria, which is seen in 35% of patients; nephrotic syndrome and a mild decrease in renal function, seen in 35% of patients; chronic glomerulonephritis, usually progressive, in 20% of patients; and acute renal failure with proteinuria and an active urine sediment with RBC casts, in 10%. Hypertension is a very common presenting finding, occurring in 50% to 80% of patients, and the urinary sediment is often active. One quarter of patients with MPGN type II may also manifest partial lipodystrophy that preferentially involves the face and upper body.

Although patients present with evidence of glomerular disease, clues to a secondary cause may also be present, such as features of cryoglobulinemia (e.g., weakness, arthralgia, purpura), viral infection (e.g., hepatitis B, hepatitis C, HIV), bacterial infection (e.g., endocarditis, abscess), and liver disease. Laboratory evidence for MPGN can be categorized as follows: the presence

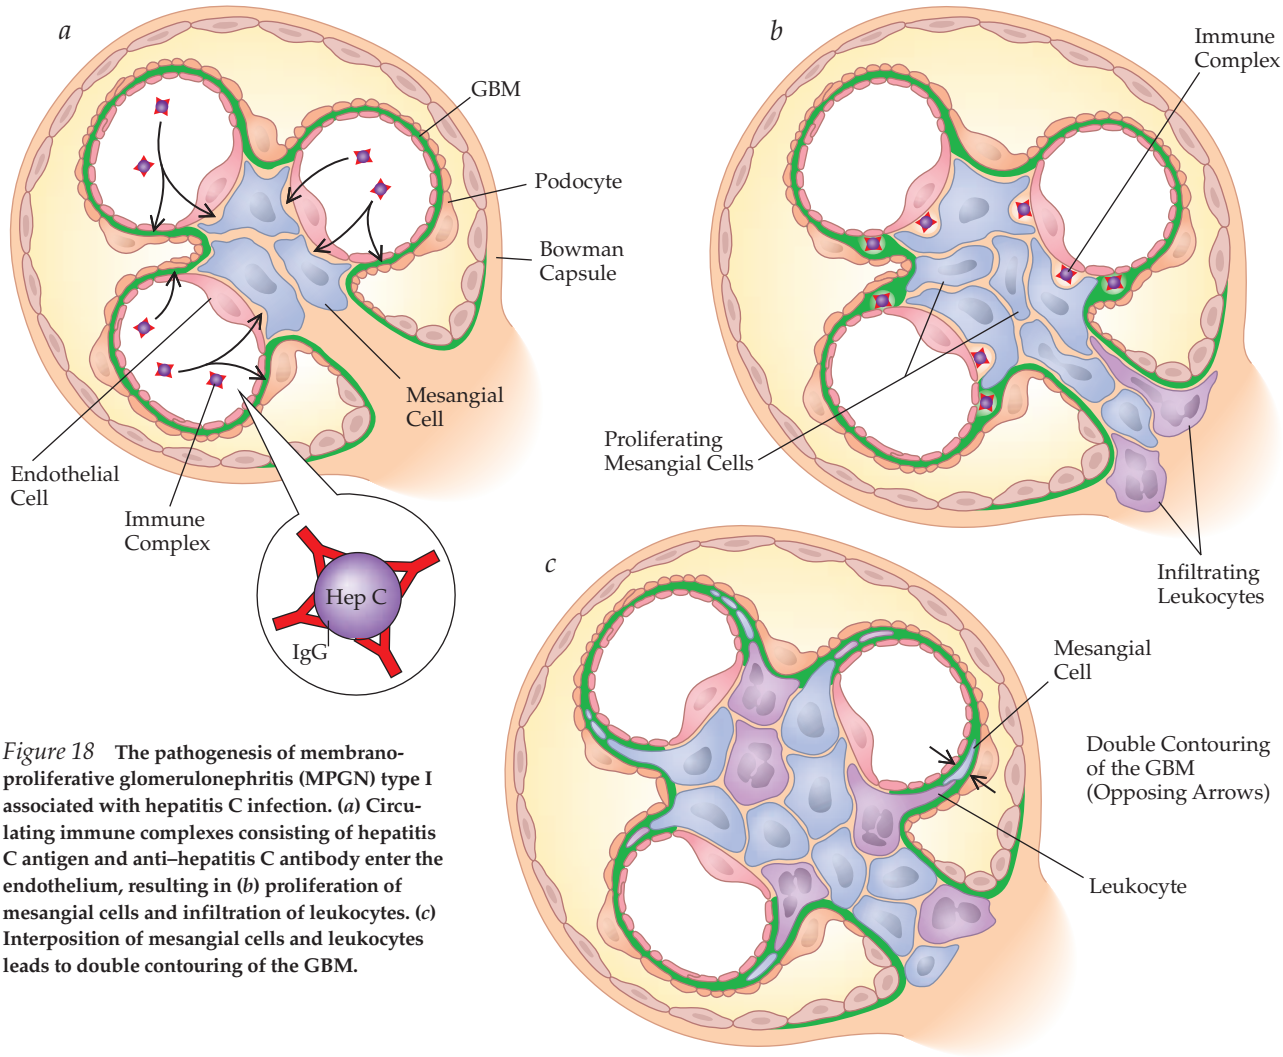


Figure 18 **The pathogenesis of membranoproliferative glomerulonephritis (MPGN) type I associated with hepatitis C infection. (*a*) Circulating immune complexes consisting of hepatitis C antigen and anti–hepatitis C antibody enter the endothelium, resulting in (*b*) proliferation of mesangial cells and infiltration of leukocytes. (*c*) Interposition of mesangial cells and leukocytes leads to double contouring of the GBM.**

of the nephrotic syndrome or renal failure, or both, and the complications thereof; activation of the classic complement cascade, with low levels of C1q, C4, and CH_{50}, which is seen in MPGN types I and III; and activation of the alternative pathway, with low levels of C3 and CH_{50} and normal levels of C1q and C4, which is characteristic of MPGN type II. In addition, the clinician should look for evidence of an underlying cause of MPGN, such as the presence of circulating immune complexes, cryoglobulins, rheumatoid factor, and specific viruses (e.g., hepatitis C virus RNA, hepatitis B markers, HIV).

Treatment and prognosis Hepatitis C–associated MPGN with cryoglobulinemia is usually treated with antiviral therapy (i.e., PEG-interferon alpha-2b and ribavirin, if renal function allows). Remission occurs in 60% of patients, but more than 80% of patients experience relapses. Other infection-associated MPGN usually responds to specific antimicrobial therapy, which reduces the antigen levels and therefore the immune complexes. Persistent signs of renal disease and hypocomplementemia usually indicate inadequate therapy. Steroids have been administered on alternate days in children with MPGN, but the use of steroids remains controversial in adults. On the basis of pediatric studies, long-term low-dose prednisone may be tried in adults with nephrotic-range proteinuria. For MPGN associated with rapidly progressive renal failure, combination therapy with steroids and cytotoxic agents is frequently used.[92]

The prognosis of MPGN depends in part on the presence of any underlying disease, which must be treated with specific therapy. Idiopathic MPGN has a poor prognosis: 40% to 50% of patients progress to renal failure within 10 years. Optimal therapy has not been established. In adults, studies have shown potential benefit with antiplatelet therapy such as aspirin (975 mg/day) and dipyridamole (225 mg/day), anticoagulation therapy such as warfarin, and steroids. Controlled trials of alkylating agents have not shown long-term benefit, and the therapeutic benefit of cyclosporine has not been adequately proved. MPGN recurs in renal transplant patients with type I disease (20% to 50% of patients) and type II disease (80% of patients) but is usually milder than in native kidneys.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VI ACUTE RENAL FAILURE

Mary Jo Shaver, m.d.
Sudhir V. Shah, m.d., f.a.c.p.

Acute renal failure (ARF) can be broadly defined as an abrupt decrease in renal function occurring over hours to days and sufficient to result in retention of nitrogenous waste (i.e., azotemia), as measured by elevations in blood urea nitrogen (BUN) and creatinine levels. The usual criteria for ARF are an increase in serum creatinine of 0.5 mg/dl, a 25% increase in serum creatinine, or a 25% decrease in glomerular filtration rate (GFR). However, it is now recognized that even a modest rise in serum creatinine of 0.3 mg/dl is associated with increased mortality and morbidity, and this may lead to revision of the criteria for ARF.

ARF is further defined pathophysiologically, depending on whether it results from a decrease in renal blood flow (prerenal azotemia), intrinsic renal parenchymal diseases (renal azotemia), or obstruction of urine flow (postrenal azotemia) [*see Table 1*]. The most common intrinsic renal disease that leads to ARF is acute tubular necrosis (ATN). Clinical recognition is based largely on exclusion of prerenal and postrenal causes of sudden azotemia, followed by exclusion of other causes of intrinsic ARF (e.g., glomerulonephritis, acute interstitial nephritis [AIN], and vasculitis). Although the term acute tubular necrosis is not an entirely valid histologic description of this syndrome, the term is ingrained in clinical medicine and is therefore used in this chapter.

Despite major advances in dialysis and intensive care, the mortality in patients with severe ARF who require dialysis has not decreased significantly over the past 50 years. Because of that and because even a minor decline in renal function is associated with poor patient outcome, prevention [*see Tables 2 and 3*] and early diagnosis of ARF are the cornerstones of management. Discovery of biomarkers that can predict the development of renal dysfunction before the serum creatinine level rises may lead to early and successful treatment of ARF.

Epidemiology

The frequency of ARF varies greatly, depending on the clinical setting. The incidence of ARF has been cited as 1% on admission to the hospital, from 2% to 5% during hospitalization, in as many as 20% of patients treated in intensive care units, and in 4% to 15% of patients after cardiovascular surgery.[1-3] In a study of 2,216 medical and surgical patients, ARF developed in 5% of patients; of those cases, 55% were associated with iatrogenic factors—mostly adverse drug effects—and sepsis.[1] In a study of 681 ICU patients with ARF, the average age was 59.5 years, and many patients had complicated medical conditions; 30% had chronic kidney disease, 37% had coronary artery disease, 29% had diabetes mellitus, and 21% had chronic liver disease.[4] Female sex has been found to be an independent risk factor for developing ARF after open heart surgery.[5]

The incidence of severe ARF in adults in Western countries is approximately 140 per million population per year; 50 to 70 per million population per year require dialysis.[6]

Acute Renal Failure in the Hospitalized Patient

etiology

Prerenal azotemia is the single most common cause of ARF, accounting for 30% to 60% of all cases.[7] Prerenal azotemia, depending on its severity and duration, may lead to ATN in a susceptible person. Therefore, early identification and aggressive treatment of prerenal azotemia are important. In the hospital setting, postrenal azotemia causes 1% to 10% of cases of ARF.[7] ARF associated with postrenal azotemia should be a consideration in elderly men, especially if they are receiving medications that could impair bladder function.

ATN is the most common intrinsic renal disease leading to ARF in hospitalized patients. When prerenal and postrenal causes of ARF have been excluded, about 75% of hospitalized patients with ARF have ATN.[7] Multiple insults are usually present, but prerenal azotemia is often the predisposing factor. Iatrogenic causes, including sepsis and nephrotoxins (e.g., antibiotics, contrast dye), contribute to a large portion of these cases. Approxi-

Table 1 Causes of Acute Renal Failure

I. Prerenal azotemia
  A. Absolute decrease in effective blood volume
    Hemorrhage, skin losses (burns, sweating), gastrointestinal losses (diarrhea, vomiting), renal losses (diuretics, glycosuria), fluid pooling (peritonitis, burns)
  B. Relative decrease in blood volume (ineffective arterial volume)
    Congestive heart failure, sepsis, anaphylaxis, liver failure
  C. Arterial occlusion
    Bilateral thromboembolism, thromboembolism of solitary kidney
II. Renal azotemia
  A. Vascular causes
    Vasculitis, malignant hypertension, microscopic polyarteritis
  B. Acute glomerulonephritis
    Postinfectious glomerulonephritis, anti–basement membrane–antibody disease
  C. Acute interstitial nephritis
    Drug-associated acute interstitial nephritis (methicillin nephrotoxicity)
  D. Acute tubular necrosis
    1. Ischemia
      Prerenal azotemia (if severe enough), postsurgical complication
    2. Sepsis syndrome
    3. Nephrotoxicity
      a. Exogenous nephrotoxins
        Antibiotics (aminoglycosides, cephalosporin, amphotericin B); iodinated contrast agents; chemotherapeutic agents (cisplatin); solvents (carbon tetrachloride, ethylene glycol)
      b. Endogenous nephrotoxins
        Intratubular pigments (hemoglobinuria, myoglobinuria), intratubular proteins (myeloma), intratubular crystals (uric acid, oxalate), tumor lysis syndrome
III. Postrenal azotemia (obstruction of collecting system)
  Bladder outlet obstruction, bilateral ureteral obstruction (unusual), ureteral obstruction in a solitary kidney

Table 2 Prevention of Acute Renal Failure

1. Identify patients with risk factors
   - Old age
   - Abnormal renal function or diabetes
   - Volume depletion
   - Recent vascular surgery
   - Recent trauma
2. Avoid nephrotoxic agents
   - Nonsteroidal anti-inflammatory drugs
   - Aminoglycosides
   - Amphotericin B
   - Chemotherapeutic agents (e.g., cisplatin)
   - Angiotensin-converting enzyme inhibitors in volume-depleted patients
3. Apply preventive strategies in specific circumstances [*see Table 3*]
   - Use of contrast media
   - Tumor lysis syndrome
   - Rhabdomyolysis
   - Surgical procedures

mately 40% to 60% of ATN cases occur in the postoperative or trauma setting. Depending on the clinical setting, other diagnoses to be considered are AIN (e.g., secondary to use of methicillin), glomerulonephritis, atheromatous emboli (in association with previous aortic surgery, aortography, or both), ureteral obstruction (in association with pelvic or abdominal pathology or secondary to complications of pelvic or abdominal surgery), or intrarenal obstruction (e.g., acute uric acid nephropathy).

PATHOPHYSIOLOGY

Prerenal Azotemia

Prerenal ARF occurs when glomerular perfusion falls, as a result of either an absolute reduction in the volume of extracellular fluid or a reduction in circulating volume despite a normal total extracellular fluid volume, as may occur in conditions such as heart failure, advanced cirrhosis, and septic states. The kidney has the capacity to autoregulate GFR and blood flow simultaneously during renal hypoperfusion through the independent regulation of afferent and efferent arteriolar tone. While the afferent arteriole dilates in response to renal hypoperfusion, the efferent arteriole constricts, maintaining glomerular intracapillary pressure, which is the driving force for glomerular filtration. Thus, during the early phase of mild to moderate prerenal conditions, renal blood flow and GFR are maintained within normal ranges, and BUN and creatinine levels remain normal. When prerenal conditions become severe and renal adaptive mechanisms cannot compensate, GFR falls and the BUN and creatinine levels begin to increase.

Prerenal ARF is characterized by renal hypoperfusion, a high ratio of BUN to serum creatinine, and a low urine volume. Levels of antidiuretic hormone are elevated, thus increasing the reabsorption of both water and urea. Prerenal failure is a response to severe volume depletion, heart failure, or sepsis. Prerenal failure can also occur with the presentation of a large solute load to the kidney, along with stimulation of volume loss by an osmotic diuresis, as occurs in hyperglycemia.[8]

Acute Tubular Necrosis

ATN is a clinical syndrome of abrupt and sustained decline in GFR that is triggered by an acute ischemic or nephrotoxic event and develops within minutes to days after the insult. Leakage of glomerular ultrafiltrate from the tubular lumen into the renal interstitium across the damaged renal tubular cells, obstruction of flow within the tubule by debris or crystals in the lumen, and a decrease in the glomerular capillary ultrafiltration coefficient have all been proposed as playing a pathophysiologic role in ATN.

A variety of biochemical and cellular changes may be involved in cell injury in ARF. These include mitochondrial dysfunction, adenosine triphosphate (ATP) depletion, phospholipid degradation, elevation in cytosolic free calcium levels, a decrease in Na^+,K^+-ATPase activity, alterations in substrate metabolism, lysosomal changes, and the production of oxygen free radicals. It is not clear yet which changes are causative and which are by-products of advanced cell injury.

Ischemic ARF culminating in ATN is a very complex physiologic process resulting from a mismatch between oxygen and

Table 3 Prevention of Acute Renal Failure in High-Risk Circumstances

Procedures Involving the Use of Contrast Media
- Hydration
  - Normal saline at 1 ml/kg/hr starting 8–12 hr before the procedure and continuing for 8–12 hr afterward
  - Contrast medium
    - Limit the volume of contrast used
    - Use iso-osmolar contrast (iodixanol) for high-risk patients
  - Pharmacologic pretreatment
    - Acetylcysteine, 600 mg p.o., b.i.d., the day before and the day of the procedure

Tumor Lysis Syndrome
- Hydration and forced diuresis
  - Infuse normal saline to maintain a urine output of 3–5 L/day
- Urinary alkalinization
  - Infuse 2 to 3 ampules of sodium bicarbonate (100–150 mEq) in 5% dextrose in water to maintain urine pH > 7
  - Infuse acetazolamide, 1 g/m^2
  - Monitor basic metabolic panel and avoid significant metabolic alkalosis
- Pharmacologic treatment
  - Allopurinol, 300–600 mg/day, starting 3 days before chemotherapy; adjust dose for patients with renal impairment

Rhabdomyolysis
- Hydration
  - Infuse normal saline to replace volume if patient is volume depleted, then give 200–300 ml/hr and follow hemodynamic status; balance fluid input with urine output
- Pharmacologic treatment
  - Add 2 ampules of mannitol (25 g/100 ml) and 2 ampules of sodium bicarbonate (100 mEq/100 ml) to 800 ml of 5% dextrose in water; infuse at a rate of 250 ml/hr while frequently monitoring fluid intake, urine output, and basic metabolic panel; if the urine output is good, continue infusing until the myoglobinuria resolves; if the patient becomes oliguric (urine output < 400 ml/24 hr), stop I.V. fluids and manage as established renal failure

Surgical Procedures
- Recognize patients with high-risk conditions
  - Preexisting renal disease
  - Chronic liver disease
  - Cardiac failure
  - Old age
- Avoid volume depletion
- Avoid hypotension
- Avoid nephrotoxic agents

nutrient delivery and energy demand of the nephrons. The most important pathophysiologic component of ischemic ARF may be a reduction in the local blood flow to the outer medulla.[9] There appears to be an excess of constrictor hormones relative to hormones that dilate the afferent arteriole; subsequently, there is a drop in glomerular perfusion pressure and depression of the GFR. The brunt of the postischemic injury is in the proximal tubular cells, with loss of cell polarity and redistribution of Na^+/K^+-ATPase from its normal location on the basolateral plasma membrane. This leads to an increase in the delivery of sodium to the macula densa that stimulates afferent arteriole vasoconstriction.[10]

Inflammatory cells appear to be involved in the pathogenesis of ATN.[9,11] In addition, whereas previous studies focused on the renal tubular injury to epithelial cells, current research also emphasizes the importance of endothelial cells in ATN. As endothelial cells are injured, the cells swell, cell adhesion molecules are expressed, leukocytes are activated, and renal injury is potentiated. Vasoactive mediators promote vasoconstriction and further compromise in local blood flow and tubular cell metabolism.[12]

Despite the common use of the term ATN, necrosis of the tubules is seen infrequently in either ischemic or nephrotoxic ARF. Cell death may be of two kinds: apoptotic or necrotic. Advances in the understanding of cell death have led to the recognition that the pathways traditionally associated with apoptosis may be critical in determining the form of cell injury associated with necrosis. Apoptotic pathways, in which endonucleases play an important role, appear to be regulated by mediators such as oxidants, caspases, and ceramide. Which pathway the cell follows seems to depend on both the nature and the severity of the insult. It is likely that the pathway followed is to a large extent affected by the expression of the many genes involved in cell cycle regulation and by inflammatory and chemotactic genes. It is also likely that the cascades that lead to either apoptotic or necrotic cell death are activated almost simultaneously and may share some common pathways.

Natural history Persistent renal impairment from ATN may be oliguric or nonoliguric and typically lasts for 1 to 2 weeks, but it can persist for 4 to 6 weeks. This is followed by the diuretic phase, which eventually leads to normalization of kidney function over a few days to a week. Most patients achieve complete recovery of renal function, except for perhaps some defect in the concentrating ability of the kidney. However, there is increased recognition that a small but significant percentage of patients with ATN do not recover renal function and may require long-term dialysis.

DIAGNOSIS

To determine the cause of ARF, the physician must follow a systematic approach, which should start with excluding or correcting both prerenal and postrenal azotemia. Often, the difficulty in arriving at a correct etiologic diagnosis of ARF in a hospitalized patient is not in identifying a possible cause but, rather, in selecting the actual cause from among several possible ones.

Correct diagnosis depends on basic knowledge of the natural history of ARF from different causes, review of the chronologic sequence of events in the deterioration in the patient's renal function, and analysis of the available patient data. Despite the exhaustive list of conditions that can cause acute azotemia in hospitalized patients, a careful history and physical examination and simple laboratory tests often suffice for diagnosis.

Clinical Manifestations

In a hospital setting, ARF is most commonly recognized when patients exhibit oliguria, rising BUN and creatinine levels, or both oliguria and rising BUN and creatinine. Thus, it is unusual for ARF to go unrecognized until the patient develops symptoms suggestive of uremia, such as fatigue, weakness, nausea, vomiting, loss of appetite, metallic taste in the mouth, itching, confusion, fluid retention, and hypertension.

Chart Review, History, and Physical Examination

Evaluation of the patient with ARF should start with a complete medical history and a review of the hospital records. Some of the important data that should be sought from chart review are presented [*see Tables 4 and 5 and Figure 1*].

Reduced body weight, marked orthostatic decrease in blood pressure, an increase in pulse, and lack of jugular venous distention all suggest a reduction in extracellular fluid volume. Patients with prerenal azotemia can appear to be experiencing volume overload in association with extracellular fluid expansion (e.g., cardiac failure, cirrhosis, nephrotic syndrome), but the effective blood volume is decreased and thus renal perfusion is impaired.

Careful abdominal examination may reveal a distended, tender bladder, indicating lower urinary tract obstruction. In men in whom lower tract obstruction is suspected as a cause of acute azotemia, examination of the prostate and a sterile postvoid bladder catheterization with urinalysis should be performed.

Additional findings that may be helpful are fever and rash, which occur in some patients with AIN. A history of a recent aortic catheterization (e.g., cardiac catheterization) and the finding of livedo reticularis are diagnostic clues for cholesterol or atheromatous emboli.

Differentiating prerenal azotemia from ATN may be difficult, partly because of the difficulty in evaluating the volume status in a critically ill patient and also because prerenal azotemia from any cause, if severe enough, may lead to ATN. Evaluation of the urine volume and urine sediment and a number of urinary indices (most useful in patients with oliguria) are particularly helpful in making the correct diagnosis.

Laboratory Tests

Ratio of blood urea nitrogen to creatinine Initial laboratory tests include measurement of BUN and serum creatinine, sodium, chloride, potassium, and bicarbonate levels. These tests are important not only for the diagnosis but for assessment of complications of ARF. In prerenal conditions resulting from enhanced salt and water avidity, there is a disproportionate increase in the ratio of BUN to creatinine (> 20:1). Other causes of BUN elevation include gastrointestinal bleeding, use of systemic steroids, catabolism caused by the underlying medical condition, or a high-protein diet. An elevation in the creatinine level that exceeds the elevation in BUN suggests rhabdomyolysis; such patients will also have an elevated creatine phosphokinase (CPK) or myoglobin level.

Urinary volume ARF is traditionally divided into anuric (urine output of < 100 ml/day), oliguric (urine output of 100 to 400 ml/day), and nonoliguric (urine output of > 400 ml/day). In a hospitalized patient, a normal urine output in the face of a rise in creatinine level most often signifies ATN, because prerenal azotemia should lead to oliguria. Wide variations in daily urinary output suggest obstruction. Complete anuria (no urine output) suggests obstruction or an acute vascular catastrophe, such as renal vein or

Table 4 Diagnostic Evaluation of a Patient with Acute Renal Failure

Types of Evaluation	*Comments*
Chart Review	
Previous renal function	Patients with previous renal insufficiency are more susceptible to ARF
Medications	Aminoglycosides are important causes of ATN in hospitalized patients (nonoliguric and in the first 2 wk of therapy); certain antibiotics, NSAIDs, and a host of medications can cause AIN; contrast agents are an important cause of ARF
Start date	
Drug levels	
Nephrotoxins?	
NSAIDs?	
Aminoglycosides?	
Amphotericin B?	
Contrast agent used?	
Surgery	Cardiac and vascular surgery patients are particularly susceptible to ATN
Type and duration	
Hemodynamics	
Blood loss	
Anesthetic used	Methoxyflurane and enflurane (which is related to methoxyflurane but is less toxic) can cause nonoliguric ATN
Infection	Infection or sepsis can cause ARF even in the absence of hypertension
Fever?	
Positive blood cultures?	
Hemodynamics	Hypotension can cause prerenal azotemia and ischemic ATN
Blood pressure	
Heart rate	
Weight (in and out)	
Physical Examination	
Volume status	
Edema?	Pretibial in the ambulatory patient, sacral in the bedridden patient
Jugular vein distention?	
Crackles?	
S_3 gallop?	
Skin	
Diffuse rash?	Skin rash seen in ARF induced by some drugs (e.g., antibiotics and allopurinol); a purpuric skin rash may be seen with Henoch-Schönlein purpura and cryoglobulinemia
Livedo reticularis?	
Atheroemboli?	
Bladder	Distended bladder
Suprapubic fullness	To assess postvoid residual urinary volume and to relieve bladder obstruction
Bladder catheterization

AIN—acute interstitial necrosis ARF—acute renal failure ATN—acute tubular necrosis NSAIDs—nonsteroidal anti-inflammatory drugs

renal artery thrombosis or large emboli in the renal arteries, although it can be seen in ATN and AIN. To cause total anuria, a vascular event must affect both kidneys or a single functioning kidney.

Urinalysis and urine sediment The following is a list of findings on urinalysis, including urine sediment analysis, and their implications for renal failure:

1. In prerenal failure, a moderate number of hyaline and finely granular casts may be seen, but coarsely granular and cellular casts are infrequent. Finely granular casts can also be seen in the sediment of patients with chronic renal failure.
2. In ATN, a characteristic sediment is found in 70% to 80% of patients, particularly those with oliguric ATN; it consists of dirty-brown, coarse, granular casts, free renal tubular epithelial cells, and epithelial cell casts. With more severe renal injury, there may be a 24- to 48-hour delay before the appearance of dirty-brown casts.
3. A seemingly benign urine sediment containing few formed elements suggests possible obstruction.
4. Proliferative glomerulonephritis is characterized by urine containing 3+ to 4+ protein; 2+ to 3+ blood; and active sediment, defined as sediment containing red blood cells (RBCs) and RBC casts. An accurate history and careful physical examination (which may, for example, suggest systemic lupus erythematosus), determination of complement levels, antinuclear antibody testing, and kidney biopsy (if the kidney is of normal size) generally help clarify the diagnosis.
5. Findings of only a few RBCs in the urine sediment and strongly heme-positive urine or heme-positive urine supernatant (after removal of the RBCs by centrifugation) usually indicate myoglobinuria or hemoglobinuria. Patients with rhabdomyolysis have a marked increase in the level of muscle enzyme, such as CPK. The urine sediment in patients with myoglobinuria may show RBCs, pigmented casts, granular casts, and numerous uric acid crystals.

Table 5 Daily Evaluation and Management of the Hospitalized Patient with Acute Renal Failure

Weight	Weight loss of 0.5 to 1 lb/day in a patient with ATN will help prevent volume overload
Jugular vein distention or crackles	Indicate volume overload with possible congestive heart failure; restrict volume, add diuretics, consider dialysis
CVP, PCWP	Assessment of these parameters may be indicated to differentiate volume overload from the presence of noncardiogenic pulmonary infiltrates; low PCWP suggests noncardiogenic pulmonary edema
Intake/output	In euvolemic patients, assess volume of previous day's urine output (in stable patients, add 400 ml for insensible losses); insensible losses may be higher in catabolic, febrile, or agitated patients
Blood urea nitrogen	Disproportionately high values suggest gastrointestinal bleeding, steroid use, hypercatabolic state, or prerenal ARF
Creatinine	Disproportionately high values suggest muscle breakdown, as caused by rhabdomyolysis
Electrolytes	[*see* Complications, *in text*]

Figure 1 **This figure shows a worksheet for the evaluation of acute renal failure in hospitalized patients. The worksheet may be used to chart a chronologic outline of the events that may have contributed to the insult. In using such an approach, particular attention should be paid to the events that occurred a few days before the acute rise in the serum creatinine level. (BUN—blood urea nitrogen; CO_2—carbon dioxide; Hgb—hemoglobin; Hct—hematocrit; WBC—white blood cell count)**

6. The presence of white blood cells (WBCs) in clumps and in casts, in the absence of evidence of bacteria, suggests AIN. This can be associated with microscopic hematuria and RBC casts. The presence of eosinophils in the urine is less helpful in the diagnosis of AIN than was once thought.
7. A urine sediment with abundant uric acid crystals or oxalate crystals suggests uric acid deposition (associated with hyperuricemia after chemotherapy) or intratubular oxalate (e.g., methoxyflurane anesthesia), respectively.

Urinary indices Urinary indices are often used to differentiate prerenal azotemia from ATN. However, interpretation of urinary indices in a patient with chronic kidney disease is often difficult because of underlying sodium wasting in the baseline state that cannot be corrected rapidly with volume depletion. The rationale for the use of these indices is as follows: The ratio of urine to plasma creatinine (U/P_{Cr}) provides an index of the fraction of filtered water excreted. If it is assumed that all of the creatinine filtered at the glomerulus is excreted into the urine and that relatively little is added by secretion, any incremental increase in the concentration of creatinine in urine over that in plasma must be the result of the removal of water. In prerenal azotemia, because of the reduction in the amount of glomerular filtrate entering each nephron and because of an increase in the retention of salt and water, U/P_{Cr} typically is considerably greater than it is in ATN, and urinary sodium concentrations are characteristically lower [*see Table 6*]. In contrast, in ARF associated with ATN, the nephrons excrete a large fraction of their filtered sodium and water, resulting in lower U/P_{Cr} and a higher fractional excretion of sodium (FE_{Na}). Fractional excretion of urea (FE_{Urea}) has also been reported to help differentiate prerenal azotemia from renal azotemia [*see Table 6*]. The use of FE_{Urea} appears to have a particular diagnostic advantage over FE_{Na} in patients who have been receiving diuretics; in one study, the FE_{Na} was low in only 48% of diuretic-treated patients with prerenal azotemia.[13] It must be kept in mind, however, that FE_{Urea} values in chronic kidney disease have not been standardized.

Interpretations of urinary indices must be made in conjunction with other assessments of the patient because there are clinically important exceptions to these generalizations. For example, patients with certain types of ATN, such as radiographic dye–induced renal injury, may present with all the clinical characteristics of ATN but with FE_{Na} rates of less than 1%.

Imaging Studies

If the diagnosis of prerenal azotemia or ATN is reasonably certain and the clinical situation does not require that other causes of acute azotemia be excluded, generally no further diagnostic evaluation is necessary. Further diagnostic evaluation is indicated under the following circumstances: (1) the diagnosis is uncertain, especially if the clinical situation suggests other possibilities (e.g., obstruction or vascular accident); (2) clinical findings (e.g., total anuria) make the diagnosis of prerenal azotemia or ATN less likely; or (3) the oliguria persists longer than 4 weeks.

Renal ultrasonography is the initial diagnostic procedure of choice in renal failure because it is noninvasive and reliable. A finding of normal-size kidneys in a patient with advanced azotemia generally suggests acute rather than chronic renal fail-

Table 6 Urinary Diagnostic Indices

Indices	*Prerenal Azotemia*	*Acute Tubular Necrosis*
Urinary sodium (U_{Na}) (mEq/L)	< 20	> 40
Urine osmolarity (U_{osm}) (mOsm/kg H_2O)	> 500	< 450
Fractional excretion of sodium ($U_{Na}P_{Cr}/P_{Na}U_{Cr}$) (100)	< 1%	> 1%
BUN-to-creatinine ratio	> 20:1	—
Urine creatinine–plasma creatinine [U_{Cr} (mg/dl)/P_{Cr} (mg/dl)]	> 40	< 20

BUN—blood urea nitrogen P_{Cr}—plasma creatinine P_{Na}—plasma sodium

ure; however, several important causes of chronic renal failure, including diabetes mellitus, HIV infection, multiple myeloma, and amyloidosis, may be associated with normal-sized kidneys. The renal ultrasound examination is helpful in confirming or excluding obstruction, identifying polycystic kidney disease, determining whether one or two kidneys are present, and localizing the kidney for renal biopsy.

A high-resolution CT scan is considered the test of choice for suspected urinary tract calculi. Radionuclide methods are available for assessing renal blood flow and excretory (secretory) function. Blood flow studies can be used to easily determine whether the kidneys are perfused and, if so, whether blood flow to the two kidneys is symmetrical; such tests are less accurate in quantitating flow rates. Magnetic resonance angiography is recommended to evaluate renal arterial or venous thrombosis or obstruction. Radionuclide WBC scans have a limited role in diagnosing AIN.

Renal Biopsy

Renal biopsy is rarely required for ARF that occurs in the hospital setting. In contrast, renal biopsy is indicated somewhat more frequently for ARF that occurs outside the hospital.

Community-Acquired Acute Renal Failure

Azotemia that first occurs outside the hospital may be either acute or chronic. Useful points in determining whether the renal failure is acute or chronic are summarized [*see Table 7*]. The majority of patients who present with advanced azotemia have chronic renal failure.

Most cases of ARF occur in the elderly, possibly because of the anatomic and physiologic changes of aging. In a study evaluating 748 patients presenting with ARF, 36% were older than 70 years.[14] Frequent causes of community-acquired ARF are hypovolemia, ingestion of over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs) and prescription medications, and obstruction. Before a detailed evaluation is carried out, priority should be given to identifying complications of renal failure that may be lethal unless treated promptly. Some of these, such as marked fluid overload and pericardial tamponade, may be detected on clinical examination. Other life-threatening complications, however, such as severe hyperkalemia or extreme metabolic acidosis, require laboratory evaluation. The electrocardiogram is valuable in assessing the effects of hyperkalemia on the heart [*see* Treatment of Complications, Hyperkalemia, *below*]. Even before the underlying disease that is causing the azotemia is known, often a decision whether to initiate dialysis has to be made. Dialysis should be instituted promptly in patients with severe hyperkalemia, acidosis, marked fluid overload, or signs or symptoms of uremia. Although many manifestations of uremia are nonspecific, a pericardial rub or neurologic manifestations (e.g., asterixis or confusion) are indications for prompt dialysis.

After serious electrolyte and acid-base imbalances have been addressed, other clinical information important in the evaluation can be ascertained.

DIAGNOSIS

Clinical Manifestations

A patient presenting with ARF may have very nonspecific complaints, including fatigue, weakness, restlessness, loss of appetite, nausea, vomiting, decreased urine output, swelling, and hiccups. When levels of uremic toxins are markedly elevated, changes in mental status and seizures may occur. A history of having recently started new medications may suggest drug-related renal injury. A history of nausea, vomiting, diarrhea, or other volume losses suggests ARF resulting from a prerenal condition. Recent trauma with muscle injury suggests rhabdomyolysis as the cause of ARF. Fever, skin rash, and joint pains raise the possibility of a rheumatic disease, such as systemic lupus erythematosus, vasculitis, endocarditis, or drug allergy with AIN. A history of shortness of breath or pulmonary hemorrhage suggests a pulmonary renal syndrome, such as Goodpasture syndrome, Wegener granulomatosis, Churg-Strauss disease, or pulmonary edema associated with acute glomerulonephritis. Abrupt anuria suggests acute obstruction, severe glomerulonephritis, or a sudden vascular event. Painless hematuria suggests acute glomerulonephritis, whereas painful hematuria is more consistent with obstruction.

Clinical and Laboratory Evaluation

Use of physical examination, laboratory tests, and imaging studies in community-acquired ARF is largely identical to that in patients with hospital-acquired ARF (see above).

Specific Causes of Acute Renal Failure

EXOGENOUS NEPHROTOXINS

Radiocontrast

Radiocontrast is a common cause of ARF.[15] In patients with normal renal function who have no other risk factors for ARF, the incidence of contrast-induced renal injury is low (< 1%). The incidence of contrast-induced nephropathy is approximately 150,000 cases a year in the United States.[16,17] Contrast-induced nephropathy is defined as ARF occurring shortly after exposure to intravenous contrast—typically within 48 hours—in the absence of other causes of renal failure. The most important risk factor is preexisting renal insufficiency; other risk factors include diabetes,[16,18] volume depletion, advanced age, heart failure, states of reduced renal perfusion, high total dose of contrast, and concomitant exposure to other nephrotoxins. A meta-analysis of 31 controlled, randomized trials, which included more than 5,000 patients, compared high-osmolar agents with low-osmolar agents; in all but nine studies, a favorable outcome was reported for patients receiving low-osmolar agents.[19] The odds ratio for an increase in serum creatinine of greater than 0.5 mg/dl

(44 μmol/L) with low-osmolar agents was 0.61 times that of the odds ratio associated with high-osmolar agents. Low-osmolar contrast media are the first choice for patients at risk for contrast media–induced ARF. Iodixanol, a nonionic, iso-osmolar contrast medium, has been shown to be beneficial in preventing contrast nephropathy in high-risk patients.[20] Extracellular fluid volume expansion with saline plays a key role in the prevention of contrast-induced ARF.[21-23] High-risk patients should be kept well hydrated by administration of normal saline at the rate of 1 ml/kg/hr for 8 to 12 hours before and after the procedure. The addition of diuretics and mannitol to accelerate diuresis has not been shown to provide any benefit over volume expansion alone, and it may be harmful. However, diuretics may be useful for fluid management in patients with volume overload or low cardiac output. For patients at high risk for contrast-induced ARF, consideration should be given to the volume of contrast used, because there is an increased risk of renal injury with higher doses and with doses that are repeated within 48 hours. In high-risk patients, consideration should be given to the use of diagnostic procedures that do not require contrast.

Acetylcysteine is commonly used to minimize toxicity of contrast in high-risk patients. Clinical studies of acetylcysteine for preventing contrast media–induced ARF have yielded conflicting results, however, and further studies are in order before this measure can be routinely recommended.[24,25] The use of fenoldopam, a selective D_1 dopamine receptor agonist that causes both systemic and renal arteriolar vasodilatation, has been advocated for helping to prevent contrast-induced nephropathy. In a randomized, controlled, multicenter study of patients with chronic renal insufficiency, however, fenoldopam was ineffective in preventing further deterioration of renal function after administration of contrast dye.[26]

Hydration with sodium bicarbonate before administration of contrast medium appears to be more effective than hydration with sodium chloride. In a randomized, controlled trial in 199 patients whose serum creatinine level was at least 1.1 mg/dl (1.1 to 3.7 mg/dl), contrast-induced nephropathy occurred in eight patients (13.6%) who received sodium chloride by infusion but in only one patient (1.7%) who received sodium bicarbonate.[27] These encouraging data need to be confirmed by other studies. In the typical hydration protocol, 154 mEq/L of sodium bicarbonate in 5% dextrose in water (D5W) was infused at a rate of 3 ml/kg/hr for 1 hour immediately before radiocontrast administration, followed by 1 ml/kg/hr during contrast administration and for 6 hours after the procedure.

Nephrotoxic Drugs

Aminoglycosides The most important manifestation of aminoglycoside nephrotoxicity is ARF secondary to ATN, which occurs in about 10% to 20% of patients receiving aminoglycosides (e.g., tobramycin, gentamicin, amikacin).[28,29] Maintaining blood levels in the therapeutic range reduces but does not eliminate the risk of nephrotoxicity. Aminoglycoside-associated ARF is usually mild and nonoliguric; it is manifested by an increase in the serum creatinine level after about 1 week of aminoglycoside therapy. Patients with aminoglycoside nephrotoxicity may present with polyuria and hypomagnesemia; these conditions occur as a result of a decrease in the urinary concentrating ability and enhanced urinary loss, respectively.[28] Several clinical factors or conditions can potentiate the effect of aminoglycosides on the kidney and can thus potentiate nephrotoxicity; these include renal ischemia induced by hypotension or volume depletion, the dosing schedule and the serum levels of aminoglycosides, sepsis, administration of other nephrotoxins, and liver disease. Once-daily dosing of aminoglycosides is as effective in controlling infection as more frequent dosing, with less nephrotoxic effect; there is no difference in the incidence of ototoxicity with once-daily dosing versus more frequent dosing.[30] Individualized pharmacokinetic dosing of aminoglycosides has been shown to reduce the incidence of nephrotoxicity while allowing for higher doses of the drug to be administered.[31]

The only treatment for aminoglycoside nephrotoxicity is to discontinue the medication and to support the patient during the period of ARF. The prognosis for recovery of renal function after several days is excellent, although some patients may need dialysis before full recovery is achieved.

Amphotericin B Amphotericin B is a relatively frequent cause of ARF. Hydration with normal saline before the infusion of amphotericin B decreases the incidence of ARF from this medication. Amphotericin B in lipid emulsion may be less nephrotoxic than nonlipid formulations and is recommended for patients at high risk for nephrotoxicity. Permanent renal failure from amphotericin B nephrotoxicity is very uncommon.

Table 7 Features That Help Differentiate between Acute and Chronic Renal Failure

	Acute Renal Failure	*Chronic Renal Failure*
Previous laboratory assay	Normal renal function	Abnormal renal function is documented on old laboratory studies
Medical history	None	Longstanding and poorly controlled diabetes, hypertension, and severe vascular disease are risk factors
Renal ultrasonography	Normal	Small, echogenic kidneys; patients with diabetes, HIV infection, multiple myeloma/amyloidosis, and polycystic kidney disease may have large kidneys
Bone films	Normal	Possible evidence of renal osteodystrophy with osteitis fibrosa, osteomalacia, mixed and adynamic bone lesions, and dialysis-related amyloidosis; subperiosteal erosions of the phalanges and tuft; bone cysts with amyloidosis
Hemoglobin/hematocrit	Anemia is possible, but a normal hemoglobin level in a patient with advanced azotemia is presumptive evidence of acute renal failure	Anemia is common

Nonsteroidal anti-inflammatory drugs NSAIDs are potent inhibitors of prostaglandin synthesis, a property that contributes to their nephrotoxic potential in certain high-risk patients who require prostaglandins for maintaining renal vasodilatation. The most frequent pattern of injury related to the use of NSAIDs is prerenal azotemia; this is particularly the case for patients with volume depletion or a reduced effective circulating volume. Susceptible patients include those with heart failure, cirrhosis, diabetes, chronic renal disease, nephrotic syndrome, and septic shock, as well as those of advanced age or who require use of a diuretic.[32]

A hyperchloremic metabolic acidosis, often associated with hyperkalemia, has also been recognized as an effect of NSAIDs, particularly in patients with preexisting chronic interstitial renal disease. In such persons, hyporeninemic hypoaldosteronism occurs during states of renal prostaglandin inhibition. NSAIDs have been associated with the development of AIN, which is often associated with renal insufficiency and marked proteinuria.[33] This complication appears to be an idiosyncratic reaction and is particularly associated with the use of propionic acid derivatives, such as ibuprofen, naproxen, and fenoprofen.[34] In contrast to AIN associated with other drugs, AIN associated with NSAIDs is marked by a low incidence of hypersensitivity symptoms and eosinophilia. This disorder usually resolves with discontinuance of the offending agent.[35] High-risk patients should be educated about the risk of using NSAIDs, and they should be advised to avoid these medications if possible. ARF caused by cyclooxygenase-2 inhibitors has been reported; thus, the same cautions apply to these agents as to nonspecific NSAIDs.

Cisplatin Renal injury is a well-recognized complication of the use of cisplatin for the management of many carcinomas. Cisplatin-associated nephrotoxicity affects a significant percentage of such patients; 25% to 35% develop a mild and reversible decrease in GFR after their first dose of cisplatin. With subsequent doses, the incidence and severity of renal failure increases, until irreversible renal injury occurs. Hypomagnesemia caused by renal losses of magnesium may be severe and can occur in as many as 50% of patients. Patients should be well hydrated with normal saline (200 to 250 ml/hr) before administration of cisplatin; other known nephrotoxins should be avoided whenever possible.[36] The usual lesion is that of ATN, but with severe damage or recurrent administration of the drug, chronic interstitial disease in the setting of persistent inflammation may ensue.[11]

Angiotensin-converting enzyme inhibitors ARF that is associated with the use of angiotensin-converting enzyme (ACE) inhibitors is thought to be hemodynamic in origin; it is believed to occur as a result of the loss of autoregulation of renal blood flow and has typically been reported when ACE inhibitors are given to patients with bilateral renal artery stenosis. A 30% increase from baseline in serum creatinine levels is acceptable when ACE inhibitors are initiated.[37] If the serum creatinine level continues to rise, the ACE inhibitor should be discontinued, and an investigation for renal vascular disease should be considered. ACE inhibitors are not directly nephrotoxic; therefore, discontinuance of the medication should allow renal function to return to baseline if no other insults have occurred.

Ethylene Glycol Toxicity

Ethylene glycol is a colorless, odorless, sweet liquid found in solvents and antifreeze. Ingestion of ethylene glycol, usually in the form of antifreeze, produces a syndrome of severe metabolic acidosis characterized by a high anion gap and a large osmolar gap. Anion gap and osmolar gap are defined as follows:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

$$\text{Plasma osmolality (calculated)} = 2(Na^+) + (\text{BUN}/2.8) + (\text{glucose}/18) + (\text{ethanol}/4.7)$$

$$\text{Osmolar gap} = \text{measured osmolality} - \text{calculated osmolality}$$

The normal value for the anion gap has been 12 ± 4 mEq/L. However, in a retrospective analysis of 222 patients with normal serum creatinine and albumin levels, the range for the anion gap was found to be much narrower: 6.6 ± 2 mEq/L. This difference was thought to be the result of the use of automated laboratory analysis techniques that use ion-selective electrodes.[38]

The osmolar gap is the difference between the measured and the calculated osmolality. The calculated osmolar gap is derived by use of the serum sodium, glucose, and urea levels. The addition of solutes to plasma can contribute to the osmolar gap; if such solutes are contributing to the osmolar gap, the measured osmolality will be found to be higher than the calculated osmolality. Alcohol intoxication is probably the most common cause of an osmolar gap.

Ethylene glycol is metabolized by alcohol dehydrogenase to glycolic acid, which is believed to be the major contributor to acidosis.[39] The key clinical findings in patients who have ingested ethylene glycol are initial disorientation and agitation, with progression to central nervous system depression, renal failure, metabolic acidosis, respiratory failure, and circulatory insufficiency. Hypocalcemia is a prominent feature that occurs as a result of the deposition of calcium oxalate in multiple tissues; it may be aggravated by a decrease in parathyroid hormone response. Calcium oxalate crystals are typically found in the urine sediment. ARF generally manifests after 48 to 72 hours.

Aggressive intervention should be initiated at the time of diagnosis. Intervention should consist of intravenous infusion of sodium bicarbonate to enhance renal clearance of glycolate through ion trapping; intravenous infusions of ethanol or fomepizole to block the metabolism of ethylene glycol; and hemodialysis for the removal of ethylene glycol and glycolate.[40] Regular monitoring of the osmolar gap (corrected for ethanol level if I.V. ethanol is being used during treatment) and the anion gap will help guide therapy during hemodialysis.[39]

ENDOGENOUS NEPHROTOXINS

Rhabdomyolysis

Since the first description of the causative association between rhabdomyolysis and ARF in victims of crush injuries in World War II, the spectrum of recognized causes of rhabdomyolysis, myoglobinuria, and renal failure has markedly broadened. The most frequent causes are trauma or other injury that leads to muscle compression; ischemia; excess muscle activity, such as occurs during exercise or seizures; metabolic derangements; drugs; and infections.[41] Some important metabolic derangements that can cause rhabdomyolysis include hypokalemia and hypophosphatemia; the risk of rhabdomyolysis associated with these electrolyte imbalances is increased in patients with chronic alcoholism. Cocaine use, neuroleptic malignant syndrome, and the use of statin drugs can also contribute to or cause rhabdomyolysis.

Muscle pain and dark-brown urine that is positive for blood on dipstick testing (orthotoluidine positive) but that does not

contain RBCs are important diagnostic clues. However, the diagnosis must be confirmed by findings of elevated CPK and myoglobin levels. About one third of patients with rhabdomyolysis develop ARF; many of these patients have hyperkalemia, hyperuricemia, hyperphosphatemia, early hypocalcemia, and a reduced BUN-to-creatinine ratio because of excessive creatinine release from muscle. Late hypercalcemia is also a typical feature of the disease.

Early recognition of rhabdomyolysis and initiation of treatment are the keys to minimizing ARF. These patients commonly develop hypovolemic shock, particularly when the injury is associated with trauma and massive muscle crushing.

The most important aspect of management of rhabdomyolysis is rapid volume repletion. Patients who are encountered in the field should receive immediate treatment with intravenous normal saline, 200 to 300 ml/hr. If urine output increases in 4 to 6 hours, the infusion should be continued (at a rate that matches the urine output) until the rhabdomyolysis resolves. However, if the patient continues to be oliguric (i.e., urine output is less than 400 ml/day), the infusion should be discontinued and the patient treated for ARF. Experience from recent disasters has shown that early aggressive hydration and alkalinization can prevent myoglobinuric ARF by protecting the kidney from the nephrotoxicity of myoglobin and urate.[42] This therapy consists of sodium bicarbonate and D5W, in a ratio of three ampules of sodium bicarbonate to 1 L of D5W, infused at a rate of 250 ml/hr. The metabolic alkalosis induced will help protect the patient from hyperkalemia, which can be a lethal complication of rhabdomyolysis. Urinary alkalinization is controversial; some investigators consider it no better than saline diuresis, as well as potentially hazardous because it may contribute to intratubular calcium and phosphate deposition.[43]

A clinical presentation that is similar to that of rhabdomyolysis occurs after the release of heme pigments after intravascular hemolysis.

Hyperuricemic Acute Renal Failure

ARF may occur in patients with malignancies that are associated with a high rate of tumor cell turnover (tumor lysis syndrome) [*see 12:XII Oncologic Emergencies*]. Such turnover may occur either spontaneously or after chemotherapy; high cell turnover is particularly associated with poorly differentiated lymphomas and acute lymphoblastic leukemia. Uric acid production and hyperuricosuria may increase, causing uric acid nephropathy. In addition, during massive cell lysis, phosphate and potassium are released in large amounts, resulting in hyperphosphatemia and hyperkalemia. In some patients, the precipitation of calcium and phosphate in the renal tubules can induce ARF independently of and in addition to uric acid deposition. The peak uric acid level often exceeds 20 mg/dl, and a ratio of urinary uric acid to creatinine concentrations greater than 1 to 1 suggests the diagnosis of acute uric acid nephropathy.

Prevention of ARF from tumor lysis syndrome involves establishing a urine output of greater than 3 to 5 L/24 hr and initiating treatment with allopurinol before institution of cytotoxic therapy. Establishing a high urinary output results in high intratubular pressure and thereby helps prevent intratubular obstruction. Allopurinol, which blocks the synthesis of uric acid by inhibiting xanthine oxidase, should be administered in dosages of 300 to 600 mg/day; therapy should begin 3 days before initiation of chemotherapy. In patients with underlying renal impairment, the allopurinol dose should be adjusted for renal function. In patients with initial hyperuricemia, allopurinol should be started and chemotherapy delayed until the serum uric acid concentration has become normal. Urinary alkalinization increases the solubility of xanthine and enhances its excretion. Urinary alkalinization can be achieved by the infusion of sodium bicarbonate in amounts sufficient to keep the urinary pH above 7 or by the administration of acetazolamide, which inhibits the reabsorption of sodium bicarbonate in the proximal tubule, thereby making the tubular fluid and the urine alkaline. Sodium bicarbonate and acetazolamide can be used in combination.

Rasburicase is a recombinant form of urate oxidase, which is a nonhuman proteolytic enzyme that oxidizes uric acid to allantoin. Rasburicase has been shown to reduce serum uric acid levels with associated diuresis more effectively and much faster than allopurinol, and it should be considered in the treatment of hyperuricemia and ARF.[44]

The development of oliguria with hyperuricemia may be an indication for dialysis. Early dialysis in these patients, started before severe renal impairment or uremia manifests, can help minimize further injury.

Hepatorenal Syndrome

The hepatorenal syndrome (HRS) is defined as kidney failure in patients with severely compromised liver function in the absence of clinical, laboratory, or anatomic evidence of other known causes of renal failure. HRS closely resembles prerenal failure, except that it does not respond to conventional volume replacement. The etiology of HRS is thought to involve significant reductions in renal perfusion associated with splanchnic vasodilatation.[45] In the United States and Europe, the great majority of HRS cases occurs in patients with advanced alcoholic cirrhosis. In persons who have cirrhosis with ascites, the probability of developing HRS is 18% at 1 year and 39% at 5 years.[46]

HRS may begin insidiously over a period of weeks to months or may appear suddenly and cause severe azotemia within days. Common precipitating causes are deterioration of liver function, sepsis, the use of nephrotoxic antibiotics or NSAIDs, overzealous use of diuretics, diarrhea, or GI bleeding. Large-volume paracentesis has the potential to initiate and exacerbate hepatorenal dysfunction. Support with intravenous albumin infusion during large-volume paracentesis may prevent circulatory dysfunction and decreased renal perfusion.[47] HRS can, however, occur without any apparent precipitating cause. The diagnosis is one of exclusion and should be suspected in any patient with advanced acute or chronic liver disease, portal hypertension, and progressive renal insufficiency associated with an increase in serum BUN and creatinine levels.

The initial step in management is to search diligently for and treat correctable causes of azotemia. All nephrotoxic agents should be discontinued. It is important to exclude reversible prerenal azotemia. Because HRS and prerenal azotemia produce similar urinary diagnostic indices, differentiating these two entities often requires a functional approach, such as volume expansion. Once a diagnosis of HRS is established, there is no specific treatment; management is conservative. If the patient is hypotensive, normalization of blood pressure may lead to improvement in renal perfusion and thus to stabilization of renal function. In patients with spontaneous bacterial peritonitis, intravenous albumin infusion (1.5 g/kg at the time of diagnosis followed by 1 g/kg on day 3) plus antibiotic treatment has proved more effective than antibiotic treatment alone in decreasing the incidence of renal impairment and death.[48]

Several agents have been investigated for pharmacologic treatment of hepatorenal syndrome; all are intended to increase renal blood flow. Octreotide is known to cause selective splanchnic vasoconstriction and may be beneficial for prolonged therapy and subcutaneous administration while patients await liver transplantation.[49] Midodrine, octreotide, and albumin therapy followed by a transjugular intrahepatic portosystemic stent shunt has been shown to be beneficial in a few cases of type 1 HRS, which is characterized by rapid and progressive renal impairment (doubling of the serum creatinine level to more than 2.5 mg/dl in less than 2 weeks, commonly with associated oliguria or anuria) and typically is precipitated by spontaneous bacterial peritonitis.[50] The combination of albumin infusion with the vasopressin analogue terlipressin has proved effective in reversing HRS in cirrhotic patients.[51]

The prognosis for patients with hepatorenal syndrome is poor unless their liver function can be improved. This typically requires liver transplantation.

ACUTE RENAL FAILURE RELATED TO PREGNANCY

In industrialized nations, ARF rarely occurs in association with pregnancy; the incidence is approximately one in 20,000 deliveries.[52] The low incidence is directly related to legalization of abortion in many countries.[52]

Infection after an abortion may precipitate ARF by causing hypotension, hemorrhage, sepsis, and disseminated intravascular coagulopathy. Hemolysis may result from toxin production. Although many organisms can be involved, *Clostridium* species are the most common pathogens, and cause the most serious of such infections. Aggressive management with broad-spectrum antibiotics and dialysis is the mainstay of therapy for these patients.

Urinary tract infections are among the most common medical complications of pregnancy and can progress to pyelonephritis. Approximately 25% of pregnant patients with pyelonephritis develop a transient decline in GFR.[53] These patients should be treated initially with intravenous antibiotics, followed by up to 2 weeks of therapy with oral antibiotics.

Third-trimester and peripartum complications of pregnancy that may lead to ARF include preeclampsia, postpartum hemorrhage, amniotic fluid embolism, placental abruption, and retained fetal or placental parts. A renal failure pattern similar to that of ATN is seen in patients with preeclampsia and peripartum hemorrhage. Bilateral cortical necrosis may follow any type of ischemic renal injury; the incidence seems disproportionately higher in pregnant patients than in nonpregnant adult patients. Although abruptio placentae can also cause ATN, renal cortical necrosis is the most common cause of ATN. The HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome has been associated with ARF in up to 7.7% of pregnant patients.

Postpartum ARF, also known as postpartum hemolytic-uremic syndrome (HUS), is characterized by hypertension and microangiopathic hemolytic anemia. It can occur from postpartum day 1 to several months after delivery, but peak onset is from postpartum week 2 to week 5. Glomerular lesions resemble those found in adult HUS and are characterized by fibrin deposition, thickened capillary walls, and subendothelial swelling associated with large granular subendothelial deposits. Genetic factors may be involved in the etiology of postpartum HUS, given that women who have experienced one episode are at increased risk for recurrence with subsequent pregnancies, and occurrence of the disease has been documented in sisters. Postpartum HUS is associated with elevations in the lactate dehydrogenase (LDH) level; the HELLP syndrome, in contrast, is associated with elevations in transaminase levels. This difference is useful in distinguishing between these two syndromes. The mainstay of treatment for postpartum HUS is plasma exchange. Before the advent of plasma exchange therapy, mortality was 90%; current maternal survival rates are 70% to 80%.[54]

Other renal disorders may cause ARF during pregnancy. If active urine sediment occurs in a pregnant patient before the 20th week of gestation, acute glomerulonephritis should be considered. Lupus nephritis may develop in patients with a history of lupus nephritis or extrarenal lupus. Because complement levels are typically elevated during pregnancy, the finding of low complement levels in a pregnant woman (with additional supportive serology) is especially suggestive of lupus nephritis. Renal biopsy is not contraindicated during pregnancy. If a proliferative lesion is suspected, renal biopsy should be performed to facilitate early initiation of aggressive therapy. Any of the other prerenal and nephrotoxic causes of ARF can affect pregnant patients and should be considered. After the 20th week of gestation, ARF in a patient with hypertension is most likely the result of preeclampsia.

ACUTE INTERSTITIAL NEPHRITIS

AIN is often underdiagnosed as a cause of ARF. The diagnosis should not be overlooked, because this disorder requires specific intervention. Antibiotics are a major cause of AIN. This etiology is especially important to consider when a patient who is recovering from sepsis-induced ARF develops ARF while receiving antibiotics.

AIN is sometimes an immunologically induced hypersensitivity reaction to an antigen, usually a drug. AIN is detected in 2% to 3% of all renal biopsies but in up to 25% of renal biopsies that are performed specifically in the setting of drug-induced ARF. The drugs most commonly involved in the induction of AIN are NSAIDs and antibiotics[55] [*see 10:VIII Tubulointerstitial Diseases and Table 2*].

AIN is suggested by laboratory findings that indicate an abrupt deterioration of renal function and by urinalysis and urine sediment findings of blood, protein, and WBCs in clumps and in casts in the absence of evidence of infection. Clinically, the only complaint may be flank pain, caused by distention of the renal capsule; there may also be systemic signs and symptoms of a hypersensitivity reaction, such as rash, joint pain, and fever. The complete blood count may reveal eosinophilia.

Definitive diagnosis is made by renal biopsy. Noninvasive techniques suggestive of AIN, which may include an increased urinary eosinophil count (using Hansel stain) and a positive gallium scan, are not specific.

Management of Acute Renal Failure

Management of ARF entails close monitoring of the patient, supportive therapy, and targeted treatment of specific complications that may arise. The signs and symptoms of ARF reflect loss of the regulatory, excretory, and endocrine functions of the kidney. The loss of the excretory ability of the kidney is reflected in a rise in the plasma concentration of specific substances normally excreted by the kidney. The most widely monitored indices are the concentrations of BUN and creatinine in the serum. In patients without complications, BUN increases by 10 to 20 mg/dl/day, and bicarbonate decreases to a steady-state level of 16 to 18 mEq/L. The serum potassium concentration need not

rise appreciably unless the patient experiences a hypercatabolic state, GI bleeding, or extensive tissue trauma.

PREVENTION

The estimated cost of dialysis and aggressive care of a critically ill patient with ARF is approximately $128,000 per quality-adjusted life-year saved (QALYS). With the accepted upper limit of cost-effective care being $50,000 per QALYS, ARF places an overwhelming burden on the health care system.[56] Thus, prevention is the cornerstone of patient care.

Approximately 25% of all hospital-acquired cases of ARF are related to the use of one or more nephrotoxic agents.[7,57,58] Consequently, the best strategy for prevention of ARF is to avoid drug-related nephrotoxicity, especially in high-risk situations. Patients at risk are the elderly, those with preexisting renal disease, and those with volume depletion. The serum creatinine level is a poor marker of actual renal function, especially in elderly persons. An estimate of renal function is needed, especially in elderly patients, to permit proper management of the drug levels of all potential nephrotoxic agents and to enhance awareness of diminished renal function when the serum creatinine level falls within the normal range. The Modification of Diet in Renal Disease (MDRD) formula gives an acceptable estimate of GFR. Calculators for the MDRD GFR are available on the Internet (http://www.nkdep.nih.gov/healthprofessionals/tools). Measurement of serum cystatin C can help with recognition of the initial stages of renal impairment.[59]

Correcting fluid deficiencies before surgery and providing adequate hydration for patients who are particularly at risk before use of radiocontrast studies are useful measures. Nephrotoxic drugs should be used only when necessary; when such drugs are used, the patient should be monitored carefully. Pretreatment with allopurinol before chemotherapy of massive tumors diminishes uric acid excretion and thus lowers the potential for nephrotoxicity.

EMERGENT INTERVENTION

Hyperkalemia is a life-threatening complication of ARF that often necessitates urgent intervention [*see* Treatment of Complications, Hyperkalemia, *below*]. The electromechanical effects of hyperkalemia on the heart are potentiated by hypocalcemia, acidosis, and hyponatremia. Thus, the ECG, which measures the summation of these effects, is a better guide to therapy than a single determination of serum potassium. It must be emphasized that hyperkalemia is the biochemical abnormality that is most often responsible for death in patients with ATN. In contrast, moderate acidosis is generally well tolerated and usually does not require treatment; treatment may be necessary as adjunct therapy to control hyperkalemia or if the plasma bicarbonate level falls below 15 mEq/L.

SUPPORTIVE THERAPY

Because ATN is inherently a catabolic disorder, patients with ATN generally lose about 0.5 lb a day. Further weight loss may be minimized by providing adequate calories (1,800 to 2,500 kcal or 35 kcal/kg/day) and about 1.0 to 1.4 g protein/kg/day. The use of hyperalimentation with 50% dextrose and essential amino acids has had little effect on reducing mortality and morbidity in patients with ATN, except in patients who also have significant burns.

DIALYSIS

Indications for initiating dialysis are as follows: (1) severe hyperkalemia, acidosis that is not easily controlled by medical treatment, or both; (2) fluid overload that is not responsive to fluid restriction, diuretics, or both; and (3) signs or symptoms of uremia (e.g., a pericardial friction rub, asterixis, mental status changes that are not accounted for by some other disorder, or seizures). In the absence of any of these indications, most nephrologists advocate dialysis when the BUN level reaches 80 to 100 mg/dl, because the goal of modern therapy is to avoid the occurrence of uremic symptoms. Thus, the patient undergoes dialysis as frequently as necessary to keep the BUN level below 80 mg/dl. When this approach is used, most patients do not develop uremic symptoms, the diet and fluid intake can be liberalized, and the overall management of the patient is easier. It is critical to carefully review the indications for, and the doses of, all drugs administered to patients with ARF. Monitoring of blood concentrations of drugs is an important adjunct to effective treatment. Dialysis is discussed in detail elsewhere [*see 10:X Chronic Renal Failure and Dialysis*].

In a patient who receives appropriate therapy with early dialysis, many of the uremic manifestations associated with ARF either do not develop or are minimal. Infection remains the main cause of death despite vigorous dialysis. Thus, meticulous aseptic care of intravenous catheters and wounds and avoidance of the use of indwelling urinary catheters are important in the management of such patients.

DOPAMINE

There are no clinical data to support the use of low-dose dopamine for the protection or improvement of renal function in patients with ATN or ARF. In a multicenter study comparing dopamine with placebo, dopamine was not found to improve survival or eliminate the need for dialysis.[60] In both animal and human studies, use of low-dose dopamine was found to be associated with an increase in renal blood flow and natriuresis in the context of euvolemia and normal renal function.

TREATMENT OF COMPLICATIONS

Volume Overload

Volume overload is one of the first manifestations of ARF caused by salt and water retention secondary to a decrease in GFR. In addition, volume overload may be exacerbated by intravenous fluids given in an aggressive attempt to reverse ARF or to treat oliguria. Consequently, volume status needs to be evaluated daily in patients with ARF. This evaluation includes assessment of weight, blood pressure, and heart rate. Physical examination is also important and should be directed specifically toward the detection of skin turgor, peripheral edema, pulmonary edema, and a third heart sound.

Records of the patient's daily fluid intake and output should be reviewed, but insensible fluid losses, as well as weight loss resulting from a high catabolic state, must be taken into consideration.[61,62] A normal adult loses about 200 to 300 g of body weight a day as a result of catabolism, and the average 70 kg person has insensible losses of around 850 to 1,000 ml/day. With fever, the insensible water loss increases by about 13% for each degree centigrade rise above normal (7% for each degree Fahrenheit). Daily assessment and modification of fluid therapy is essential. Water is continuously generated from endogenous sources by the oxidation of protein (41 ml/100 g), fat (107 ml/100 g), and carbohydrates (55 ml/100 g). Adequate carbohydrates will help reduce protein metabolism, with a small decrease in water generation.

The most useful therapy for volume overload is loop diuretics.[63,64] Furosemide can be given intravenously in a bolus or by continuous infusion [*see Table 8*]. If started in the early stages of ARF, this intervention, along with fluid restriction, can be very beneficial in preventing or minimizing volume overload. The main risk of using high doses of furosemide is deafness, which can be transient or permanent.[65] This risk is increased if the serum albumin level is low and if other ototoxic medications are being used simultaneously with furosemide.[66] There is no good evidence that the use of diuretics alters the course of ATN; however, in patients with fluid overload, diuretics may be useful in increasing urine output and preventing the need for dialysis. If diuretic treatment does not correct volume overload and the patient remains oliguric, early intervention with dialysis should be considered. However, there is evidence that outcomes may be worse in patients who receive diuretics than in patients who do not.[67]

Table 8 Furosemide Dosing

Bolus dosing	Initially, 20 mg I.V.; if no response in 30 min to 1 hr, double the dose to 40 mg If no response, increase the dose slowly until a response is achieved Give repeat doses every 8 to 12 hr to maintain diuresis Single bolus doses should not exceed 240 mg
Continuous infusion	Safer and more effective than bolus dosing in patients with refractory disease Initial I.V. bolus of 0.1 mg/kg (or a bolus dose previously determined to initiate diuresis) Continuous infusion of 0.1 mg/kg/hr; double every 2 hr to a maximum of 0.4 mg/kg/hr *or* After an initial bolus, continuous infusion of 20 mg/hr If diuresis is not sustained, give a second, larger bolus and increase the infusion rate to 40 mg/hr Risk of toxicity increases with continuous infusion rates above 80 mg/hr
For refractory cases	Consider the addition of an intravenous thiazide diuretic Consider fluid removal via hemofiltration (dialysis)

Hyponatremia

Hyponatremia is a common problem in patients who have ARF that is related to a decrease in GFR and impaired tubular function. Usually, such hyponatremia is associated with hypervolemia. Sources of excess water intake include the administration of hypotonic solutions such as D5W or free-water intake through enteral or parenteral feeding.

The clinical manifestations of hyponatremia are primarily neurologic in nature. Symptoms are related to cell swelling and may include headache, behavioral disturbances, lethargy, ataxia, and seizures; symptoms can progress to coma, respiratory depression, and death.

Symptomatic hyponatremia should be treated aggressively, but also with caution, because overly aggressive correction of a low serum sodium level can lead to central pontine myelinolysis if the duration of electrolyte imbalance has been longer than 48 hours [*see 11:VII Anoxic, Metabolic, and Toxic Encephalopathies*]. The initial approach in a patient who has volume overload and hyponatremia is to administer loop diuretics and restrict free water. If symptoms of hyponatremia occur in a patient with ARF that is unresponsive to diuretics or saline replacement, the removal of free water may be warranted as the initial step in renal replacement therapy. Correction of hyponatremia should proceed gradually, with the rise in sodium level targeted at a rate of 1 to 2 mEq/L/hr until symptoms resolve or until the serum sodium level approaches 120 mEq/L. Therefore, continuous monitoring of the patient's condition and measurement of serum electrolytes every 1 to 2 hours is warranted.

Hyperkalemia

Hyperkalemia is common in patients with ARF. Causal factors include a decrease in GFR, a low rate of urinary flow to the collecting duct, distal tubular damage, and concomitant conditions that contributed to or are associated with ARF, such as rhabdomyolysis, acidosis, and the hypercatabolic state. ACE inhibitors and NSAIDs may also play a role.

A small portion of the total body potassium—1.5% to 2.5%, or around 60 mEq—is found in the extracellular compartment. The intracellular compartment has a potassium concentration about 38-fold higher than that of the extracellular compartment. Thus, any process that leads to cellular destruction can contribute to hyperkalemia, especially in patients with ARF.

The cardiac effects of hyperkalemia are primarily associated with the blunting of the magnitude of the action potential in response to a depolarizing stimulus. The sequential ECG changes observed in hyperkalemia are peaked T waves, prolongation of the PR interval, widening of the QRS complex, and a sine wave pattern; these findings call for prompt treatment. Other symptoms consistent with hyperkalemia include paresthesias, muscular weakness, and depressed deep tendon reflexes. These symptoms can progress to flaccid paralysis and acute respiratory failure. Severe hyperkalemia is life-threatening and should be considered a medical emergency.

The treatment of hyperkalemia associated with ECG changes starts with the administration of calcium chloride or calcium gluconate, which will work to immediately antagonize the effect of potassium on the heart. Insulin and glucose, inhaled beta-adrenergic receptor agonists, or intravenous sodium bicarbonate in patients known to have acidosis will help redistribute potassium to the intracellular space. These measures require 30 to 60 minutes to take effect and have a short duration of action. In patients with renal failure, the only certain way of lowering the potassium is to remove it from the body by using sodium polystyrene sulfonate (orally or as an enema), dialysis, or both.

Dietary intake of potassium should be restricted to less than 50 mEq/day; intravenous or oral sources of potassium should be discontinued, and medications that inhibit potassium excretion (e.g., potassium-sparing diuretics, NSAIDs, ACE inhibitors, and angiotensin receptor blockers) should be stopped.

Acidosis

A healthy adult produces 1 mEq/kg/day of hydrogen ions; this production is influenced to a large degree by dietary intake. The kidney plays a major role in acid-base balance through the excretion of nonvolatile acids and by the reabsorption and regeneration of bicarbonate. In patients with ARF, the serum bicarbonate level decreases by 1 to 2 mEq/day and typically stabilizes around 16 to 18 mEq/L. A more severe drop may be precipitated by a hypercatabolic state, infection, inadequate nutrition, and other causes of metabolic acidosis.

Clinical manifestations of acidosis are partly related to the rapidity with which the acidosis develops. When metabolic acidosis develops rapidly, the body's attempt to compensate by blowing off carbon dioxide may result in Kussmaul respiration, which is characterized by deep inspiration and a normal or reduced respiratory rate. Other clinical consequences include cardiac arrhythmias, depressed myocardial contractility, peripheral vasodilatation, abdominal pain, nausea and vomiting, headache and lethargy, and an increased catabolic rate.

Metabolic acidosis is defined as a low arterial pH in conjunction with a low serum bicarbonate level. Mild to moderate metabolic acidosis with a pH greater than 7.2 can be treated with oral sodium bicarbonate. Severe metabolic acidosis with a pH of 7.1 or less that is associated with ARF should be treated more aggressively, with intravenous sodium bicarbonate, renal replacement therapy, or both; continuous renal replacement therapy is the preferred approach. Because intravenous sodium bicarbonate replacement poses many risks, critically ill patients who receive it require close monitoring. If needed, intravenous bicarbonate can be administered as an isotonic solution by adding 3 ampules of sodium bicarbonate (50 mEq/50 ml) to 1 L of D5W; the solution is infused at a variable but slow rate, depending on the patient's condition and volume status. Particular attention should be given to cardiac, respiratory, and hemodynamic status. Serum electrolyte levels, including the serum calcium level, should be monitored and corrected as needed.

Early in the recovery phase of ARF, there may be modest reductions in GFR and in the ability to concentrate and acidify the urine. Thus, patients may continue to need support with intravenous fluids and oral or intravenous bicarbonate.

Calcium and Phosphate Imbalances

Hypocalcemia is a common finding in patients with ARF, but it rarely requires intervention. In patients with ARF, hypocalcemia can result from several mechanisms, the most common being hyperphosphatemia. Resistance to parathyroid hormone, altered vitamin D metabolism, and calcium sequestration in tissues all play a role. Transfusions of blood products that have been stored in citrate and infusions of sodium bicarbonate can contribute to a decrease in the serum calcium level. Calcium supplementation should be undertaken only if it is clinically indicated and should be carried out with caution.

Hypercalcemia is rare in patients with ARF and may be indicative of other underlying medical conditions. The most common underlying disorders are malignancies, particularly multiple myeloma. Hypercalcemia occurs in about 30% of patients during the recovery phase of ARF-associated rhabdomyolysis.

Hyperphosphatemia is common in patients with ARF. The elevation in the phosphate level results primarily from a decrease in renal excretion; tissue destruction and shifts from the intracellular to extracellular space as a result of acidosis and catabolism can be contributing factors. In patients who can ingest food, hyperphosphatemia should be treated with phosphate binders; these agents prevent absorption of dietary phosphorus into the bloodstream. Phosphate binders include calcium salts (calcium carbonate or calcium acetate), aluminum hydroxide, and sevelamer, which is a cationic polymer that binds phosphate through ion exchange. If the calcium-times-phosphorus product is high (i.e., > 70), a non–calcium-based binder such as sevelamer should be administered to minimize metastatic calcification in soft tissues.

Anemia

A normochromic-normocytic anemia develops in 65% to 95% of patients with ARF. These patients have normal serum iron levels and normal or hypercellular bone marrow. An increase in the rate of destruction of RBCs as a result of increased erythrocyte fragility may play a role in the early decrease in the hemoglobin level in patients with ARF. The most important cause of ARF-associated anemia is inadequate production of erythropoietin, but in critically ill patients, a decrease in erythropoietin responsiveness also plays a role.

Blood loss may contribute to anemia in patients with ARF. These patients have an increased tendency to bleed because of platelet dysfunction secondary to azotemia. Conjugated estrogen and 1-desamino-8-D-arginine vasopressin (DDAVP or desmopressin) may help correct this bleeding tendency. DDAVP is given at a dosage of 0.3 μg/kg infused as an intravenous piggyback over 20 to 30 minutes.[68]

Because anemia can produce significant complications in critically ill patients, hemoglobin levels should be maintained above 10 g/L. Erythropoietin is increasingly used in such patients to reverse anemia and to reduce the need for blood transfusions [*see 5:III Anemia: Production Defects*].

Prognosis of Patients with Acute Renal Failure

Mortality can be as high as 50% to 80% in patients who have ARF in association with sepsis, hypotension, and respiratory failure.[57] The prognosis for hospitalized patients with ARF depends largely on the setting (i.e., hospital ward or ICU); the presence of comorbidities; the underlying cause of the renal failure; the severity of the renal failure; and how early in its course the condition is diagnosed and treatment initiated. In a review of 22,589 patients who underwent open heart surgery, mortality was 61.2% in those with ARF requiring dialysis, 14.1% in those with ARF not requiring dialysis, and only 0.68% in those who did not develop ARF.[5] In a study of ICU patients with ARF, 64% required dialysis; in-hospital mortality was 37%, and 50% of patients died or failed to recover renal function.[4]

In hospitalized patients with ARF caused by ATN, about one fourth to one third of deaths occur during the diuretic phase. This is not surprising, because with the availability of dialysis, the most important determinant of the outcome is not the uremia itself but, rather, the underlying disease causing the ATN. Infection is a common cause of death in patients with ATN-related ARF. In patients who survive the acute episode, renal function essentially returns to normal.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII VASCULAR DISEASES OF THE KIDNEY

Abhijit V. Kshirsagar, m.d., m.p.h.
Ronald J. Falk, m.d.

A number of local and systemic disease processes affect the renal vascular tree [*see Figure 1*]. Although the underlying mechanisms may differ, vascular diseases of the kidney all share an important feature: they characteristically cause varying degrees of vessel obstruction, eventually leading to an impairment of renal blood flow. Reduction of renal blood flow often leads to two important physiologic adaptations: elevated blood pressure and reduced glomerular filtration rate (GFR). Hypertension and renal insufficiency are often important clues to the diagnosis of renal vascular disease. Rapid diagnosis is necessary to prevent the development of irreversible kidney disease, including end-stage renal disease (ESRD).

This chapter discusses the major vascular diseases of the kidney, categorized according to the size of the affected vessel. Large vessels include the main renal arteries and their major branches, as well as the renal vein and its main branches. Medium-sized vessels refer mainly to arteries. Small vessels include arterioles, capillaries, and venules.

Large Vessel Diseases

RENAL ARTERY STENOSIS

Renal artery stenosis (RAS) refers to a group of diseases characterized by narrowing of the main renal artery and its major branches. Atherosclerosis and fibromuscular dysplasia (FMD) are the two major causes of RAS; atherosclerosis is responsible for over 90% of cases, with FMD accounting for almost all of the remainder.

Atherosclerotic Renal Artery Stenosis

Atherosclerotic RAS has come to be defined as lumen narrowing of at least 50%, although some researchers have advocated that significant narrowing is 70% or greater. Atherosclerosis of the renal artery is a relatively common finding in both men and women after the fifth decade of life, but the exact prevalence of atherosclerotic RAS is not known, because there are no economical screening tests for the general population. Screening for RAS in highly selected populations consisting of patients with a high burden of atherosclerosis (i.e., those who have diabetes, who have recently had a stroke or myocardial infarction, or who have peripheral vascular disease) has revealed a prevalence of 10% to 30%.[1-4] Although early reports suggested that there was a higher prevalence in whites, current evidence suggests that atherosclerotic RAS is also found in significant numbers of African Americans.[5,6] There are no reported gender differences in prevalence. Risk factors for the development of atherosclerotic RAS include hypercholesterolemia, advanced age, cigarette smoking, hypertension, and diabetes mellitus.

The lesions of atherosclerosis occur primarily in the large and medium-sized arteries. They are characterized by the infiltration of the intimal layer by macrophages and monocytes and the deposition of oxidized low-density lipoprotein. Most cases of atherosclerotic RAS involve the opening of the renal artery from the aorta (ostium), the proximal third of the main renal artery, or the perirenal aorta. Segmental and diffuse intrarenal atherosclerosis may be observed in advanced cases of RAS, especially in patients with diabetes mellitus.

Renal Artery Stenosis from Fibromuscular Dysplasia

FMD refers to a group of uncommon diseases known to cause stenosis of several vascular beds, notably the renal and carotid arteries. They are characterized by noninflammatory and non-

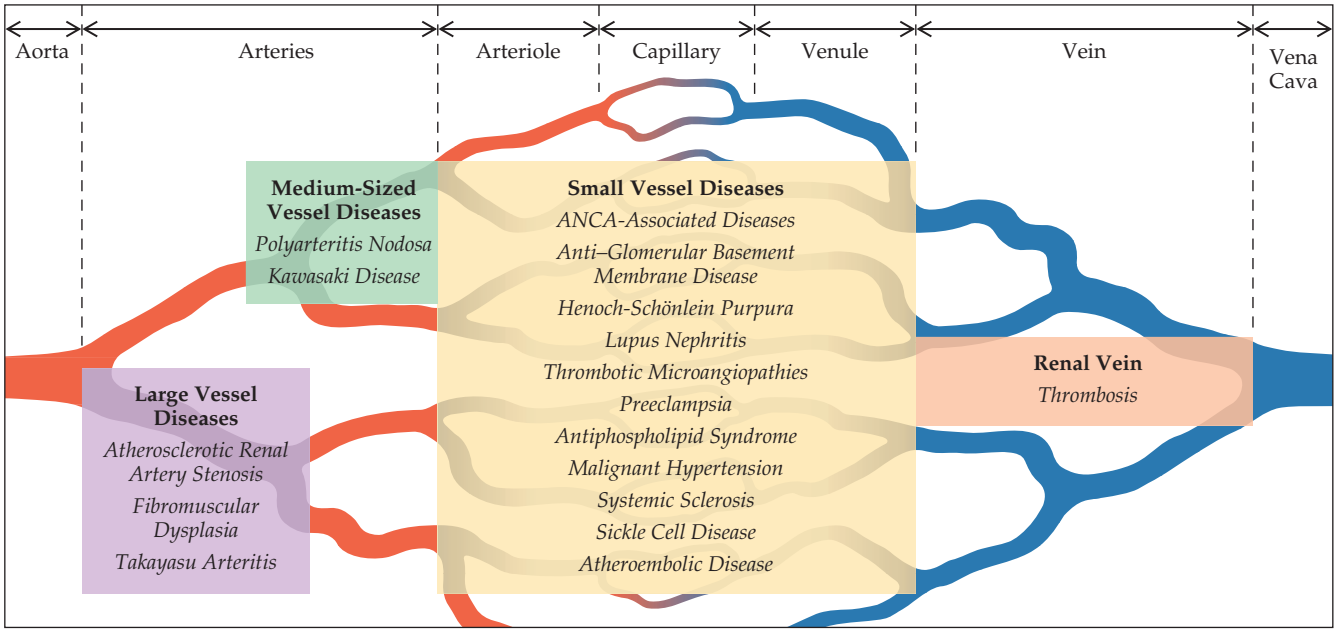

Figure 1 **Overview of vascular disease of the kidney. (ANCA—antineutrophil cytoplasmic autoantibody)**

atherosclerotic dysplastic changes of any of the three layers of the artery—the intima, media, or adventitia. The prevalence of FMD is not clearly known, but the condition is probably rare. FMD accounts for about 10% of all cases of RAS. In turn, RAS is thought to cause less than 5% of all cases of hypertension.

The renal vasculature is most frequently affected by FMD; renovascular FMD accounts for 60% to 75% of all cases of FMD. Bilateral renal involvement occurs in 35% of all cases of renal involvement. FMD of the renal vessels tends to affect women younger than 50 years—typically, younger than 30 years. The cause of FMD is not currently known.

Medial fibroplasia, the most common subtype of FMD, is characterized by a predominance of fibrotic material in the media, with sparing of the intima and adventitia. It affects the distal two thirds of the main renal artery and its branches. The segmental nature of medial fibroplasia, together with localized poststenotic dilatation, result in the classic so-called beads-on-a-string appearance on angiography.

Perimedial fibroplasia is characterized by the appearance of an area of elastic tissue circumscribing the entire diameter of the vessel at the junction of the media and adventitia. Angiographically, perimedial fibroplasia typically appears as focal stenosis, with the development of extensive collateral circulation.

Medial hyperplasia, the last type of medial FMD, is exceedingly rare and is characterized by proliferation of smooth muscle cells. Angiographically, medial hyperplasia is indistinguishable from intimal fibroplasia.

Intimal fibroplasia is characterized by a predominance of fibrotic material in the intima. It is the second most common type of FMD, accounting for about 10% of all cases. It affects the midportion of the main renal artery and its branches. Angiographic evaluation typically reveals long, smooth narrowing or focal, concentric stenosis.

Adventitial hyperplasia is often termed periarterial because of the hyperplastic changes that seem to surround the entire artery. An extremely rare disorder, it is reported to affect the middle to the distal portions of the renal artery.

Pathophysiology

Narrowing of the renal arteries may lead to two important clinical consequences: elevated blood pressure and renal insufficiency. The mechanism of elevated blood pressure is akin to that demonstrated by Goldblatt in the 1930s with the so-called one-clip model, in which ligation of one renal artery led to the production of vasoactive hormones distal to the stenosis and an increase in systemic arterial pressure.[7]

The mechanisms of renal insufficiency are not clear; renal insufficiency is not merely the direct result of decreased renal blood flow. Experimental models offer an imperfect guide, because they use methods that induce acute narrowing rather than the progressive narrowing that occurs with atherosclerosis and FMD. In addition, the clustering of atherosclerosis with other risk factors for renal insufficiency—notably, diabetes mellitus—makes it difficult to ascribe the renal insufficiency to atherosclerotic RAS alone. When renal insufficiency occurs in the setting of atherosclerotic RAS, it is often termed ischemic nephropathy.

Diagnosis

Certain clinical and laboratory findings are suggestive of RAS. These include the abrupt onset or worsening of hypertension, hypokalemia, abdominal bruits, peripheral vascular disease, carotid artery disease, and various renal abnormalities. The renal abnormalities include unexplained azotemia, azotemia induced by the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs), and asymmetrical kidney size on radiologic testing. In addition, recurrent episodes of flash pulmonary edema may be associated with bilateral RAS.

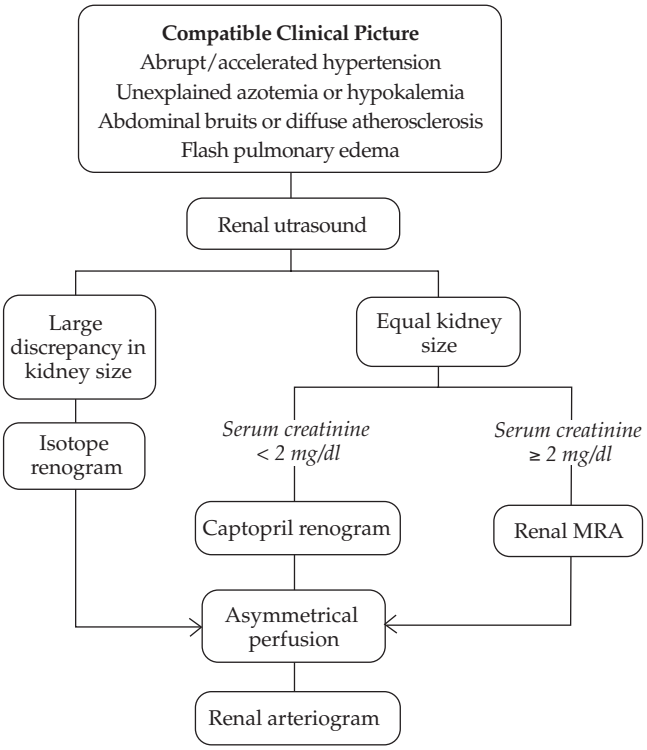

Figure 2 **Workup of suspected renal artery stenosis. (MRA—magnetic resonance angiogram with gadolinium)**

In patients with a compatible clinical picture, evaluation for RAS starts with renal ultrasonography to measure kidney size [*see Figure 2*]. If there is a large discrepancy in kidney sizes (i.e., > 2 cm in the longitudinal axis), significant arterial stenosis is or was likely present. An isotope renogram can then be performed to determine the relative perfusion to each kidney. If asymmetrical perfusion is seen, invasive treatment may be indicated, although this is a matter of debate [*see* Treatment, *below*].

Even if the ultrasound scan shows that the kidneys are equal in size, further diagnostic testing is required. The choice of procedures is determined by the level of renal function: patients with a serum creatinine level below 2 mg/dl should undergo renography; those with a serum creatinine of 2 mg/dl or greater should undergo magnetic resonance angiography (MRA). The captopril renogram, using a variety of radioisotopes, has a sensitivity of 93% and a specificity of 70% for RAS.[8] Gadolinium-enhanced MRA has a sensitivity of 88% and a specificity of 98% for RAS.[9]

The gold standard for the diagnosis of RAS remains a renal arteriogram. Given the known risks of contrast media exposure and manipulation of atherosclerotic plaques, it is important to limit renal arteriography to patients with positive results on noninvasive renal testing.

Treatment

Atherosclerotic RAS Radiographic studies have demonstrated that the lesions of atherosclerotic RAS progress, yet functional studies that measure GFR or surrogate indices have not consistently demonstrated progressive renal insufficiency. It is

therefore not clear whether intervention alters the natural course of the disease process. Thus, the choice between medical management and intervention for atherosclerotic RAS remains controversial. Medical management with various antihypertensive agents remains the most common method of managing hypertension and renal insufficiency. Agents that preferentially reduce efferent arterial tone—ACE inhibitors and ARBs—are contraindicated because of the risk of inducing acute renal failure. Percutaneous angioplasty has been presented as a favorable alternative, but numerous studies have demonstrated its equivalence to conventional pharmacologic therapy.[10] Angioplasty with stenting has been touted as technically superior to angioplasty alone,[11] but a comprehensive review showed that this procedure cures hypertension in fewer than 20% of patients and that it provides no apparent benefit in renal function.[12] Similarly, long-term follow-up studies have failed to demonstrate that surgical revascularization of the stenotic lesion is superior to pharmacologic therapy.[13] Thus, a consensus has been forming that pharmacologic therapy is probably equivalent to more invasive interventions for the vast majority of patients with atherosclerotic RAS.

Some researchers have attempted to determine whether certain variables predict success or failure with intervention in atherosclerotic RAS. Factors that correlate with a lack of improvement include unilateral involvement, stenosis less than 50% of the luminal diameter, baseline kidney size of less than 8 to 9 cm longitudinally, diabetic nephropathy, and severe proteinuria. Recent interest has focused on the resistive index, an estimate of the cumulative resistance of the segmental arteries, and possibly the smaller vessels. Univariate analysis has demonstrated that a high resistive index is a better predictor than level of renal function, kidney size, and proteinuria for a poor outcome with RAS revascularization.[14]

Fibromuscular dysplasia Most forms of FMD progress radiographically, but it is unclear whether there is any associated development of renal insufficiency. In medial FMD, 30% of patients have progressive narrowing without dissection or thrombosis. Both intimal and periarterial FMD are associated with dissection and thrombosis and, rarely, acute renal infarction. Percutaneous intervention has been the standard of care, but large comparative trials are not feasible, given the relative rarity of these conditions. Angioplasty and stenting completely cure hypertension in about 22% of patients.[15] Surgical revascularization has a higher cure rate, about 79% at 1 year,[16] but probably causes more short-term morbidity than angioplasty. Surgical repair of aneurysms (the "beads" seen on arteriography) is required if their diameter is greater than 1.5 cm and if patients have uncontrolled hypertension or are pregnant.

TAKAYASU ARTERITIS

Takayasu arteritis is an inflammatory arteritis involving the aorta and its branches. It primarily affects the ascending aorta and its arterial branches (the carotid, subclavian, and axillary arteries). Involvement of the lower branches of the aorta, including the main renal artery and its branches, occurs as the disease process progresses.

Takayasu arteritis was first described in Japan in the 1800s. Cases occur primarily in women, with a female-to-male ratio as high as 9:1. The incidence varies dramatically worldwide. In Asia, new cases occur up to 100 times more frequently than in the Western world. The usual age at presentation is from 10 to 40 years.

Histologically, Takayasu arteritis may be divided into an acute inflammatory phase and a chronic fibrotic phase. In the acute phase, changes occur in all three layers of the artery: smooth muscle cell proliferation and mucopolysaccharide deposition in the intima; infiltration of media by lymphocytes and giant cells; and vasa vasoritis in the adventitia, characterized by infiltration of T cells, B cells, and dendritic cells. The chronic phase is marked by fibrosis and destruction of the vessel architecture.

The pathogenesis of Takayasu arteritis remains unknown, but it likely involves a combination of host and environmental factors. For example, Takayasu arteritis has been associated with certain human leukocyte antigens (HLA), including HLA B52, DRBI*1502, DRB5*0102, and DQAI*0103. Furthermore, chronic infections, such as tuberculosis, may trigger an immune response that eventually leads to Takayasu arteritis.

Diagnosis

Clinical suspicion of Takayasu arteritis is typically raised when a female presents with uncontrolled hypertension. Diminished or absent pulses are found in 84% to 96% of patients, along with limb claudication and blood pressure discrepancies.[17,18] Vascular bruits, often multiple, are present in 80% to 94% of patients. Aortic regurgitation, a result of dilatation of the ascending aorta, may be found in up to 25% of patients.

Histologically, Takayasu arteritis may be indistinguishable from giant cell arteritis, another systemic vasculitis of large arteries. Takayasu arteritis affects the aorta and its branches, however, and giant cell arteritis primarily affects the external carotid and its branches. Furthermore, renal artery involvement is extremely rare in giant cell arteritis. Other demographic factors also help to distinguish the two disorders. Onset of giant cell arteritis typically occurs after 50 years of age, whereas onset of Takayasu arteritis is typically before age 40. Takayasu arteritis is more common in Asians, whereas giant cell arteritis is more common in persons of European descent. The female-to-male ratio, which is as high as 9:1 for Takayasu arteritis, is 3:2 for giant cell arteritis.

In 1990, the American College of Rheumatology developed specific diagnostic criteria for Takayasu arteritis [*see Table 1*].[19] To make the diagnosis, at least three of the six criteria must be met. The diagnostic strategy for establishing renal involvement is similar to the workup for renal artery stenosis [*see Figure 2*].

Table 1 American College of Rheumatology Classification Criteria for Takayasu Arteritis*

Age of onset ≤ 40 yr
Claudication of extremities†
Decreased brachial pulse
Blood pressure difference > 10 mm Hg‡
Bruit over subclavian arteries or aorta
Arteriogram abnormalities§

*At least three of the six criteria must be met to make the diagnosis.

†Fatigue and discomfort in muscles of one or more extremities, especially the upper extremities.

‡Typically, systolic blood pressure, between arms.

§Narrowing or occlusion of aorta, primary branches, or large arteries in the proximal upper or lower extremity not caused by other conditions (e.g., atherosclerosis, fibromuscular dysplasia).

Treatment

Treatment of Takayasu arteritis consists of antihypertensive therapy, immunosuppressive therapy, and surgical bypass of severely stenotic arterial lesions. Most antihypertensive agents are suitable for use in Takayasu arteritis, although the use of ACE inhibitors or ARBs should be closely monitored because of the potential for abrupt changes in the GFR. Steroids are the first-line immunosuppressive therapy, with approximately 50% of patients achieving remission.[20] Prednisone at 45 to 60 mg/day orally or another steroid at an equivalent dose is administered until symptoms improve. The dose is then tapered; if symptoms recur, the dose is restored to the starting dose. Given the waxing and waning nature of the disease, the optimal duration of steroid therapy is variable. The second-line therapy, methotrexate, is generally used because of its low side-effect profile compared with other cytotoxic agents, such as cyclophosphamide. Approximately 50% of patients respond to oral methotrexate at a dosage of 5 to 20 mg a week, along with corticosteroids.[21] Azathioprine has been used, with a reported effect similar to that of cyclophosphamide.[22] Agents such as mycophenolate mofetil have been studied, but the data are too preliminary to support formal recommendations.

Surgical correction of arterial stenosis is indicated for patients with critical renal artery stenosis and hypertension, extremity claudication, cerebrovascular disease, splanchnic ischemia, aortic regurgitation, or coronary disease. Surgical intervention should take place during a quiescent phase of disease activity, usually after immunosuppressive therapy.

Prognosis

The prognosis for patients with Takayasu arteritis varies with the extent of vessel involvement. Five-year survival for all patients with Takayasu arteritis is between 80% and 90%,[18,23] but it drops to 60% for those patients with multiple arterial involvement.

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) is a complication of the nephrotic syndrome. Loss of glomerular basement membrane selectivity leads to the excretion of numerous serum proteins, including anticoagulant proteins such as antithrombin III, protein C, and protein S. Furthermore, the blood in the renal veins may be relatively hemoconcentrated after ultrafiltration of the plasma.

The exact prevalence of RVT is not known. Estimates range widely; the disorder may develop in anywhere from 5% to 60% of patients with nephrotic syndrome. RVT has been most frequently associated with idiopathic and secondary membranous nephropathy; 30% of these patients may have RVT. Pulmonary embolism may develop in up to 30% of patients with RVT, although alarmingly, the vast majority of these cases are asymptomatic.

The classic clinical presentation of RVT is acute lower back pain and gross hematuria. Patients typically do not have renal insufficiency or hypertension. RVT can be diagnosed by computed tomography, magnetic resonance imaging, and contrast venography. Doppler ultrasound imaging is notoriously operator dependent and therefore should not be used for diagnosis of RVT.

Anticoagulation with warfarin is indicated for patients with RVT. The therapeutic goal is an international normalized ratio (INR) of 2 to 3. The appropriate duration of therapy is likely lifelong. Thrombolytic therapy or surgical thrombectomy is sometimes considered when bilateral RVT occurs in association with acute renal failure. The value of prophylactic anticoagulation in patients with nephrotic syndrome, especially membranous nephropathy, is open to debate. The prognosis for patients with RVT is generally good.

Disease of Medium-Sized Renal Vessels

Diseases affecting medium-sized arteries and veins of the kidney are relatively rare. Two types of systemic vasculitis that infrequently affect the kidney are polyarteritis nodosa and Kawasaki disease.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) was first described by Kussmaul and Maier in 1866 as periarteritis nodosa. It is a systemic arterial vasculitis that can involve the kidney. For many years, conditions now known to be associated with antineutrophil cytoplasmic autoantibodies (ANCA) may have been incorrectly diagnosed or classified as PAN. The Chapel Hill Consensus Conference provided strict criteria for the diagnosis of ANCA-associated diseases and PAN.[24]

Polyarteritis nodosa is now defined by three criteria: (1) necrotizing vasculitis affecting small arteries; (2) sparing of the smaller vessels (i.e., arterioles, capillaries, and venules); and (3) no association with a primary or secondary glomerulopathy. The condition is rare; idiopathic PAN affects two to nine persons per million population annually,[25,26] although annual incidence rates as high as 77 cases per million have been reported in areas endemic for hepatitis B virus infection.[27] No racial, ethnic, or gender predilection for idiopathic PAN has been observed.

The pathogenesis of PAN is unclear. There appears to be an association with hepatitis B viral infection. In the past, most reported cases of idiopathic PAN may actually have been long-term complications of hepatitis B resulting from immune complex deposition. Childhood cases of PAN may be associated with streptococcal infection.

Histologically, PAN appears as a pleomorphic cellular infiltration of the adventitia. Polymorphonuclear cell degranulation leads to leukocytoclasis and, eventually, to transmural necrosis. Segmental necrosis of the artery may occur, which then leads to the formation of aneurysms. In later stages of the inflammatory process, endothelial damage and thrombosis result in complete obstruction of an affected vessel.

Clinically, PAN develops in an insidious manner, with constitutional symptoms appearing over many weeks to even months. Early nonspecific signs and symptoms include fevers, weight loss, malaise, and anorexia. Large-joint arthralgias without true arthritis may occur in the knees, ankles, elbows, and wrists. Findings that are more suggestive of PAN include livedo reticularis (a purplish rash over the lower extremities and abdominal wall), dermal nodules or ulcerations, and digital ischemia—all of which are sequelae of arteritis and disordered blood flow through medium-sized arteries. PAN may also affect a host of organ systems, including the gut, heart, and kidney. Renal involvement typically leads to hypertension. If extensive renal involvement is present, renal insufficiency may also develop.

The diagnosis of PAN is made by demonstration of the characteristic lesion in an artery. Biopsy of a cutaneous nodule is preferred because of its relative accessibility, but such nodules are notoriously uncommon. Arteriography may represent a suitable alternative. Serologic tests are not diagnostic in PAN, but low-titer antibodies to rheumatoid factor (RF) and nuclear antigen

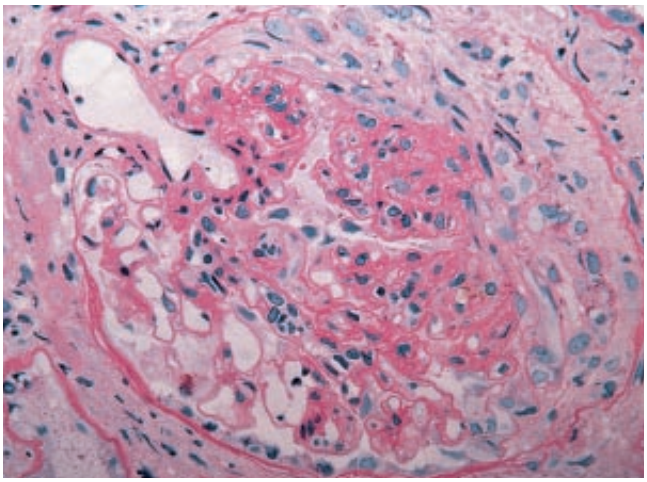

Figure 3 **Light microscopy of a renal biopsy specimen from a patient with crescentic glomerulonephritis shows compression of the glomerular tuft by a large crescent. Although an identical renal lesion can be observed in a variety of renal disorders, the finding of negative immunofluorescent staining for antigen-antibody complexes is highly suggestive of a systemic necrotizing vasculitis, such as Wegener granulomatosis or polyarteritis nodosa. Most other causes of crescentic glomerulonephritis are typified by characteristic patterns of immune staining, such as the linear immunofluorescent pattern seen in Goodpasture syndrome.**

(ANA) may be present. PAN secondary to hepatitis B has been associated with hypocomplementemia. Finally, immunofluorescence antibody staining for cytoplasmic and perinuclear ANCA may be positive, but the more specific test, serum enzyme-linked immunosorbent assay (ELISA) titers for antibodies against both serine protease 3 (PR3) and myeloperoxidase (MPO), is negative.

If left untreated, patients with PAN have a poor prognosis. In such cases, patients are at risk for ischemia of numerous organ systems; the major causes of morbidity and mortality include renal failure, mesenteric ischemia, and cerebrovascular accidents. Corticosteroids and cytotoxic agents have been the mainstays of therapy for idiopathic PAN, although the optimal therapy remains unknown.

Approximately 50% of patients with idiopathic PAN achieve remission with high-dose steroids (e.g., prednisone, 1 mg/kg/day) for 3 to 6 months.[28] Cyclophosphamide, either intravenous (0.6 g/m^2/mo) or oral (2 mg/kg/day), for up to 1 year is used in patients whose disease does not respond to steroids or in patients who are at risk for serious complications. A method for determining the need for cytotoxic therapy is the five-factor score, which comprises the following: (1) gastrointestinal signs, including bleeding, perforation, infarction, or pancreatitis; (2) renal insufficiency; (3) proteinuria; (4) CNS involvement; and (5) cardiac involvement.[29] The five factor score is slightly dated; according to the Chapel Hill nomenclature, proteinuria would no longer be a valid criterion for PAN. ACE inhibitors and ARBs should be used cautiously in patients with PAN, because renal involvement may produce a functional equivalent of classic RAS.

KAWASAKI DISEASE

Kawasaki disease (KD) is another systemic vasculitis affecting medium-sized arteries. Renal involvement in KD has been varied. Vasculitic lesions of the renal vessels are rare, for unclear reasons. Sterile pyuria, interstitial nephritis, and proteinuria may be associated with KD in the kidney. The diagnosis and treatment of KD are discussed in detail elsewhere [*see 15:VIII Systemic Vasculitis Syndromes*].

Small Vessel Disease

CONDITIONS ASSOCIATED WITH GLOMERULOPATHY

Many small vessel diseases of the kidney are associated with glomerulopathy. Although these diseases are often considered to be forms of glomerulonephritis, the sentinel lesion occurs at the level of the glomerular capillary, where in situ and exogenous antigens incite an aggressive inflammatory response. This can lead to a significant breakdown of glomerular architecture, including rupture of the Bowman capsule (crescent formation), as well as leakage of protein and red blood cells into the tubular space. Several of these vascular diseases have been described as rapidly progressive glomerulonephritis (RPGN) because of the loss of renal function within days to weeks [*see Figure 3*].

These small vessel diseases share a similar clinical presentation. Most patients have evidence of systemic illness. They have a history of malaise, anorexia, weight loss, fevers, rash, arthralgias, and discolored urine. With pulmonary-renal syndromes, patients may also have hemoptysis, epistaxis, or chronic sinusitis. Key features of the physical examination for all these diseases include assessment of blood pressure, joints, skin, nasopharynx, lymph nodes, abdominal organs, and eyes (retina). Urinalysis shows hematuria or proteinuria, and microscopic evaluation of the urine reveals red blood cell casts, oval fat bodies, and dysmorphic red blood cells.

Rapidly Progressive Glomerulonephritis

ANCA-associated vasculitis Vasculitis associated with ANCA is the most common small-vessel vasculitis in adults. It includes three main categories: Wegener granulomatosis, microscopic polyangiitis (MPA), and Churg-Strauss disease. All three conditions are associated with a pauci-immune glomerulonephritis, although traditionally this is seen at a lower frequency in Churg-Strauss disease than in the other two ANCA diseases. Wegener granulomatosis manifests primarily in the kidney, upper respiratory tract, and lung, whereas MPA occurs primarily in the kidney. Churg-Strauss disease is found typically in the lungs and is associated with asthma and eosinophilia [*see 15:VIII Systemic Vasculitis Syndromes*].

ANCA-associated vasculitis may affect persons of all ages, but it is most common in middle-aged and older adults (> 50 years). It is equally distributed among men and women, and in the United States, it is most common in whites. Its documented incidence is between one and two cases per 100,000 population.[30,31]

Information on the pathogenesis of ANCA-associated vasculitis is growing. There are likely environmental and infectious stimuli. For example, viral and bacterial respiratory tract infections often precede the first occurrence of disease. Furthermore, therapy to suppress staphylococcal species decreases the frequency of recurrences.[32] The pathologic effect of the autoantibodies may result from activation of neutrophils.

The histologic appearance of ANCA-associated vasculitis is leukocytoclastic infiltration of arterioles, capillaries, and venules throughout the body. Fibrinoid necrosis of the muscularis layer, often extending into the perivascular tissue, may also be present.

Figure 4 **Purpuric eruptions can be seen in a variety of small vessel vasculitides, Henoch-Schönlein purpura, hypersensitivity vasculitis, and ANCA-associated disease. The lesions are palpable, and immunofluorescent staining of the dermal vessels on skin biopsy may be diagnostic. For example, IgA deposition is highly suggestive of Henoch-Schönlein purpura in this setting.**

The histologic lesion, fibrinoid necrosis, is indistinguishable from that seen in other vasculitides; the type and location of the involved vessel help identify the specific disease process.

The clinical presentation of small-vessel vasculitis often starts with constitutional signs and symptoms such as fever, malaise, myalgias, and arthralgias. Blood vessels throughout the body—including skeletal muscle, peripheral nerves, gastrointestinal tract, kidneys, respiratory tract, and skin—may be affected; thus, signs and symptoms are variable. Leukocytoclastic angiitis of dermal vessels leads to the most common skin finding—purpura [*see Figure 4*]. These purpuric lesions are often raised, and for unclear reasons, they tend to form on the lower extremities, often distal to the knees. Angiitis of vessels supplying peripheral nerves may lead to mononeuritis multiplex, the most common neurologic manifestation.[33,34] Renal involvement typically leads to glomerulopathy, with subsequent hematuria and proteinuria. Respiratory tract involvement leads to epistaxis and hemoptysis. Asthma is specific to Churg-Strauss disease.

The diagnosis of ANCA-associated vasculitis is aided by serum ANCA testing. The former ANCA nomenclature has been replaced by more specific terminology, with cytoplasmic ANCA (c-ANCA) succeeded by PR3-ANCA (serine protease 3) and perinuclear ANCA (p-ANCA) replaced by MPO-ANCA (myeloperoxidase). Approximately 80% of patients with Wegener granulomatosis have high-titer antibodies to PR3-ANCA, whereas 80% of those with microscopic polyangiitis have high-titer antibodies to MPO-ANCA. Up to 10% of patients with a typical clinical presentation for ANCA-associated vasculitis may have negative or low-titer serum antibodies to MPO or PR3.[35]

The prognosis for patients with untreated ANCA-associated vasculitis is poor. Death results from renal failure or pulmonary hemorrhage. Consequently, intervention early in the course of disease is important, preferably before the serum creatinine concentration reaches 4 mg/dl.[36] Corticosteroids and cyclophosphamide are the mainstays of induction therapy [*see Table 2*]. This regimen produces complete remission in about 75% of patients and improvement in up to 90%.[31] Plasma exchange should be initiated promptly with cytotoxic therapy in the setting of concomitant pulmonary hemorrhage. Plasma exchange is performed every second day, with each exchange consisting of 1 to 1.5 plasma volumes, for a total of three to six procedures.

The optimal maintenance therapy has yet to be determined. Both cyclophosphamide (oral and intravenous) and oral mycophenolate mofetil have been used. Attention has recently focused on an old agent, azathioprine; oral azathioprine has proved to be equivalent to oral cyclophosphamide with respect to relapses and severe adverse effects.[37] Relapses of ANCA-associated vasculitis are generally treated as de novo disease, with high-dose corticosteroids and cyclophosphamide.

Anti–glomerular basement membrane disease Nearly 20% of RPGN cases are caused by anti–glomerular basement membrane (anti-GBM) disease. This condition is defined by the presence of circulating IgG antibodies to type IV collagen—specifically, to the NC1 domain of the α3 chain.

Anti-GBM disease has been reported to occur at the extremes of age: the youngest patient was 4 years old, and the oldest was 81 years old. Classically, the disease occurs in two distinct groups[38]: men younger than 30 years and women older than 60 years. Young men with anti-GBM disease tend to have both kidney and lung involvement. This condition is termed Goodpasture syndrome, in honor of Ernest Goodpasture, who is credited with the first description of anti-GBM disease, in a young man

Table 2 Induction Therapy for Rapidly Progressive Glomerulonephritis*

Pulse corticosteroids:
Methylprednisolone, 7 mg/kg/day I.V. (maximum dose, 500 mg) × 3 days

then

Oral corticosteroids:
Prednisone, 1 mg/kg/day p.o. × 3–6 mo

plus

Cyclophosphamide:
Oral: 2–3 mg/kg/day × 6 mo; round dose down to nearest 50 mg; reduce to 2 mg/kg/day in patients > 55 yr

Intravenous: 0.5 g/m^2 monthly for six doses

plus

Exchange transfusion, if indicated

*See text for details on individual diseases.

with acute renal failure and pulmonary hemorrhage; interestingly, the presentation was ascribed to the influenza pandemic of the early 1900s. Older women typically present with disease limited to the kidneys. In both men and women, there appears to be a strong racial predilection for whites.

The agent or agents that incite the development of autoantibodies in anti-GBM disease remain unknown. Isolated reports have suggested that the disease develops after pulmonary infections or exposure to aerosolized hydrocarbons, yet large epidemiologic studies have yet to substantiate these observations. Type IV collagen is found predominantly in the GBM and in the alveolar basement membrane in the lungs. Interestingly, there are persons with a hereditary lack of type IV collagen (Alport syndrome) who may experience anti-GBM disease if they receive a kidney transplant from an unrelated donor. Alveolar type IV collagen is relatively unexposed to the serum, which may help to explain the lower frequency of lung involvement. Injury to the barrier in the lung, by such mechanisms as cigarette smoking, may unmask the type IV collagen.

On light microscopy, the histologic appearance of anti-GBM disease is similar to that of the other forms of RPGN. The lesions demonstrate aggressive changes: diffuse cellular and mesangial expansion, karyorrhexis, and crescent formation (breakdown of Bowman capsule). Anti-GBM disease is distinguished from these other forms by immunohistologic staining that reveals linear IgG along the basement membrane.

High serum antibody titers to GBM help confirm the diagnosis. Over 30% of patients with anti-GBM disease may also demonstrate ANCA antibodies.[39] The presence of ANCA antibodies predicts a better response to immunosuppressive therapy.

The prognosis for patients with untreated anti-GBM disease is dismal; nearly all patients die of either renal failure or pulmonary hemorrhage. With therapy, however, the prognosis is good. One-year survival is about 75% to 90%.[38] As in ANCA disease, early intervention provides a substantial survival benefit. Corticosteroids, cyclophosphamide, and plasma exchange are the cornerstones of therapy [*see Table 2*]. These three modalities act to eliminate the pathogenic antibody from circulation, thereby limiting additional glomerular and alveolar damage. Plasma exchange consists of a 4-liter exchange for 5% human albumin solution, performed daily for 14 days. Because these exchanges may deplete intrinsic clotting factors, fresh frozen plasma should be given within 3 days of any planned invasive procedure (e.g., biopsy) or in the event of pulmonary hemorrhage. Relapses are exceedingly rare, and immunosuppressive therapy can generally be discontinued after the initial course of treatment.

Immune complex glomerulonephritis The immune complex glomerulonephritides are a diverse group of conditions accounting for 30% to 40% of RPGN. They often develop in patients with a preexisting glomerular disease; histopathologic study shows an aggressive variation of the underlying glomerulonephritis. IgA nephropathy, lupus nephritis, membranoproliferative glomerulonephritis, and postinfectious glomerulonephritis all may present as an immune complex RPGN. Diagnostic testing depends on the underlying glomerular disease.

Lupus nephritis typically presents as renal insufficiency with a nephritic sediment in urine. This disorder affects significantly more women than men (ratio of 9 to 1), and generally occurs between 20 and 40 years of age. Histologically, lupus nephritis is characterized according to the extent of mesangial and cellular proliferation in the glomerulus and is categorized as World Health Organization (WHO) classes I through V.[40] Class III (focal proliferative glomerulonephritis) and class IV (diffuse proliferative glomerulonephritis) have particular clinical significance. In addition, patients with lupus and lupus anticoagulant antibodies may have renal disease with features of a thrombotic microangiopathy (TMA) (see below).

As is true of systemic lupus erythematosus (SLE), the cause of lupus nephritis is not yet known. The diagnosis of lupus nephritis is aided by the fact that it usually occurs along with other features of SLE, such as rash or arthritis. Serum complement levels (both C3 and C4) are typically depressed. Other helpful serologic tests include measurement of ANA and of antibodies against double-stranded DNA (dsDNA). ANA testing has high specificity, with titers greater than 1:160 strongly suggesting disease. Furthermore, a negative ANA confirms the absence of disease. A positive dsDNA antibody assay helps confirm the presence of SLE [*see 15:IV Systemic Lupus Erythematosus*]. Lupus nephritis is confirmed with a kidney biopsy.

Without therapeutic intervention, the prognosis is poor for patients with class III or IV lupus nephritis or TMA. Most patients progress to ESRD or die. As with other types of RPGN, therapy consists of corticosteroids, cytotoxic agents, and, occasionally, plasma exchange [*see Table 2*]. Plasma exchange is indicated with concomitant pulmonary hemorrhage or TMA; the regimen is one exchange every second day, with each exchange consisting of 1 to 1.5 plasma volumes, for a total of three to six procedures. Data have also been mounting regarding the efficacy of oral mycophenolate mofetil (500 to 2,000 mg daily for up to 2 years) as either primary therapy[41] or maintenance therapy[42] for class III or IV lupus nephritis.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is a systemic vasculitis characterized by IgA-dominant immune complex deposition in the venules, capillaries, and arterioles. Renal involvement in HSP is indistinguishable from idiopathic IgA nephropathy. The involvement of other organ systems, such as the skin, nerves, or gastrointestinal tract, helps distinguish HPA from IgA nephropathy.

HSP is a disease of childhood, with peak occurrence at 5 years of age. Renal involvement tends to occur in older children and in adults. HSP in adults is generally more severe than that in children. There is a stronger predilection for HSP in Europeans and Asians than in other ethnic groups, and there may be a slightly higher frequency of the disease in men than in women.

The etiologic agent of HSP is not known. The disease often begins after a respiratory infection. Exposure to viruses such as adenovirus may trigger an immune complex response leading to the deposition of IgA subtype A1 in arterioles, venules, and capillaries throughout the body.

In the kidney, IgA deposition is visualized by immunofluorescence staining. It is often accompanied by mesangial matrix expansion and hypercellularity (neither finding is specific to HSP). In the skin, the characteristic lesion is a leukocytoclastic vasculitis.

The clinical presentation of HSP is variable. The classic tetrad of signs and symptoms comprises rash, arthralgias, abdominal pain, and renal disease. The rash is purpuric. The arthralgias are symmetrical and affect small joints. The abdominal pain is diffuse and waxes and wanes. The renal disease, typically with hematuria and proteinuria, is found in over 50% of patients with HSP. Renal insufficiency affects only 10% to 20% of patients. In rare cases, pulmonary disease and peripheral neuropathy may occur.

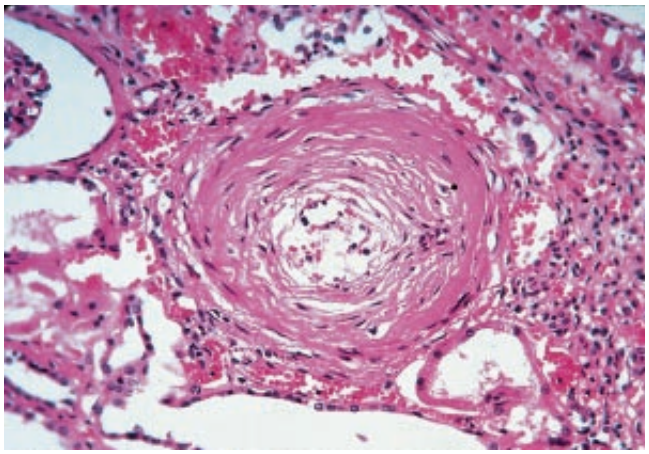

Figure 5 **Light microscopy reveals the characteristic onion-skin lesion seen in scleroderma renal crisis. This finding is typical of disorders that present as a thrombotic microangiopathy, such as malignant hypertension, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, and catastrophic antiphospholipid syndrome.**

The prognosis for most patients with HSP is good. Almost 95% of children and 90% of adults have complete recovery. Supportive therapy, therefore, is sufficient for most patients. Progressive renal insufficiency leading to ESRD occurs in about 5% of patients. The optimal therapy in such cases is not known. Immunosuppressive agents (e.g., corticosteroids, cyclophosphamide, and azathioprine) and anticoagulants have been used in HSP, with inconsistent results. Thus, therapy is usually reserved for aggressive forms of HSP marked by renal insufficiency and diffuse gastrointestinal involvement; it includes a combination of corticosteroids, cyclophosphamide, and plasma exchange.

THROMBOTIC MICROANGIOPATHY

TMA comprises a group of occlusive vascular diseases characterized by endothelial disruption, systemic or intrarenal platelet aggregation, thrombocytopenia, and mechanical injury to erythrocytes. The platelet thrombi contain large amounts of von Willebrand factor (vWF) but no fibrin or fibrinogen. Furthermore, intimal thickening of the small arteries and arterioles occurs diffusely and has an appearance that has been described as an onion-skin lesion.

The classic TMAs include thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS). Antiphospholipid syndrome (APS), preeclampsia, systemic sclerosis with renal crisis, malignant hypertension, and certain drugs can produce a clinical picture that is phenotypically similar to classic TMA [*see Figures 5 and 6*]. All of these conditions often present as acute renal failure and can cause acute cortical necrosis, which is generally considered irreversible. Furthermore, hemolytic anemia and thrombocytopenia are present. The renal lesions are remarkably similar in all of these diseases, so the history is often crucial in determining the exact type of TMA.

Thrombotic Thrombocytopenic Purpura

Eli Moschowitz first described TTP in 1924, in a 16-year-old girl with abrupt onset of fever and petechiae followed by paralysis and death. Autopsy revealed diffuse hyaline thrombi affecting the terminal arterioles and capillaries in numerous organs. Subsequently, TTP came to be defined by a pentad of clinical findings: fever, thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, and renal dysfunction.

TTP can occur in any age group. There are no apparent differences in occurrence of the disease by race or gender.

The critical role of a metalloprotease (ADAMTS-13 [a disintegrin and metalloprotease with thrombospondin type 1 motif, 13 isoform]) in the pathogenesis of TTP has emerged in the past 10 years. ADAMTS-13, which is found on the surface of endothelial cells, normally cleaves large multimers of the von Willebrand antigen as they are secreted by the cell. These large multimers bind more efficiently than the cleaved von Willebrand antigen to platelets (at the Ibα component of platelet glycoprotein Ib/IX/V vWA receptor). Plasma ADAMTS-13 activity must be severely depressed for TTP to develop. The level of ADAMTS-13 plasma activity is modestly depressed in patients with liver disease, disseminated cancer, chronic metabolic and inflammatory conditions, and pregnancy, as well as in newborns.[43] When plasma activity of ADAMTS-13 falls to less than 5% of normal, these large von Willebrand antigens predominate, bind to platelets, and cause aggregation and thrombi in small vessels.

Several mechanisms have been postulated for the abnormal functioning of ADAMTS-13 and noncleavage of von Willebrand antigens. Familial or chronic relapsing TTP may result from a mutation in the gene that codes for ADAMTS-13; this would explain why infusion of fresh frozen plasma, which is known to contain ADAMTS-13, is the only effective therapy in these cases. Autoantibodies against ADAMTS-13 may form with exposure to certain drugs (e.g., ticlopidine) or in idiopathic single-episode TTP. Removal of the autoantibody against ADAMTS-13 would explain the efficacy of plasmapheresis in the treatment of TTP in these cases.

Another newly postulated mechanism for the development of the familial form of TTP is a deficiency in plasma factor H. Factor

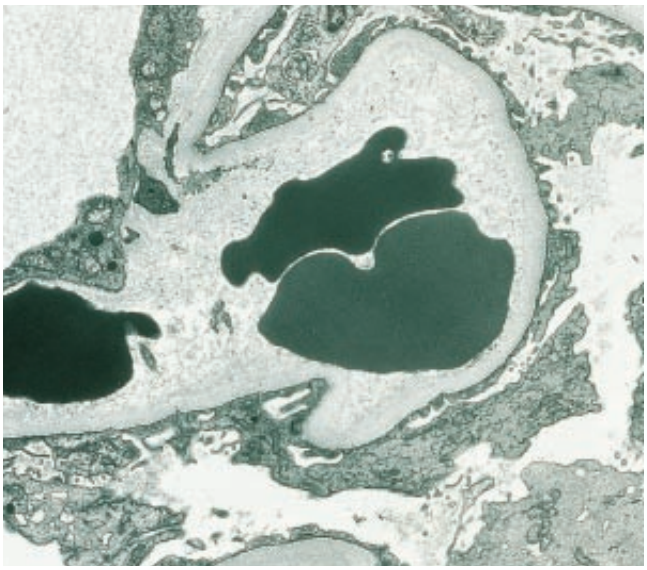

Figure 6 **Electron microscopy shows a glomerular capillary in a patient with thrombotic thrombocytopenic purpura. The capillary lumen is in the center and contains three red cells. The fluffy-appearing material between the red cells and the glomerular basement membrane is characteristic of this disorder and may represent incompletely polymerized fibrin; it has separated the endothelial cells from the basement membrane. In more chronic cases, a vascular lesion similar to that observed in scleroderma [*see Figure* 5] may be seen.**

H is a 150 kd plasma protein that inhibits the activation of the alternative pathway of complement.[44-46] Specifically, factor H exposes C3b to cleavage by factor I. A deficiency in factor H therefore leads to unregulated C3, potentiating immune complex–mediated or autoantibody-mediated glomerular endothelial injury. Exposure of the glomerular subendothelium leads to the adhesion and aggregation of platelets. Thus far, most of the defects in factor H have been determined to be frameshifts, deletions, and point mutations.

A mutation in the membrane cofactor protein (MCP) has been suggested to cause a form of TTP that is phenotypically similar to factor H deficiency.[47] The MCP, a widely expressed transmembrane glycoprotein, serves as a necessary cofactor to factor I. An abnormal MCP would prevent factor I–driven inactivation of C3b, resulting in overactivation of the alternative complement system.

Although TTP is often defined by the classic pentad of findings (see above), a presumptive diagnosis can often be based on a triad of laboratory observations: thrombocytopenia, schistocytes, and elevated levels of serum lactate dehydrogenase (from shredded erythrocytes). The differential diagnosis includes other TMAs. A drug history that reveals exposure to agents such as cyclosporine, tacrolimus, mitomycin C, quinine, ticlopidine, and clopidogrel suggests drug-induced TTP. Quinine is no longer an over-the-counter medication, but it is still found in tonic water and herbal medications containing bark from the cinchona tree. A history of ingesting undercooked meat or unpasteurized dairy products or juices and, possibly, an antecedent diarrheal illness suggest HUS. In a pregnant woman, the triad of laboratory findings raises the possibility of preeclampsia and its variant, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets). The renal crisis phase of systemic sclerosis (scleroderma) may also be difficult to distinguish from TTP; a history of scleroderma, compatible physical findings, and the presence of antibodies to Scl-70 help confirm scleroderma renal crisis. Finally, a history of poorly controlled hypertension and severe elevations of blood pressure (generally, a diastolic pressure greater than 130 mm Hg) and papilledema suggest malignant hypertension.

Conditions other than TMA may also be difficult to distinguish from TTP. Disseminated intravascular coagulation (DIC), thought to be triggered by sepsis, shock, or obstetric complications, leads to intravascular activation of the coagulation cascade and consumption of coagulation factors. The formation of intravascular fibrin thrombi leads to a microangiopathic hemolytic anemia. It may be possible to presumptively distinguish DIC from TTP by measuring the prothrombin time (PT) and partial thromboplastin time (PTT); both the PT and the PTT should be elevated in DIC.

The prognosis is poor for patients with untreated TTP. Therapy is targeted at the postulated underlying mechanism. Because familial and chronic relapsing TTP are thought to result from the production of functionally deficient ADAMTS-13, these conditions are treated with infusion of platelet-poor fresh frozen plasma or cryoprecipitate-poor plasma, rather than being treated with plasmapheresis. Plasma contains active metalloproteases, including ADAMTS-13, and a plasma transfusion will increase plasma activity for up to 3 weeks. Gene therapy may soon be possible, because the sequence of the gene that codes for ADAMTS-13 has been determined.

Acquired TTP is treated with plasma exchange. Plasma exchange has two components: (1) plasmapheresis to remove the von Willebrand multimers and autoantibodies to ADAMTS-13 and (2) infusion of fresh frozen plasma to help reconstitute plasma volume and proteins, including coagulation factors. Plasma exchange is typically administered every other day, for a total of six sessions. Patients treated with plasma exchange have a 90% chance of surviving an acute episode of TTP.[48] Antiplatelet therapy with aspirin is no longer routinely recommended for TTP, because it can cause severe bleeding in patients with severe thrombocytopenia.[49]

Hemolytic-Uremic Syndrome

HUS is defined as a TMA that occurs after exposure to *Escherichia coli* 0157:H7 or other enteropathogenic serotypes of *E. coli*, *Shigella dysenteriae*, and, occasionally, some other enteropathogenic organism. It is predominantly a disease of children, especially those younger than 5 years. HUS occurs in 9% to 30% of children who experience bloody diarrhea from *E. coli* 0157:H7; the HUS follows the diarrhea approximately 1 week later[50-52] [*see 7:VIII Infections Due to Escherichia coli and Other Enteric Gram-Negative Bacilli*]. Cattle are reservoirs of *E. coli* 0157:H7. The organism is harmless to cattle because it is unable to penetrate their intestinal mucosa. The toxins produced by the bacteria can be transmitted via unpasteurized milk products, as well as by undercooked meat.

In humans, *E. coli* 0157:H7 is able to adhere to the colonic mucosal cells, invade, and replicate. The ensuing inflammatory response leads to the disruption of the normal mucosal architecture, with bloody diarrhea and systemic bacterial invasion. Systemically, Shiga toxins play two key roles in the development of thrombi. First, they impair the secretion of ADAMTS-13 through an unspecified mechanism, resulting in large von Willebrand multimers. Second, they activate platelet adherence via the glycoprotein Ibα component of glycoprotein Ib/Ix/V1 and V2, which may then promote von Willebrand antigen and platelet aggregation.

The prognosis for patients with HUS is variable. Children with oliguria for less than 24 hours generally have full recovery of renal function. Adults generally have a worse prognosis for recovery of renal function. Supportive therapy with dialysis may be needed.

There is at present no effective therapy for HUS. Plasma infusion and exchange have demonstrated equivocal results,[53,54] but given the overlap of HUS with TTP, both modalities are often tried. The optimal treatment is primary prevention. Meat products, especially ground beef and hot dogs, should be thoroughly cooked. Unpasteurized dairy products should be avoided.

Preeclampsia

Preeclampsia is a multisystem vascular disease of gravid women in their second and third trimester. It affects 3% to 5% of all pregnancies.[55] Preeclampsia remains a major cause of maternal-fetal morbidity and mortality. Renal involvement in preeclampsia is common and can be used to support the diagnosis.

Studies have long suggested that risk factors for the development of preeclampsia are related to decreased placental perfusion. For example, primigravidas, who tend to have a relatively small placenta, have twice the risk of developing preeclampsia than women in their second or third pregnancies.[56] Other risk factors linked to decreased placental perfusion include diabetes mellitus, preexisting hypertension, thrombophilia, and the presence of a hydatidiform mole or multiple gestations.

Recent hypotheses regarding the pathophysiology of preeclampsia have focused on immune tolerance and circulating

angiogenic factors. The placenta is a conglomerate of two genotypically different populations of cells. Preeclampsia may result from a maternal intolerance to fetal cells. Repeated low-level exposure to these antigens may promote tolerance; this would explain why studies have shown a protective effect of sperm exposure and multiple pregnancies with the same partner but an increased risk of preeclampsia with changes in partners or donor insemination.[57] Circulating soluble fms-like tyrosine kinase–1 (sFlt-1) may also have an important role in the pathogenesis of preeclampsia. This molecule typically binds vascular endothelium growth factor (VEGF), which is necessary for normal angiogenesis, including in the placenta. In normotensive pregnancies, sFlt-1 levels start to increase at 33 to 36 weeks of gestation; in preeclampsia, the levels are postulated to increase earlier in gestation. The resultant decrease in VEGF may then lead to insufficient angiogenesis of the placenta. A case-control study demonstrated that elevated sFlt-1 levels and decreased VEGF levels were associated with the development of preeclampsia.[58]

The classic presentation of preeclampsia is the triad of hypertension, edema, and proteinuria. Hypertension (blood pressure ≥ 140/90 mm Hg) is a relatively sensitive finding but is not highly specific, given that it may occur in 12% to 22% of all pregnancies.[59-61] Leakage of protein into the Bowman space and subsequently into the urine is thought to result from glomerular capillary endotheliosis (proliferation of endothelium). Urine protein excretion exceeds 0.3 g in 24 hours and can often be in the nephrotic range (≥ 3.5 g/24 hr). Edema is thought to result from the loss of oncotic pressure in the vessels and is believed to affect all organs, but it is often apparent only in the upper extremities or face. Liver edema may result in the development of epigastric and right upper quadrant abdominal pain. Capillary obstruction undoubtedly leads to a decrease in renal blood flow and GFR. Reductions in GFR may not be detected until the late stages of preeclampsia because of the normal elevation of GFR during pregnancy and the insensitivity of serum creatinine concentration measurement. An increased serum uric acid concentration, which is indicative of decreased tubular secretory function, may be a better indicator of early renal dysfunction in preeclampsia. In developed countries, acute renal failure is rare because of successful delivery of premature fetuses. Ischemic acute tubular necrosis and cortical necrosis from preeclampsia now account for less than 4% of all cases of acute renal failure associated with pregnancy.

Although preeclampsia might seem easy to diagnose, it has often been mistaken for such varied conditions as acute pancreatitis, gallbladder disease, appendicitis, nephrolithiasis, and glomerulonephritis.[62] Distinguishing between preeclampsia and glomerulonephritis may be difficult. A history of proteinuria and hematuria before the pregnancy strongly suggests an underlying glomerulonephritis. Yet, often the patient's old records are not available. Also, the severity of proteinuria and hematuria can markedly increase during pregnancy. Thus, a renal biopsy may be the only way to distinguish preeclampsia from glomerulonephritis. On biopsy, the histologic change considered specific to preeclampsia, endotheliosis, can help distinguish it from other forms of TMA. A renal biopsy is indicated in suspected preeclampsia before 28 weeks' gestation if the survival of the fetus is desired.[63] In general, the procedure is well tolerated by both mother and fetus.[64]

If left untreated, preeclampsia will progress rapidly to eclampsia, the constellation of signs that result from the development of cerebral edema. These signs include encephalopathy, papilledema, central visual loss, and seizures. Permanent neurologic sequelae, acute cortical necrosis of the kidney, and death may occur. Delivery of the fetus and placenta is considered the treatment of choice for preeclampsia.

Prevention of preeclampsia is a standard aspect of obstetric care. Dipstick assays for proteinuria and measurement of blood pressure are performed at all prenatal visits. The development of hypertension during pregnancy brings closer supervision, with more frequent urine protein screening and measurement of serum uric acid. Antihypertensive therapy is considered if the blood pressure rises above 160/110 mm Hg and is mandated when levels surpass 170/110 mm Hg.[65] The aim of therapy is to keep the mean arterial pressure at 125 to 105 mm Hg and to maintain the diastolic blood pressure at 105 to 90 mm Hg.[62] Currently, hydralazine, nifedipine, α-methyldopa, and labetalol are the preferred agents. ACE inhibitors, which are often used in other kidney diseases, are contraindicated, especially in the second and third trimesters, because of their potential to cause adverse effects in both mother and fetus. Corticosteroids are administered to promote the production of surfactant in the fetus. Magnesium sulfate is used to prevent both seizures and preterm delivery. Compared with placebo, interventions such as oral calcium, aspirin, and salt reduction have not been shown to significantly reduce the incidence of preeclampsia.

Antiphospholipid Syndrome

APS refers to hypercoagulability in the presence of autoantibodies to negatively charged phospholipids. These antibodies have traditionally been believed to cause thrombosis of large arteries and veins and to lead to miscarriages. The full spectrum of disease has now been clarified. Renal involvement is common in APS. Furthermore, when renal involvement occurs, it typically presents as a TMA.

The term antiphospholipid antibodies is actually a misnomer. With the exception of cardiolipin, the target antigens are plasma proteins bound to phospholipids. Antiphospholipid antibodies are currently grouped into four categories,[66,67] although there may be overlap, because the antibodies share antigen affinity. The four subtypes are as follows: (1) anticardiolipin antibodies (ACAs), (2) lupus anticoagulant, (3) anti–β_2-glycoprotein I antibodies, and (4) antiprothrombin antibodies. ACAs were first isolated from patients with syphilis almost 100 years ago. They were later found to be directed against a mitochondrial phospholipid, cardiolipin. Lupus anticoagulant is a group of immunoglobulins originally found in patients with systemic SLE about 50 years ago. Despite its name—which is derived from its in vitro property of slowing thrombin generation—lupus anticoagulant is an in vivo procoagulant. Lupus anticoagulant is directed against plasma proteins (primarily prothrombin, but also annexin and β_2-glycoprotein) bound to negatively charged phospholipids. β_2-glycoprotein I is an important inhibitor of the coagulation cascade. Antibodies to this protein were described nearly a decade ago. Antibodies directed against prothrombin that are different from lupus anticoagulant have been described within the past 5 years.

It is still not clear why antiphospholipid antibodies cause thrombosis. Antiphospholipid antibodies have both procoagulant and anticoagulant effects. Also, it is not known what agents incite the production of these antibodies. Given that β_2-glycoprotein I antibodies may cross-react with bacterial antigens, it may be speculated that exposure to bacterial pathogens and, possibly, viral pathogens induces the formation of these antibodies.

Antiphospholipid antibodies are quite common. They can be found in 1% to 5% of healthy persons.[68] It is not clear whether they cause APS in healthy persons, although epidemiologic studies have shown an association between these antibodies and myocardial infarction (MI), stroke, and venous thrombosis. Between 12% and 30% of patients with SLE have ACA,[69,70] and 15% to 34% have lupus anticoagulant.[69,71] APS may develop in 50% to 70% of patients with lupus and antiphospholipid antibodies.[68,72]

The clinical presentation of APS most often comprises a single thrombotic event in either the arterial or venous system. Deep vein thrombosis of the lower extremities is the most common occurrence. Arterial thrombosis occurs less frequently than venous thrombosis and primarily affects the brain (stroke) or coronary vessels (acute MI). During pregnancy, miscarriage may occur.

A second type of presentation is catastrophic APS, which is a TMA.[67] The kidney is the organ most often affected in these cases, followed by the lung, central nervous system, heart, and skin. Most patients with kidney involvement develop hypertension, and up to 25% develop progressive renal insufficiency, necessitating supportive dialysis. DIC may develop in the setting of catastrophic APS.

The prognosis of APS varies with the clinical severity, and management strategies vary accordingly. In patients who have antiphospholipid antibodies but have never experienced APS, it is not clear whether anticoagulation is indicated for the primary prevention of thrombosis. A careful review should be performed to eliminate conditions or situations that may increase the patient's risk for thrombosis. For example, oral contraceptive use should be discouraged, as should the use of venous catheters in hemodialysis patients. Prophylactic anticoagulation is indicated if the use of oral contraceptives or venous catheters cannot be eliminated.

In patients with antiphospholipid antibodies who have experienced a single episode of thrombosis, anticoagulation with warfarin is indicated for secondary prevention. The therapeutic goal is an INR of 2 to 3; therapy should probably be continued lifelong.

Mortality in patients with catastrophic APS is high—up to 50%. Death generally results from multiorgan failure. Treatment with plasmapheresis and plasma exchange, along with high-dose corticosteroid therapy at doses similar to those used for pulmonary-renal syndrome, has been used. Immunoglobulin therapy may also be tried, in an attempt to bind the offending autoantibody. Outcome data on the efficacy of these interventions for catastrophic APS remain sparse.

Renal Disease Associated with Systemic Sclerosis

Systemic sclerosis is a subtype of the scleroderma disorders, a varied group of diseases that generally share the finding of thickened, sclerotic skin lesions. Several organ systems are involved, including the heart, lungs, gastrointestinal tract, muscles, and kidneys.

Systemic sclerosis is relatively uncommon. In the United States, the prevalence ranges from four to 253 cases per one million population.[73] Females are more commonly affected than males, at a ratio of 3:1 to 8:1.[74] In the United States, there is a slightly higher occurrence in blacks than in whites.[75]

Renal involvement is common in systemic sclerosis. About 10% to 15% of patients with systemic sclerosis experience renal crisis, a syndrome marked by acute renal failure, severe hypertension, encephalopathy, and, in some cases, heart failure. More commonly, patients with systemic sclerosis have less dramatic evidence of renal involvement. Nearly all patients with systemic sclerosis have abnormal renal blood flow,[76] and two thirds have renal vascular lesions.[77] Half of all patients with systemic sclerosis may have hypertension, an elevated plasma creatinine concentration, or proteinuria.[78,79] Important risk factors for the development of renal disease in systemic sclerosis include black race, high-dose corticosteroid use (dosages above 15 mg/day), and diffuse skin involvement.

Most cases of systemic sclerosis are idiopathic. As with most connective tissue diseases, a complex interplay of host and environmental factors is undoubtedly involved. Some cases of systemic sclerosis overlap with other rheumatologic conditions, including SLE, rheumatoid arthritis, and undifferentiated mixed connective tissue disorder. Environmental exposure to organic solvents such as benzene, toluene, and trichloroethylene has been implicated as a secondary cause of systemic sclerosis. The proposed mechanisms have been that these organic solvents are metabolized to epoxy compounds that bind proteins and produce autoantigens[80] or that solvent-induced injury leads to microvascular abnormalities and target-organ fibrosis.[81] However, an extensive review found insufficient evidence to support a causal link between chemicals and systemic sclerosis.[82]

The pathognomonic findings in systemic sclerosis are the irreversible proliferation of connective tissue, mucoid thickening of vascular walls, and narrowing of the vascular lumen. In most cases, the mucoid changes are found in the renal arterioles. In renal crisis, these histopathologic changes are in the arcuate and interlobular arteries and in the glomeruli. Fibrin thrombi are seen in the arterioles and capillaries, as well as in areas of fibrinoid necrosis. Concentric onion-skin hypertrophy of the interlobular arteries results from repeated cycles of disease activity and quiescence.

The diagnosis of renal disease may not be difficult in the setting of established systemic sclerosis. The differential diagnosis includes other types of TMA. Serologic tests are helpful in confirming systemic sclerosis: anti–Scl-70 has a high specificity, albeit low sensitivity. Capillary loss and enlargement on nail-fold capillaroscopy are sensitive and specific.[83] Renal biopsy is not routinely indicated but should be done in atypical cases. For example, there is a small subset of patients who have systemic sclerosis without the typical skin findings (called scleroderma sine scleroderma). Some patients experiencing scleroderma renal crisis may not have elevated blood pressure. Biopsy of the skin or kidney may help confirm the diagnosis in these scenarios.

Scleroderma renal crisis was once deemed a uniformly fatal complication of systemic sclerosis. With the introduction of dialysis therapy, mortality decreased, and the use of pharmacologic therapy brought a further reduction of nearly 50% in morbidity and mortality.

Control of systemic arterial pressure is the cornerstone of therapy in systemic sclerosis with renal crisis. Blood pressure control is best achieved gradually, with reduction in pressure by 10 to 15 mm Hg a day until the diastolic blood pressure reaches 85 to 90 mm Hg. ACE inhibitors are the agents of choice; they have been shown to reduce the risk of ESRD[84] and the need for renal replacement therapy.[85] These benefits may flow from a unique property of this class of drugs or from greater efficacy in reduction of blood pressure. An important caveat is that the majority of studies have used captopril, and thus, the beneficial effect may not occur with other ACE inhibitors or with ARBs. The dihydropyridine calcium channel blocker nifedipine has been suggested as an additional blood pressure agent for patients who show an inadequate response to an ACE inhibitor. Recurrent renal crises are unusual if control of blood pressure is attained.

Malignant Hypertension

Malignant hypertension is defined as a syndrome of acute vascular damage to the kidneys, retina, and brain in the setting of severe elevations of blood pressure. Typically, the systolic blood pressure exceeds 180 mm Hg and the diastolic pressure exceeds 120 mm Hg.

Traditional risk factors for malignant hypertension are male gender, black race, and noncompliance with medication use. The frequency of malignant hypertension has been decreasing. This is likely the result of increased awareness, treatment of hypertension, and access to medical care for minorities.

Histologically, malignant hypertension is marked by diffuse fibrinoid necrosis and intimal thickening of small vessels (arterioles). In the kidney, these changes are indistinguishable from those seen in other TMAs, systemic sclerosis, and preeclampsia. Renal function is typically depressed and can decline rapidly over weeks to months in the absence of treatment.

Current understanding of the pathophysiology of malignant hypertension has focused on the role of the endothelium.[86] During severe elevations of blood pressure, endothelial control of vascular tone is overwhelmed, leading to end-organ hyperperfusion, arteriolar fibrinoid necrosis, and increased endothelial permeability with perivascular edema. The subsequent disruption of the endothelium leads to the loss of its fibrinolytic activity and exposes platelets to cellular adhesion molecules.

The prognosis of patients with malignant hypertension has improved tremendously over the past 40 years. This condition was originally termed malignant because it typically conferred the same abbreviation of life expectancy as an advanced malignancy. It is now known that aggressive blood pressure control with a variety of agents alleviates most of the target-organ damage [*see 1:III Hypertension*]. Initially, there were concerns that reduction of mean arterial pressure would cause progressive azotemia, but studies have instead demonstrated long-term stabilization or improvement of renal function in most cases.

Sickle Cell Disease

Sickle cell disease (SCD) is an autosomal recessive condition that results from the substitution of valine for glutamine at the sixth position of the β-hemoglobin subunit. Persons who are homozygous for sickle hemoglobin are susceptible to sickle cell crisis from capillary occlusion [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*]. Heterozygosity for sickle hemoglobin may provide protection against malaria.

SCD occurs primarily in persons of eastern Mediterranean and sub-Saharan African ancestry. In the United States, SCD predominantly affects the African-American population. SCD is a systemic vascular disease, with morbidity and mortality deriving primarily from vaso-occlusive injury to the lungs, central nervous system, spleen, and kidneys.[87]

Traditionally, hypoxemia has been considered central to the pathophysiology of sickle hemoglobin. Under low partial pressure of oxygen, polymerization of the hemoglobin molecule occurs, leading to the sickling of the erythrocyte; these sickled cells produce stasis and occlusion of capillaries. Recent investigations have also suggested that dysregulation of erythrocyte volume and interaction between the erythrocyte cell membrane and vascular endothelium may also contribute to vaso-occlusive events.[88] Finally, compensatory glomerular hypertrophy may have a role in the proteinuria and renal insufficiency seen in patients with SCD.[89]

a

b

Figure 7 **In an injection microradioangiogram of a normal kidney (*a*), vasa recta radiating into the renal papilla are visible. In contrast, in an injection microradioangiogram from a patient with sickle cell disease (*b*), vasa recta are virtually absent.[62]**

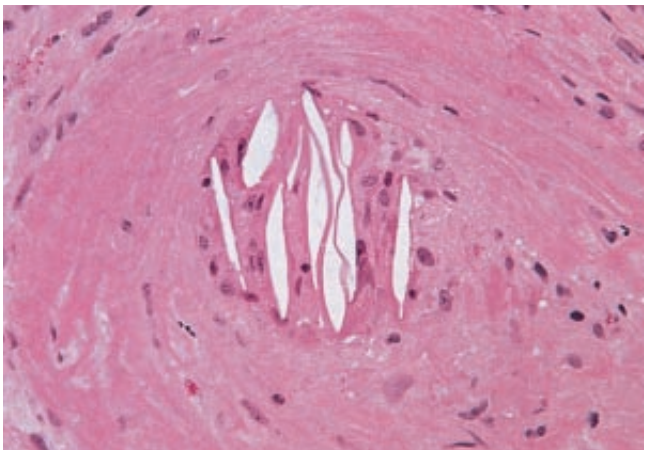

Figure 8 **Light microscopy reveals an atheroembolus lodged in a small renal artery and occlusion of the vascular lumen. The biconcave parallel slits, which represent cholesterol crystals that have dissolved during paraffin fixation, are characteristic of this disorder.**

Renal involvement is relatively common in SCD. The renal medulla, an area of chronic hypoxia, is the principal site of involvement. Stasis of erythrocytes in the vasa recta of the medulla can lead to focal areas of hemorrhage and necrosis and eventually to interstitial inflammation, fibrosis, tubular atrophy, and papillary infarction (necrosis). Over time, these vaso-occlusive events lead to an almost complete loss of the vasa recta [*see Figure 7*].

Three pathologic renal lesions have been described in SCD. Necrosis of the renal papillae is a frequent complication, occurring in 15% to 67% of patients.[90-92] It develops as a result of papillary infarction from repeated vaso-occlusive events. Patients with papillary necrosis may be asymptomatic or may present with gross hematuria and renal failure. Focal segmental glomerulosclerosis (FSGS) is the most common glomerulopathy found in patients with SCD and proteinuria.[93-95] FSGS has been proposed to result from hyperfiltration, exposure to reactive oxygen species, and exposure to filtered plasma proteins. A third pathologic lesion, type I membranoproliferative glomerulopathy, has been described in only a few patients with SCD.[89]

In addition to the pathologic findings, 26% of patients with SCD have proteinuria and up to 7% have some level of renal insufficiency[95]; a significant minority progresses to ESRD. Diminished urinary concentrating ability is almost universal in SCD. Vaso-occlusive episodes in the vasa recta are thought to interfere with countercurrent exchange, leading to a maximum urine osmolality of 400 to 450 mOsm/kg. An incomplete distal renal tubular acidosis may also develop because of impaired hydrogen and potassium secretion.

The diagnosis of renal disease associated with SCD is generally not difficult to make. Renal complications tend to occur late in the course of disease, when the primary diagnosis has already been made [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*].

The prognosis of SCD has improved tremendously over the past 30 years. Sickle cell anemia was initially considered to be a childhood disease, because the vast majority of patients did not survive into adulthood. Survival has been improving, however,[87,96] with a greater proportion of patients reaching young adulthood. Better supportive care, as well as aggressive treatment of infections, may account for the improvement. Induction of fetal hemoglobin production has been a mainstay of therapy. Hydroxyurea, a myelosuppressive antitumor drug, has been shown to reduce the occurrence of acute chest, painful crises, and need for transfusions.[88] Future directions include the development of drugs that may inhibit polymerization of the sickle hemoglobin molecule, bone marrow transplantation, and the introduction of wild type β-hemoglobin via a virus vector.

Atheroembolism

Atheroembolism is a rare condition that affects several vascular beds but, most notably, the small vessels of the kidney. It is characterized by the deposition of cholesterol crystals in glomerular capillaries and arterioles. Other terms for this condition are cholesterol crystal embolization disease, cholesterol atheroembolic disease, and cholesterol embolism.

The epidemiology of atheroembolic disease is not clear.[97] It is not possible to estimate incidence and prevalence in the general population; most information is abstracted from highly selected groups. As a rule of thumb, atheroembolic disease tends to occur in persons with risk factors for atherosclerosis and with extensive generalized atherosclerosis. Thus, risk factors include age over 55 years, hypercholesterolemia, diabetes mellitus and hypertension, peripheral vascular disease, abdominal aortic atherosclerosis, and atherosclerotic RAS. Episodes of atheroembolism almost always follow manipulation of or trauma to an atheromatous plaque. Thus, episodes may occur after arteriography, especially of the large vessels such as the aorta, renal arteries, and coronary arteries, or after thrombolytic therapy. In one study, atheroembolism occurred in 12% of patients undergoing coronary angiography and bypass surgery.[98]

Histologically, the lesion of atheroembolic disease is characterized by the occlusion of arcuate and interlobular arteries (150 to 200 μm in diameter) and glomerular capillaries by embolized cholesterol crystals. The crystals dissolve during routine preparation of tissue but leave a characteristic biconvex, needle-shaped cleft outline, referred to as a ghost [*see Figure 8*]. Initially, infiltration of polymorphonuclear leukocytes and eosinophils is seen around the occluded vessel. Over time, the crystals can attract a mononuclear inflammatory cellular infiltrate, and intimal hyperplasia and perivascular fibrosis of the affected vessels may occur. Recanalization may be observed in the occluded vessel.

Large vessel atherosclerosis is obviously an important component in the pathogenesis of atheroembolic disease. Atheromatous plaques in the aorta and renal arteries are typically the source of the cholesterol emboli to the kidney. Activation of the classic or alternative complement pathways by cholesterol crystals may help explain the inflammatory component of the disease observed on biopsy.

Atheroembolic disease is difficult to diagnose. Cases may occur spontaneously, but most are temporally related to invasive vascular procedures or thrombolytic therapy. However, the temporal relationships to these invasive vascular procedures are variable; the disease may occur immediately after the event or may develop insidiously over a period of weeks or months. Furthermore, patients typically have symptoms and signs involving multiple organs: kidneys (renal insufficiency, proteinuria, hematuria), skin (livedo reticularis, purple toes, gangrene), gastrointestinal tract (anorexia, nausea, bowel ischemia or infarction, pancreatitis, abnormal liver enzymes), nervous system (headache, amaurosis fugax, mononeuropathy, cerebrovascular disease), and eyes (Hollenhorst plaques). Furthermore, nonspecific consti-

tutional symptoms such as fever, malaise, and weight loss are often present and may further obscure the diagnosis. Laboratory findings include a hypocomplementemia (both C3 and C4) and elevated inflammatory markers (ESR, C-reactive protein level); some patients have elevated levels of serum creatinine and blood urea nitrogen, proteinuria, and hematuria.

A practical approach to diagnosis of renal atheroembolic disease is to maintain a high index of suspicion for the disorder in patients with acute renal failure, especially after invasive vascular procedures or thrombolytic therapy. For example, 80% of patients with atheroembolism and renal involvement have a serum creatinine level above 2 mg/dl and hypertension (with worsening control).[99] Cutaneous manifestations that suggest atheroembolism include livedo reticularis and purple digits (especially toes). Low complement levels further strengthen the case for atheroembolic disease. Diagnosis is made by biopsy of affected skin, muscle, or kidney.

The prognosis for patients with atheroembolic disease, especially with renal involvement, is poor. Mortality varies from 60% to 80%.[99] There is no specific therapy for the condition, so treatment usually consists of supportive care (including dialysis).

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VIII TUBULOINTERSTITIAL DISEASES

Gerald B. Appel, m.d.

Overview

Tubulointerstitial diseases involve the tubules and the interstitium (the space between the tubules), rather than the glomeruli and the vasculature of the kidney [*see Figure 1*].[1-3] Tubulointerstitial diseases may be acute or chronic and may present as a primary condition or may be associated with systemic disease. They can cause subtle tubular defects or fulminant renal failure and can lead to structural and functional changes that are either reversible or permanent. Although tubulointerstitial diseases make up only a small percentage of the cases of chronic renal failure and end-stage renal disease in the United States, damage to the tubulointerstitium of the kidney contributes significantly to the progression of most of the important forms of renal disease. Numerous studies have found that in many forms of chronic renal failure, including chronic renal failure of glomerular origin, glomerular filtration correlates better with the degree of tubulointerstitial damage than with the degree of glomerular injury. There are numerous potential mechanisms for tubulointerstitial damage. Some involve immunologic insults (e.g., antibodies directed against tubular basement membrane, immune complex deposition along the tubular basement, or cell-mediated immune responses), whereas other insults relate to toxic damage to tubular cells or other structural components of the interstitium. How these primary insults of tubulointerstitial damage are translated into chronic tubulointerstitial damage and fibrosis is an area of intensive investigation.[4,5]

Specific laboratory findings in patients who have tubulointerstitial diseases reflect the underlying etiology; the extent of injury, whether focal or diffuse; and the chronicity of the insult [*see Table 1*]. The urinary sediment often contains erythrocytes, leukocytes, and white blood cell casts. Proteinuria, when present, predominantly results from loss of low-molecular-weight proteins (e.g., β_2-microglobulin) rather than loss of albumin. Common defects in tubulointerstitial diseases include isolated tubular defects (e.g., renal tubular acidosis, glycosuria, aminoaciduria, potassium wasting or retention, and magnesium wasting) and urinary concentrating defects (manifested by nocturia and polyuria). Hypertension is often less severe than it is in the glomerulonephritides [*see 10:V Glomerular Diseases*]; salt wasting and a predisposition to volume depletion are common findings. Metabolic acidosis, when present, often results from defective ammoniagenesis and is associated with a normal anion gap rather than a high anion gap, which is seen in severe glomerular disease. Findings typical of glomerular disease—heavy albuminuria (> 2 g/day), red blood cell casts, and deformed erythrocytes in the urine sediment—are usually absent in tubulointerstital diseases unless there is associated glomerular pathology.

Drug-Induced Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is a form of acute tubulointerstitial damage that is usually related to drug use and is associated with acute renal failure.[6-8] AIN is found in 1% to 2% of all renal biopsies but in as many as 15% of renal biopsies in patients with acute renal failure.[9] It is important to recognize medication-related AIN because severe or irreversible renal damage is often preventable or correctable. AIN has been associated with an ever-increasing list of medications that can be classified into a number of pharmacologic or functional classes [*see Table 2*].

antibiotic-induced AIN

AIN Caused by β-Lactam Antibiotics

Virtually all β-lactam antibiotics (penicillins and cephalosporins) can produce AIN, but methicillin has been the most common offending agent in this class.[6-8] Neither simple pharmacokinetic studies nor tissue-binding studies explain this predilection. AIN from β-lactam antibiotics can affect both males and females of any age. It usually occurs after several weeks of high-dose antibiotic therapy.

Pathogenesis The pathogenesis of β-lactam–associated AIN remains unknown.[2-4,6-8] The disease is not dose related and occurs in only a small number of the millions of people taking β-lactam drugs each year. It can recur or can be exacerbated on rechallenge with a second β-lactam drug. Only rarely has evidence of circulating anti–tubular basement membrane antibodies been found. The nature of the cellular infiltrates supports a role for cell-mediated or eosinophil-mediated damage. Whether subclinical episodes of AIN contribute to chronic renal failure in some patients is unknown.

Diagnosis Classically, patients exhibit a triad of hypersensitivity reactions: rash, fever, and eosinophilia. The secondary fever associated with AIN usually occurs after defervescence from the original infectious disease and during the onset of the allergic reaction. Eosinophilia may vary from only a few percent to more than 20%. Urinary findings in patients with AIN include the nonspecific findings of sterile pyuria and mild proteinuria, as well as the more significant finding of hematuria, which may be gross in some cases. Eosinophils may be found in the urinary sediment on Wright or Hansel staining and are strongly suggestive of AIN but cannot confirm the diagnosis.[9] Although

Figure 1 **Normal tubulointerstitial architecture can be observed in this micrograph. The tubules, outlined in black by silver stain, are back to back (arrow). The interstitium is the space between these tubules, the vessels, and the glomeruli.**

Table 1 Etiologies of Tubulointerstitial Diseases

- Drug-induced acute interstitial nephritis (AIN)
- Drug-induced chronic interstitial nephritis: analgesic agents, lithium, cisplatin, nitrosoureas, and cyclosporine
- Physical factors: reflux, obstruction, and radiation nephritis
- Infections: pyelonephritis and remote infections
- Metabolites and toxins: heavy metals, urate, calcium, oxalate, and hypokalemia
- Vascular conditions: hypertension, sickle cell anemia, cholesterol emboli, and renal vein thrombosis
- Dysproteinemias
- Cystic renal disease
- Other causes: transplant rejection, Balkan nephropathy, systemic diseases, and idiopathic AIN

eosinophiluria is not specific for AIN (it is also seen in chronic pyelonephritis, rapidly progressive glomerulonephritis, acute interstitial cystitis, prostatitis, and renal atheroemboli), it is highly suggestive of AIN in a patient with acute renal failure.[6-8]

Occasionally, patients experience only isolated renal tubular defects (e.g., Fanconi syndrome, renal tubular acidosis, and potassium excretory defects), but most patients have progressive acute renal failure, with rising blood urea nitrogen (BUN) and serum creatinine levels. Only a minority of patients with AIN are oliguric. Gallium scanning may show diffuse, intense bilateral uptake, whereas it is typically negative in acute tubular necrosis, which is the primary differential diagnosis for AIN.[10]

The histopathology of β-lactam–associated AIN includes edema and focal renal infiltrates that contain predominantly T cells and monocytes.[1,6,8] In cases in which biopsies are done early in the disease course, the infiltrates may include eosinophils, plasma cells, and neutrophils [*see Figures 2 and 3*], with inflammatory cells at times invading the spaces between the cells lining the tubular basement membrane (so-called tubulitis). In some cases, granuloma formation may be seen. Immunofluorescence or electron microscopy seldom reveals any changes.

Treatment β-lactam–associated AIN is treated by discontinuing the drug and avoiding other β-lactam antibiotics.[6-8,11] Most patients regain renal function, and many regain baseline renal function. Even patients requiring dialysis supportive care may regain renal function.

The use of corticosteroids to treat renal failure associated with AIN remains controversial. No randomized, controlled trials have yet proved that corticosteroid therapy has any advantages over discontinuance of medication. Some retrospective reviews suggest improved renal function and less residual interstitial damage in patients treated with a short course of corticosteroids for severe AIN. Other studies have reported no benefit with corticosteroid therapy.

AIN Caused by Other Antibiotics

Other antibiotics associated with a pattern of acute renal failure consistent with AIN include the sulfonamides, the combination of trimethoprim and sulfamethoxazole, vancomycin, and the quinolone antibiotics, including ciprofloxacin.[6-8] They can produce the classic pattern of rash, fever, and eosinophilia. Rifampin is most commonly associated with AIN when used intermittently (several times a week) or on rechallenge after a brief suspension of drug use. The clinical features are acute oliguric renal failure with back and loin pain; the triad of rash, fever, and eosinophilia; and AIN on renal biopsy.

A number of types of diuretics can produce AIN, but prerenal azotemia from volume depletion is a much more common cause of diuretic-induced renal insufficiency. AIN can also result from the use of such drugs as sulfinpyrazone, cimetidine, ranitidine, aminosalicylates (e.g., mesalamine), and allopurinol [*see Table 2*]. Allopurinol may produce a vasculitis or glomerulonephritis concurrently with AIN.

NSAID-INDUCED AIN

The nonsteroidal anti-inflammatory drugs (NSAIDs) produce a unique clinical picture of AIN.[6-8] Patients with the NSAID-induced disorder are typically older and have taken the agent for many weeks or months before the reaction occurs.

Table 2 Drugs Associated with Acute Interstitial Nephritis

β-Lactam Antibiotics
- Methicillin*
- Penicillin G
- Ampicillin
- Flucloxacillin
- Oxacillin
- Nafcillin
- Carbenicillin
- Amoxicillin
- Mezlocillin
- Piperacillin
- Cephalothin
- Cephalexin
- Cephradine
- Cefotaxime
- Cefoxitin
- Cefaclor
- Cefazolin
- Cefotetan

Other Antibiotics
- Sulfonamides*
- Trimethoprim-sulfamethoxazole*
- Rifampin*
- Polymyxin B sulfate
- Ethambutol
- Vancomycin
- Chloramphenicol
- Gentamicin?
- Isoniazid?
- Minocycline
- Aminosalicylic acid
- Ciprofloxacin
- Nitrofurantoin
- Norfloxacin
- Erythromycin
- Spiramycin
- Acyclovir
- Foscarnet

Diuretics
- Thiazides*
- Furosemide
- Chlorthalidone
- Triamterene
- Indapamide

Nonsteroidal Anti-inflammatory Drugs
- Fenoprofen*
- Indomethacin
- Naproxen
- Ibuprofen
- Mefenamic acid
- Tolmetin
- Diflunisal
- Piroxicam
- Diclofenac
- Ketoprofen
- Suprofen
- Sulindac

Other Drugs
- Phenytoin*
- Cimetidine*
- Omeprazole
- Sulfinpyrazone*
- Allopurinol*
- Aspirin
- Carbamazepine
- Clofibrate
- Azathioprine
- Phenylpropanolamine
- Methyldopa
- Phenobarbital
- Interferon alfa
- Floctafenine
- Haloperidol
- Warfarin
- Diazepam
- Valproate
- Chlorprothixene
- Captopril
- Propranolol
- Amphetamines
- Doxepin
- Quinine
- Ranitidine
- Interleukin-2
- Propylthiouracil

*Most common causative agents af AIN. ? May cause AIN.

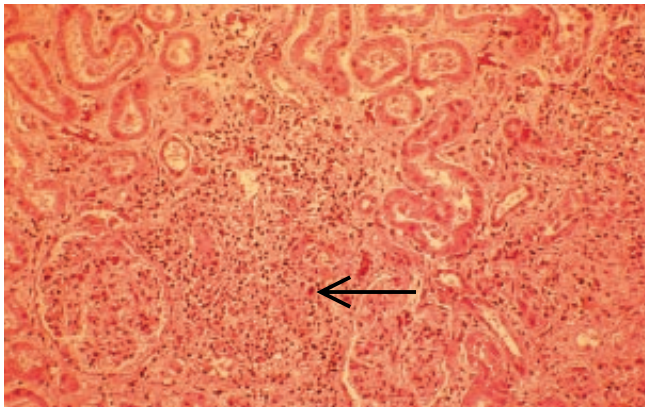

Figure 2 **Acute interstitial nephritis (AIN) caused by a β-lactam antibiotic is apparent in this low-power light micrograph. The patchy infiltrate (arrow) obscures some but not all of the tubular architecture.**

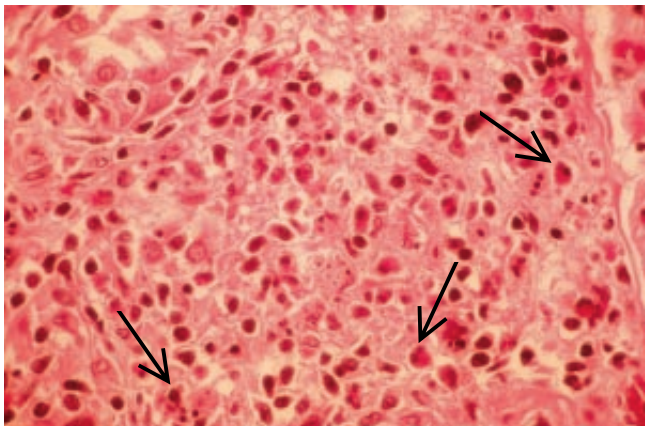

Figure 3 **The pleomorphic infiltrate, including binucleated eosinophils (arrows), which is characteristic of drug-induced AIN, can be seen in this high-power light micrograph.**

Pathogenesis

The pathogenesis of this lesion remains unknown. Studies with monoclonal antibodies have revealed no consistent differences between β-lactam–associated and NSAID-associated AIN in terms of number and types of invading lymphocytes.[12]

Diagnosis

Rash, fever, and eosinophilia may not be present, even when eosinophilic infiltrates are noted on kidney biopsy. The most striking finding is the association of AIN with the glomerular lesions of minimal-change nephrotic syndrome. Although isolated cases of this syndrome have been reported in patients taking ampicillin, rifampin, interferon, or ranitidine, NSAIDs are the only drugs frequently reported to cause AIN associated with a glomerular lesion. This has been reported most frequently with fenoprofen, but it has been seen with many structurally dissimilar NSAIDs, such as the cyclooxygenase-2 (COX-2) inhibitors.[13,14] Light microscopy shows normal glomeruli (fused foot processes are revealed by electron microscopy) and the tubulointerstitial changes of AIN.[2,15]

Treatment

Reversal of renal failure and remission of the nephrotic syndrome usually occur after discontinuance of the NSAID. Some patients with persistent renal failure or unremitting nephrotic syndrome have been treated successfully with a short course of corticosteroids. Membranous nephropathy with or without AIN has been reported in association with NSAIDs, including COX-2 inhibitors.[13,14]

Drug-Induced Chronic Interstitial Nephritis

Certain drugs have been associated with the development of chronic renal insufficiency and chronic interstitial damage. The relation between drug use and renal lesions in chronic interstitial nephritis (CIN) has often been more difficult to define than that in AIN. This difficulty arises from the slower, more insidious nature of the disease process in CIN and from the complex medication regimens of many patients with AIN or CIN who develop renal lesions. Drugs that can cause CIN include analgesic agents such as phenacetin, acetaminophen, and aspirin; lithium; the antineoplastic agents cisplatin, semustine, and carmustine; and cyclosporine.

ANALGESIC NEPHROPATHY

Epidemiology

Analgesic agents in over-the-counter preparations are extensively used, and there is considerable concern and controversy concerning their nephrotoxic potential.[16-19] Epidemiologic studies have provided conflicting reports on the incidence and causal agents of analgesic nephropathy; however, the mixed findings are largely due to the retrospective nature and design limitations of the studies.[15,17,18] The pathogenesis of chronic renal insufficiency and interstitial damage produced by analgesic agents is influenced by social, cultural, and personal factors, as well as by the type and dose of analgesic agent taken and the duration of therapy. The incidence of analgesic nephropathy varies greatly among countries and even within regions of one country. In general, countries with a higher per capita consumption of phenacetin and other analgesic compound combinations have a higher incidence of analgesic nephropathy.[16,19] Studies have documented analgesic nephropathy as a major cause of end-stage renal disease (ESRD), occurring in more than 15% of ESRD patients in some European countries and Australia. Restrictions on the sale and use of phenacetin or analgesic mixtures have led to a dramatic decrease in the incidence of analgesic nephropathy as a cause of ESRD in some European countries and a major decline in the incidence in Australia. In the United States, reports of the prevalence of analgesic nephropathy vary from more than 10% in the southeast to less than 2% elsewhere in the country.

A well-controlled study of more than 600 middle-aged Swiss working women clearly documented a higher incidence of renal insufficiency and increased mortality from urinary tract disease and cardiovascular disease in a population consuming phenacetin.[20] A retrospective, case-control study in North Carolina also found significantly more renal disease in consumers of analgesic agents than in the control population.[21] The risk of renal disease was increased with daily consumption of phenacetin and acetaminophen but not with daily use of aspirin. This study confirms the risk of renal damage with phenacetin (which has since been removed from analgesic preparations in the United States) but also suggests that acetaminophen, a major metabolite of phenacetin, is nephrotoxic as well. Other recent studies have confirmed the association between daily acetaminophen con-

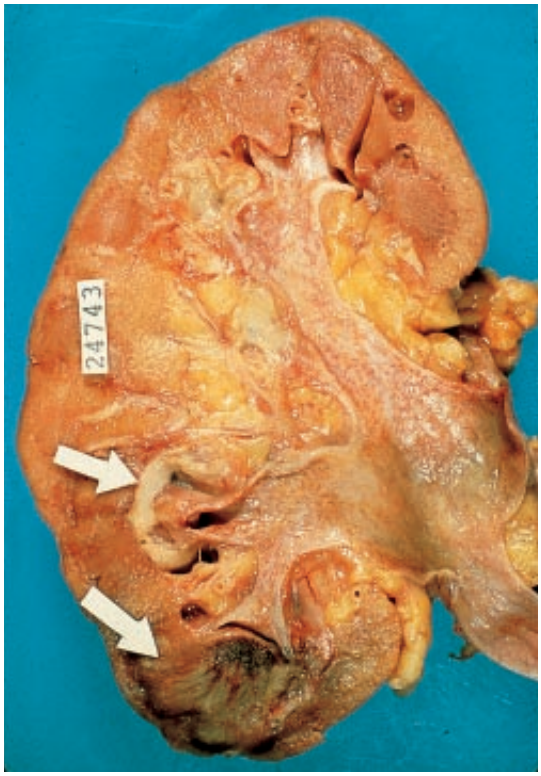

Figure 4 **Areas of renal papillary necrosis (arrows) that developed secondary to analgesic nephropathy and chronic tubulointerstitial nephritis can be observed in this cross section of kidney.**

sumption and the risk of renal failure, although evidence of renal damage from acetaminophen as part of analgesic combinations is much more convincing.[15,17-19,22] One case-control study of almost 1,000 Swedish patients with new-onset renal dysfunction documents the use of acetaminophen as a risk factor for chronic renal failure and provides evidence of increased risk associated with increased dosage.[16]

Pathogenesis

Acetaminophen can accumulate in the renal medulla, where it may be oxidized into reactive intermediates that cause cell necrosis, perhaps through lipid peroxidation. This is especially true when reduced glutathione has been depleted. By inhibiting prostaglandin synthesis and decreasing renal blood flow, some analgesic agents (e.g., aspirin) can further decrease the oxygen supply to the medulla. This decrease, along with salicylate's ability to lower concentrations of reduced glutathione, may account for the potential increased toxicity of analgesic mixtures that contain a combination of phenacetin and aspirin or their metabolites. The findings in the kidneys of patients with analgesic nephropathy reflect this predominant medullary damage. Prominent thickening of the capillaries of the vasa recta is associated with papillary tubular necrosis. Similar capillary changes are found in the renal pelvis and ureters. In later stages, papillary necrosis with associated interstitial fibrosis and chronic inflammatory cell infiltrates are noted.

Most epidemiologic and clinical data suggest that aspirin alone does not cause nephrotoxicity, as is seen with other analgesics. A position paper from an expert panel convened by the National Kidney Foundation concluded that aspirin alone in routine doses in normal persons does not impair renal function, that the habitual consumption of acetaminophen alone should be discouraged, and that the habitual use of analgesic combinations is associated with an increased prevalence of kidney injury and chronic renal failure.[23]

Diagnosis

The typical patient with chronic analgesic nephropathy is a middle-aged woman (four to seven times more women than men have this disorder) who has chronic headaches or arthritic problems and has consumed large amounts of phenacetin, acetaminophen, or aspirin compounds daily for many years. Ingestion of 1 g of analgesic preparations daily for more than 2 years is considered the minimum dosage and time required to produce clinical analgesic nephropathy. Systemic symptoms, such as malaise, weight loss, emotional and psychiatric disorders, anemia, and peptic ulcer disease, may be related in part to analgesic nephropathy and in part to the characteristics of the population that overuses these medications. Diagnosis can be difficult because most patients do not consider over-the-counter preparations to be medications and do not volunteer information regarding their use. NSAID-induced nephropathy is more easily identified than nephropathy caused by acetaminophen, aspirin, and other over-the-counter analgesic drugs; because NSAIDs are frequently prescribed for arthritis, headache, and backache, information on their use may be more readily volunteered by patients [*see* NSAID-Induced Nephropathy, *below*.]

Renal findings are related to chronic interstitial disease and may include nocturia and polyuria, sterile pyuria, urinary tract infections, acidification defects, a predisposition to volume depletion, renal colic and hematuria, and hypertension. Renal insufficiency may be present in asymptomatic patients and is often progressive if analgesic consumption is continued. In rare cases, patients will have flank pain or gross hematuria associated with sloughed or obstructing papillae. Renal papillary necrosis [*see Figure 4*] on intravenous pyelography (IVP) or computed tomography helps establish the diagnosis of analgesic nephropathy.[24]

Ultrasonography is not as sensitive as IVP or CT in the detection of renal papillary necrosis. On noncontrast CT scan of the kidneys, the characteristic findings of analgesic nephropathy are papillary calcifications, decreased renal size, and bumpy renal contours. Patients with analgesic nephropathy also have an increased incidence (up to 8%) of uroepithelial tumors and may have accelerated atherosclerosis. At a late stage of renal dysfunction in analgesic nephropathy, proteinuria and focal glomerulosclerosis can be found, resulting from secondary hemodynamic changes associated with nephron loss.[25]

Treatment

Management of patients with analgesic nephropathy includes total cessation of analgesic use, adequate hydration, and control of hypertension. These measures improve or stabilize renal function in most patients. Regular surveillance of urine cytology will detect uroepithelial tumors, which may arise after discontinuance of the analgesic agent.

NSAID-INDUCED NEPHROPATHY

A number of NSAIDs, including indomethacin, phenylbutazone, ibuprofen, naproxen, ketoprofen, mefenamic acid, and fenoprofen, have been reported to be associated with the development of CIN and renal papillary necrosis. A prospective study of 69 new cases of analgesic nephropathy with papillary

necrosis confirmed by IVP, ultrasonography, or CT found that 42% of the patients had consumed excessive amounts of NSAIDs and that an additional 13% had consumed NSAIDs with other analgesic agents.[26] In contrast to the typical patients with analgesic nephropathy (see above), most of these patients took the NSAIDs as prescribed for arthritis, headache, and backache; male patients outnumbered female patients; and patients did not have emotional or psychiatric symptoms. However, a number of epidemiologic studies have been unable to incriminate long-term use of NSAIDs in the development of CIN. It is likely that only a small percentage of patients with a history of long-term use of NSAIDs develop significant chronic renal damage, and even these may have prior predisposing factors.

LITHIUM-INDUCED CIN

Lithium salts, which are widely used to treat bipolar and affective disorders, have been associated with a number of renal abnormalities—most prominently, a syndrome of nephrogenic diabetes insipidus and polyuria. Although reductions in the glomerular filtration rate (GFR) and development of CIN have been attributed to lithium use, the relation has not been clearly established. Some studies have found that a small percentage of patients given lithium develop an abnormal plasma creatinine level, but other studies have not confirmed this finding. A composite review of studies of almost 500 patients taking lithium found that only 15% to 17% of the patients had a reduced GFR.[27] In patients with a decreased GFR, the reduction was mild; most patients had a GFR of 60 to 75 ml/min. The renal dysfunction in these patients cannot be attributed solely to lithium use, because some psychiatric patients who are not taking lithium also exhibit a reduced GFR and chronic inflammatory changes on renal biopsy. Although early studies failed to document a positive correlation between duration of lithium treatment and the reduction in GFR, studies in which the average duration of lithium treatment was longest (6.5 to 10 years) have noted a positive correlation.[28,29]

A histopathologic study of the renal findings of 24 patients with chronic lithium toxicity clearly defined the biopsy findings.[29] A chronic tubulointerstitial nephropathy was found in every case, in association with cortical and medullary tubular cysts. Distal tubules and collecting ducts were predominantly affected. Many patients had evidence of secondary glomerular focal sclerosis, presumably caused by a hyperfiltration mechanism. Such changes have been noted in both patients with a normal GFR and patients with a decreased GFR.

Prolonged use of lithium for many years is probably associated with some decline in the GFR and with interstitial damage.[28,29] Most patients present with polyuria, nocturia, polydipsia, and elevated BUN and serum creatinine levels. Although the damage is usually mild to moderate, some studies indicate that patients with serum creatinine levels greater than 2.5 mg/dl typically progress to renal failure even after discontinuing lithium.[27,29] The contribution to renal disease of other psychotropic medications or other factors associated with affective disorders is not known. Discontinuance of lithium in patients with less severe renal impairment often leads to stabilization of kidney function.

CHEMOTHERAPY-INDUCED CIN

Most patients with chemotherapy-induced CIN present with asymptomatic worsening of renal function and elevated BUN and creatinine levels. Cisplatin, an antineoplastic agent that is widely used to treat carcinomas and germ cell tumors, may cause acute renal failure and, less frequently, chronic renal insufficiency.[30,31] Cisplatin therapy results in a decrease in glomerular filtration rate in 20% to 30% of patients receiving the drug, and a long-term decrease in renal function is present in up to 20%. Interstitial fibrosis and chronic inflammatory changes have been noted on renal biopsy in patients with chronic renal damage. Only in rare instances has renal failure been reported with the newer agent carboplatin.[32] Studies have shown that the tubulointerstitial damage caused by cisplatin also causes renal salt wasting (leading to orthostatic hypotension) and magnesium wasting (leading to hypomagnesemia and hypocalcemia).[30,31] Hypertension develops in up to 25% of patients receiving cisplatin-based chemotherapy and may contribute to chronic renal damage.

Ifosfamide, a synthetic analogue of cyclophosphamide that is used in treating sarcomas and germ cell tumors, can produce acute renal dysfunction, tubular defects, and chronic renal insufficiency with tubulointerstitial damage.[33,34] The major metabolite of the drug, chloroacetaldehyde, is nephrotoxic to renal tubular cells. Although acute renal dysfunction is usually reversible, chronic renal insufficiency requiring dialysis has been documented.[33,34]

Multiple agents of the nitrosourea class of antineoplastic drugs can produce dose-related nephrotoxicity and CIN. Carmustine (BCNU), semustine (methyl-CCNU), lomustine (CCNU), and streptozotocin have all been reported to cause chronic renal damage. Renal biopsies from patients who sustained renal damage after taking these drugs have shown severe tubular atrophy, glomerulosclerosis, and interstitial fibrosis with chronic inflammatory infiltrates. In some patients, the chronic tubulointerstitial damage has led to ESRD.

Therapy, as in other forms of drug-induced CIN, involves discontinuance of the offending agent and avoidance of other nephrotoxins.

CIN CAUSED BY CYCLOSPORINE AND TACROLIMUS

Cyclosporine and tacrolimus are potent immunosuppressive agents that are widely used in transplantation. Cyclosporine can cause not only acute renal damage but also chronic tubulointerstitial fibrosis.[35,36] The fibrosis usually occurs after months of treatment and is often associated with drug-related obliterative arteriolopathy and microvascular damage to the renal arterioles. The tubulointerstitial damage may occur in a bandlike pattern in the kidney (so-called striped fibrosis). Secondary scarring of the glomeruli may also be present. This damage has been seen both in transplant populations and in patients without prior renal disease who are taking cyclosporine for autoimmune disorders.[37] In patients with autoimmune diseases, the likelihood that cyclosporine nephrotoxicity will develop increases with older age, a higher daily dose of the drug, and a greater initial rise in the serum creatinine level from baseline when drug therapy is started. The disorder is usually associated with a decreased GFR and progressive renal insufficiency.

Although many therapies have been suggested to ameliorate nephrotoxicity caused by cyclosporine, the only treatment that provides consistent results is a reduction in the dose of the drug, which often leads to some improvement in GFR.[38] Tacrolimus has been shown to have acute and chronic nephrotoxicities similar to those associated with cyclosporine.[39] Reduction in drug dose is the recommended treatment to ameliorate nephrotoxicity.

Interstitial Damage Resulting from Physical Factors

OBSTRUCTIVE NEPHROPATHY

Obstructive nephropathy results from the impaired outflow of urine.[40] Although urinary obstruction may cause acute renal failure, it may also produce chronic interstitial damage, especially when the obstruction is partial or intermittent and long-standing. Obstructive nephropathy from congenital abnormalities is common in children but in persons older than 60 years, benign prostatic hypertrophy and prostatic and gynecologic cancers are more common etiologies. Although obstruction from stones, clots, and strictures usually leads to acute renal failure, such obstructions can also produce chronic tubulointerstitial damage to the kidney. Less common causes of slow chronic obstruction (e.g., ureteropelvic junction obstruction and retroperitoneal fibrosis) are often associated with chronic tubulointerstitital damage and renal insufficiency.[41]

Pathogenesis

The pathophysiology of obstructive nephropathy involves increased intratubular pressure, local ischemia, and, often, associated infection, which combine to produce tubulointerstitial damage.[40] Infiltration by inflammatory T cells and macrophages, an autoimmune response to refluxed urinary Tamm-Horsfall mucoprotein (a protein produced by cells of the ascending limb of the loop of Henle), and vasoactive hormones may all play a role in renal damage. The pathologic findings consist of dilatation of the collecting ducts and distal tubules, along with chronic tubular atrophy with little glomerular damage.

Diagnosis

Most patients with tubulointerstitial damage caused by obstruction present with symptoms related to the decreased GFR or to tubular defects, such as loss of urinary concentrating ability (polyuria and nocturia), hyperkalemia associated with a type 4 renal tubular acidosis, or salt wasting that predisposes to volume depletion. Pain is not a prominent symptom of slowly developing obstructive nephropathy but, rather, is a feature of acute distention of the bladder, collecting system, or renal capsule. The diagnosis of obstructive nephropathy is typically based on evidence of renal dysfunction and blockage of urine outflow in the absence of other causes of renal damage. Ultrasonography usually shows dilatation of the urinary collecting system and hydronephrosis. In some patients, CT scanning or IVP will be helpful to delineate the location and nature of the obstruction.

Treatment

Treatment of obstructive nephropathy consists of relieving the obstruction. Every effort should be made to rapidly diagnose and correct any obstruction; data from animal models and human studies have demonstrated return of considerable renal function, even after prolonged partial obstruction of a single kidney.

REFLUX NEPHROPATHY

The abnormal backflow of urine from the bladder into the upper urinary tract (i.e., vesicoureteral reflux) can cause chronic tubulointerstitial damage, known as reflux nephropathy.[42-44] Various anatomic factors appear to play a role in incompetence at the vesicoureteral junction. A number of these factors have been defined: a shortened ureteral intravesicular submucosal tunnel, abnormal amounts or types of muscle fibers around the intravesicular ureter, an abnormality of the trigone, and chronic increased intravesicular pressure without other factors. In each case, the incompetent vesicoureteral junction allows urine to reflux into the ureters and collecting system of the kidneys. The reflux may be unilateral or bilateral, and the severity is variable. When infection is present, even low-pressure refluxed urine that reaches the kidney can produce chronic interstitial inflammation and scarring. However, it is unclear whether repeated episodes of high-pressure sterile reflux alone can damage the kidney. An autoimmune inflammatory response to refluxed Tamm-Horsfall mucoprotein has been proposed as one mechanism of renal damage from sterile reflux.

Reflux in young children causes irregular scars at the poles of the kidney, where compound papillae allow the higher pressures in the urinary collecting system to be directly transmitted to the renal parenchyma.[42,44] The areas of scarring are associated with tubulointerstitial fibrosis overlying deformed calyxes of the collecting system. Glomeruli show only minor changes until there has been considerable parenchymal damage. At this point, the glomeruli exhibit focal segmental glomerulosclerosis from hyperfiltration and hemodynamic changes. There is often a poor relation between the severity of a patient's symptoms, the degree of reflux, and the number of infections the patient has experienced.

Diagnosis

Presenting features of reflux nephropathy can include signs or symptoms of urinary tract infection such as back or flank pain, fever, and dysuria. Hypertension, when present, is often associated with high levels of renin, which may derive from the segmental areas of scarred parenchyma. Patients often have a urinary concentrating defect, leading to nocturia and polyuria. Proteinuria is mild unless the patient has developed advanced renal insufficiency, with glomerular hyperfiltration, and focal segmental glomerulosclerosis.[42-44]

Diagnosis of reflux nephropathy is based on evidence of the reflux of urine and on characteristic parenchymal and clinical findings. Reflux is demonstrated with a voiding cystourethrogram, either with contrast agents or by radionuclide scanning. Because urinary tract infection may be associated with reflux, it is best to wait several weeks after treating a urinary tract infection before trying to diagnose reflux nephropathy.

Treatment

The treatment of low-grade reflux (i.e., reflux without major dilatation of the collecting system) is medical: long-term antibiotic therapy is used to sterilize the urine and prevent reinfection. Many persons with such mild reflux undergo spontaneous remission with time.[45] More severe reflux (i.e., reflux with major dilatation of the collecting system) may require surgical intervention, although most comparative studies have not found an advantage with surgical intervention over medical therapy.[46] In general, patients with proteinuria (> 1.5 g/day), a very depressed GFR, and large amounts of renal scarring show little response to such interventions and go on to develop progressive renal failure.

RADIATION NEPHRITIS

Radiation-induced renal damage is a rare form of tubulointerstitial damage that occurs when the kidneys are exposed to high doses of radiation over a short period. The incidence of ra-

diation nephritis has greatly declined with the ability to precisely deliver high-dose radiation to a given abdominal port and with better shielding of the kidneys from radiation exposure. Current cases usually occur in patients who received high-dose, diffuse abdominal radiation, often in combination with radiomimetic chemotherapeutic agents.[47] The pathogenesis of radiation nephritis remains unknown.

The clinical picture produced by radiation damage has been divided into a number of distinct syndromes, including acute radiation nephritis; chronic radiation nephritis; and radiation-related hypertension (mild or severe), proteinuria, or both. There is often no clear clinical or pathologic distinction between these entities, however. Acute radiation nephritis occurs 6 to 12 months after exposure to radiation and is characterized by severe hypertension, salt retention and edema, mild hematuria and proteinuria (usually < 2 g/day), and renal dysfunction (i.e., reduced GFR). Anemia may be out of proportion to the degree of depression of the GFR. Chronic radiation damage occurs in patients who have survived acute radiation damage or in those who received smaller radiation doses (500 to 1,000 cGy) over longer periods. Clinical manifestations may appear years after radiation exposure, with the insidious onset of hypertension, renal dysfunction, a urinary concentrating defect, and mild to moderate proteinuria (< 2 g/day). Some patients manifest mild or severe hypertension or isolated proteinuria after radiation exposure. In some cases, hypertension has been documented to be caused by renin oversecretion by the shrunken, irradiated kidney; this condition has responded to uninephrectomy.

On histopathologic examination, kidneys affected by radiation nephritis typically show damage to all structural components. There may be various degrees of glomerular proliferation or sclerosis, tubular degeneration and atrophy, fibrinoid necrosis and intimal proliferation of the small arteries and arterioles, and interstitial edema and fibrosis. The only treatment for radiation nephritis entails control of hypertension. Preventing the development of radiation nephritis by appropriate delivery of radiation, with shielding of the kidneys, is crucial.

Infectious Tubulointerstitial Nephritis

Infectious agents can produce acute and chronic tubulointerstitial damage. Some organisms directly invade the normal kidney, leading to acute bacterial pyelonephritis. Other organisms invade the kidney when obstruction or urinary reflux is present, contributing to tubulointerstitial damage in the form of chronic pyelonephritis. Some systemic infections lead to an acute interstitial reaction without direct invasion of the renal parenchyma. The diagnosis and treatment of urinary tract infections are covered elsewhere [*see 7:XXIII Infections of the Urinary Tract*], but the relation between these infections and structural renal damage is important to understand.

Acute Bacterial Pyelonephritis

Acute bacterial pyelonephritis accounts for over 250,000 hospital admissions in the United States annually. It is characterized by fever, chills, sweating, and flank, back, or abdominal pain.[48] It may be associated with dysuria, frequency, urgency, and other symptoms related to lower urinary tract infection. Pyuria, hematuria, and leukocyte casts in the urine sediment are often present. Urine cultures are usually positive, and blood cultures are positive in 10% to 20% of cases. The histopathology reveals patchy areas of edema and acute inflammatory cell infiltrates (polymorphonuclear cells, lymphocytes, and other cell types) that obliterate the normal tubulointerstitial architecture. There is tubular atrophy and necrosis in these areas; tubulointerstitial areas remote from the infection may appear normal. Most cases of acute bacterial pyelonephritis that occur in previously normal kidneys resolve after antibiotic therapy without residual damage. In rare instances, chronic pyelonephritic changes result from repeated or unresolved cases of acute infection in unobstructed and nonrefluxing kidneys.

Chronic Pyelonephritis

Chronic pyelonephritis, a term misused in the past to describe kidneys with tubulointerstitial damage of many causes, properly refers to the chronic damage caused by infection of the pyelocalyceal system and renal parenchyma.[49] Chronic pyelonephritis often presents insidiously with signs of chronic infection or renal insufficiency. Thus, some patients may experience dysuria, fever, and vague flank or back pain, whereas others may exhibit hypertension, salt wasting, a urinary concentrating defect, and hyperkalemia. The urinary sediment usually contains leukocytes, leukocyte casts, and broad casts, which denote chronicity of the tubulointerstitial process. Chronic pyelonephritis is most often the result of chronic or repeated bacterial infection complicating vesicoureteral reflux, but it may also be the result of infection complicating preexisting obstruction or structural renal problems. The kidneys are often contracted, with asymmetrical cortical scars corresponding to deformity of the underlying calyceal system. The histopathology is characterized by tubular atrophy and interstitial fibrosis, with a chronic inflammatory infiltrate of lymphocytes and mononuclear cells.

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis refers to an unusual form of localized chronic bacterial renal infection. Characterized by inflammation and granuloma formation with lipid-laden macrophages, xanthogranulomatous pyelonephritis is typically found in obstructed kidneys containing stones. Symptoms may include those of acute bacterial pyelonephritis (see above), as well as hypertension; in many patients, a palpable mass is present.[48] The kidney, which may be nonfunctional, contains a localized abscessed area that may be mistaken for a tumor on intravenous urography. CT and magnetic resonance imaging may help clarify the diagnosis. Most patients have a positive urine culture; often, more than one organism is present. The pathogenesis of xanthogranulomatous pyelonephritis is unknown. Treatment consists of antibiotic therapy and surgical resection of the abscessed area.

Interstitial Inflammation Secondary to Systemic Infection

Infections remote from the kidney may be associated with an acute interstitial inflammatory reaction.[6] This adverse renal reaction has been associated with bacterial, viral, and parasitic infections, including streptococcal infections, diphtheria, leptospirosis, leishmaniasis, toxoplasmosis, infectious mononucleosis, Epstein-Barr virus infection, measles, brucellosis, syphilis, mycoplasmal pneumonia, HIV infections, Kawasaki disease, and Legionnaires disease. Some infectious agents, such as those responsible for leptospirosis, mycobacterial infections, cytomegalovirus infection, Rocky Mountain spotted fever, and hantavirus infection, may directly infect the kidney and cause interstitial inflammation during the course of systemic infection.

The acute inflammatory infiltrate can be composed of lymphocytes, plasma cells, monocytes, and polymorphonuclear cells, but eosinophils are not commonly found. The acute renal dysfunction is manifested by an acute decrease in the GFR or isolated tubular defects. All manifestations generally resolve if the systemic infection is successfully treated.

VIRAL-RELATED TUBULOINTERSTITIAL NEPHRITIS IN IMMUNOSUPPRESSED PATIENTS

Although viral infections can cause tubulointerstitial disease by direct invasion of the kidney or remote effects, certain forms of viral-related tubulointerstitial nephritis warrant special comment. Certain polyomaviruses (e.g., BK virus and JC virus) can cause tubulointerstitial disease in immunosuppressed patients with organ transplants or HIV infection.[50-52] Tubulointerstitial nephritis may mimic renal transplant rejection, and the increased immunosuppression used for rejection may worsen the renal dysfunction. Also, although HIV infection is classically associated with a glomerular lesion of a collapsing form of focal sclerosis, tubulointerstitial disease may be prominent in this entity.[53] Microcystic dilatation of the tubules is responsible for the large echogenic kidneys seen in HIV-associated nephropathy.

Metabolic and Toxic Tubulointerstitial Nephritis

A number of metabolic disturbances, including disorders affecting the metabolism of oxalate, calcium, uric acid, and potassium, can produce renal tubulointerstitial abnormalities. Exposure to certain heavy metals, such as lead and cadmium, can also produce chronic renal damage.

HYPEROXALURIA

Oxalic acid is a dicarboxylic end product of metabolism that is removed from the body only by renal excretion. Normal urinary excretion is between 15 and 50 mg daily. Oxalate is highly insoluble when combined with calcium, and urinary excretion of oxalate in amounts greater than normal readily exceeds the solubility product for calcium oxalate. Precipitation of calcium oxalate can produce nephrolithiasis, acute renal failure, or chronic tubulointerstitial damage. The histopathology of chronic tubulointerstitial damage from oxalate deposition shows calcium oxalate crystals (which are birefringent under polarizing light) in the tubular lumina and the interstitium, surrounded by inflammation (which may include giant cells) and interstitial fibrosis.

Excessive oxalate excretion can result from two genetic disorders: primary hyperoxaluria 1 and 2 (PHO1 and PHO2).[54-56] Both are caused by autosomal recessive enzymatic defects in the metabolic pathway of glyoxylic acid. In each disorder, the excretion of oxalate typically ranges from 100 mg to more than 250 mg daily. PHO1 is the more common disorder; a defective gene on chromosome 2 causes a deficiency of the hepatic enzyme alanine-glyoxylate aminotransferase that leads to excessive excretion of glycolate, glyoxylate, and oxalate. Calcium oxalate precipitates in the kidney, cardiac system, joints, peripheral blood vessels, and other organs. Patients may have hematuria, renal colic from oxalate stones, livedo reticularis, urinary tract infections and pyuria, hypertension, and renal tubular acidosis. Most patients develop ESRD by 20 years of age. PHO2 is much rarer; it is caused by a deficiency of D-glycerate dehydrogenase and glyoxalate reductase that leads to excessive excretion of oxalate and L-glycerate. It also leads to nephrolithiasis and renal insufficiency. The treatment of choice for many patients is combined liver-kidney transplantation.[57,58]

Metabolism of exogenous substances into oxalate or excessive absorption of oxalate from the gut may also cause oxalate-induced damage.[59] Ethylene glycol ingestion and methoxyflurane anesthesia, although usually associated with acute renal failure, may cause residual tubulointerstitial damage in patients who recover from the acute event. Patients who ingest large amounts of ascorbic acid may metabolize it to glyoxylate and oxalate, causing both stones and renal damage. Patients with steatorrhea resulting from various intestinal diseases—including celiac disease, Crohn disease, Wilson disease, and chronic pancreatitis—or from small bowel resection or bypass operations for obesity may hyperabsorb oxalate from the large bowel. The pathogenesis of oxalate hyperabsorption involves abnormal binding of intraluminal gut calcium to fats, freeing more oxalate for absorption. In addition, the solubilizing effect of bile acids on the large bowel permits greater absorption of oxalate. The result can be nephrolithiasis, acute renal insufficiency, or chronic tubulointerstitial damage.

The treatment of chronic renal damage from oxalate deposition is correction of the primary cause when possible (e.g., stopping excessive ascorbic acid ingestion or preventing steatorrhea in a gastrointestinal disorder). Other measures include following a low-oxalate diet, increasing intake of fluids to increase urinary volume, increasing oral calcium intake to bind gut oxalate, and taking pyridoxine supplements.

HYPERURICEMIA AND HYPERURICOSURIA

Hyperuricemia and hyperuricosuria can lead to uric acid nephrolithiasis and acute oliguric renal failure from urate deposition. These conditions occur after massive release of uric acid, as in tumor lysis syndrome, or chronic renal failure. Chronic urate nephropathy is characterized by urate crystal deposition in the interstitium accompanied by tubular atrophy, chronic inflammatory infiltrates, and fibrosis. It is unclear whether patients with long-standing gout or chronic asymptomatic hyperuricemia have a higher incidence of chronic tubulointerstitial damage from excretion of urate. It was thought that patients with gout or asymptomatic hyperuricemia who experienced renal dysfunction had gouty nephropathy, characterized by urate crystal deposition in the interstitium accompanied by tubular atrophy. Studies suggest, however, that much of the renal dysfunction seen in patients with gout or chronic hyperuricemia can be explained by concurrent hypertension, ischemia, diabetes, and other causes of renal damage. Some patients are shown to have excessive lead concentrations when tested by ethylenediaminetetraacetic acid (EDTA) loading. It has been suggested that these patients actually have chronic lead nephropathy (see below) rather than gouty nephropathy. Moreover, many tubulointerstitial diseases are associated with decreased urate excretion and thus with a higher incidence of hyperuricemia and gout. However, recent evidence supports a primary role for uric acid in renal damage.[60] Chronic hyperuricemia and gout are only two of a number of contributing factors to produce chronic renal damage; thus, therapy should focus on all aspects of this multifactorial disorder and not just on lowering the uric acid level.

HYPERCALCEMIA AND HYPERCALCIURIA

Hypercalcemia and hypercalciuria can also produce a number of adverse renal effects. Hypercalcemia may contribute to hypertension by causing vasoconstriction, may cause nephroli-

thiasis and vasopressin-resistant urinary concentrating defects, and may lead to chronic tubulointerstitial damage. In primary hyperparathyroidism, renal insufficiency is related to the degree and duration of the hypercalcemia. Chronic elevations of the calcium level can lead to calcium salt deposition in the tubules and interstitial regions, associated with chronic interstitial inflammation, tubular atrophy, and fibrosis. Some patients exhibit only a reduced GFR, whereas others exhibit polyuria and nocturia from the concentrating defect, salt wasting, loss of urinary magnesium or potassium, and renal tubular acidosis or hypertension.

CHRONIC HYPOKALEMIA

Persistently low levels of serum potassium, as seen in patients who abuse laxatives or diuretics or who have chronic hyperaldosteronism, have been associated with structural and physiologic changes in the kidney. In animal models, chronic hypokalemia can lead to tubulointerstitial damage. In humans, chronic hypokalemia is associated with prominent vacuolation of the proximal tubular cells caused by dilated intercellular spaces, basal infoldings, or dilated cisternae of the endoplasmic reticulum. Chronic hypokalemia is associated with impaired urinary concentration, impaired ability to conserve salt on a low-salt diet, and hypertension from impaired ability to excrete a salt load. It is unclear how often uncomplicated chronic hypokalemia leads to chronic tubulointerstitial damage. Interstitial inflammatory changes and fibrosis have been noted on kidney biopsies of patients with chronic hypokalemia, and renal medullary cysts may form. The mechanisms involved in cyst formation are unknown but may relate to excess ammoniagenesis or growth factors and cytokine production.[61,62]

NEPHROTOXICITY CAUSED BY LEAD OR CADMIUM EXPOSURE

Two heavy metals, lead and cadmium, clearly produce tubulointerstitial damage. A number of other metals and elements that cause acute tubular damage and acute renal failure (e.g., mercury or arsenic) may be associated with residual tubulointerstitial damage after the patient recovers from acute exposure.

Lead-Induced Nephrotoxicity

Etiology and pathogenesis Exposure to lead can occur from ingestion of lead-based paints, storage of alcoholic beverages in crystal decanters made with lead, production of moonshine whiskey in a lead-containing still, the manufacture or destruction of lead batteries, or ingestion of lead-containing aerosols in the workplace. Lead accumulates in the proximal tubules of the kidney and can lead to cell damage and tubular defects, such as Fanconi syndrome, aminoaciduria, and renal glycosuria. Observational studies suggest that chronic low-level exposure over years may result in a decreased GFR.[63,64] Long-term lead exposure can result in chronic tubulointerstitial nephritis and renal insufficiency, hypertension, and saturnine gout from reduced renal excretion of uric acid. Epidemiologic studies confirm an inverse relation between blood lead levels and renal function.[63,65] Long-term exposure induces progressive tubular atrophy, fibrosis, and chronic renal failure.

Diagnosis Although acute lead toxicity is associated with abdominal pain, anemia, and encephalopathy, these findings are not usually present in lead nephropathy, which presents as hypertension and insidious renal dysfunction. The histopathology of lead nephropathy resembles that of CIN. The diagnosis of lead-induced nephrotoxicity cannot be made from serum levels, but it can be made by demonstrating excessive urinary excretion of chelated lead after an intravenous or intramuscular injection of EDTA.[66] Because hypertension and hyperuricemia are common in patients with this condition, it is easy to confuse the diagnosis of lead nephropathy with hypertensive nephrosclerosis or chronic urate nephropathy.

Treatment Chelation therapy with EDTA or oral succimer (2,3-dimercaptosuccinic acid) may slow the progression of renal insufficiency in chronic lead tubulointerstitial damage.[66]

Cadmium-Induced Nephrotoxicity

Cadmium, used in metallurgy, can produce chronic tubulointerstitial damage after prolonged exposure.[67,68] Some patients have tubular defects such as Fanconi syndrome, glycosuria, aminoaciduria, and tubular proteinuria with β_2-microglobulin excretion. Other patients have a decreased GFR. The diagnosis is based on evidence of excessive urinary cadmium levels. There is no specific treatment for cadmium nephrotoxicity.

CHINESE-HERB NEPHROTOXICITY

Certain Chinese herbs, many used in weight-reduction programs, have been associated with tubulointerstitial nephritis and progression to renal failure.[69,70] Over 100 cases have been reported, and many have progressed to dialysis and transplantation.[70] Additional agents, such as appetite suppressants (e.g., fenfluramine and diethylpropion) with vasoconstrictive properties, were ingested by some of the affected patients and may have contributed to the renal interstitial damage.

The pathogenesis, although incompletely understood, may relate to a plant nephrotoxin aristolochic acid, which can produce similar interstitial fibrosis in animal models.[71]

Patients with Chinese-herb nephrotoxicity present with renal insufficiency, mild hypertension, mild proteinuria (< 1.5 g/day), and bland urinary sediment. On biopsy there is extensive cortical interstitial fibrosis with atrophy and tubular dropout and only a sparse interstitial inflammatory infiltrate. There is a high incidence of uroepithelial carcinomas of the genitourinary tract in patients with Chinese-herb nephropathy.[72]

There is no proven therapy for this form of tubulointerstitial nephropathy, but an uncontrolled report has shown that corticosteroids may slow the progression.[70]

Interstitial Disease Associated with Vascular Damage

HYPERTENSION

Hypertensive nephrosclerosis is first associated with changes predominantly in the renal interlobular and afferent arterioles. Subsequent ischemia can lead to glomerular lesions, as well as to tubular atrophy and interstitial damage characterized by patchy, chronic inflammatory changes and fibrosis in the renal cortex. The renal medulla is often spared, in contrast to what occurs in chronic pyelonephritis. Malignant or accelerated hypertension is commonly associated with such interstitial changes. Hypertension is the primary clinical finding; laboratory tests usually reveal azotemia and proteinuria that is rarely in the nephrotic range.

SICKLE CELL ANEMIA

Patients with sickle cell anemia and other hemoglobinopathies can demonstrate various physiologic, morphologic, and clinical renal manifestations.[73,74] Almost 8% of African Americans

carry the sickle cell trait, and 0.2% have sickle cell disease. Other African Americans have sickle cell–hemoglobin C disease or other hemoglobinopathies associated with altered red blood cell deformity.

Children and teenagers with sickle cell disease may present with some clinical renal abnormalities, but the spectrum of tubulointerstitial abnormalities is typically revealed in adults. Sickled erythrocytes impair blood flow in the renal microcirculation, as in other organs, leading to local ischemia and infarction. Ischemia is prominent in the hypertonic, acidotic, relatively hypoxemic environment of the vasa recta of the renal medulla. Medullary renal infarction leads to areas of tubular necrosis and interstitial fibrosis and, eventually, papillary necrosis. Patients with sickle cell disease exhibit impaired urinary concentrating ability, leading to polyuria and nocturia. Fluid and volume loss predispose to acute declines in the GFR when intercurrent illness prevents adequate fluid intake to match urinary losses. Microscopic and gross hematuria are common, resulting from microinfarcts in the renal medulla. A distal or type 4 renal tubular acidosis, with hyperchloremic metabolic acidosis and impaired potassium excretion, is often found in adults with sickle cell disease. Papillary necrosis occurs in most adults with this disease but only rarely leads to obstructive uropathy from a sloughed papilla or to major declines in the GFR. In rare instances, patients with sickle cell disease develop ESRD, but such patients usually have an associated glomerular lesion or large-vessel renal infarcts. Sickle cell nephropathy has been associated with the rare renal neoplasm of renal medullary carcinoma.[75]

The treatment of sickle cell nephropathy entails correction of volume depletion and electrolyte imbalances.[73-75] Episodes of gross hematuria should be investigated to rule out associated urinary tract pathology, but most patients require only symptomatic treatment, with hydration and transfusion to correct blood loss and raise the concentration of nonsickling erythrocytes. Nephrectomy should be avoided because the hematuria is usually self-limited and because patients may develop gross hematuria from the other kidney.

CHOLESTEROL EMBOLI

Cholesterol embolization may cause both acute and chronic renal insufficiency and is associated with damage to both glomeruli and the tubulointerstitial region of the kidney.[76-78] Atheromatous renal emboli containing cholesterol crystals may occur spontaneously in older patients with severe atherosclerotic plaques of the aorta and major vessels. Cholesterol emboli may also occur in patients undergoing angiographic or vascular surgical procedures. The number of renal cholesterol emboli found at autopsy parallels the degree of aortic atherosclerosis of the person.

Symptoms and signs of embolization include fever, myalgias, lower-extremity livedo reticularis, petechial skin lesions, digital ischemia, and amaurosis fugax and other fleeting neurologic deficits. Patients may have bland urinary sediment or microhematuria, leukocytosis, transient eosinophilia or eosinophiluria, hypocomplementemia, thrombocytopenia, and an elevated erythrocyte sedimentation rate. Most patients present with progressive renal dysfunction over months to years. When cholesterol embolization is associated with a surgical or angiographic procedure, patients typically develop hypertension and progressive renal insufficiency, with rising BUN and serum creatinine levels, several weeks after the procedure.

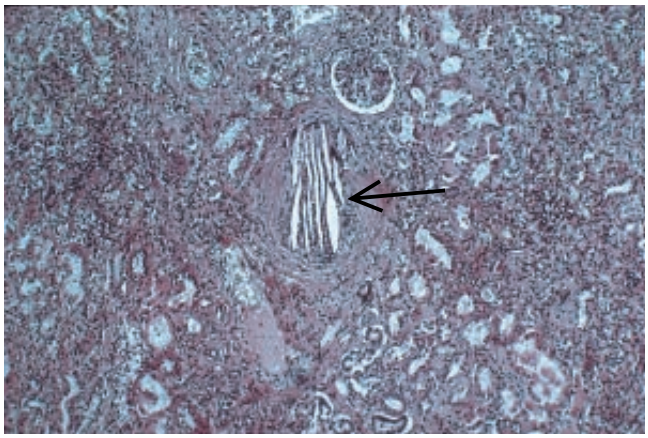

Figure 5 **Cholesterol emboli (arrow) can be seen occluding a medium-sized vessel; an intense interstitial inflammatory reaction is also apparent in the surrounding interstitial area.**

Cholesterol emboli can produce a spectrum of renal function impairments, ranging from mild, stable renal insufficiency to end-stage renal failure. The characteristic histopathologic finding is occlusion of the lumina of the small arteries and arterioles by atheromatous debris. Cholesterol crystals dissolve in the tissue-fixation process, leaving telltale biconcave, needle-shaped clefts in the center of the occluded vessels [*see Figure 5*]. Interstitial fibrosis may result from combined ischemia and inflammatory damage. The diagnosis of renal cholesterol embolization is suggested by the clinical features and the presence of retinal vessel involvement documented by ophthalmoscopy. Cholesterol embolization is confirmed histopathologically by the finding of biconcave clefts in small vessels in biopsy samples of muscle, skin, kidney, or other organs.

There is no effective therapy for renal cholesterol emboli. Management entails controlling hypertension; discontinuing anticoagulation, which may worsen the renal dysfunction; and providing supportive care.[79] In some patients who receive supportive care, gradual abatement of symptoms and even of severe renal insufficiency may occur. The progressive and long-term survival of patients with cholesterol emboli has greatly improved.

RENAL VEIN THROMBOSIS

Manifestations of renal vein thrombosis can range from asymptomatic occurrence in a nephrotic adult to acute oliguric renal failure in a volume-depleted child. Most patients with renal vein thrombosis have underlying nephrosis, renal tumors that invade the renal veins, or clotting abnormalities that predispose to coagulation (e.g., anticardiolipin syndrome or protein C or S deficiency).[80,81] Clinical manifestations and physiologic effects depend on the rapidity and completeness of renal vein occlusion. Slowly progressing renal vein thrombosis permits development of adequate collateral circulation, and despite the potential for pulmonary emboli, few renal manifestations occur. Rapid development of near-total venous occlusion can lead to flank pain, gross hematuria, a decline in the GFR, increased proteinuria, and fluid retention in the nephrotic patient. The histopathology of acute renal vein thrombosis includes interstitial edema with sparse cellular infiltrates; in contrast, chronic renal vein thrombosis is associated with tubular atrophy and interstitial fibrosis.

Tubulointerstitial Disease Caused by Dysproteinemias and Other Tumors

Multiple myeloma and other dysproteinemias, characterized by the excessive production of monoclonal immunoglobulins or their fragments, may cause both glomerular and tubulointerstitial injury to the kidney.[82-84] Whereas the glomerulopathies are predominantly associated with the glomerular precipitation of paraproteins, the tubulointerstitial damage can be caused either by a similar mechanism or by a number of metabolic and complicating features, such as hypercalciuria and hyperuricemia.[82,83]

MULTIPLE MYELOMA

Renal insufficiency and acute renal failure are common and significant contributors to morbidity and mortality in multiple myeloma.[82,83,85] Most patients present with isolated proteinuria as the first renal manifestation of dysproteinemia. Clinical indications that a patient with unexplained renal disease has multiple myeloma include (1) low-level proteinuria by urinary dipstick measurement but high-level proteinuria by 24-hour quantitative measurement (the dipstick primarily detects albumin, not Bence Jones protein), (2) a low anion gap (caused by the cationic charge on some monoclonal immunoglobulins), (3) hypercalcemia in the presence of renal failure and a high serum phosphate level, and (4) anemia out of proportion to the degree of renal insufficiency. A common manifestation of myeloma is renal insufficiency, which is present in more than 50% of patients. Patients with renal insufficiency have a shorter survival than those with normal renal function. Renal insufficiency may be indolent, chronic and progressive, or rapidly progressive. The degree of insufficiency is usually closely correlated with the excretion of light-chain proteins. A plasma creatinine level greater than 2 mg/dl is found in about 30% of patients at presentation and in 50% during the course of the disorder. A smaller percentage present with acute renal failure.

Excessive production and filtration of monoclonal light chains (Bence Jones protein) can cause direct tubular cell damage, as well as tubular obstruction by casts. When human Bence Jones proteins are injected into animal models, only some of the proteins coaggregate with Tamm-Horsfall mucoproteins (normally secreted by the tubules) to form obstructing casts in the distal tubules. In classic myeloma kidney, there are a large number of refractile, fractured-appearing casts, especially in the lumina of the distal tubules. These casts cause tubular cell damage, with peritubular inflammatory infiltrates of neutrophils and mononuclear cells; giant cells surround some casts [*see Figure 6*]. The casts may ultimately be found free in the interstitium, surrounded only by fibrous tissue and a few chronic inflammatory cells. Dysproteinemias can also be associated with tubulointerstitial precipitation of urate crystals caused by urate overproduction or lysis of plasma cells. In addition, the tubulointerstitial area can be damaged by deposition of calcium salt crystals as a result of hypercalciuria from lytic bone lesions and calcium-mobilizing humoral factors. Upper and lower urinary tract infections, resulting from suppression of normal humoral immunity, are also common in patients with myeloma and can cause acute and chronic tubulointerstitial damage. In rare instances, abnormal plasma cells infiltrate the interstitial area of the kidney, leading to renal dysfunction. Finally, many therapeutic agents cause renal toxicity (e.g., aminoglycosides and other antibiotics and contrast agents), especially when they are used in patients with myeloma who are dehydrated and volume depleted. Therapy for myeloma-induced renal damage consists of adequate hydration, treatment of hypercalcemia and other metabolic abnormalities, and methods to decrease the production and renal excretion of abnormal paraproteins. These include chemotherapy with melphalan or multidrug regimens (e.g., vincristine, doxorubicin, and dexamethasone), plasmapheresis for acute renal failure, and stem cell transplantation for selected patients.

AMYLOIDOSIS

Amyloidosis, which is caused by the extracellular deposition of fibrillary proteins in a β-pleated sheet, typically leads to glomerulopathy with heavy albuminuria. Tubular and interstitial deposition may also occur, however, leading to tubulointerstitial damage and isolated tubular defects. Proximal and distal renal tubular acidosis and vasopressin-resistant nephrogenic diabetes insipidus have been reported in patients with amyloidosis. In amyloidosis associated with the precipitation of serum amyloid A protein, especially in chronic heroin addicts, there is often a prominent tubulointerstitial inflammatory reaction.[86]

LIGHT-CHAIN DEPOSITION DISEASE

Tubulointerstitial inflammatory infiltrates and fibrosis can occur in light-chain deposition disease, in which light chains that do not have the configuration or staining properties of amyloid are deposited in the kidney and in other organs and tissues.[84] In light-chain deposition disease, tubular basement membrane deposits of light chains are found even more commonly than glomerular basement membrane deposits. Almost 50% of patients with light-chain deposition disease have been shown to have associated cast nephropathy (akin to patients with myeloma cast nephropathy) in addition to their glomerular findings.[87]

DYSPROTEINEMIAS AND OTHER TUMORS

In Waldenström macroglobulinemia, IgM is typically deposited in the glomeruli, but the disease is also associated with the presence of aggregates of atypical lymphocytes in the interstitial regions of the renal cortex and medulla.

Other tumors may cause tubulointerstitial damage through metabolic disturbances secondary to hyperuricemia and hyperuricosuria, hypokalemia, and hypercalcemia and hypercalciuria. The metabolic disturbances may be caused by the elaboration of hormonal substances or other tumor products or by chemotherapy. Direct tumor invasion of the kidney, which has

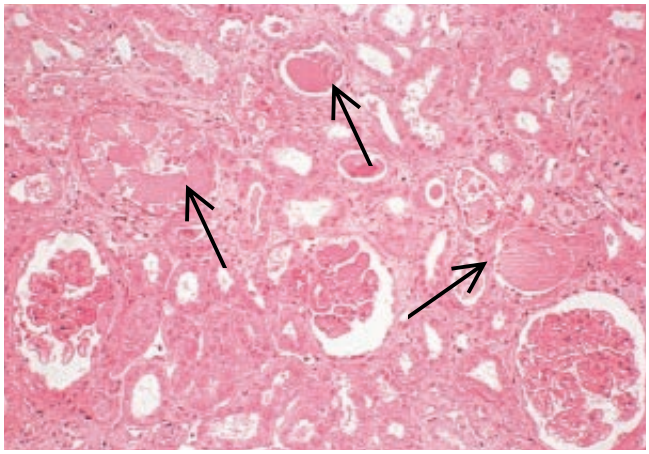

Figure 6 **Bence Jones cast nephropathy in multiple myeloma is associated with glassy, fracturing casts occluding the tubular lumina (arrows). Multinucleated giant cells surround some casts.**

been noted at autopsy, occurs often with leukemias and less often with lymphomas. However, only a few patients with leukemia or lymphoma have large kidneys or renal insufficiency.

Cystic Disease of the Kidney

As knowledge of the genetic background of cystic kidney disease has increased, the clinical spectrum and terminology have become clearer. Common forms of renal cystic involvement include simple cysts, autosomal dominant polycystic kidney disease (ADPKD), autosomal recessive polycystic kidney disease, acquired cystic disease, nephronophthisis–medullary cystic disease, and medullary sponge kidney. Each has typical clinical and histopathologic features.

SIMPLE RENAL CYSTS

Simple renal cysts, which are also known as solitary or single cysts, are fluid-filled cavities lined by epithelium.[88] These lesions are found with ultrasonogaphy or CT in approximately 25% to 30% of patients older than 50 years and in 50% of this age group at autopsy. Almost all of these cysts are asymptomatic. In rare instances, hematuria, pain, hypertension, or infection can complicate a simple renal cyst.

POLYCYSTIC KIDNEY DISEASE

ADPKD has a high prevalence in whites in the United States, occurring in one in 400 to one in 1,000, and is transmitted to 50% of the offspring of affected persons.[89] ADPKD is an inherited systemic disorder that commonly leads to progressive renal failure but that can also affect a number of other organ systems. Almost 90% of patients with ADPKD have an abnormal gene on the short arm of chromosome 16 (the ADPKD1 locus).[90] This gene encodes for polycystin, a plasma membrane protein that is expressed in most cystic epithelia from patients with PKD1.[91] The physiologic role of polycystin in PKD1 is not fully defined, although it may be involved in cell-cell or cell-matrix interactions. The remaining patients have the so-called non-PKD1 abnormality and have a different clinical course.[92] In most other patients, a locus for this abnormality has been found on chromosome 4 (the PKD2 locus); it encodes for polycystin 2, which may be involved in cell calcium signaling. As many as 75% of all ADPKD patients have a positive family history.[90,92,93] In ADPKD, the cysts arise from outpouchings of the renal tubule and Bowman space. They are lined by epithelium and contain fluid derived from the glomerular filtrate and modified by the action of the tubular epithelial lining. The underlying mechanisms of cyst formation in ADPKD are unclear.[90,91,93] Cyst formation begins in utero, and cysts increase in size and number as the patient ages. Most patients come to medical attention in middle age. Cyst enlargement and ESRD occur later in life in PKD2.[92] As the cysts enlarge, they compress adjacent normal tissue and lead to interstitial scarring. Although the exact mechanism responsible for this interstitial damage is unclear, increased cyst growth is associated with a decline in the GFR. Symptoms and signs include flank or back pain, abdominal masses, gross hematuria, urinary tract infections, and stone disease. Patients are typically less anemic than is expected for their degree of renal insufficiency. Hypertension that is related to increased activation of the renin-angiotensin-aldosterone system is found in 60% to 75% of adults with ADPKD and is an early manifestation of the disease.

Although CT may be a more sensitive technique for diagnosis of PKD, ultrasonography is usually the diagnostic procedure of choice because it is sensitive and inexpensive and does not expose the patient to radiation. In a patient younger than 30 years, diagnostic criteria for PKD1 include the finding of two cysts either unilaterally or bilaterally; in a patient between 30 and 60 years, the finding of at least two cysts in each kidney; and in patients older than 60 years, the finding of at least four cysts in each kidney. The presence of at least three cysts in each kidney of a patient with a family history of ADPKD confirms the diagnosis, and the presence of any cysts on ultrasonography in a child with a family history of ADPKD is strongly suggestive. The absence of cysts on ultrasonography at 30 years of age excludes the diagnosis in almost 100% of patients.

The kidneys typically enlarge progressively as the patient ages and the cysts grow.[93,94] The kidneys may reach massive proportions, causing abdominal distention [*see Figures 7 and 8*]. Half of affected persons with the ADPKD1 abnormality progress to

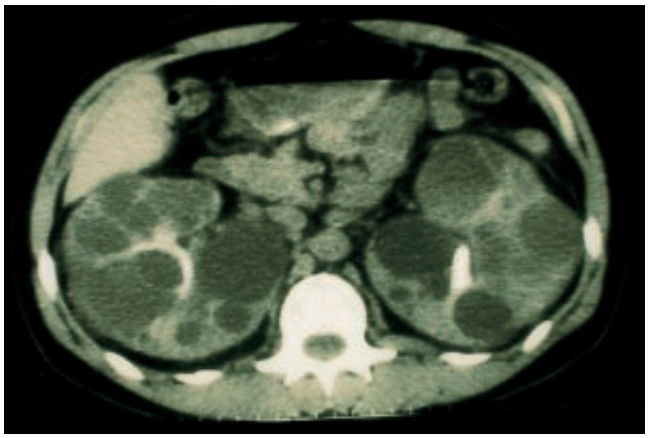

Figure 7 **Computed tomography of the abdomen demonstrates multiple bilateral renal cysts in a patient with autosomal dominant polycystic kidney disease.**

Figure 8 **Multiple cysts of all sizes can be observed in this gross section of enlarged kidneys from a patient with autosomal dominant polycystic kidney disease.**

renal failure by 60 years of age. The mean age of end-stage renal failure in patients with ADPKD1 is 55 to 60 years, compared with 70 years for non-ADPKD1 patients who die of renal failure. Other factors that presage more rapidly progressive renal disease are diagnosis at a younger age, black race, male sex, larger renal volume, and the presence of hypertension, hepatic cysts (in women), and gross hematuria. Cysts can also occur in the liver, pancreas, and spleen [*see Figure 9*].[95,96] Hepatic cysts increase with age—from 10% of patients younger than 30 years to more than 40% of patients older than 60 years—and are more common in women, especially in those who have had several pregnancies. Other systemic findings that commonly occur in patients with polycystic kidney disease are berry aneurysms of the circle of Willis [*see Figures 10 and 11*], which occur in 4% to 10% of patients; mitral valve prolapse, which is revealed by echocardiography in as many as 25% of patients; and colonic diverticula and diverticulitis and hiatal hernias.[97,98]

There is no specific treatment for ADPKD. Ascending infections can be treated with conventional antibiotics, but infected cysts must be treated with lipid-soluble antibiotics such as trimethoprim-sulfamethoxazole, chloramphenicol, and ciprofloxacin.[99] Control of infections and hypertension may slow the progression of renal dysfunction.[94] Although early studies suggested a benefit of a protein-restricted diet in PKD1, this has been only moderately supported by large trials.[100] Cyst puncture or surgical decompression may relieve pressure symptoms, although it will not alter the course of the disease.[101] Genetic counseling is useful because the chromosomal abnormalities can be detected reliably in almost all patients with ADPKD.

Autosomal recessive polycystic kidney disease, formerly called infantile polycystic disease, is a rare disorder, with an incidence of one in 40,000 persons to one in 10,000 persons.[102] It presents as severe cystic involvement in infancy or early childhood; may be associated with hepatic cysts, fibrosis, and portal hypertension; and leads to progressive severe renal failure. Often, death occurs at an early age.

ACQUIRED CYSTIC DISEASE

Acquired cystic disease is diagnosed when patients with renal insufficiency or renal failure are found to have more than five cysts per kidney in the absence of a family history.[103] In acquired cystic disease, in contrast to ADPKD, the kidneys are not enlarged but rather are small and scarred; in addition, there are no systemic manifestations. Such cysts develop in approximately 20% to 25% of dialysis patients and in as many as 50% of patients on dialysis for more than 5 years. The cysts are far more common in men than in women. The pathogenesis of these cysts is not understood, but they are limited to the kidney and arise from the renal tubules, especially from the proximal tubules, and vary in size from microscopic to several centimeters in diameter. Although most patients with acquired cystic disease do not have symptoms related to the cysts, some have hematuria, pain, fever with infection, and erythrocytosis. Renal tumors can develop within the cysts.[104] In dialysis patients with cystic disease, the incidence of adenomas is 5% to 10% and that of adenocarcinomas is 4% to 7%. The incidence of malignant tumors increases with increasing time on dialysis, and in 50% of cases, the tumors are multiple or bilateral.[105]

Multiple cysts have also been described in patients with hypokalemia and hyperaldosteronism. These cysts may disappear after successful removal of an adrenal adenoma and are usually of no major significance.

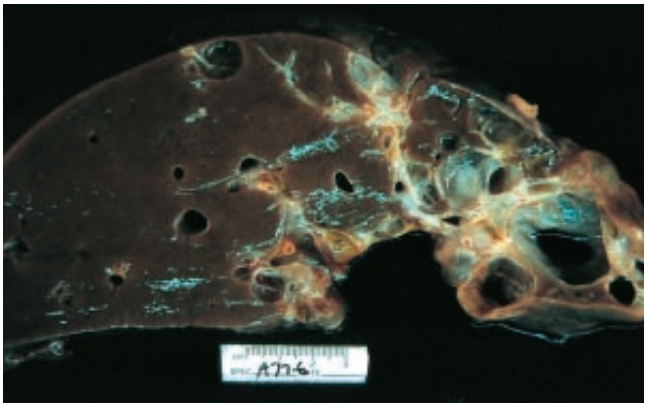

Figure 9 **Cysts are apparent in the liver of a patient with autosomal dominant polycystic kidney disease.**

NEPHRONOPHTHISIS AND MEDULLARY CYSTIC DISEASE

Familial juvenile nephronophthisis and medullary cystic disease constitute a group of disorders characterized by cystic in-

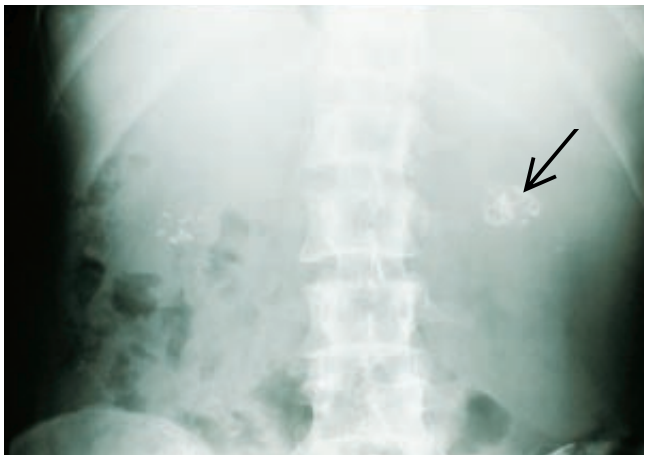

Figure 12 **Abdominal x-ray without contrast shows calcifications (arrow) in dilated collecting ducts in medullary sponge kidney.**

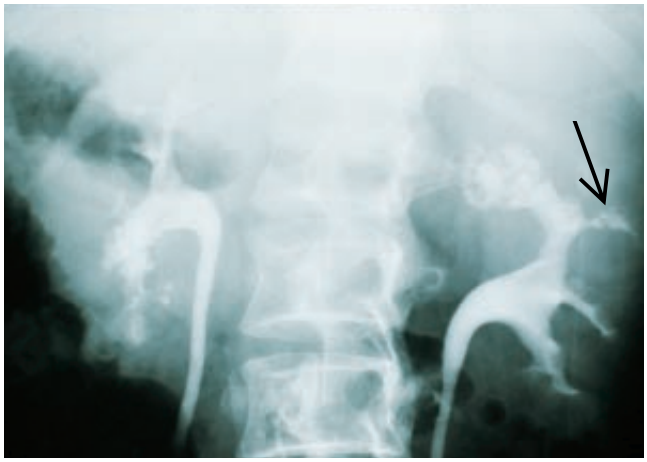

Figure 13 **Intravenous pyelogram of medullary sponge kidney reveals the so-called flower-spray or paintbrush dilatations of the collecting ducts of Bellini (arrow).**

volvement of the renal medulla and insidious progression to renal insufficiency and ESRD. Nephronophthisis typically occurs in the first 2 decades of life. It is inherited as an autosomal recessive trait, which in many families localizes to chomosome 2q13, where it encodes for the protein nephrocystin.[106,107] In some patients, it is associated with retinal pigment degeneration (i.e., the retinal-renal dysplasia syndrome). Medullary cystic disease presents most often in the third or fourth decade and is typically inherited as an autosomal dominant trait with genetic heterogeneity.[108] In both diseases, the kidneys are shrunken and have a thinned cortex. The cysts arise from the distal and collecting tubule cells and are most prominent at the corticomedullary junction, where they are surrounded by scarring and interstitial fibrosis. Patients typically present with polyuria, polydipsia, and nocturia, which result from impaired renal concentrating ability. Such patients often excrete large amounts of sodium in the urine, which can lead to volume depletion during periods of limited fluid access. These disorders invariably progress to renal failure, and the anemia is proportional to the degree of renal failure.

MEDULLARY SPONGE KIDNEY

In medullary sponge kidney, small cystic outpouchings form in the collecting ducts of the renal papillae. In some cases, families exhibit a dominant inheritance pattern, but other cases are sporadic. Asymptomatic ectasias 1 to 7 mm long are found diffusely and bilaterally in the collecting tubules by use of intravenous urography. They give a so-called paintbrush or flower-spray appearance to the renal papillae. At times, calcifications in the ducts can be seen on plain abdominal radiographs [*see Figures 12 and 13*]. Medullary sponge kidney may be associated with microscopic or gross hematuria, hypercalciuria, nephrocalcinosis and calcium stone disease, urinary tract infections, and, occasionally, isolated tubular defects (e.g., a distal renal tubular acidosis) and potassium-excreting and potassium-conserving defects.[109] The disease does not cause a major decline in the GFR and does not lead to renal failure.

Other Diseases Associated with Tubulointerstitial Nephritis

IDIOPATHIC ACUTE INTERSTITIAL NEPHRITIS

Patients with biopsy-documented AIN who are taking no medications and have no associated systemic or renal infections are classified as having idiopathic AIN.[2] In rare cases, the presence of circulating antibodies against the tubular basement membrane or the demonstration of linear immunofluorescence along the renal tubular basement membranes documents the immune nature of the renal insult. The pathogenesis is unclear in most patients who have either undefined granular immune deposits or no immune deposition. Patients usually present with either acute renal insufficiency or renal failure; on rare occasions, patients present with isolated tubular defects. Acute renal failure sometimes responds dramatically to short courses of corticosteroids or other immunosuppressive therapy.

A small group of patients, usually young women, have eosinophilic AIN associated with a variable combination of anemia, azotemia, uveitis, peripheral eosinophilia, and granulomas of the bone marrow or lymph nodes.[110] Such patients with the so-called TINU syndrome (tubulointerstitial nephritis and uveitis) may have tubular defects or acute renal failure. Although the uveitis may recur, the renal disease in TINU syndrome is often cured by treatment with corticosteroids.

SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER IMMUNE COMPLEX DISEASES

Although systemic lupus erythematosus is commonly associated with glomerular lesions, renal biopsies often show TIN or immune complex deposits along the tubular basement membrane as well.[111] Of patients with severe lupus nephritis, 60% to 70% have such interstitial involvement. In rare instances, TIN occurs in systemic lupus erythematosus without associated glomerular changes. In general, the degree of interstitial inflammation correlates with the degree of renal dysfunction, the presence of hypertension, and the severity of the glomerular damage. Such inflammation also augurs a greater decline in renal function, which is independent of glomerular histology. In comparison, immune complex deposition along the tubular basement membranes correlates with serologic activity (a high anti–DNA antibody titer and low complement level), but it does not correlate with other clinical features. Immune complex deposition is probably only one of many mechanisms that lead to tubulointerstitial damage. On rare occasions, patients with systemic lupus erythematosus have isolated tubular defects in acid-

ification or potassium excretion. In patients with mixed cryoglobulinemia or Sjögren syndrome, acute and chronic interstitial infiltrates may be found in the kidney with or without clinical features of renal dysfunction and such tubular disorders as Fanconi syndrome, distal renal tubular acidosis, nephrogenic diabetes insipidus, and hypokalemia.

SARCOIDOSIS

CIN is common in sarcoidosis.[112,113] Renal involvement typically includes diffuse interstitial noncaseating granulomas that displace and disrupt the renal parenchyma, nephrocalcinosis secondary to hypercalcemia and hypercalciuria, and acute interstitial lymphocytic inflammatory infiltrates with giant cells. The interstitial inflammation is often asymptomatic; as many as 20% of patients without clinical renal disease have interstitial granulomas at autopsy. Patients with clinically evident renal dysfunction usually have clear evidence of diffuse active sarcoidosis. Patients usually have mild proteinuria, tubular defects, sterile pyuria, and concentrating and acidifying defects. On rare occasions, patients present with acute renal failure associated with acute severe interstitial inflammation and granuloma formation, which may respond dramatically to corticosteroid therapy.

BALKAN NEPHROPATHY

Balkan nephropathy is a chronic progressive interstitial nephritis of unknown etiology that is found in long-term inhabitants of the rural areas surrounding the tributaries of the Danube River.[114] Although multiple environmental and genetic factors have been proposed as the etiology of Balkan nephropathy, none has been proved. Patients present in later life with tubular proteinuria, glycosuria, renal tubular acidosis, and progressive azotemia. The renal histopathology is characterized by an atrophic cortex, severe tubular degeneration, and interstitial fibrosis. Uroepithelial cancers of the renal pelvis and ureters develop in more than one third of patients.

ACUTE RENAL TRANSPLANT REJECTION

Acute rejection of a renal allograft is characterized by interstitial and perivascular infiltrates of lymphocytic cells, with lymphocytes invading the spaces between the cells lining the tubules (so-called lymphocytic tubulitis), and intimal arteritis.[115] Acute cellular rejection is associated with a decrease in the GFR and is a potentially treatable form of transplant rejection. If the rejection episode does not respond to corticosteroid therapy or other immunosuppressive medications, it can result in varying degrees of chronic interstitial fibrosis and scarring.

IX PHARMACOLOGIC APPROACH TO RENAL INSUFFICIENCY

Suzanne K. Swan, m.d.

The metabolism and elimination of many pharmacologic agents depend on normal renal function, in part because these agents have pharmacologically active metabolites that undergo renal excretion. In addition, many agents that do not undergo renal elimination from the body may nonetheless cause adverse effects in patients with renal failure. As a result, dosage adjustment of many drugs is required for patients with renal insufficiency to prevent toxicity and ensure efficacy. The clinician who prescribes therapy for patients with altered renal function must be familiar with basic pharmacologic principles because such patients must often be maintained within a narrow therapeutic window; that is, both drug accumulation and subtherapeutic dosing must be prevented.

This subsection addresses the pharmacologic parameters that are altered by renal dysfunction and presents a systematic, stepwise approach to dosage adjustment. Drug removal by dialysis and specific pharmacologic considerations in the setting of renal insufficiency are also outlined. Dosage recommendations appear in tabular form as the appendix to this subsection and represent a rough guide to drug therapy in patients with renal insufficiency. These dosing recommendations are derived from an extensive database in the medical literature that is often conflicting, that applies to varied patient populations, and that is seldom based on prospective, controlled trials. Thus, the prescribing clinician must not depend solely on dosing tables or nomograms; rather, such information should be used as a starting point in the treatment of patients with renal insufficiency.

Altered Pharmacokinetic Principles in Renal Failure

A given compound may travel through several different compartments in the body before being eliminated [*see Figure 1*]. Alterations in renal function affect several pharmacokinetic factors, including bioavailability, volume of distribution (V_D), protein binding, and biotransformation.

bioavailability

The bioavailability of a drug refers to the fraction, expressed as a percentage, of a given dose that reaches the systemic circulation. Bioavailability is primarily determined by the rate and route of administration. In general, a drug that is administered intravenously has 100% bioavailability because all of the dose reaches the systemic circulation; when it is given by the oral, intramuscular, or subcutaneous route, a smaller percentage of the dose often reaches target tissues. For example, furosemide has 100% bioavailability when given intravenously but only 50% when given orally. This finding underlies the common practice of doubling the dose of furosemide when a patient is switched from an intravenous to an oral regimen.

Drug absorption dictates bioavailability and may be altered in patients with renal failure. Diminished absorption may result from uremia-induced vomiting or gastroparesis caused by the neuropathic changes associated with diabetes mellitus or aging. The bowel wall edema commonly seen in patients with cirrhosis, nephrosis, or congestive heart failure may also impair absorption. Concomitant administration of certain medications, such as aluminum- or calcium-containing phosphate binders with antibiotics or iron supplements, can result in the formation of insoluble complexes that both limit absorption and slow gut motility. Absorption is also impaired by the concomitant administration of drugs that increase gastric pH, which include the phosphate binders and the H_2-receptor blockers, such as ranitidine and cimetidine.

volume of distribution

The V_D of a pharmacologic agent does not refer to a specific anatomic compartment but is a value derived by dividing the total amount of drug in the body by its concentration in the blood. Clinically, it can be used to calculate the dose required to achieve a desired systemic drug level. As a general rule, there is an inverse correlation between the serum concentration and the V_D. Alterations in extracellular fluid volume can affect the V_D; volume contraction corresponds to a fall in the V_D and a subsequent rise in the serum concentration, particularly of hydrophilic compounds, such as the aminoglycosides. Conversely, edema and ascites tend to increase the V_D of these agents, which results in lower serum concentrations. Both digoxin and insulin have a markedly decreased V_D in uremic patients, as evidenced by the increased serum concentrations of these agents in such patients.

protein binding

The portion of a given agent that is bound to protein can be thought of as the storage pool for that agent. Although compounds circulate in both bound and unbound forms, it is only the unbound, or free, form that is ultimately distributed and biologically active. Renal failure tends to decrease protein binding for most agents [*see Table 1*] because organic waste products block the binding sites on carrier proteins and thus displace the pharmacologic agent. As a result, a larger proportion of the drug circulates in its unbound, active form. Because standard drug as-

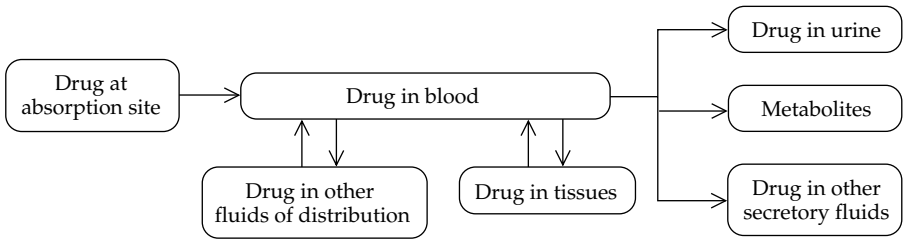

Figure 1 **Compounds may traverse several different compartments in the body before being eliminated. Changes in renal function affect pharmacokinetic factors, often necessitating dosage adjustment in patients with renal insufficiency.**

Table 1 Compounds with Decreased Protein Binding in Uremic Patients

Cephalosporins	Phenytoin
Clofibrate	Primidone
Diazepam	Salicylate
Diazoxide	Sulfonamide
Furosemide	Theophylline
Morphine	Valproic acid
Penicillins	Warfarin
Phenobarbital	

says tend to measure total drug concentrations (i.e., both bound and unbound drug levels), it may be prudent to specifically monitor unbound drug levels (e.g., in the case of a patient who is receiving phenytoin) when the therapeutic index is narrow.

BIOTRANSFORMATION

The biotransformation of a drug is its biochemical conversion from one chemical form to another. Biotransformation usually occurs via one of the hepatic metabolic pathways, such as oxidation, reduction, acetylation, or hydrolysis, and results in a more polar, less lipid-soluble, and more readily excreted metabolite. Pharmacologically active metabolites that depend on renal excretion for elimination from the body may be formed; such is the case with *N*-acetylprocainamide, the pharmacologically active metabolite of procainamide, an antiarrhythmic agent [*see Table 2*]. Toxic metabolites that depend on renal excretion may also be formed. For example, meperidine, a commonly prescribed narcotic, is metabolized to normeperidine, which undergoes renal excretion. Although this metabolite has little narcotic effect, it lowers the seizure threshold when it accumulates in uremic patients.

Stepwise Approach to Dosage Adjustment

The following five steps provide a framework for dosage adjustment in patients with renal failure [*see Figure 2*]. It must be emphasized that this stepwise approach is only a starting point from which dosage adjustment must be closely monitored and modified on a patient-by-patient basis.

STEP 1: ELICIT HISTORY AND PERFORM PHYSICAL EXAMINATION

Eliciting the patient's history and performing a physical examination are the first steps in determining the need for dosage adjustment in any patient. Renal dysfunction should be defined as acute or chronic, and if possible, the cause of the dysfunction should be ascertained. Whether the patient has a history of prior drug intolerance, allergy, or nephrotoxicity should also be determined. The physician should review the medications, both prescription and nonprescription, that the patient is taking to identify potential nephrotoxins.

At this stage, the patient's ideal body weight (IBW) should be calculated using the patient's height: for women, IBW is 45.5 kg plus 2.3 kg for every 2.5 cm over 152 cm; for men, IBW is 50 kg plus 2.3 kg for every 2.5 cm over 152 cm. The patient's volume status should be assessed because the V_D of a drug can be altered by marked shifts in extracellular fluid volume. Finally, whether the patient has hepatic dysfunction in addition to renal impairment should be determined, because concomitant hepatic dysfunction may necessitate even greater dosage adjustments.

STEP 2: ASSESS RENAL FUNCTION

Because drug elimination by the kidney correlates with the glomerular filtration rate (GFR), it is logical to use this measurement to gauge dosage adjustment. Creatinine clearance (C_{Cr}) is traditionally used to approximate the GFR because blood urea nitrogen (BUN) and serum creatinine (S_{Cr}) values are, at best, crude markers of renal function. The Cockcroft-Gault formula,[1] which includes the variables of age (in years), IBW (in kilograms), and S_{Cr} (in milligrams per deciliter), should be used to calculate the C_{Cr} (in milliliters per minute):

$$C_{Cr} = \frac{(140 - \text{age}) \times \text{IBW}}{72 \times S_{Cr}}$$

In women, the result should be multiplied by 0.85. It is important to remember that the C_{Cr} overestimates glomerular filtration. For purposes of dosage adjustment, patients with acute renal failure should be assumed to have a C_{Cr} of less than 10 ml/min.

Iohexol is a new marker of the GFR that is currently used in both research and clinical settings to accurately and efficiently quantitate renal function without exposing the patient to radiolabeled material.[2,3]

Recently, a new formula to predict renal function was reported.[4] The Modification of Diet in Renal Disease (MDRD) Study prediction equation estimates GFR rather than creatinine clearance and as such may provide a more accurate estimate of renal function. Factors contributing to greater accuracy of this equation include use of a creatinine assay (the kinetic alkaline picrate reaction) that is least subject to artifactual interference, equation validation in a cohort of patients that differed from the cohort used to derive the equation, prediction of GFR over a wide range of values, inclusion of variables for ethnicity as well as the serum albumin concentration, and no reliance on timed urine collections. The MDRD Study prediction equation can be expressed as follows:

$$\text{GFR} = 170 \times [\text{Scr}]^{-0.999} \times [\text{Age}]^{-0.176} \times [0.762 \text{ if female}] \times [1.180 \text{ if patient is black}] \times [\text{BUN}]^{-0.170} \times [\text{Albumin}]^{-0.318}$$

Whether this equation will be routinely implemented into clinical laboratory reports remains to be seen

STEP 3: DETERMINE LOADING DOSE

In patients with normal renal function, steady-state drug concentrations are achieved after approximately 3.3 half-lives. In patients with renal failure, a drug's half-life may be greatly prolonged, and if no loading dose is given, achievement of steady-state levels and therapeutic efficacy may be significantly delayed. In general, the standard loading dose that is given to patients with normal renal function should also be given to those with renal insufficiency so that therapeutic drug levels are reached rapidly. Digoxin is the major exception to this rule: only 50% to 75% of the usual loading dose of digoxin should be administered to patients with renal failure, because this drug has a marked reduction in its V_D in this setting.

The loading dose can be calculated by the following formula, in which the V_D is in liters per kilogram, IBW is in kilograms, and [Cp] is the desired plasma concentration in milligrams per liter:

$$\text{Loading dose} = V_D \times \text{IBW} \times [\text{Cp}]$$

Table 2 Drugs with Active or Toxic Metabolites Excreted by the Kidney

Acebutolol	Imipramine
Allopurinol	Meperidine
Cephalosporins	Methyldopa
Chlorpropamide	Nitrofurantoin
Clofibrate	Prednisone
Daunorubicin	Procainamide
Diazepam	Propoxyphene
Digoxin	Rifampin
Doxorubicin	Sodium nitroprusside
Enalapril	Succinylcholine
Flurazepam	Sulfonamides

STEP 4: DETERMINE MAINTENANCE DOSE

Two methods can be used to adjust the maintenance dose in patients with renal insufficiency. One method involves lengthening the dosing interval to correspond to the degree of renal impairment according to the following formula:

$$\text{Dosing interval} = \frac{\text{normal } C_{Cr}}{\text{patient's } C_{Cr}} \times \text{ normal interval}$$

Thus, if the patient's C_{Cr} is approximately 50 ml/min and the normal C_{Cr} is assumed to be approximately 100 to 120 ml/min, the dosing interval for that patient would essentially be doubled.

Alternatively, the dose can be reduced in proportion to the patient's degree of renal insufficiency while the dosing interval remains unchanged, as shown in the following formula:

$$\text{Dose} = \frac{\text{patient's } C_{Cr}}{\text{normal } C_{Cr}} \times \text{normal dose}$$

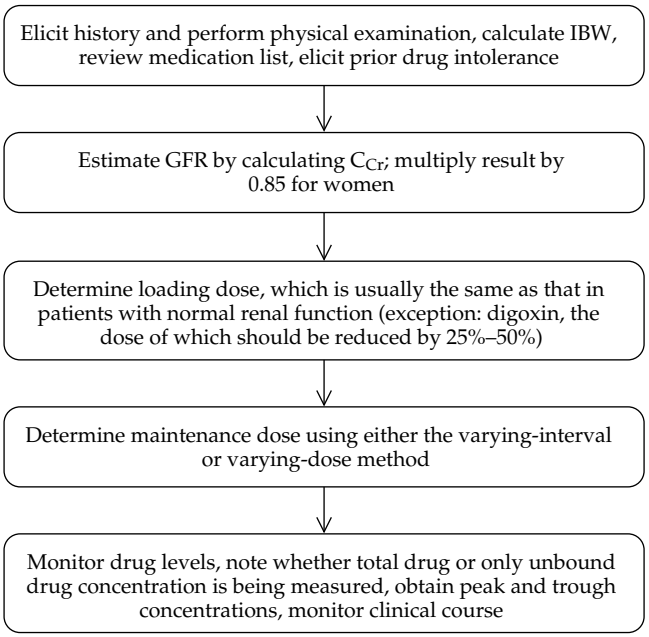

Figure 2 **A stepwise approach to dosage adjustment in patients with renal failure. (IBW—ideal body weight; GFR—glomerular filtration rate; C_{Cr}—creatinine clearance)**

In this case, assuming a C_{Cr} of 50 ml/min for the patient and a normal C_{Cr} of 100 ml/min would result in halving the standard dose but administering it at the same interval used for patients with normal renal function.

The first, or varying-interval, method may provide adequate peak concentrations of a drug while putting the patient at risk for periods of subtherapeutic levels. The second, or varying-dose, method may provide more constant drug levels but puts the patient at risk for toxicity caused by higher trough concentrations.

STEP 5: MONITOR DRUG LEVELS

Varying the dose or dosing interval for a given therapeutic agent may not be sufficient to prevent toxicity and guarantee therapeutic efficacy in patients with renal failure. Monitoring of drug levels can greatly enhance patient care, particularly in the setting of renal disease. Interpreting drug concentrations requires a knowledge of the exact dose given, the route of administration used, the time that has elapsed since the last dose was given, and the drug's elimination half-life.

Monitoring of drug levels may be performed after an appropriate loading dose or three or four maintenance doses have been administered to ensure that steady-state concentrations have been reached. Peak levels reflect the highest drug concentration achieved after an initial rapid distribution phase and tend to correlate with drug efficacy. Trough levels are generally obtained immediately before the next dose is given to ascertain the lowest concentration of drug in the body and, thus, systemic clearance. Drug trough levels are generally used as markers of toxicity.

Although monitoring of drug levels may help ensure therapeutic efficacy and safety, this service is expensive and is not always available. In addition, for some classes of drugs, such as the aminoglycoside antibiotics, monitoring of drug levels has not reduced the incidence of toxicity because of the poor correlation between serum levels and the uptake of drug into certain tissues, such as the renal cortex and inner ear. Interpretation of drug levels must be paired with ongoing clinical assessment of the patient, because toxicity can occur when drug levels are within the so-called therapeutic range. For example, digoxin intoxication can occur despite therapeutic serum levels if the patient has hypokalemia or metabolic alkalosis. Similarly, an increase in the unbound, biologically active fraction of a given pharmacologic agent may not be evident on monitoring of drug levels, because most assays measure total drug concentrations (i.e., both protein-bound and protein-unbound fractions).

Drug Clearance in Dialysis

Patients who are receiving dialysis therapy require special attention with regard to the scheduling of drug administration and may need supplemental dosing of agents that are substantially cleared by dialysis. In general, whenever possible, scheduled doses should be given after completion of a dialysis treatment. If such scheduling is not feasible and the dialytic therapy is known to increase total body clearance by 30% or more, supplemental dosing may be indicated.

The molecular weight, extent of protein binding, and water solubility of a compound are the primary determinants of dialyzability (e.g., small [< 500 daltons], hydrophilic, unbound drugs are readily cleared). The other drug properties that affect clearance by dialysis are the drug's ionic charge, V_D, nonrenal

Table 3 Drug Interference with Renal Function Testing

	Drug	*Test and Mechanism of Interference*
Increased Serum Creatinine	Ascorbic acid	Elevates total chromogen
	Levodopa Methyldopa	Interfere with autoanalyzer method
	Aspirin Cimetidine Trimethoprim	Block tubular secretion of creatinine
	Cefotetan Cefoxitin	Interfere with Jaffé reaction
Increased BUN	Acetaminophen Aminophylline Ascorbic acid Salicylates	Interfere with nonenzymatic method
	Methyldopa	Interferes with phosphotungstate method
	Levodopa	Interferes with autoanalyzer method

BUN—blood urea nitrogen

excretion, and erythrocyte partitioning. Properties of the dialysate (e.g., flow rate, temperature, solute composition, pH, and, in patients who are receiving peritoneal dialysis, volume) and of the dialyzer membrane (e.g., blood-flow rate, pore size, and surface area) also affect drug clearance.

Continuous renal replacement therapies (CRRTs), such as continuous venovenous hemofiltration and continuous arteriovenous hemofiltration, are increasingly being used in medical and surgical intensive care units and achieve C_{Cr} rates of as high as 20 to 30 ml/min. During CRRT, solutes and pharmacologic agents are removed by convective transport. Unless they are bound to protein, solutes and drugs dissolved in plasma water cross the dialysis membrane via plasma water ultrafiltration, in which the ultrafiltrate drug concentration equals the plasma concentration multiplied by the percentage of unbound drug. Pharmacologic agents may also be removed excessively from the body by membrane-drug binding. Because few data exist regarding drug removal and dosage adjustment during CRRT, close monitoring of the patient's clinical status, as well as drug levels, when available, is necessary.

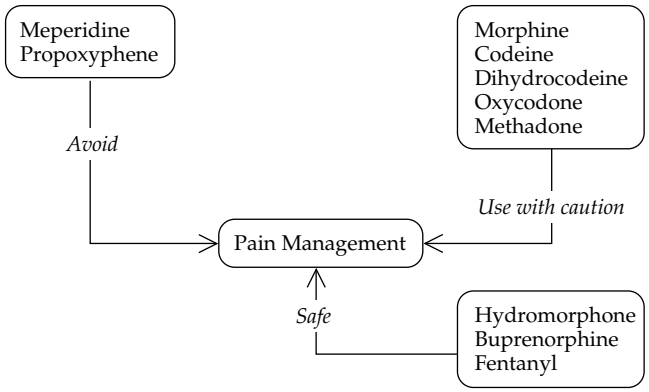

Figure 3 **Flowchart showing the relative safety of narcotic therapy for pain management in end-stage renal disease patients.**

Specific Pharmacologic Considerations

A number of pharmacologic agents can lead to aberrant results on renal function testing. These results can cause unnecessary concern and lead to costly evaluation if the clinician is unfamiliar with the causes of spurious elevations in the S_{Cr} level, the BUN level, or both.

There are several mechanisms by which various compounds interfere with laboratory markers of renal function [*see Table 3*]. Drugs can cause a rise in the S_{Cr} concentration either by interfering with the chromogen assay or by inhibiting renal tubular secretion of creatinine. Clinicians may need to discontinue such agents, at least temporarily, when S_{Cr} values rise unexpectedly. A number of drugs can also cause a rise in the BUN value by interfering with the various available assay methods.

Many patients with reduced renal function may be capable of maintaining metabolic balance as long as certain medications are avoided, because the limited nephron mass of these patients may be unable to meet the excretory demands of the agents. Some drugs may carry so-called metabolic loads of excess acid, alkali, magnesium, potassium, or sodium that overwhelm the failing kidney's excretory capacity. Other drugs may induce metabolic loads by increasing creatinine production, urea production, or both (e.g., glucocorticoids and androgens) or may impair the patient's ability to excrete free water (e.g., nonsteroidal anti-inflammatory drugs).

Thus, responses to pharmacologic therapy by patients with renal insufficiency are complex and heterogeneous and require an understanding of basic pharmacologic principles. Furthermore, such patients require close monitoring, not only of drug levels but also of their clinical course. Although reductions in the GFR should be factored in to dosage adjustment strategies, such a calculation is merely the initial step in considering the many pharmacokinetic and pharmacodynamic parameters involved in pharmacotherapy for patients with impaired renal function.

NARCOTIC USE IN PAIN MANAGEMENT

Although many options exist for pain management with narcotics, limitations in these options arise in the dialysis population. It should be noted that few, if any, data exist in the published literature regarding the use of narcotics in patients with reduced renal function.

It is possible to categorize narcotic use in renal failure on the basis of relative safety recommendations [*see Figure 3*]. Administration of medications such as meperidine, in which multiple dosing should be avoided, may still be an option as one-time therapy for procedure-related analgesia. Normeperidine, a metabolite of meperidine, lowers the seizure threshold of the central nervous system. It is eliminated by the kidneys and may accumulate in patients with reduced renal function; close monitoring is necessary, especially when repeated dosing is used. Respiratory depression or increased sedation may indicate accumulation of a parent compound or active metabolite.[4]

X CHRONIC RENAL FAILURE AND DIALYSIS

ERIC P. COHEN, M.D.

Chronic Renal Failure

DEFINITIONS

Chronic renal failure (CRF) is defined as a persistent impairment of kidney function. Clinically, it often involves a progressive loss of kidney function and may result in complete renal failure, necessitating renal replacement therapy (i.e., dialysis or transplantation). When renal replacement therapy is required, the condition is termed end-stage renal disease (ESRD). In this chapter, the term CRF is used to designate an established impairment of renal function that does not require treatment by dialysis or transplantation.

EPIDEMIOLOGY

End-stage Renal Disease

The incidence and prevalence of ESRD in the United States are very well known, because cases of ESRD that are managed with long-term dialysis or kidney transplantation are reported to the Health Care Financing Administration as part of the Medicare entitlement that is granted for ESRD. These reports are the basis for the United States Renal Data System (USRDS), a database that enables ongoing surveillance and analysis of ESRD. The most recent report of the USRDS is available on the Internet (http://www.usrds.org).

ESRD develops in almost 100,000 persons a year in the United States.[1] By comparison, there are approximately 180,000 new cases of lung cancer and more than one million new cases of myocardial infarction a year in the United States.[2,3] Of the 400,000 or more patients in the United States who have ESRD, about 300,000 are receiving long-term dialysis.

Rates of ESRD vary with race [*see Figure* 1]. Both the incidence and the prevalence of ESRD are three to four times higher in African Americans than in whites.[1] ESRD is also more common in Native Americans than in whites. In Native Americans, 60% of new cases of ESRD are the result of type 2 diabetes mellitus, whereas only 30% of new ESRD cases in whites are caused by type 2 diabetes. Also, there is a greater prevalence of both type 2 diabetes mellitus and ESRD in people of Hispanic origin than in whites.[4]

The reasons for the greater prevalence of ESRD in nonwhite populations remain unclear. The greater prevalence of hypertension in African Americans has been cited as a factor. Limited access to medical care has been suggested as a factor in African Americans,[4] but nonwhites in Great Britain also have a higher incidence of ESRD per million population than whites, despite the fact that nonwhites have equal access to medical care in that country.[5]

Chronic Renal Failure

The incidence and prevalence of CRF in the United States are uncertain. The incidence of CRF has recently been calculated at 1,700 per million population in a mixed urban and rural area of England.[6] The prevalence of CRF in the United States has been estimated to be two to three times that of ESRD. The third National Health and Nutrition Examination Survey (NHANES III) showed that one million people in the United States have a serum creatinine level of 2 mg/dl or greater.[7] By way of comparison, the estimated prevalence of CRF is comparable to that of Parkinson disease. It is likely that CRF has a racial distribution similar to that of ESRD.

CRF has long been known to be more prevalent in men than in women. Eight of 10 of Bright's original cases were in men,[8] and in a recent population survey in England, 60% more men than women had a plasma creatinine level greater than 1.6 mg/dl.[6] This gender disparity, which remains incompletely explained, extends to ESRD: data published in 2003 by the USRDS showed that 55% of cases of ESRD are in men.[1]

ETIOLOGY

Diabetes mellitus is the most frequent cause of ESRD [*see Table 1*]. Type 2 diabetes mellitus accounts for about two thirds of diabetes-related cases. Hypertension is the second most frequent cause of ESRD. Renal arterial disease—including both large- and small-vessel disease—appears to be rising in incidence, especially in the elderly.[9] The etiologic picture for CRF is similar to that for ESRD.

PATHOPHYSIOLOGY

The mechanisms by which renal failure progresses in patients with CRF have received ample attention over the past 20 years. Generally, progressive loss of renal function in CRF has been related to arterial hypertension, glomerular hypertension, proteinuria, and other metabolic derangements (e.g., hyperlipidemia).[10]

Both experimentally and clinically, arterial hypertension has been associated with more rapid decline in kidney function.[11] In the Multiple Risk Factor Intervention Trial, kidney function of-

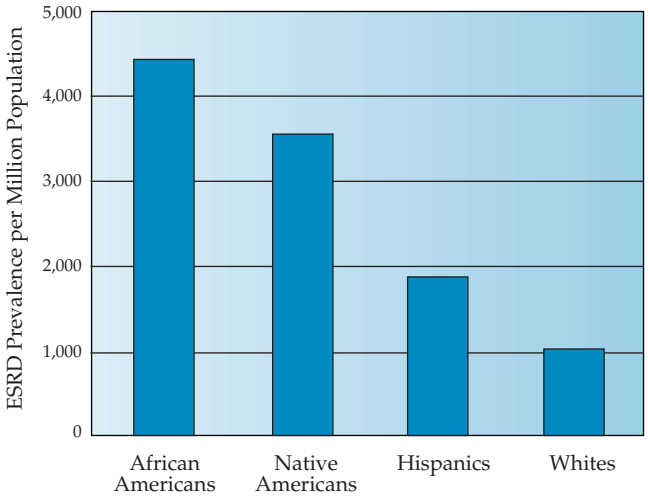

Figure 1 **Prevalence per million population of end-stage renal disease (ESRD) in the United States, according to ethnic group. The overrepresentation of ESRD in nonwhites is obvious.**

Table 1 Prevalence of End-Stage Renal Disease in the United States[1]

Primary Disease	*Number of Patients with End-Stage Renal Disease*
Diabetes	142,963
Hypertension	93,608
Glomerulonephritis	62,908
Cystic kidneys	17,489
Other known cause	53,990
Unknown	15,875

ten stabilized or even improved with a decrease in diastolic blood pressure to less than 95 mm Hg, whereas kidney function tended to decline in patients whose diastolic blood pressure remained above 95 mm Hg.[12] This relation between kidney function and arterial hypertension was also evident in a cohort study of 30,000 kidney transplant recipients, in whom increasing elevations in systolic blood pressure correlated with a progressive increase in late graft failure.[13]

Although animal studies using the remnant kidney model[14] have found that glomerular hypertension—so-called hyperfiltration—plays a role in progressive renal failure, this association has not been confirmed in humans. The proposed mechanism is that excessive filtration pressure within the glomerulus leads to scarring and, ultimately, kidney failure. Such excess pressure may lead to greater protein leakage across the glomerular filtration barrier, although the severity of proteinuria may be a function of the extent of glomerular injury rather than the degree of filtration pressure elevation.

The scarring process may also involve the tubules and interstitium, thereby altering intrarenal function and hemodynamics. Interstitial scarring may also directly impair nephron function as a result of associated peritubular fibrosis and tubular constriction.[15] Sodium excretion may diminish relative to arterial perfusion pressure, which may predispose to hypertension and loss of renal function.[16]

On the cellular level, the presence of activated fibroblasts, known as myofibroblasts, has been associated with loss of renal function in experimental and clinical kidney disease.[17] One mediator that may play a role in renal scarring, perhaps in part through the induction of myofibroblast formation, is transforming growth factor–β_1 (TGF-β_1), a polypeptide that has been implicated in chronic glomerulonephritis, chronic rejection of kidney transplants, and even diabetic nephropathy.[18] This multifunctional molecule can enhance matrix formation and reduce matrix degradation, thus promoting fibrosis. Experimental data suggest that molecular inactivation of TGF-β_1 may be therapeutically useful.

The relationship between proteinuria and loss of renal function has been addressed in both animal and human studies.[19] Proteinuria itself could cause downstream damage to the tubular epithelium; alternatively, some filtered proteins may carry iron, which can induce oxidative membrane damage. Whatever the mechanism, more severe proteinuria is clinically associated with faster loss of kidney function. Stable proteinuria of less than 2 g/day has been associated with little or no tendency to progression, whereas proteinuria of 5 g/day or more portends rapid loss of kidney function.

The early changes seen in diabetic nephropathy deserve special attention. In both type 1 and type 2 diabetes mellitus, microalbuminuria may precede gross proteinuria. Microalbuminuria is defined as the urinary excretion of albumin at a rate of 30 to 300 mg/day; this amount of albumin will not register on a dipstick or be detectable in a 24-hour urine collection. Microalbuminuria may coincide with early histologic changes, such as thickening of glomerular basement membranes and mesangial expansion.[20] If not treated, microalbuminuria tends to progress to overt proteinuria, then to loss of renal function.

DIAGNOSIS AND CLINICAL COURSE

A combination of clinical manifestations and laboratory tests often determine the diagnosis of CRF—in particular, the differentiation of CRF from acute renal failure (ARF) [*see Table 2*]. This differentiation has major implications for prognosis and treatment [*see 10:III Approach to the Patient with Renal Disease*]. Duration of illness is significant: long-standing symptoms point to chronic disease. For the most part, CRF and ARF produce the same symptoms. Itching, however, occurs in CRF but not ARF, so its presence has diagnostic value.

On laboratory testing, a cardinal sign of renal failure is azotemia—an increased concentration of nitrogenous waste products in the blood (i.e., the blood urea nitrogen [BUN] level). In contrast, the term uremia denotes symptomatic renal failure.

The symptoms and signs of chronic renal failure correlate with the degree of renal function impairment [*see Figure 2*]. However, a doubling of the serum creatinine level from 1 mg/dl to 2 mg/dl, which represents as much as a 50% loss in renal function, may result in few clinical manifestations. Proteinuria, especially proteinuria that is in the nephrotic range, predisposes to fluid retention, which, in turn, causes hypertension and edema. Thus, development of edema or hypertension points to possible kidney disease and should prompt urine and blood tests.

With increasing loss of renal function, parenchymal synthesis of calcitriol (1,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$]) decreases and blood concentrations of parathyroid hormone rise. When renal function drops to 50% to 75% of normal, renal concentrating capacity declines, and as a result, nocturia may occur.

Once the glomerular filtration rate (GFR) has declined to 30% or less of normal, signs and symptoms of CRF become more evident [*see Figure 2*]. Anemia is directly related to azotemia and is usually evident once the serum creatinine level exceeds 3 mg/dl. Fatigue and lack of physical endurance may result not only from anemia but also from acidosis. The acidosis associated with CRF is primarily caused by an inability of the kidneys to raise the level of ammoniagenesis (and ammonium excretion) to more than four times the baseline value. Thus,

Table 2 Differential Diagnosis of Chronic and Acute Renal Failure

Diagnostic Feature	*Acute*	*Chronic*
Duration of symptoms	Short	Long
Itching	No	Yes
Anemia	±	Yes
Echogenic kidneys (on ultrasound)	No	Yes
Bone disease (on x-ray)	No	Yes

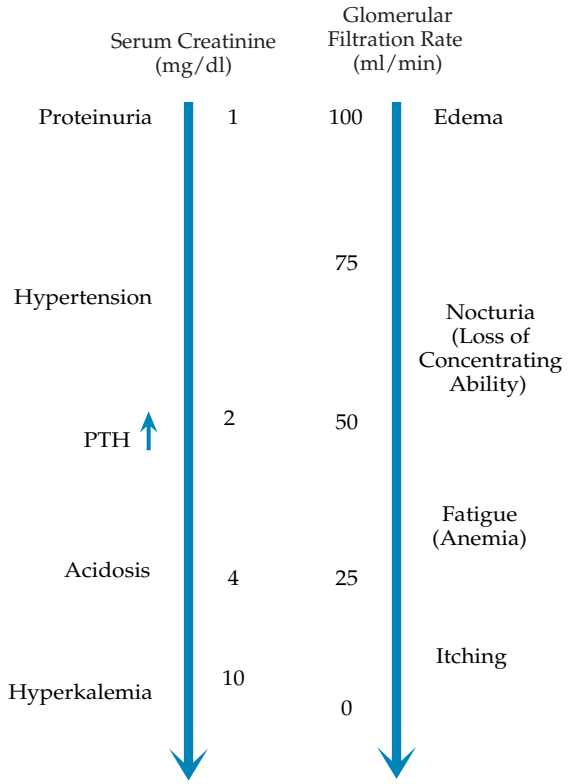

Figure 2 **Relationship between the level of kidney function and common signs and symptoms in chronic renal failure. Signs are shown on the left and symptoms on the right. Progression of chronic renal failure, which is typically linear over time, is displayed as the two downward directed arrows. The glomerular filtration rate (GFR), in ml/min, is linearly related to the reciprocal of the serum creatinine level times 100, and that relation is shown by comparison of the paired serum creatinine and GFR values of the diagram. Proteinuria and edema may occur early in the nephrotic syndrome, when kidney function is still normal, or may be absent in early chronic disease. Hypertension that is secondary to kidney disease generally does not occur until there has been some loss of function. Parathyroid hormone (PTH) levels begin to rise when GFR is 50 ml/min or less. Deficient urinary acid excretion manifests as a systemic acidosis when GFR is approximately 25 ml/min; acidosis occurs because the maximum fourfold compensatory ammoniagenesis per nephron unit can no longer keep up with the daily acid load. The hematocrit level declines linearly with the rising serum creatinine level, but there is a wide scatter in this relation [*see Figure 4*]. Fatigue and other symptoms of anemia do not usually occur until the hematocrit has dropped to 30%; at that level, the GFR is about 25 or 30 ml/min. Itching caused by renal failure occurs with a GFR of 15 ml/min or less and bears some relation to the severity of azotemia. Hyperkalemia may occur as a result of tubular disease, but the fractional excretion of potassium is enhanced as GFR falls; as a generic manifestation of renal failure, hyperkalemia does not usually occur until the very last stages.**

acidosis is the rule when kidney function drops below 25% of normal. Itching is a late symptom of CRF and generally occurs at or about the time a patient needs to begin long-term dialysis treatments.[21]

Hyperkalemia usually occurs late in the course of CRF, when the GFR is 10% of normal or less. However, it can occur when the GFR is 25% to 50% of normal, and in such cases, it may be a side effect of medication. Angiotensin-converting enzyme (ACE) inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with hyperkalemia.

The evolution of kidney disease from the initial sign or symptom to development of ESRD may take months or years. However, the rate of progression of kidney failure and the clinical course vary with the specific kidney disease. For example, kidney failure is rapid in diabetic nephropathy, intermediate in polycystic kidney disease, and slow in lithium nephropathy. In diabetic nephropathy, the rate of loss of GFR may be as high as 1 to 2 ml/min/mo, whereas in polycystic kidney disease, the loss rate is usually 1 ml/min/mo or less.

Certain accompanying features are specific to particular types of kidney disease. Both retinopathy and neuropathy often accompany diabetic kidney failure. Diabetic neuropathy may cause autonomic disturbances, such as gastroparesis and vomiting, that will add to uremic symptoms. In polycystic kidney disease, berry aneurysms of the circle of Willis may occur. Anemia may be less severe in patients with polycystic kidney disease than it is in patients with CRF from other causes.[22]

Calculation and Tracking of Renal Function

The urinary clearance of endogenous creatinine, measured in milliliters per minute, provides an adequate estimation of GFR [*see Figure 3*]. Because the creatinine in plasma (or serum) derives from muscle, body size must be taken into account; age is also a significant variable. The Cockcroft-Gault formula, which corrects for these factors, remains widely accepted as a way of estimating the creatinine clearance and, correspondingly, the GFR.[23] For men, the formula is as follows:

$$\text{Creatinine clearance (ml/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)}}{72 \times \text{serum creatinine (mg/dl)}}$$

For women, this quotient is multiplied by 0.85, because of their lesser muscle mass. The normal GFR is approximately 95 ± 20 ml/min in women and 125 ± 25 ml/min in men.

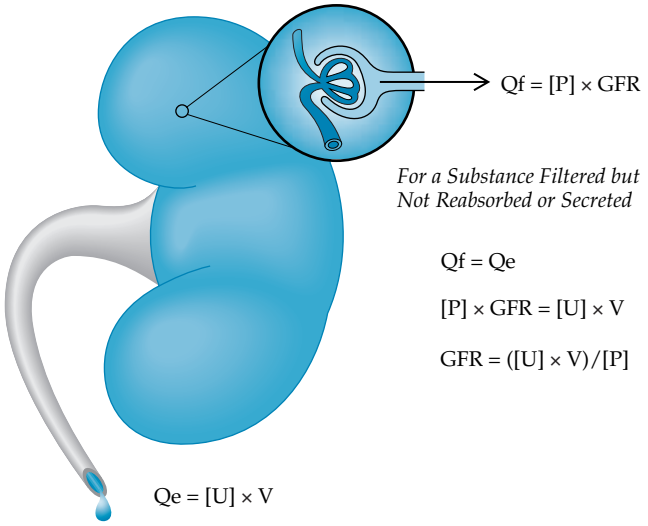

Figure 3 **Schema of the calculation of the GFR. A single kidney is shown. A magnified glomerulus represents filtration, the quantity of a filtered substance (Qf) being equal to its plasma concentration ([P]) multiplied by the GFR. An excreted substance appears in the urine in a quantity (Qe) equal to its urine concentration ([U]) multiplied by the urine volume (V). If a substance is only filtered and is neither reabsorbed nor secreted by the tubules, Qf = Qe; and the GFR may be calculated. Endogenous creatinine is freely filtered, not reabsorbed, and not secreted to a major extent. Its clearance thus approximates the GFR.**

The Cockcroft-Gault formula has been validated in persons older than 65 years,[24] as well as in diabetic patients with kidney disease.[25] The GFR can also be calculated by an equation developed by Levey and coworkers,[26] which utilizes the plasma creatinine, albumin, and urea concentrations, along with patient age and gender.

Measurement of the serum cystatin C concentration has been advocated as a more sensitive way to assess decrements in GFR.[27] The normal serum concentration of this 13 kd protein is about 0.7 mg/L, and the concentration increases when the GFR declines. It is possible that the serum cystatin C concentration may increase before the plasma creatinine concentration does; if so, the cystatin C concentration would be a more sensitive and useful test than measurement of the plasma creatinine concentration. However, a serum cystatin C test costs four times as much as a plasma creatinine test and, therefore, has not entered routine use.

Most types of chronic kidney disease tend to progress and are characterized by gradual loss of function. This loss of function is constant over time[25]—a fact that enables the clinician to quantify the rate of progression in a given case. A simple graph that plots the plasma creatinine level on the y-axis (expressed as 100 divided by the serum creatinine concentration) and the passage of time on the x-axis allows a rapid estimation of the rate at which the GFR declines [*see Figure 4*]. This estimation is possible because of the inverse (hyperbolic) relation of plasma creatinine level to GFR and the corresponding inverse relation of the plasma creatinine level to its reciprocal. Such graphs are easily constructed with spreadsheet computer programs.

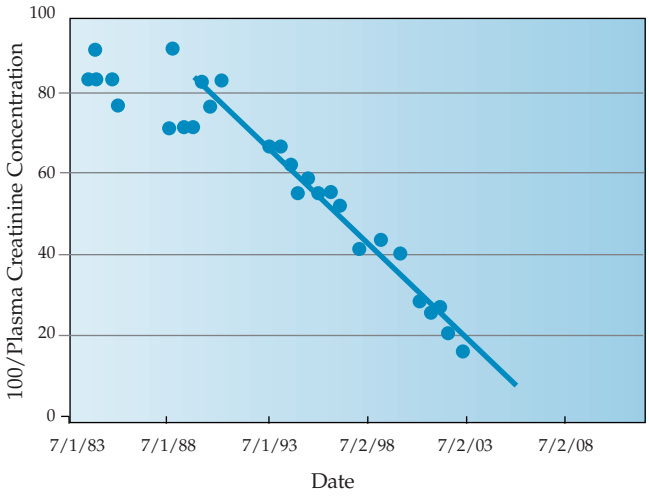

Figure 4 **Deterioration of kidney function over time in a patient with autosomal dominant polycystic kidney disease. This patient began to lose kidney function in or about 1990, when he was 35 years old; from that point onward, the glomerular filtration rate declined by approximately 3.9 ml/min/yr. He developed uremic symptoms in 2003 and underwent kidney transplantation in the fall of that year.**

TREATMENT

The goal of treatment in patients with CRF is to interrupt the progressive loss of kidney function. This goal is now genuinely possible for most glomerular diseases, including diabetic nephropathy.

In the case of type 1 diabetes mellitus, good control of the blood glucose level does diminish the frequency of diabetic complications[28]; however, even with good control, diabetic nephropathy with proteinuria and loss of renal function may still occur. The use of ACE inhibitors, in combination with other antihypertensive drugs, will slow the loss of kidney function in patients with diabetic nephropathy. For example, in a randomized, double-blind study, patients receiving captopril (25 mg p.o., t.i.d.) had a 50% lower risk of death or of ESRD than patients receiving placebo.[29] In this study, the blood pressure levels of patients in both the captopril and the placebo groups were maintained at 140/90 mm Hg or less, which is a mean arterial pressure of 107 mm Hg. There is evidence that in patients with type 1 diabetes mellitus, the greatest slowing of the loss of kidney function is associated with achievement of a mean arterial pressure as low as 90 mm Hg,[30] which corresponds to a blood pressure of 110/80 mm Hg.

In patients with type 2 diabetes and renal impairment, a randomized, prospective study showed that nondihydropyridine calcium channel blockers (diltiazem and verapamil) reduced proteinuria and slowed the progression of renal failure.[31] Calcium channel blockers were more effective than atenolol when blood pressure was maintained at similar levels (approximately 140/90 mm Hg or less). In a randomized, open-label, parallel group trial, verapamil and the ACE inhibitor trandolapril were combined for treatment of nephropathy in patients with type 2 diabetes; the combination of these agents was more effective in reducing proteinuria than either agent used alone.[32] In this study, the average blood pressure was 140/90 mm Hg or less. These and other studies have clearly demonstrated that more than one antihypertensive drug is usually needed to control the blood pressure in diabetic patients.

For early diabetic nephropathy—that is, for patients with microalbuminuria—there are similar promising data. In a placebo-controlled trial in patients with type 2 diabetes who had microalbuminuria, enalapril (10 mg daily) was more effective than placebo in preventing a worsening of albuminuria and in stabilizing renal function.[33] ACE inhibitors are thus recommended for the treatment of diabetic patients with microalbuminuria, as well as treatment of those with overt proteinuria.

The value of ACE inhibitors is not limited to patients with CRF from diabetes. In a 3-year randomized, double-blind study of more than 500 patients with diverse forms of CRF whose serum creatinine levels were between 1.5 and 4.0 mg/dl, the ACE inhibitor benazepril (10 mg/day) was compared with placebo.[34] Benazepril lowered urinary protein levels and blood pressure and slowed the loss of kidney function by about 50%, especially in those patients with type 2 diabetes or chronic glomerulonephritis. Progression of kidney failure was not slowed in patients with polycystic kidney disease. In this study, more than one antihypertensive drug was required for control of blood pressure.

As a group, ACE inhibitors appear to slow the progression of CRF in disease affecting the glomeruli. Some calcium channel blockers also appear to be effective. There is some evidence that maintenance of blood pressure at even less than 140/90 mm Hg may be beneficial. Although treatment with these medications is costly, it is less costly than dialysis or transplantation for ESRD. A cost-effectiveness study of patients with CRF showed a savings of $4,000 per patient after 3 years of use of benazepril versus placebo.[35] However, use of ACE inhibitors—even in investigational settings—appears to reduce the rate of progression of kidney failure by only 50%. The implication is that additional factors, perhaps unrelated to the renin-angiotensin system or its inhibition, may account for loss of function in CRF.

Whereas ACE inhibitors block the synthesis of angiotensin II, the newer angiotensin receptor blockers (ARBs) work by blocking the action of angiotensin I on its receptor. Compared with placebo or the calcium antagonist amlodipine, the ARB irbesartan has been shown to slow the progression of renal failure in patients with type 2 diabetes.[36]

CONSIDERATIONS IN LONG-TERM MANAGEMENT

Several general therapeutic measures can slow the progressive loss of renal function in CRF [*see Table 3*]. Use of nephrotoxins must be avoided—especially NSAIDs, which may impair renal function because of their effects on prostaglandin synthesis. Patient education on this topic is important, because NSAIDs such as ibuprofen and naproxen are available without prescription. The newer cyclooxygenase-2 (COX-2) NSAIDs also reduce kidney function.[37] Limiting dietary protein, controlling hyperphosphatemia, and treating acidosis are additional general measures to be considered for patients with CRF.

Role of Dietary Protein

Dietary protein both contributes to uremic symptoms and promotes the progressive loss of renal function in CRF. A prospective observational study confirmed that patients with CRF spontaneously reduce their intake of dietary protein as they lose renal function.[38] When the GFR is less than 20 ml/min, aversion to meat is not uncommon. At that level of renal function, the spontaneous intake of dietary protein may be 0.8 g/kg/day or lower. Historically, low-protein diets were prescribed to reduce uremic symptoms. Anecdotal evidence suggests that restriction of dietary protein may relieve specific uremic symptoms, such as itching.[39] However, adherence to a low-protein diet is difficult. There is controversy as to whether restricting the intake of daily protein to less than 1 g/kg/day slows the progression of CRF. A randomized study of 64 Australian patients with CRF showed a slowing of renal function loss in patients who consumed a diet containing 0.4 g/kg/day of protein, compared with patients receiving 0.75 g/kg/day of protein.[40] The Modification of Diet in Renal Disease[41] study evaluated 840 patients with moderate or severe CRF (i.e., with a GFR of 25 to 55 ml/min or of 12 to 25 ml/min, respectively). Patients were followed for an average of 2 years or more. When compared with a diet containing 1.3 g/kg/day of protein, a diet containing 0.6 g/kg/day of protein did not appreciably slow the loss of renal function in those patients with moderate CRF. A very low protein diet—0.3 g/kg/day—did not slow the progression of renal failure when compared with a 0.6 g/kg/day protein diet in patients with severe CRF. The average mean arterial pressure in the study patients was less than 100 mm Hg (which corresponds to a blood pressure of 130/80 mm Hg), so it is possible that the benefit from this good control of blood pressure eclipsed the benefit derived from dietary restriction of protein.

Table 3 Evidence-based General Interventions to Slow the Loss of Renal Function in Chronic Renal Failure

Intervention	*Comment*
Control of arterial blood pressure to < 140/90 mm Hg	Lower limit of blood pressure control not established
Use of ACE inhibitors or ARBs	Effective in diabetic nephropathy
Avoidance of nephrotoxins	Over-the-counter nonsteroidal anti-inflammatory drugs may be a culprit in worsening renal function

ACE—angiotensin-converting enzyme ARBs—angiotensin receptor blockers

Control of Hyperphosphatemia

Hyperphosphatemia plays a major role in the development of the secondary hyperparathyroidism seen in CRF. Yi and coworkers[42] showed that a halving of usual dietary phosphorus, independent of calcium or protein intake, reduced secondary hyperparathyroidism in rats with CRF. This effect had been previously shown in a cohort-intervention study in children whose dietary phosphorus was reduced from 1,200 mg/day to 250 mg/day.[43] Reduction of dietary phosphorus may reduce renal osteodystrophy, but long-term compliance with dietary phosphorus restriction is difficult.[44] The use of phosphate binders, such as calcium carbonate or aluminum hydroxide, may reduce the absorption of ingested phosphorus, thus lowering plasma phosphate levels and enhancing the effects of dietary restriction. In children with CRF, phosphate-binder therapy has been associated with a reduction in secondary hyperparathyroidism and improved growth velocity.[45] Dietary phosphorus restriction may slow the loss of renal function in animals, but its effect in humans has not been demonstrated consistently.[46] Nonetheless, the restriction of dietary phosphorus, either by itself or in conjunction with the use of phosphate binders, is advisable for treating or preventing hyperphosphatemia in patients with CRF.

In a review, Coburn and Elangovan[44] summarized the available data regarding use of calcitriol in patients with CRF. Calcitriol, which is the active form of vitamin D, may be deficient in patients with CRF because of reduction in functional kidney parenchyma and, consequently, diminished 1a-hydroxylation of vitamin D. In modest doses (0.25 to 1 mg daily), calcitriol may reduce secondary hyperparathyroidism and improve bone histology. However, incautious use of calcitriol may cause hypercalcemia, which can worsen kidney function. On balance, use of calcitriol should be undertaken only with appropriate monitoring and an awareness of the potential hazards.

Control of Acidosis

Metabolic acidosis contributes to bone mineral loss and is thus a likely factor in the development of the renal osteodystrophy seen in CRF.[47] Metabolic acidosis also may enhance muscle catabolism and decrease albumin synthesis.[48,49] In addition, metabolic acidosis appears to decrease thyroid hormone secretion[50]—an effect that may explain the twofold greater occurrence of hypothyroidism in patients on long-term dialysis than in persons without kidney disease.[51] Correction of acidosis in CRF may raise serum concentrations of calcitriol and lower those of parathyroid hormone.[52] In children with renal tubular acidosis, long-term alkali supplementation improves growth rates.[53] These effects and the effects on bone provide justification for the use of alkali supplements in patients with CRF who have metabolic acidosis. Sodium bicarbonate tablets (650 mg or 7.6 mEq) may be used. Alternatively, baking soda (42 mEq of bicarbonate per teaspoon) may be used. As much as 1 mEq/kg body weight of bicarbonate may be needed daily to maintain the plasma bicarbonate level over 20 mEq/L in patients with CRF.

Treatment of Concomitant Conditions

Anemia With declining renal function, anemia becomes likely. Studies in patients with CRF have shown an inverse correlation of hematocrit with azotemia[54] [*see Figure 5*]. This decline in the hematocrit is largely the result of a reduction in the production of erythropoietin by the kidney. Since 1989, exogenous erythropoietin has been used to treat anemia in patients with renal failure.

Erythropoietin will raise the hematocrit and may improve the appetite and well-being of patients with CRF.[55] This protein hormone must be given by subcutaneous or intravenous injection. The subcutaneous route is preferable, and the initial dosage is 50 to 75 U/kg/wk or, typically, 4,000 units once a week. An erythropoietin with two more carbohydrate side chains, darbepoetin, has been synthesized. It is also effective in treating anemia of CRF, and its typical once-weekly dose is 0.5 μg/kg body weight.

Iron stores must be adequate for erythropoietin therapy to be effective; they may be evaluated by measuring the serum ferritin level or the transferrin saturation. The serum ferritin level should be greater than 100 mg/L; transferrin saturation should be greater than 20%. The goal of treatment is to raise the hematocrit level to at least 30% but, generally, not higher than 40%. The increase in hematocrit may lead to an increase in blood pressure; erythropoietin itself may also contribute to an increase in blood pressure. At one time, there was concern that the use of erythropoietin would accelerate the progression of CRF, but this does not appear to be the case.

Uremic bleeding Patients with CRF may have decreased platelet function and therefore may bleed.[56] The bleeding can range from mild subepidermal bleeding to a life-threatening gastrointestinal hemorrhage. If the platelet count is normal but the bleeding time is prolonged, a defect in platelet function is likely. Such a defect may occur when the BUN level is greater than 60 mg/dl, although diminished platelet function is seen across a considerable range of BUN levels in patients with CRF.[57] Excessive bleeding that is caused by such a defect may be treated with cryoprecipitate or estrogens. Desmopressin (0.3 mg/kg I.V. every 6 hours for up to three doses) is an alternative. Uremic bleeding is probably less frequent today than it was in previous decades, perhaps because long-term dialysis is initiated at lower levels of azotemia than in the past.

Cardiovascular disease There appears to be a surfeit of cardiovascular disease in persons with impaired kidney function.[58] An analysis by the USRDS of patients older than 67 years showed that the incidence of new cardiovascular disease was more than 50% higher in those with reduced kidney function than in those with normal kidney function.[1] Typical risk factors such as hypertension and hyperlipidemia account for some of this overrepresentation, and it is possible that additional factors, such as hyperhomocysteinemia or even an inflammatory state, may play a role.

INDICATIONS FOR INITIATION OF DIALYSIS

Half of patients with a plasma creatinine concentration greater than 6 mg/dl will require dialysis within 3 months.[59] If these patients are not referred to a nephrologist, their conditions often worsen until they require emergent dialysis [*see Figure 6*].[60] Emergent dialysis costs about $50,000 more per patient than nonemergent dialysis. This increased cost stems from the need for emergent access procedures, the greater morbidity at the time dialysis is initiated, and longer hospital stays.

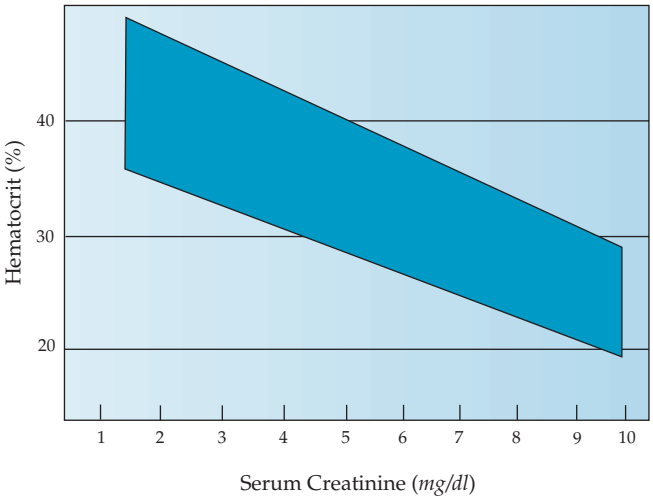

Figure 5 **Relation of hematocrit to serum creatinine in patients with chronic renal failure. Anemia (characterized by a hematocrit of less than 30%) is the rule when the serum creatinine level reaches 10 mg/dl. The polygon encompasses the area of the actual data points.[54]**

Edema, myoclonus, lethargy, and pericarditis are signs that are typically associated with advancing renal failure; typical symptoms include dyspnea, muscle cramps, and itching. On average, three or four signs or symptoms are present when dialysis is required.[61] As of 2002, the average BUN level at the start of dialysis was 85 mg/dl, and the average serum creatinine concentration was 8 mg/dl.[1] It should be emphasized that the serum creatinine level alone does not determine when dialysis should be initiated. Rather, the decision to start dialysis is based on the patient's signs and symptoms. A young, muscular patient may be uremic only with a serum creatinine level of 15 mg/dl, whereas an older diabetic patient may require dialysis when the serum creatinine level is 5 mg/dl. In diabetic patients, in particular, daily creatinine production may be reduced because of coexisting diabetic neuropathy, and the serum creatinine level may be correspondingly lower despite a GFR that is in the uremic range.

Long-term Dialysis

Despite advances in medical care, progressive loss of kidney function still occurs in CRF, with the eventual need for renal replacement therapy. Fewer than 5% of patients who experience ESRD may undergo kidney transplantation without needing long-term dialysis. The great majority of new ESRD patients—over 90,000 persons a year in the United States—require dialysis.

Long-term dialysis—either peritoneal dialysis or hemodialysis—requires access to the circulatory system. For patients receiving peritoneal dialysis therapy, that access is achieved via a peritoneal catheter; for patients receiving hemodialysis, circulatory access is through a native or artificial arteriovenous fistula. None of these forms of access are immediately usable on the day that they are placed. Typically, a fistula is not usable until 1 month after it is placed; an arteriovenous graft may be ready for use 2 weeks after placement. Thus, if a patient has severe CRF and urgently needs to start dialysis, a temporary catheter may be needed. Use of such catheters, which are placed in the large central veins, may result in hemorrhage or infection. Therefore, the need for long-term dialysis should be anticipated and appropri-

ate plans made far enough in advance to avoid temporary catheterization.

Of the 300,000 Americans who were on long-term dialysis in 2001, 275,000 were receiving hemodialysis. About 25,000 were receiving peritoneal dialysis.[1]

PERITONEAL DIALYSIS

Peritoneal dialysis is performed through a plastic catheter permanently implanted into the peritoneal cavity. Typically, 2 or 2.5 L of electrolyte solution is allowed to flow into the peritoneal cavity, where it remains for 4 to 6 hours and is then allowed to flow out. This process, which is repeated throughout the day, allows adequate removal of toxins, salt, and water. Toxin removal occurs by diffusion across the peritoneal membrane. Removal of salt and water occurs by osmosis because of high glucose concentrations in the peritoneal dialysis fluid. Peritoneal dialysis is sometimes performed at night, depending on the characteristics of peritoneal transport. Peritoneal dialysis is sometimes referred to as continuous ambulatory peritoneal dialysis (CAPD), a term that emphasizes the continuous nature of this therapy—in contrast to hemodialysis, which is administered intermittently—as well as the fact that patients on peritoneal dialysis are ambulatory. Patients can undergo peritoneal dialysis while at home or at work. Peritoneal dialysis is less popular than hemodialysis because of the sometimes lesser effectiveness of peritoneal dialysis and because of the risk of peritonitis and its complications.

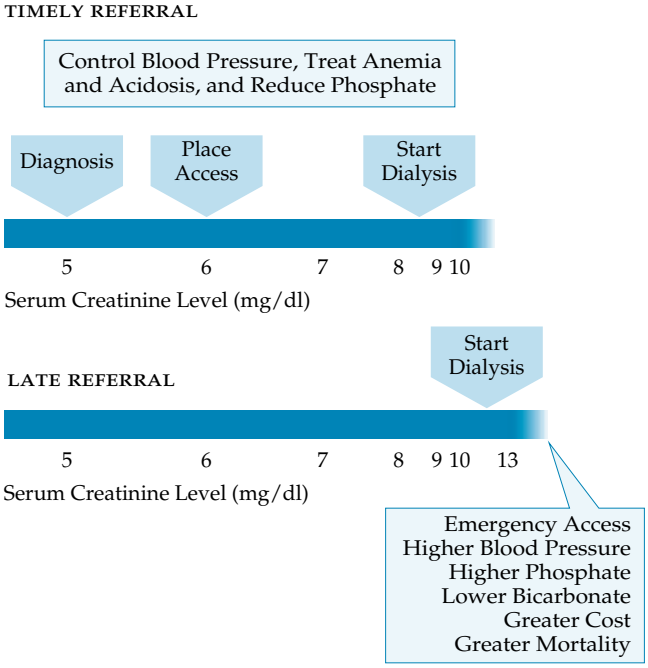

Figure 6 **Schematic comparison of timely versus late referral for dialysis. With timely referral (i.e., referral occurring before the plasma creatinine level has reached 5 mg/dl), it is possible to treat anemia and acidosis and thereby alleviate symptoms. Control of the blood pressure may exert long-term reduction in cardiovascular risk. Access to the circulatory system should be established before such access is actually needed to avoid use of temporary catheters. With late referral, the metabolic derangements at the start of dialysis are more severe, the need for emergency access creates additional risk, and the ultimate financial cost is higher. An emergent start of long-term dialysis is also more psychologically stressful.**

HEMODIALYSIS

Hemodialysis is a technique in which blood is circulated outside the body through a hemodialyzer [*see Figure 7*]. The essential principles of hemodialysis used for treatment of azotemia have not changed greatly since Kolff's pioneering work of over 50 years ago.[62] The hemodialyzer is composed of multiple tubules, each 200 mm in diameter. The tubules are hollow fibers made of semipermeable membranes through which the patient's blood flows. The outer surfaces of the tubules (i.e., the surfaces that are not in contact with the patient's blood) are bathed in a dialysate solution containing sodium (135 to 140 mmol/L), potassium (usually 2 mmol/L), chloride (100 mmol/L), a combination of bicarbonate and acetate (35 to 40 mmol/L), and calcium (1 to 1.5 mmol/L). No urea, creatinine, phosphate, or other electrolyte is present in the dialysate. Thus, diffusion of urea and other waste products takes place across the dialyzer membrane into the dialysate. Molecules larger than 1,000 daltons do not traverse the membrane well. Thus, there is virtually no loss of plasma proteins during dialysis. Uremic toxin removal is enhanced through use of bigger dialyzers, which have greater membrane surface areas. Toxin removal also increases with increasing amounts of blood circulated through the dialyzer. For these reasons, adequate blood flow and sufficient dialysis session time are essential.

Because there is no protein in the dialysate, the calcium that is present in the solution is diffusible. At 1.0 to 1.5 mmol/L, the calcium concentration in the dialysate is actually higher than the usual diffusable plasma calcium concentration of 1.0 to 1.2 mmol/L. Thus, a hemodialysis session does not remove calcium but rather delivers it to the patient. The immediate postdialysis blood calcium concentration may be transiently elevated. It is likely that such a temporary positive calcium balance is helpful in attenuating secondary hyperparathyroidism, perhaps by direct suppression of parathyroid hormone secretion.[63]

In a manner analogous to diffusive calcium delivery, there is delivery of alkali by diffusion from the dialysate to the patient. Diffusive alkali delivery is useful in reducing the metabolic acidosis that is almost always present in CRF. Alkali delivery was formerly achieved by adding acetate to the dialysate; the acetate would be metabolized by the patient's liver, and as a result, bicarbonate would be generated. Acetate may cause hypotension, which may be symptomatic. Modern dialyzers use a buffer system that is predominantly bicarbonate; this buffer system directly delivers bicarbonate to the patient's blood while avoiding the side effects of acetate. As with calcium, the blood bicarbonate concentration may be elevated immediately after a dialysis treatment session. The bicarbonate level will subsequently fall as the bicarbonate is titrated by the fixed acid of protein catabolism.

Salt and water removal is achieved by convective movement of serum water and electrolytes across the dialyzer's semipermeable membrane. The rate of this movement is a function of hydraulic pressure across the semipermeable membrane. This transmembrane pressure is determined by a negative pressure applied to the dialysate. Interdialytic weight gains are typically in the range of 2 to 3 kg. During a dialysis session, this excess fluid must be removed. Modern machines allow easy determination of fluid removal rates, which range from 0.1 to 2 L/hr.

Additional aspects of dialyzer use include the type of semipermeable membrane employed and its biocompatibility, dialyzer cost, and whether the dialyzer may be recycled (reused) for more than one dialysis treatment. Removal of other toxins of uremia, such as β_2-microglobulin—a culprit in dialysis-related

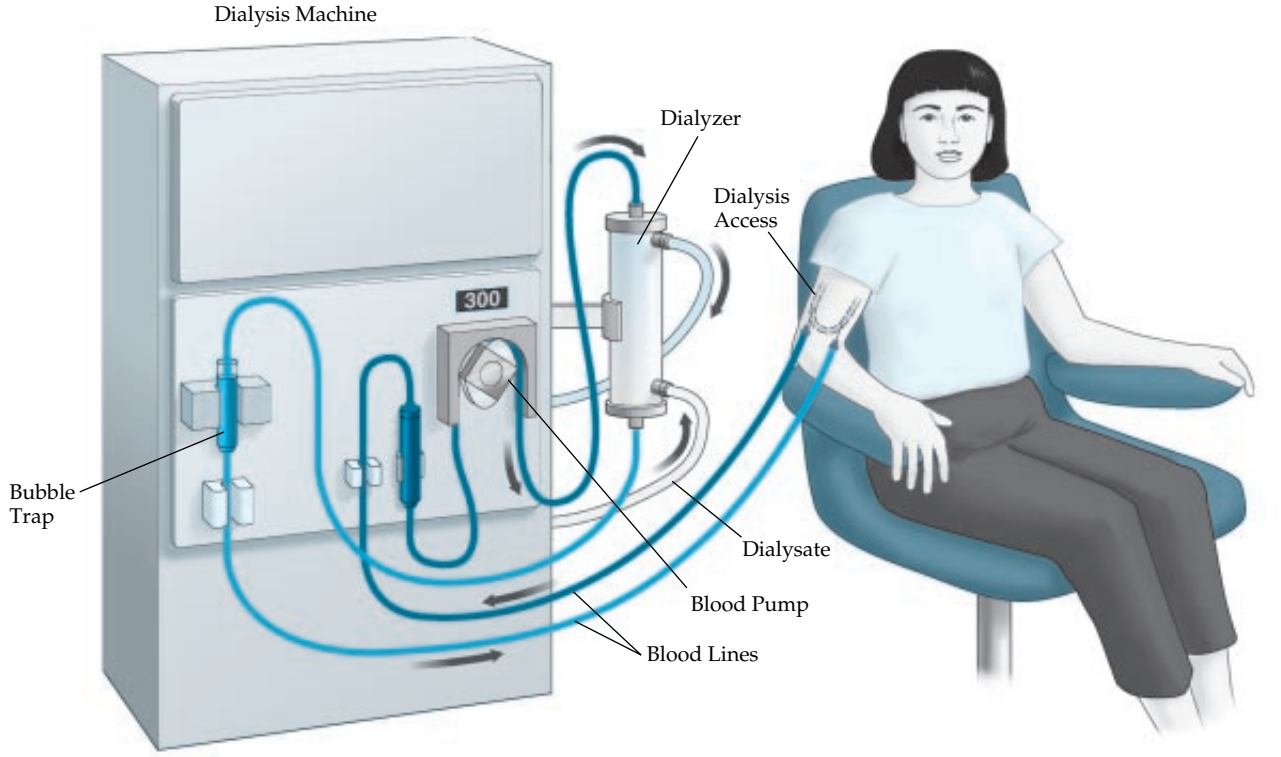

Figure 7 **The process of hemodialysis. The patient has a right arm arteriovenous graft, in which the needles connected to the blood lines are inserted. The blood lines lead to and from the dialyzer, the performance of which is controlled by the dialysis machine. In the dialyzer, blood circulates through hundreds of hollow fibers made of a semipermeable membrane. Dialysate solution flows around the fibers in the opposite direction (counterflow). Toxin removal occurs by passage of toxin from blood to dialysate by diffusion. Fluid removal occurs because of a machine-created hydraulic pressure across the dialyzer semipermeable membrane. An alternative method of accessing the peripheral bloodstream is by use of a cannula. The equipment used for hemodialysis includes reservoirs for purified water and concentrated dialysate solution, a mixing unit that measures conductivity and temperature, an ultrafiltration control unit that maintains dialysate pressure, a flowmeter, a blood pump, the dialysis cartridge (dialyzer), and an air detector.**

amyloidosis—is also related to hemodialyzer use. These issues are beyond the scope of this chapter.

MANAGEMENT AND CARE OF PATIENTS RECEIVING LONG-TERM DIALYSIS

Long-term hemodialysis is performed three times a week, with each session lasting 3 to 5 hours. Some centers are performing daily short dialysis treatments, and these may also be done at home. Because of logistical issues, however, few patients currently use daily dialysis.

Hemodialysis removes toxins, salt, and water from the blood by dialysis. Access to the blood circulation is achieved by use of a central venous catheter or a native or artificial arteriovenous fistula [*see Figure 7*]. Central venous catheters may be required for emergent dialysis, but they should otherwise be avoided. The preferred method for gaining access to the circulation for hemodialysis is through a surgically created arteriovenous fistula, which is often created at the wrist between the radial artery and the cephalic vein or at the elbow between the brachial artery and the basilic vein.[64] Preexisting venous injury, from disease or the use of indwelling catheters, may force the use of artificial arteriovenous fistulas. Artificial fistulas, which are made of polytetrafluoroethylene (PTFE), are prone to clotting, and their use increases the risk of infection. Despite these disadvantages, artificial fistulas are currently the most common way of achieving access to the circulation for the purpose of hemodialysis. The maintenance of adequate blood flow and hemodialysis function requires the ongoing and integrated efforts of nephrologists, surgeons, and interventional radiologists.[65]

Both long-term hemodialysis and long-term peritoneal dialysis usually provide no more than about 10% of the normal kidney function. Thus, persistent uremia, hypertension, and intercurrent illness are often major problems in patients receiving dialysis therapy. The National Kidney Foundation has issued quality-of-care guidelines for patients on long-term dialysis, which can be found at their Web site (http://www.kidney.org).

Adequacy of Dialysis

For patients receiving long-term dialysis, it is critical that enough dialysis be delivered. Cohort-intervention studies and comparative trials have shown that inefficient dialysis leads to buildup of uremic toxins, which is associated with greater morbidity, increased hospitalization, and decreased survival as compared with efficient dialysis.[66,67] Even with newer, more efficient dialyzers, providing sufficient time for each hemodialysis session is vital. Patients beginning hemodialysis therapy may be started at three sessions a week, with each session lasting 4 hours, but even longer session times are associated with the best outcomes.[68] Dialysis efficacy is also directly correlated with outcome in patients on peritoneal dialysis.[69] Measurements of urea or even creatinine in the peritoneal fluid allow quantification of peritoneal dialysis. The quantity of hemodialysis that is deliv-

ered may be measured by the percentage reduction in BUN that is achieved in a particular dialysis session. The BUN reduction should be at least 65%; in diabetic patients, it should be even higher—more than 70%. Changes in urea that result from dialysis may be evaluated mathematically by use of the KT/V quotient; in this expression, K is dialyzer clearance (ml/min), T is time (minutes), and V is the patient's body water volume (ml). Dialyzer clearance measures its ability to remove a substance from the blood. The National Kidney Foundation currently recommends that KT/V be delivered at 1.2 or higher for patients receiving long-term hemodialysis. A multicenter study of prevalent chronic hemodialysis patients has shown no apparent benefit for KT/V greater than 1.3.[70] However, a larger study that included all incident United States hemodialysis patients who started dialysis in 1998 suggested that an even higher KT/V, up to 1.7, was associated with improved survival.[71] Accordingly, patients must be monitored for clinical symptoms reflecting azotemia. Itching, lack of appetite, or insomnia may be evidence of inadequate dialysis, even when the urea reduction ratio seems to be adequate. In patients suspected of being inadequately dialyzed, ongoing clinical monitoring of symptoms is essential. It is worth emphasizing that uremia is more than an elevated BUN. By extension, adequacy of urea removal by dialysis may not fully correspond to adequacy of treatment for ESRD.

Control of Concomitant Conditions

Hypertension Most patients who begin long-term dialysis have hypertension, and hypertension persists in the majority of patients on long-term dialysis. Hypertension has been associated with cardiovascular morbidity and mortality in patients on dialysis.[72] Debate persists, however, as to whether the control of blood pressure has a bearing on long-term outcome in patients with ESRD. One cohort study found no relation of hypertension to 1-year mortality,[73] and another study found that a predialysis systolic blood pressure of less than 140 mm Hg was actually associated with worse outcome than higher predialysis blood pressure.[74] The best long-term survival for patients on long-term dialysis is strongly associated with maintaining the predialysis mean arterial blood pressure at 100 mm Hg or less.[68] This blood pressure is achieved by assiduous control of the volume status through removal of excess extracellular fluid during sufficiently long dialysis sessions. Intervention studies have shown regression of left ventricular hypertrophy by similar methods.[75]

Hyperphosphatemia Hyperphosphatemia promotes secondary hyperparathyroidism in dialysis patients just as it does in predialysis patients with CRF. Its control is achieved by dietary phosphorus restriction, use of phosphate binders, and ongoing dialysis. Cross-sectional data have shown a greater risk of mortality when the serum phosphorus level is greater than 6.5 mg/dl in patients on long-term dialysis, a finding that emphasizes the importance of interventions to limit hyperphosphatemia.[76]

Secondary hyperparathyroidism Virtually all patients on long-term dialysis have secondary hyperparathyroidism. If left untreated, the hyperparathyroidism may result in bone pain, fractures, or soft tissue calcification. Management of this condition includes not only the treatment of hyperphosphatemia but also the use of parenteral vitamin D preparations—mainly calcitriol and paricalcitol, which are given intravenously during dialysis sessions. They act directly on the parathyroid glands to suppress parathormone synthesis and secretion. There is evidence that medical management of secondary hyperparathyroidism has improved over the past 10 years, thus reducing the need for surgical treatment.[77] An additional tool in the management of secondary hyperparathyroidism may be the orally active calcimimetic agent cinacalcet, which acts directly on the calcium receptors of the parathyroid gland cells to suppress parathormone secretion.[78]

Anemia Anemia is managed in the same way as it would be in the predialysis patient with CRF. Thus, a patient's hematocrit may be maintained between 30% and 35% by use of erythropoietin and sufficient iron, without recourse to transfusions. The guidelines for iron metabolism in patients with ESRD and CRF are the same: levels of ferritin should be maintained at 100 mg/L, and transferrin saturation should be maintained above 20%. In dialysis patients who do not respond to erythropoietin therapy, evaluation for anemia may reveal gastrointestinal blood loss, deficiency of folate or vitamin B_{12}, or an inflammatory syndrome that is blunting the response to erythropoietin therapy.

Other concerns Although uremic bleeding is usually not a problem in the well-dialyzed ESRD patient, the use of heparin during each hemodialysis session can predispose a patient to hemorrhagic complications. For example, subdural hematomas are more common in ESRD patients than in the general population and may be fatal in ESRD patients.[56] The use of phosphate binders that contain aluminum may lead to aluminum intoxication, although this has become less of a problem since the availability of phosphate binders that contain calcium instead of aluminum and the availability of the noncalcium phosphate binder sevelamer (RenaGel).[79] Use of medication—either prescription or nonprescription—requires special care in patients with kidney disease, regardless of whether they are on dialysis. Nonsteroidal arthritis medicines such as ibuprofen can worsen kidney function or cause gastrointestinal bleeding and anemia. The normeperidine metabolite of meperidine may accumulate in patients with CRF or ESRD and cause seizures [*see 10:IX Pharmacologic Approach to Renal Insufficiency*].

Infection ESRD patients are also at risk for infection, which is second only to cardiovascular disease as a cause of death in these patients. A recent longitudinal cohort study of ESRD patients identified low serum albumin levels and use of devices such as central venous catheters or artificial arteriovenous fistulas as major risk factors for septicemia.[80] Thus, nutritional status requires ongoing attention, and the use of temporary dialysis catheters should be avoided. Early referral to a nephrologist—well before the time when dialysis is needed—may reduce the severity of these problems by enabling improved predialysis nutrition and timely placement of permanent dialysis access.

Most deaths caused by infection are related to colonization of devices used to gain temporary access to the circulatory system, such as temporary dialysis catheters; pulmonary and intra-abdominal infections may also occur.[81] Bacteremia is a constant concern; it occurs with an incidence of about 10 episodes per 1,000 patient-months. Thus, in a dialysis unit of 100 patients, one episode a month would be expected. Over 50% of cases of bacteremia in dialysis patients are related to the dialysis access. Of the devices for gaining circulatory access, indwelling catheters carry the most risk, PTFE arteriovenous grafts carry somewhat less risk, and native arteriovenous fistulas are least likely to become infected. *Staphylococcus aureus* and *S. epidermidis* are the

most commonly identified infectious agents; both may cause septicemia and complications, such as endocarditis and septic arthritis. Empirical treatment of either bacteremia or an infection at the site of circulatory access thus requires use of an agent that is effective against staphylococci. Of course, removal of the catheter or PTFE graft may be needed. The results of cultures and sensitivity testing will guide antibiotic therapy. Vancomycin (1.0 to 1.5 g I.V. every 5 to 10 days as guided by blood levels) is often used. There is some general concern that overuse of vancomycin may predispose to overgrowth of vancomycin-resistant enterococci, but vancomycin is the drug of choice for infections caused by methicillin-resistant *S. aureus*.[82] The long-acting cephalosporin cefepime (1 to 2 g I.V. after each dialysis session for the duration of antibiotic therapy) may be useful because it has good activity against staphylococci and *Pseudomonas* and *Enterobacter*. Aminoglycosides, such as gentamicin and tobramycin, may be needed for some gram-negative infections, but if they are used for more than 1 to 2 weeks, there is substantial risk of ototoxicity or vestibular toxicity.

Advisability of Screening Examinations

Some investigators have advised that screening mammography or sigmoidoscopy be routinely used in patients receiving long-term dialysis.[83] A careful cost-to-benefit analysis has invalidated that advice.[84] Such screening examinations are unwarranted, largely because the life expectancy of patients with ESRD is very much less than that of healthy persons of similar age. The greater mortality in ESRD, which mostly results from cardiovascular disease or infections, eliminates the benefit of screening programs. Chertow and coworkers[84] point out that the money spent on screening tests would be far better spent on improving the quality of the dialysis.

COST OF ESRD

Dialysis, whether it be hemodialysis or peritoneal dialysis, involves substantial cost. Dialyzers, blood lines, and peritoneal dialysis fluid are ongoing requirements. Moreover, the average long-term dialysis patient is hospitalized once or twice a year and spends an average of 15 days in the hospital annually[1]; these hospital stays contribute substantially to the overall cost. The annual cost per patient can be $50,000 or more.[1] Although the initial cost of kidney transplantation is high, after 3 years, the cost of care of a patient who has received a successful kidney transplant is less than the cost of long-term dialysis. By comparison, the average annual cost of care of a person with multiple sclerosis has been estimated to be $30,000 to $50,000.[85]

PROGNOSIS IN ESRD

Survival of patients on long-term dialysis is distinctly less than that of the overall population.[1] On average, the mortality for patients on long-term dialysis is 20% a year. A person 50 years of age who starts long-term dialysis may expect to live only 5 to 7 more years. The main causes of death in these patients are cardiovascular disease and infections; mortality also is inversely related to adequacy of dialysis. These causes of death emphasize the importance of a better understanding of cardiovascular and infectious illness in patients with ESRD and of the provision of optimal long-term dialysis for those who need it.

XI RENAL TRANSPLANTATION

David K. Klassen, M.D.
Matthew R. Weir, M.D., F.A.C.P.

Introduction

The first kidney transplantation to achieve long-term success was performed in Boston in 1954 between identical twin brothers. This case demonstrated the potential for recovery in patients with advanced kidney failure, but transplantation could be done only in highly selected cases utilizing living-donor organs. Successful transplantation utilizing cadaveric kidneys became common in the 1960s, with the development of pharmacologic immunosuppression. A marked expansion of effective care for patients with end-stage renal disease occurred in the 1970s, when Medicare began providing payment for transplantation and long-term dialysis. Successful transplantation remained limited, however, by a continued high incidence of rejection and the complications of immunosuppressive medications such as azathioprine and corticosteroids. The introduction of cyclosporine in 1983 greatly improved the success rate of kidney transplantation and allowed a wider application of this treatment for patients with renal disease. However, the majority of the more than 300,000 patients in the United States with end-stage renal disease continue to be treated with dialysis.

Dialysis Outcomes Versus Transplantation Outcomes

Continued improvement in outcomes has made transplantation the treatment of choice for patients with end-stage renal disease. Unlike dialysis patients, transplantation patients have a documented improvement in quality of life and a comparatively high rate of return to employment.[1]

A study of more than 220,000 patients receiving treatment for end-stage renal disease in the United States[2] showed that regardless of age, race, sex, cause of end-stage renal disease, or geographic region, long-term survival of patients who received a renal transplant was superior to that of patients who either remained on the transplantation waiting list or continued with long-term dialysis. Patients who underwent transplantation had an initial increase in mortality related to the surgical procedure; however, this initial risk was rapidly eclipsed by the improved long-term survival of transplant recipients. The annual mortality for patients on dialysis is 2.6 times greater than that for patients on the waiting list for transplantation, and the annual mortality for patients on the waiting list is 1.7 times greater than that for transplant recipients.[2]

Number of Potential Transplantation Recipients Versus Number of Donors

The disparity between the number of patients on the waiting list to receive transplants and the number of organs that become available each year has increased dramatically over the past decade. Currently, over 58,000 patients are on the waiting list. In 2002, 8,287 cadaveric and 6,236 living-donor renal transplantations were performed; in 1990, 7,062 cadaveric and 1,181 living-donor transplantations were performed. The increase in the number of living-donor transplantations is partially the result of the expanded use of kidneys from living nonrelated donors, such as spouses or other persons with close emotional ties to the transplant recipients.[3,4]

In the United States, cadaveric organs are distributed to potential recipients on the basis of an algorithm that is intended to optimize transplantation outcomes and maintain equity among patients on the waiting list. Patients are assigned a point score on the basis of the degree of human leukocyte antigen (HLA) match with the available kidney, the length of waiting time, and the degree of immunologic presensitization to HLA.[5]

The degree of presensitization to HLA is an important factor in the success of kidney transplantation. A patient with a high degree of presensitization resulting, for example, from a previous blood transfusion or from multiple pregnancies is difficult to match successfully with an organ. The patient is thus given additional consideration in the distribution algorithm. Children are given extra points to limit their time on the waiting list for transplantation. Available cadaveric organs are shared nationally among patients with complete HLA matches. Kidneys for which no complete-HLA-matched recipients are available are distributed on first a local, then a regional, and then a national basis to patients with the highest point totals. Under the present distribution system, the etiology or severity of the patient's kidney disease is not considered.

Expanded-Criteria Donor Kidneys

In an attempt to encourage and facilitate deceased-donor transplantation, in 2002, new policies and procedures were developed to expedite the allocation of kidneys with unfavorable donor characteristics. These expanded-criteria donor (ECD) kidneys are defined as kidneys that have a higher rate of graft loss as a result of a combination of donor factors, including increased age, a history of hypertension, death from cerebrovascular accident, and elevations in the creatinine level at the time of kidney recovery.[6,7] In 1993, only 8% of deceased-donor transplants involved ECD kidneys; in 2003, 16% of deceased-donor transplants were performed with ECD kidneys, and this rate continues to go up. Although allograft survival rates after 1, 3, and 5 years is lower for ECD kidneys than for non-ECD kidneys (81%, 67%, and 51%, respectively, for recipients of ECD kidneys, as compared with 90%, 81%, and 68% for recipients of non-ECD kidneys),[8] most patients and physicians would agree that receiving a kidney offers substantial improvement in quality of life, as compared with remaining on dialysis. The use of ECD kidneys in older patients has become much more common; over 70% of ECD kidneys go to recipients 50 years of age or older. It is uncertain whether this pattern of use is appropriate; early evidence suggests that the risk of graft loss with ECD kidneys is increased in older patients.[9]

Recipient Evaluation

Potential transplant recipients require a careful medical assessment before being added to the waiting list.[6] The goal of this evaluation is to ensure that the transplantation procedure is done as safely as possible and to maximize the long-term survival of the recipient. Most transplantation programs offer transplants to medically appropriate recipients regardless of age. Data show that older transplant recipients have excellent sur-

Table 1 Contraindications to Transplantation

Active or recent malignancy
Active infection
Severe uncorrectable nonrenal disease
Uncontrolled psychosis
Active substance abuse

vival rates after renal transplantation and may in fact have a lower incidence of episodes of acute rejection than younger recipients.[10]

IDENTIFYING RISK FACTORS FOR POSTTRANSPLANTATION MORBIDITY AND MORTALITY

There are relatively few absolute contraindications to renal transplantation. They include active or recent malignancy that shortens life expectancy; active infection; severe uncorrectable nonrenal diseases; uncontrolled psychosis; and active substance abuse [*see Table 1*]. These conditions should be identified in any patient considered a possible candidate for transplantation.

Cardiovascular Disease

The leading cause of death in transplant recipients, as in the general population, is cardiovascular disease. The pretransplantation evaluation should identify risk factors for coronary artery disease, such as hyperlipidemia, hypertension, diabetes mellitus, and a family history of coronary artery disease.[11] Operative morbidity and mortality are increased in patients who have had a myocardial infarction within 6 months before surgery. Congestive heart failure, unstable angina, ventricular arrhythmias, and electrocardiographic abnormalities are also predictive of a higher rate of surgical complications. For a pretransplantation patient, the physical examination and history should focus on careful examination for signs and symptoms suggestive of vascular disease. Evidence of diminished pulses or bruits, as determined by physical examination, should be followed up with more direct assessment of the vascular system. Stress testing is appropriate for patients with documented risk factors for coronary artery disease, particularly for patients with diabetes, who constitute the largest single subgroup of pretransplantation patients. Studies have shown that up to one third of diabetic patients will have significant coronary artery disease,[12] and silent coronary artery disease is more common in these patients. Diabetic patients or other patients found to have significant abnormalities on stress testing should undergo a diagnostic cardiac catheterization. Correction of significant coronary artery lesions by angioplasty or coronary artery bypass grafting should be done before transplantation.

Malignancy

Patients must be evaluated for occult malignancy and to ascertain any history of malignancy. Immunosuppressive therapy may promote the growth of some malignancies, and patients who have recently had malignancies may be at increased risk for recurrence and subsequent decreased life expectancy. In such patients, transplantation is not appropriate. For most patients who have had malignancies, a 2-year period without evidence of recurrence is adequate for showing they are not at high risk for recurrence. Up to 5 years of follow-up may be appropriate for patients who have had breast cancer, colorectal cancer, and melanoma. However, some malignancies require no waiting period, such as in situ bladder and cervical cancer, Dukes stage A colon cancer, Clark level I melanoma, basal cell skin cancer, and in situ lobular breast carcinoma.[13]

Infection

Active or occult infection must be identified and treated before transplantation. Potential sources of infection include dental abscesses, infected dialysis access catheters, urinary tract infections, and tuberculosis. All patients who produce significant amounts of urine should have a urine culture. Serologic studies to document prior viral infection, particularly with herpesviruses, should be done. IgG and IgM titers for herpes simplex virus types 1 and 2, as well as titers for cytomegalovirus (CMV) and Epstein-Barr virus (EBV), are required. All patients must be screened for evidence of HIV and human T cell lymphotropic virus type I (HTLV-I). Patients should also have a chest x-ray, be screened for evidence of varicella and rubella infections, and undergo purified protein derivative (PPD) testing.

HIV-positive recipients In the past, HIV-positive patients with end-stage renal disease were excluded from consideration for transplantation. With the advent of highly active antiretroviral therapy, many of these patients have very prolonged survival on dialysis. Some transplant programs have begun to cautiously offer transplantation to highly selected HIV-positive patients. Patients with AIDS and low $CD4^+$ T cell counts are not at this time considered for transplantation. Some immunosuppressant medications appear to have antiretroviral properties. Initial reports are promising, and a multicenter trial evaluating transplantation in these patients is under way.[14]

Hepatitis C The prevalence of hepatitis C is high in the dialysis patient population. Studies have shown that hepatitis C–positive recipients have an increased risk of liver disease after transplantation.[14,15] However, it is not known whether there is a decrease in recipient survival related to hepatitis C infections. Patients identified as carriers of hepatitis C should undergo a pretransplantation liver biopsy to assess the degree of histologic disease. Patients with evidence of advanced disease are not candidates for kidney transplantation, although they may be considered for combined kidney-liver transplantation.

Hepatitis B Patients should be screened for evidence of hepatitis B infection. Transplantation is not contraindicated for patients who are positive for surface antigens as long as there is no evidence of advanced liver disease; however, patients must be screened for evidence of active viral replication with hepatitis B e antigens or with hepatitis B DNA. Patients who have active replication are at higher risk for disease progression after transplantation and generally do not receive transplants. Patients with hepatitis B or C who show evidence of abnormal liver enzymes should undergo a liver biopsy before transplantation; those found to have advanced liver disease are not candidates for transplantation.

Primary renal disease Patients with end-stage renal disease who have a primary glomerulopathy are at risk for disease recurrence in the transplanted organ. If possible, the glomerulopathy should be identified before transplantation because the recurrence rates vary with specific diseases [*see Table 2*].

As a general rule, primary glomerular diseases recur relative-

Table 2 Primary Renal Disease Recurrence after Transplantation

Disease	*Recurrence Rate (%)*	*Graft Loss with Recurrence (%)*
Membranous nephropathy	3–20	Minimal
IgA nephropathy	40–60	< 10
Focal segmental glomerulosclerosis	20–30	30–40
Type I membranoproliferative glomerulonephritis	20–30	30–40
Type II membranoproliferative glomerulonephritis	80–90	10–20
Glomerular basement membrane disease	5–10	Rare

ly commonly, but graft losses secondary to recurrence are uncommon; renal transplantation is not contraindicated in patients with primary glomerulonephritis.[16] Focal segmental glomerulosclerosis has a recurrence rate of approximately 20% to 30%. Patients at highest risk are those whose original disease was aggressive and rapidly caused the loss of renal function. In this setting, recurrent disease can occur immediately after transplantation, and graft loss may be high. Living-donor transplantation may be relatively contraindicated.

Anti–glomerular basement membrane disease has a very low recurrence rate if transplantation is delayed for 6 months after documentation of negative antibody titers. Membranous nephropathy recurs with a reported incidence of 3% to 20%, but graft loss resulting from recurrence is unusual. Type II membranoproliferative glomerulosclerosis has a recurrence rate as high as 80% to 90%, and 10% to 20% of patients who experience recurrence may have graft loss. IgA nephropathy recurs in approximately 50% of patients, but significant renal impairment is uncommon. Lupus nephritis rarely recurs after transplantation. Patients with low levels of active disease have successfully received transplants.

Hemolytic-uremic syndrome may recur in as many as 20% of patients, but graft loss is uncommon. Cyclosporine, tacrolimus, and sirolimus, which are medications commonly used as primary immunosuppressants, can cause a thrombotic microangiography that resembles hemolytic-uremic syndrome; however, these drugs are not contraindicated and may be used as immunosuppressants in transplant recipients whose primary renal disease was hemolytic-uremic syndrome.

Anti–glomerular basement membrane disease can develop in the allograft of patients with Alport syndrome. The disease results from exposure to glomerular basement membrane antigens that were absent in the native kidney. However, this complication is uncommon and is not a contraindication to transplantation.

Medical Compliance and Substance Abuse

Patients on dialysis who have a history of multiple episodes of medical noncompliance can receive transplants successfully. However, these patients need extremely close follow-up. Patients with a history of drug or alcohol abuse should show evidence of participation in a rehabilitation program and successful avoidance of drugs and alcohol. A substance-abuse screen is useful to document abstinence. The experience of most transplantation programs is that 6 months of successful participation in rehabilitation is sufficient to indicate correction of the underlying problem. Neither psychiatric illness that is controlled with active treatment nor mental retardation is an absolute contraindication to transplantation.

TIMING OF TRANSPLANTATION

Ideally, the transplantation evaluation should be initiated early in the management of chronic renal disease. Preemptive transplantation—that is, transplantation before the initiation of long-term dialysis—has been shown to result in improved patient outcome.[10,17] Patients who have received a living-donor kidney before the initiation of long-term dialysis have shown a substantially reduced risk of allograft failure for the first year and subsequent years after transplantation. In addition, longer times spent on dialysis before undergoing transplantation negatively affect posttransplantation graft and patient survival.[18,19]

The average waiting time for the receipt of a cadaveric transplant continues to increase; in most areas of the United States, the average waiting time is in excess of 3 years. Therefore, preemptive transplantation is done most effectively with the use of living-donor organs. Patients should be made aware of the potential benefits in terms of improved outcome and survival with living-donor organ transplantation and should be given assistance in identifying potential donors.

Living-Donor Evaluation

Currently, almost one half of the organ transplantation procedures done in the United States are living-donor transplantations. The percentage of living-donor organ transplantations has increased substantially in recent years, in part because of the well-documented success of transplantation using kidneys from living donors who are not biologically related to the recipient and because of the widespread use of laparoscopic donor nephrectomy.[20,21] Longitudinal studies have demonstrated conclusively that in healthy individuals, kidney donation is safe and does not result in progressive loss of renal function.[22,23] Over time, donors may experience a slight rise in blood pressure, but the clinical consequences are minimal. The donor surgical procedure has a good record of safety. Studies suggest a mortality of approximately 0.03% and a complication rate of perhaps 2% to 10%. The common postsurgical problems associated with traditional open nephrectomy techniques are hemothorax, pneumonia, pneumothorax, and wound complications. Laparoscopic donor nephrectomy is very well tolerated by donors and results in a shorter hospital stay and a quicker return to work.[24] Renal function of kidneys procured by laparoscopic techniques is comparable to that of kidneys procured by traditional surgical techniques.[25]

MEDICAL SCREENING AND BLOOD TESTING

The preliminary workup of a potential kidney donor should include a general medical screen for obvious contraindications, such as hypertension and diabetes mellitus. Medical screening should be followed by the assessment of the donor and recipient blood groups and a crossmatch between donor and recipient; ABO compatibility is usually required for successful transplantation. Tissue typing is performed to determine the degree of HLA matching between donor and recipient. The degree of HLA matching has an important effect on long-term outcome and may affect donor selection when multiple potential donors

are available. The best long-term outcomes are obtained between two haplotype-matched siblings, although excellent results are possible with lesser degrees of HLA matching.[26] A crossmatch is also performed between the donor and recipient to detect preexisting antibody sensitivity against donor antigens in the recipient. A positive crossmatch generally precludes proceeding with transplantation because, in such circumstances, there is a high risk of hyperacute rejection. ABO incompatibility or a positive crossmatch between donor and recipient previously was considered a contraindication for transplantation; however, new techniques have been developed to allow successful transplantation in some cases of ABO mismatch or positive crossmatch. These techniques generally utilize plasmapheresis to remove preformed recipient antibody and are combined with pretransplant immunosuppression to inhibit antibody formation. Initial results have been good, and these techniques are being more widely applied.

LABORATORY TESTS

If ABO compatibility and a negative crossmatch are documented, evaluation of the prospective donor can proceed. Clinical testing of the potential donor should include a complete blood count, chemistry screen, urinalysis, urine culture, and coagulation studies. A 24-hour urine collection should be done to assess for creatinine clearance and any evidence of protein excretion. Serologic testing should include antibodies to HIV, CMV, EBV, and hepatitis B and C. In addition, a chest x-ray, an ECG, and a PPD skin test should be performed. Contraindications to live donation include impaired kidney function, significant nonorthostatic proteinuria (> 200 mg/24 hr), active malignancy, active substance abuse, severe chronic illness, and pregnancy.

ARTERIAL IMAGING

A careful assessment of arterial anatomy of the kidney donor is essential. In the past, this assessment required formal contrast angiographic studies. Currently, spiral computed tomography or magnetic resonance angiography has shown adequate sensitivity in detecting multiple renal arteries. These techniques are now being utilized at many transplantation centers.

SCREENING FOR INHERITED RENAL DISEASE

On occasion, the etiology of the renal disease in the recipient is unknown. In such circumstances, a detailed history must be obtained from the donor to determine whether there is evidence of familial renal disease.[27] Polycystic kidney disease is the most common hereditary kidney disease encountered. In cases in which the recipient has polycystic kidney disease, related donors must be carefully assessed for evidence of this disease. In patients older than 30 years, assessment is easily accomplished with a high-resolution CT scan for evidence of renal cysts. For patients between 21 and 30 years of age, this approach is somewhat controversial, and genetic studies may sometimes be necessary to find evidence of polycystic kidney disease. Donors with a family history of diabetes should undergo glucose tolerance testing. Patients with abnormal glucose tolerance should be excluded from donation. Patients who are normotensive but have a strong family history of essential hypertension may not be appropriate for donation. In an attempt to expand the donor pool, some transplant programs have begun to use living donors with mild and easily controlled hypertension; however, this issue is controversial, and these situations must be assessed on a case-by-case basis. Donors with a remote history of an isolated renal stone and no evidence of current stones on radiologic screening may be considered for donation. In this situation, the risk of recurrent stone disease is low. Persons with sickle trait are acceptable as donors. In most transplantation centers, there is no upper age limit for consideration of donor nephrectomy.

PSYCHOLOGICAL ASSESSMENT

Donors' motivation should be assessed to ensure that donations are voluntary and that donors have a good understanding of the potential outcomes for both themselves and the recipients. Kidney donation appears to provide psychological benefit for most donors. However, potential donors need to be aware that the outcome for the recipient cannot be guaranteed.

Pretransplantation Patient Management

IMMUNOSUPPRESSION

Clinical immunosuppression is an empirical and imprecise practice to provide prophylaxis against acute rejection without harming the patient or the graft. The reason for the imprecision is the lack of a satisfactory in vivo technique for determining the adequacy of immunosuppressive agents in a given patient. Inadequate immunosuppression results in rejection of the transplanted organ, whereas overimmunosuppression can lead to immunodeficiency, infection, and, possibly, malignancy. Nonimmune toxicity related to individual drugs, either alone or in combination with other drugs, necessitates close patient scrutiny and careful adjustments of not only immunosuppressive drugs but also drugs that can interact with them. Thus, there is a very delicate balance that needs to be achieved, and it must be determined individually for each patient. Although protocols have been developed to streamline immunosuppression strategies and provide a broad approach, these templates are limited because they require constant, careful adjustment. With the release of many new immunosuppressive medications in the past few years, immunosuppression is more complicated than ever. We have many new options, but clinical experience is needed to determine the optimal strategies for individual patients.

Standard immunosuppressive therapy is based on the premise that immediately after transplantation, the immune response is more vigorous and will require more medication for full suppression. In time, relative tolerance occurs and less immunosuppression is needed. However, our ability to determine the appropriate level of immunosuppression during this transition period from initial exposure to long-term relative tolerance remains difficult. Consequently, most immunosuppressive protocols start with high doses in the early posttransplantation period and steadily reduce the doses over time to a level that is believed to be appropriate for a given patient. The final dose is usually administered according to protocol but is adjusted on the basis of the presence or absence of infection, rejection, or nonimmune toxicity.

Immunosuppressive Drugs

The major classes of oral immunosuppressive drugs include corticosteroids, antimetabolites (e.g., azathioprine, mycophenolate mofetil, and mycophenolic acid), calcineurin inhibitors (e.g., cyclosporine and tacrolimus), and TOR (target of rapamycin) inhibitors (sirolimus). In addition to the previously mentioned

oral medications, monoclonal antibody preparations (anti-CD25 antibodies [i.e., daclizumab and basiliximab] and OKT3) and polyclonal antibody preparations (ATGAM [antithymocyte globulin] and RATG [rabbit antithymocyte globulin, also called thymoglobulin]) can be employed to prevent or treat rejection [*see Table 3*].

Corticosteroids Although corticosteroids have been important immunosuppressive drugs for many years, there is no general consensus on how best to use these agents. In the past, with few alternatives available, extremely high doses of corticosteroids were used. The nonimmune toxicity has been well described. Toxic effects include fragile skin, diabetes, hypertension, dyslipidemia, and avascular necrosis. However, corticosteroids also provide important immunosuppressive and anti-inflammatory effects by blocking the expression of several cytokines, the most important of which are interleukin-1 (IL-1) and IL-2. Current protocols employ much lower doses of corticosteroids, and it is unlikely that doses of up to 0.1 mg/kg/day will cause long-term problems. Important new evidence from clinical trials suggests that a rapid taper of steroids within 3 to 7 days after transplantation results in low rejection rates in subgroups of patients felt to be at lower risk for acute rejection (i.e., first-time transplant recipients and white recipients), particularly if immunosuppression has been induced with anti-CD25 antibody or RATG.[28] Thus, newer immunosuppression strategies may allow for near-complete avoidance of steroid use. This strategy may be safer than elimination of steroid use in the late posttransplant period, because long-term steroid use may condition the immune response in such a way as to result in an increased risk of rejection with late cessation. A meta-analysis of immunosuppression withdrawal trials indicated that withdrawal of steroids is more likely to precipitate acute rejection than is removal of calcineurin inhibitors.[29]

Antimetabolites Antimetabolites are an important part of immunosuppressive strategies, largely because they have no demonstrable nephrotoxicity and little effect on blood pressure, cholesterol levels, or glycemic control. Mycophenolate mofetil has generally replaced azathioprine because of its greater potency and specificity for affecting lymphocytes.[30,31] Gastrointestinal toxicity in the form of diarrhea and nausea and bone marrow toxicity are clinical problems that are usually resolved by dosage adjustment.

Azathioprine is a purine analogue that is incorporated into cellular DNA, where it inhibits purine nucleotide synthesis. It also interferes with the synthesis and metabolism of RNA. Mycophenolate mofetil, which is metabolized to mycophenolic acid, is a reversible inhibitor of the enzyme inosine monophosphate dehydrogenase, which is a critical rate-limiting enzyme in the de novo synthesis of purines in lymphocytes. Because lymphocytes rely exclusively on the de novo purine synthesis pathway rather than on the salvage pathway for purine nucleotide production, they are very susceptible to the effects of mycophenolate mofetil. An oral preparation of mycophenolic acid is available that has fewer gastrointestinal side effects than mycophenolate mofetil.

Table 3 Immunosuppressive Drugs

Class	*Drug*
Corticosteroids	Prednisone
Antimetabolites	Azathioprine Mycophenolate mofetil Mycophenolic acid
Calcineurin inhibitors	Cyclosporine Tacrolimus
TOR inhibitor	Sirolimus
Polyclonal antibodies	ATGAM RATG
Monoclonal antibodies	OKT3 Anti-CD25 Basiliximab Daclizumab Anti-CD20 Rituximab Campath-1H

ATGAM—antithymocyte globulin RATG—rabbit antithymocyte globulin
TOR—target of rapamycin

Calcineurin inhibitors Calcineurin inhibitors such as cyclosporine and tacrolimus have been the cornerstone of immunosuppression for over 20 years. However, the major drawback of these drugs is primarily related to their nonimmune toxicity, particularly nephrotoxicity.[32] The toxicity of these drugs is multifactorial and may involve direct and indirect effects. The major effect is intrarenal vasoconstriction leading to intrarenal ischemia and renal tubular cell toxicity. Early in the treatment, toxic effects are reversible if the drugs are discontinued. However, with long-term treatment, effects of the drugs, such as interstitial fibrosis and tubular atrophy, may be irreversible.[33] Recipients of kidneys that have preservation or reperfusion injury are particularly vulnerable to the nephrotoxic effects of calcineurin inhibitors.[34] Long-term use of these drugs may result in progressive loss of renal function, leading to dialysis or retransplantation. Clinical studies have indicated that calcineurin inhibitors can be successfully reduced or withdrawn 1 to 2 years after transplantation in patients with chronic allograft nephropathy who are receiving mycophenolate mofetil and steroids.[35] This practice is associated with stabilization of renal function, improved graft survival, and a low likelihood of acute rejection. In particular, mycophenolate mofetil and sirolimus may prove to be useful, less nephrotoxic substitutes for calcineurin inhibitors and may also provide an opportunity for improving long-term graft function.

Other nonimmune toxicities related to calcineurin inhibitors are largely metabolic. Cyclosporine commonly induces an increase in blood pressure, cholesterol levels, and, occasionally, serum glucose.[36] Tacrolimus, although it affects blood pressure and cholesterol levels to a lesser degree than cyclosporine, has a hyperglycemic effect in predisposed individuals. Concerns about these side effects are justifiable in that they affect both patient and graft survival because of increased risk of atherosclerotic cardiovascular disease and chronic allograft nephropathy. Other side effects related to cyclosporine include hirsutism, tremor, and gingival hypertrophy. Tacrolimus may also cause tremor, alopecia, and headache.

Calcineurin inhibitors primarily interfere with the immune system by binding to a cytoplasmic receptor protein, which in turn binds to an intracellular protein known as calcineurin. This action interferes with the activation of several genes that

are critical for interleukin expression—most importantly, IL-2. This lymphokine is particularly important with regard to the clonal expansion and generation of helper T cells and cytotoxic T cells.

TOR inhibitors Sirolimus is a newer immunosuppressant whose immunosuppressive activity is unique in comparison to the previously described drugs. Although sirolimus binds to a cytoplasmic binding protein similar to the one tacrolimus binds to, the drug–binding protein complex does not attach to calcineurin but, rather, targets the TOR protein and impairs the capacity of previously synthesized cytokines to activate T cells to enter the cell-division cycle.

Clinical trials indicate that sirolimus, the calcineurin inhibitor cyclosporine, and low-dose prednisone provide effective immunosuppression.[37,38] It also may be possible to combine sirolimus with mycophenolate mofetil and steroids.

The principal drug-related toxicity of sirolimus is hypertriglyceridemia and mild thrombocytopenia. There is limited evidence of nephrotoxicity unless sirolimus is combined with cyclosporine or, in some instances, tacrolimus.

Polyclonal and monoclonal antibodies Polyclonal and monoclonal antibodies are useful short-course therapies that may be helpful in providing initial or induction immunosuppression or in treating rejection.

Polyclonal antibodies have been available for many years. The currently available products are ATGAM and RATG. These agents are used primarily for either induction immunosuppression or the treatment of rejection. The primary mode of action is related to the clearance of lymphocytes in the reticuloendothelial system or through lysis after antibodies have become bound to T cells. Allergic reactions are the most common problem. In addition, because these agents are so potent, overimmunosuppression may occur. Monitoring of total lymphocyte counts is necessary to identify the optimal therapeutic dose. These agents are usually given for 1 to 2 weeks on a daily basis.

Monoclonal antibody preparations are a technological advancement over polyclonal antibody preparations. OKT3 antibody was the first monoclonal antibody approved for clinical transplantation.[39] It is specifically directed against the CD3 antigen complex found on all mature human T cells. It is a very effective and potent agent that is administered daily for 7 to 14 days. It is particularly useful for induction immunosuppression or for the treatment of rejection. Its major side effect is an acute cytokine release syndrome, which can be very serious in some patients, necessitating mechanical ventilation. Even though this side effect is uncommon, patients should be monitored very carefully, particularly after the first few doses.

Anti-CD25 monoclonal antibodies have recently been developed.[40] Two such agents, daclizumab and basiliximab, are largely humanized murine monoclonal antibodies against the IL-2 receptor site. These agents have been shown to be very effective in reducing the incidence of acute rejection if they are administered immediately before and shortly after engraftment. Side effects are negligible. Newer antibody therapies that target B cells include two anti-CD20 monoclonal antibodies: rituximab and campath-1H. Both may hold promise for treatment of vascular rejection; they may also help with induction immunosuppression, particularly in presensitized patients, although these drugs are not approved for use in transplantation.[41]

IMMUNOSUPPRESSION STRATEGIES

Induction immunosuppression is intended to minimize the risk of early rejection and to maximize the likelihood of the development of a stable form of tolerance. In addition, induction strategies can be adjusted to provide more immunosuppression for patients at higher risk, such as those undergoing a repeat kidney transplantation, those who are highly sensitized, and those who have a poor crossmatch. Likewise, induction immunosuppression can be adjusted to reduce or eliminate the exposure of calcineurin inhibitors early in the posttransplantation period in patients who have received a kidney that was partially damaged by a preservation injury such as ischemia and a reperfusion injury. The use of anti-CD25 antibodies, OKT3, or ATGAM can intensify immunosuppression and delay the need for calcineurin inhibitors until adequate graft function has been established. This strategy is based on the premise that the use of nephrotoxic immunosuppressants early in the posttransplantation period will slow the rate of renal recovery from the ischemic insult, thereby increasing the likelihood of delayed graft function, the subsequent need for dialysis and kidney biopsies, and the risk of rejection. Consequently, the use of steroids, mycophenolate mofetil, or sirolimus in conjunction with an antibody induction regimen is a popular strategy and has demonstrated important efficacy in the prophylaxis of early rejection.

The purpose of maintenance immunosuppression is to provide long-term prophylaxis against acute rejection while minimizing the risk of immune and nonimmune toxicities. The lack of in vivo or in vitro methods to determine the adequacy of immunosuppression necessitates the use of standardized protocols that are adjusted on a case-by-case basis in the presence of rejection or immune or nonimmune toxicity. Insufficient immunosuppression, which results in rejection, will necessitate intervention with powerful antirejection therapies, such as steroids in high doses or of polyclonal or monoclonal antibody preparations, and increase the risk of complications of overimmunosuppression (e.g., opportunistic infection and malignancy). Excess immunosuppression may result in opportunistic infection.

Conventional practice is to use three oral immunosuppressive agents, most commonly a corticosteroid, a calcineurin inhibitor, and either mycophenolate mofetil or sirolimus. With the availability of more therapeutic choices, fewer than three drugs may be effective; in some patients, lower doses of four drugs may be appropriate. Many centers now use anti-CD25 or RATG, followed by steroids (either low-dose steroids or standard-dose steroids that are eliminated early on) and drugs from two of three drug classes (i.e., a calcineurin inhibitor and either mycophenolate or sirolimus) to maintain immunosuppression. Thus, there is more complexity in the current clinical approach to immunosuppression.

Because immunosuppressive agents are given for a lifetime, careful scrutiny to prevent toxicity is of paramount importance. Such monitoring is particularly appropriate with regard to kidney function, because there is some concern that the inadequacy of immunosuppression can result in a chronic rejection process that leads to vasculopathy and progressive graft dysfunction. There is also concern that the calcineurin inhibitors themselves—despite their effectiveness in preventing rejection—can lead to a progressive interstitial fibrosis and scarring, either directly or indirectly, through their effects on blood pressure, cholesterol levels, and glucose metabolism. These concerns are of particular importance in patients who manifest evidence of progressive graft dysfunction and proteinuria. Adjustments in im-

munosuppression—primarily reduction or withdrawal of calcineurin inhibitors and the substitution of other agents to maintain adequate immunosuppression—are being actively studied as possible solutions to problems caused by calcineurin inhibitors. In addition, meticulous control of blood pressure, cholesterol levels, and glucose metabolism may also prove to be extremely important in reducing the likelihood of progressive graft dysfunction.

The usual treatment of acute rejection consists of high doses of corticosteroids (methylprednisolone, 500 to 1,000 mg/day for 3 days intravenously, followed by an oral steroid taper), the administration of the monoclonal antibody preparation (e.g., OKT3), or the administration of a polyclonal antibody preparation (e.g., RATG or ATGAM). The polyclonal or monoclonal antibody preparation can be given intravenously on a daily basis for 7 to 14 days. Once treatment for acute rejection has been administered, a careful evaluation of long-term maintenance immunosuppression should be performed to adjust the medications and to prevent subsequent rejection. Adjustment may require an increase in drug dose and levels, the substitution of new drugs, or even the addition of new medications.

Table 4 Causes of Renal Transplant Dysfunction

Category	*Causes*
Structural	Extrinsic compression (fluid collection) Ureteral obstruction (stone, scarring, mass) Urethral obstruction (prostate, stricture)
Vascular	Renal artery stenosis
Volume depletion	Cardiac failure Diuretics
Renal parenchymal	Acute rejection Chronic rejection Recurrent glomerulonephritis
Drugs	ACE inhibitors Angiotensin II receptor blockers Antibiotics Calcineurin inhibitors NSAIDs

ACE—angiotensin-converting enzyme NSAIDs—nonsteroidal anti-inflammatory drugs

Posttransplantation Complications

ACUTE AND CHRONIC RENAL TRANSPLANT DYSFUNCTION

Etiology

The causes of acute or chronic renal dysfunction in the long-term renal transplant recipient should be carefully evaluated. Dysfunction can be related to vascular, structural, or renal parenchymal disorders or to volume depletion [*see Table 4*].

Structural disorders The most common cause of structural dysfunction is disruption of the drainage system, usually by ureteral scarring and obstruction or, in the case of males, because of abnormalities of prostatic urethral outflow or stricture. Fluid collections can also cause clinically significant obstruction. A renal sonogram can be very helpful in elucidating the location of a potential obstruction. An appropriate radiologic or urologic intervention can be made to relieve the obstruction.

Vascular disorders Transplantation renal artery stenosis, suggested by the presence of decreased glomerular filtration rate (GFR) and hypertension, may also cause graft dysfunction. Although it is less common than ureteral abnormalities, renal artery stenosis can lead to hypertension associated with graft dysfunction that is more difficult to treat. Radiographic imaging techniques, such as duplex ultrasound and magnetic resonance arteriography, are critical to rule out this process. Renal artery stenosis of the transplanted kidney typically requires percutaneous transluminal angioplasty or surgical correction. Patients with normal GFR and hypertension who are discovered to have renal artery stenosis should be closely observed without intervention.

Volume depletion Volume depletion caused by loop diuretics leads to a reduction in renal function. Likewise, the use of nephrotoxic drugs such as the calcineurin inhibitors, nonsteroidal anti-inflammatory drugs, antibiotics, and other agents must be reviewed carefully. The use of angiotensin II receptor blockers or angiotensin-converting enzyme (ACE) inhibitors may cause transient reductions in renal function that are usually not of clinical significance. However, these changes may be magnified in the presence of excessive diuretic use and volume depletion or transplantation renal artery stenosis. In such cases, either discontinuance of the ACE inhibitor or angiotensin II receptor blocker or a dosage adjustment may be needed.

Renal parenchymal disorders Other major causes of allograft dysfunction can be related to renal parenchymal abnormalities. The three most important areas of concern are recurrent glomerular kidney disease, acute rejection, and chronic allograft nephropathy. A percutaneous allograft biopsy with careful tissue examination by light microscopy, electron microscopy, and immunofluorescence is critical to making the correct diagnosis. Although recurrent kidney disease can occur and, in selected cases, may result in progressive loss of renal function, it is much less likely to occur than acute rejection or chronic allograft nephropathy. Acute rejection occurs rarely, usually only if there has been a major change in immunosuppression. More common is chronic allograft nephropathy, which is a multifactorial process that may involve long-term alloimmune processes, metabolic processes, and direct toxicity of the calcineurin inhibitors.

Early Diagnosis of Dysfunction

Subtle increases in serum creatinine in long-term recipients of kidney transplants are not acceptable and must be explained. A high index of suspicion during early diagnostic efforts is essential to prompt the likelihood of early recognition and management of disease.[42] An ultrasound scan, a urinalysis, and a urine culture, along with a medication-list evaluation, are critical. If necessary, radiographic procedures and percutaneous graft biopsy should be undertaken.

POSTTRANSPLANTATION INFECTIONS

Although the incidence of acute rejection has decreased dramatically over the past decade, problems with infection related to the surgical procedure and immunosuppressive medications remain. Infections occur after transplantation in a relatively predictable pattern [*see Figure 1*]. This pattern is influenced by the degree of immunosuppression.

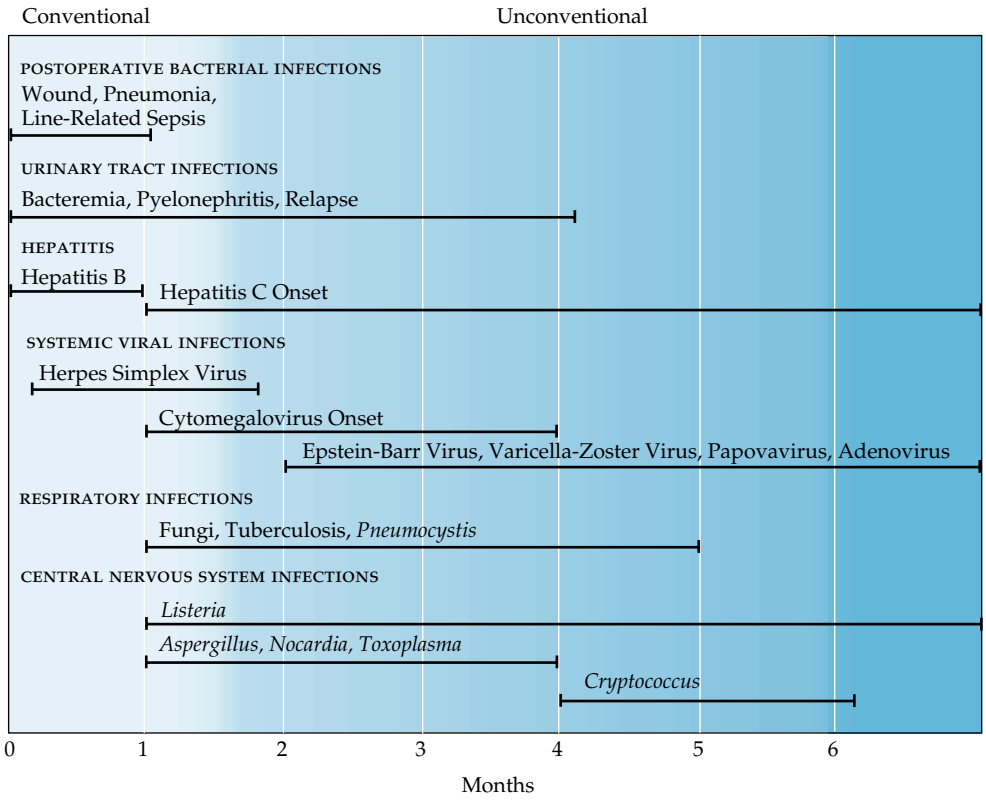

Figure 1 **Timing of conventional and unconventional infections in the renal transplant recipient.**

Fishman and Rubin have grouped the occurrence of posttransplantation infections into three periods.[43] In the first month after transplantation, the most common infections are those resulting from complications of the surgical procedure, such as wound infections, catheter-related urinary tract infections, aspiration pneumonia, and infections of hematomas or lymphoceles. Occasionally, infections may be transmitted by the allograft.

After the first month, the spectrum of infection changes. The high dose of immunosuppressive drugs used early in the transplantation procedure places the patient at risk for a variety of opportunistic bacterial, fungal, and viral infections from such organisms as *Nocardia, Aspergillus, Cryptococcus,* and *Candida*. The activation of latent viral infections from such pathogens as CMV, EBV, and varicella also pose a threat during this period.

Six months after transplantation, most immunosuppressive medications have been reduced to relatively low levels. Community-acquired respiratory infections from pneumococcal, influenzal, and other respiratory pathogens are more common than opportunistic viral or fungal infections.

Cytomegalovirus

CMV is perhaps the most important posttransplantation infection. The risk of CMV infection, which can present as a systemic viral illness, pneumonia, or gastrointestinal disease, is related to the serologic status of the donor and recipient. A primary CMV infection is transmitted by the organ of a seropositive donor to a seronegative recipient. CMV disease will occur in 60% to 75% of such cases and tends to be severe unless effective prophylactic measures are instituted. A reactivation infection occurs when latent viruses are reactivated in a seropositive recipient. In this situation, the disease is generally less severe and occurs in about 20% of such recipients. The decrease in severity of the disease may be related to the preexisting immunity of the recipient. The incidence and severity of CMV disease has been shown to be decreased by prophylactic oral ganciclovir or valganciclovir, which is started at the time of transplantation and continued for approximately 12 weeks. If CMV disease occurs, treatment with high-dose intravenous ganciclovir or valganciclovir with reduction in immunosuppressive medications provides effective control.

Polyomavirus

Most transplant recipients harbor a latent infection with the BK strain of polyomavirus. This virus is acquired in childhood by virtually all individuals and is thought to remain latent in the kidney and genitourinary tract. With chronic immunosuppression, it may reactivate and cause a progressive fibrotic and inflammatory nephropathy that results in gradual loss of renal function.[44] It may also cause ureteral obstruction. This infection results in a clinical picture that resembles chronic rejection or chronic allograft nephropathy. It has been seen with increasing frequency in association with the use of more potent immunosuppressive medications. The incidence is likely related to the overall degree of immunosuppression and not to the use of any specific drug.

Urine cytologic examination has proved to be an effective screening tool for reactivation of polyomavirus. Patients with reactivated polyomavirus will shed identifiable renal tubular cells containing viral inclusion bodies, the so-called decoy cells. Up to 20% of renal transplant recipients have been reported to shed decoy cells in their urine, although a much smaller number of patients actually have active nephropathy. A transplant biopsy is required to confirm the presence of active nephropathy. These biopsies typically show scattered inflammatory cell infiltrates

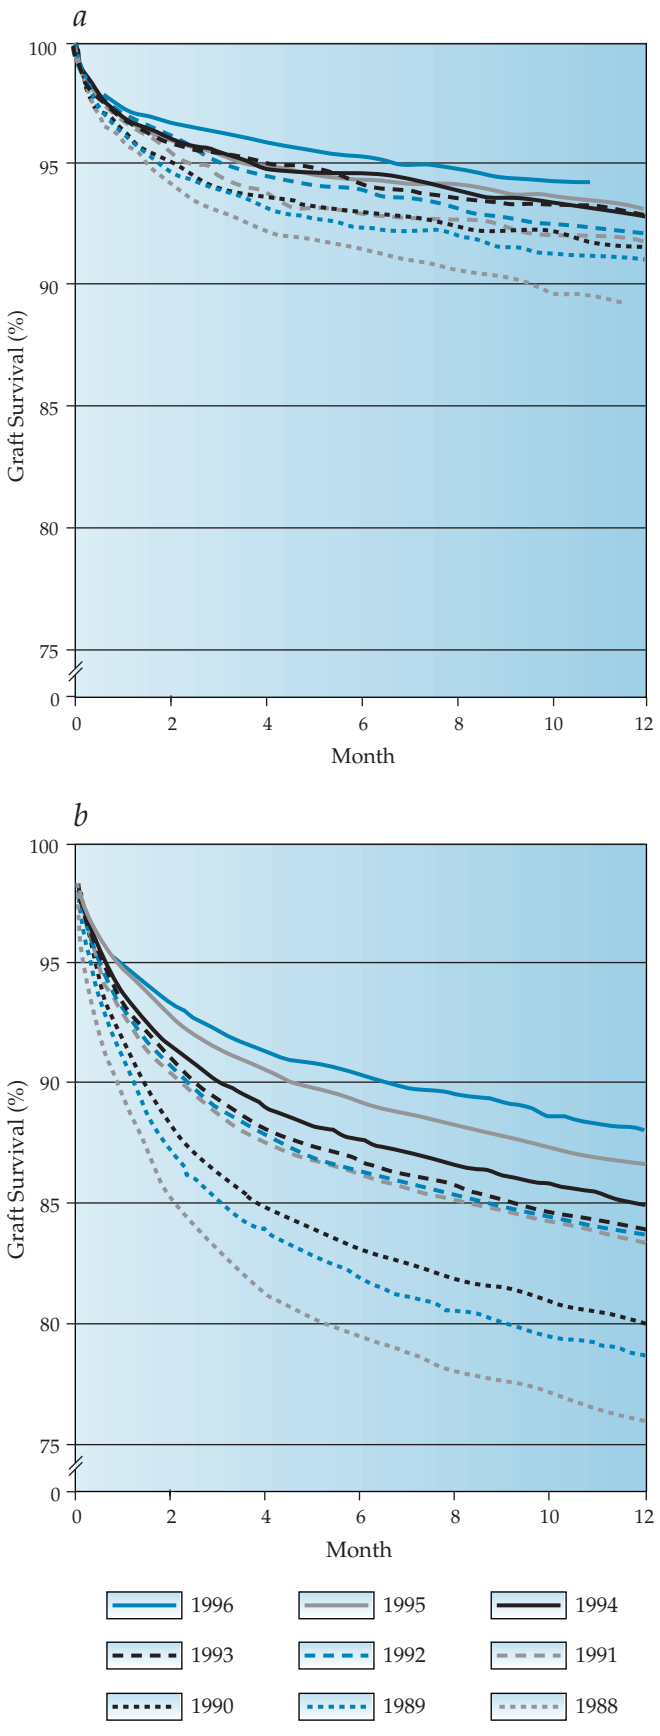

Figure 2 **Kaplan-Meier estimates of graft survival during the first year after transplantation from living donors (*a*) and cadaveric donors (*b*) from 1988 to 1996.**

and tubular cells with viral inclusion bodies. A urine cytology evaluation that does not show decoy cells virtually eliminates the possibility of active polyomavirus nephropathy.[45] There is at present no known therapeutic strategy to correct this disorder other than to reduce immunosuppression. Unfortunately, the reduction of immunosuppression occasionally results in the development of acute rejection.

Epstein-Barr Virus

Transplant recipients who are seronegative for EBV are at high risk for infection if they receive organs from seropositive donors. A primary EBV infection places patients at risk for EBV-related lymphoproliferative disease. This syndrome is a spectrum of illnesses that may range from a virally driven B cell proliferation presenting as a mononucleosis-like disorder to a high-grade malignant lymphoma. The transplantation of an allograft that is seropositive for EBV into a seronegative recipient should be avoided if possible. If such a transplantation is unavoidable, the recipient should be placed on long-term antiviral prophylaxis with acyclovir or ganciclovir.

Urinary Tract Infections

Prophylactic strategies are routinely employed to prevent postoperative urinary tract infections. Patients with structural abnormalities or functional bladder problems are at particular risk. Trimethoprim-sulfamethoxazole is commonly prescribed on a daily basis for 3 to 6 months. This regimen also provides effective prophylaxis for *Pneumocystis* pneumonia and *Nocardia* infections.

Parvovirus B19

Parvovirus B19 is the etiologic agent of the highly contagious erythema infectiosum (fifth disease). It is a common infection in childhood; half of 15-year-old adolescents have specific antiparvovirus B19 antibodies. Infection occurs at a lower rate throughout adult life.

Parvovirus B19 is known to infect the human erythroid progenitor cells in the bone marrow. Failure to develop protective antibodies following infection in an immunosuppressed patient may result in persistent B19 infection and a severe anemia resulting from a pure red cell aplasia. Assays of viral DNA are required to diagnose persistent infection. Treatment is based on the use of intravenous immunoglobulin to provide neutralizing antibodies that result in clearance of the virus and may produce a permanent cure.[46]

Long-term Management Strategies and Outcomes

The introduction of many new immunosuppressive agents, particularly cyclosporine, has dramatically improved short-term outcome of renal transplantation. The incidence of acute rejection is often less than 10% in the first year, and newer drugs have helped provide a noticeable improvement in long-term graft survival [*see Figure 2*]. Hariharan and colleagues demonstrated that from 1988 to 1996, the 1-year survival rate for kidney grafts from living donors increased from 88.8% to 93.9%, and the rate for cadaveric grafts increased from 85.7% to 87.7%.[47] More important, the projected half-life for grafts from living donors increased from 12.7 years to 21.6 years, and the projected half-life for cadaveric grafts increased from 7.9 years to 13.8 years. After censoring the data for patients who died with functioning grafts, the projected half-life for grafts from living

donors increased from 16.9 years to 35.9 years; for cadaveric grafts, half-life increased from 11.0 years to 19.5 years. Thus, the newer immunosuppressive agents have had a substantial positive effect in reducing the risk of acute rejection in the first year and on improved long-term graft survival.

Long-term graft failure is usually the result of the death of a patient with a functioning graft, chronic rejection, or recurrent kidney disease. Greater interest has been placed on strategies to improve long-term patient and graft survival.

PREVENTION OF CHRONIC REJECTION

Long-term studies show that chronic rejection remains the second most important cause of graft loss.[48] The leading cause of graft failure is patient death, which is usually caused by cardiovascular disease. The prevalence of chronic rejection ranges from 10% to 80%, depending on the duration of follow-up. Chronic rejection may be related to either past events (e.g., graft injury), current events (e.g., rejection, dyslipidemia, diabetes), or both.

The most important predictor of chronic rejection is a previous episode of acute rejection, particularly acute rejection after the first year. Other factors that may increase the risk of chronic rejection include ongoing immunologic injury, African-American ancestry, poor HLA matching, poor blood pressure control, and injury to the graft at the time of transplantation (i.e., ischemia or reperfusion injury) [*see Figure 3*]. Early factors that predispose to chronic rejection are delayed graft function and acute rejection. After 6 months, acute rejection remains an important risk factor; factors such as coexistent hypertension and diabetes increase risk.[49,50]

Because chronic rejection is not always a specific alloimmune process and may reflect a number of diseases, more attention has been focused on clinical factors that may contribute to the chronic vasculopathy that leads to progressive obsolescence of the vessels within the kidney and the progressive ischemic injury resulting in interstitial fibrosis, scarring, and nephron loss. When chronic rejection is suspected, a kidney biopsy is essential, because the kidney pathology can guide the decisions concerning treatment and changes in medication.

The critical plan is to have a high index of suspicion for kidney biopsy and undertake biopsy when there are subtle changes in kidney function or new evidence of proteinuria.

MANAGEMENT OF COEXISTING DISEASE

The long-term follow-up of renal transplant recipients should focus primarily on diseases that have been shown to be major causes of recipient morbidity and mortality and to lead to progressive injury of the allograft. The major causes of renal transplant recipient mortality are coronary artery disease, cancer, infection (sepsis), and progressive hepatic dysfunction resulting in liver failure.

The major causes of progressive cardiovascular disease in transplant recipients are primarily related to hypertension, hyperlipidemia, and diabetes mellitus.[51] Improved control of blood pressure, serum glucose level, and lipid level are some of the most important factors in preventing cardiovascular events. Kidney transplant recipients have a much greater risk of cardiovascular events compared to the general population; this increased risk is not entirely explained by traditional Framingham Heart Study cardiovascular risk factors.[52] Consequently, more attention must be placed on controlling known cardiovascular risk factors and reducing the metabolic consequences of immunosuppressive drugs.

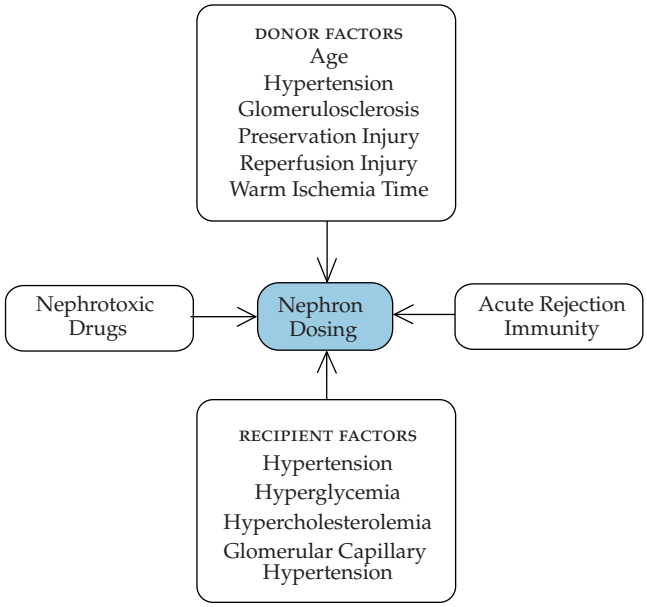

Figure 3 **Paradigm for the development of chronic allograft nephropathy.**

Hypertension

Hypertension is one of the most common complications after renal transplantation; it has multiple etiologies. Hypertension can be a pretransplant condition as well as a complication of transplantation. The prevalence of hypertension, which is frequently as high as 80% or 90%, is in large part caused by disease in the native kidneys and immunosuppressive medications such as cyclosporine and corticosteroids. Cyclosporine not only causes direct vasoconstriction but also induces preglomerular vasoconstriction, which results in a salt-sensitive, volume-dependent form of hypertension. In addition, cyclosporine may have indirect vasoconstrictive effects through an alteration of the balance of vasodilatory and vasoconstricting prostaglandins. Effects on the renin-angiotensin system, the sympathetic nervous system, or both can occur with or instead of the alteration in prostaglandin balance.[53] Graft dysfunction can also worsen the hypertensive process. Renal artery stenosis occurs infrequently but should be considered if blood pressure control is resistant to therapy or renal function worsens as blood pressure is better controlled.

Historically, high blood pressure in renal transplant recipients has not been optimally treated because of the many concomitant medications these patients require for their various medical problems. Many transplant recipients will require from three to five medications to achieve a blood pressure of 140/90 mm Hg. Epidemiologic analyses indicate that there is a direct correlation between systolic blood pressure and graft half-life.[54] A systolic blood pressure near 120 mm Hg is optimal for prolonging graft function. This level of blood pressure control is achieved in only a minority of patients in clinical practice, not only because of the many drugs required but also because of physician reluctance to accept these blood pressure goals, particularly in older hypertensive patients who have only one kidney. Current guidelines of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommend a blood pressure goal of less than 130/80 mm Hg for all patients with kidney disease, diabetes, or microalbuminuria.[55] This includes all kidney transplant recipients; howev-

er, observational data in transplant recipients suggest that 120 mm Hg is a preferable goal.

As in patients with native renal disease, drugs that block the renin-angiotensin system should be routinely employed as part of a multidrug strategy to improve blood pressure control. ACE inhibitors and angiotensin II receptor blockers provide better control of glomerular capillary pressure and proteinuria than do other commonly used drugs. This effect may be important in stabilizing renal function and preventing loss of graft function. These drugs may also produce blood pressure–independent benefits by attenuating glomerular scarring and interstitial fibrosis. Physicians frequently avoid these drugs because of concerns about increases in potassium or serum creatinine levels, which could be misconstrued as indicating rejection. These drugs can be used safely, especially 3 to 6 months after transplantation, when the risk of rejection is markedly reduced.

Hyperlipidemia

Hyperlipidemia is common after transplantation. It is usually characterized by increased total cholesterol. The etiology of posttransplantation dyslipidemia is multifactorial but is, in part, related to immunosuppressive drugs given in combination, particularly corticosteroids and cyclosporine. Newer medications, such as sirolimus, may also adversely affect lipid profiles. Frequently, lipid abnormalities will improve within 3 to 6 months after transplantation, as the doses of immunosuppressants are reduced. However, there is a clear association between cardiovascular disease and posttransplantation hyperlipidemia that needs to be considered.[56] More often than not, dietary measures are insufficient to control lipid abnormalities, and frequently, the use of HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors (statins) are necessary. Although some early reports indicate that higher doses of statins have the potential to cause rhabdomyolysis, particularly in combination with cyclosporine, this problem is unusual. Occasionally, a poorly described form of myopathic pain occurs and subsequently disappears when the medication is discontinued. Other medications, such as fibrates and nicotinic acid, may be necessary to facilitate control of lipids. Azetimide is a new nonabsorbable agent that can be combined with statins to reduce serum levels of low-density lipoprotein (LDL) cholesterol, which plays a major role in the development of atherosclerosis. Caution is warranted before combinations of cholesterol-lowering agents are administered, so that drug-drug interactions are avoided. If patients have diabetes, improved glycemic control is helpful.

Control of hyperlipidemia is an important factor that may affect not only patient survival but also graft survival. Progressive vascular disease in the form of atherosclerosis can occur in the graft as chronic vasculopathy and may contribute to the development of tubulointerstitial ischemia, scarring, and fibrosis. Current adult treatment guidelines recommend maintaining LDL cholesterol levels below 100 mg/dl in patients who have coronary artery disease or who have risk factors for coronary artery disease; however, newer clinical studies illustrate the advantage of treatment that maintains LDL cholesterol levels below 70 mg/dl.[57,58] Lower treatment goals are likely to be advantageous for kidney transplant recipients, given their high cardiovascular disease burden and high cardiovascular death rates.

Diabetes Mellitus

With the increasing numbers of patients who have type 2 (non–insulin-dependent) diabetes mellitus as the cause of end-stage renal disease and older patients who are susceptible to diabetes, abnormalities of glucose tolerance are common after transplantation.

Posttransplantation diabetes mellitus occurs de novo in 4% to 20% of patients.[59] However, it is likely that this number underrepresents the amount of glucose intolerance and clinical diabetes in transplant recipients because of the common use of random glucose or fasting glucose measurements in monitoring patients. Many of the immunosuppressive agents, particularly corticosteroids and tacrolimus, cause or exacerbate posttransplantation diabetes. Cyclosporine may also be diabetogenic.

Efforts designed to improve glycemic control may be helpful in reducing the likelihood of progressive vasculopathy in the transplanted kidney. Minimizing or stopping corticosteroid therapy can markedly improve glycemic control. In patients who are more than 6 months beyond transplantation and who have not experienced rejection, corticosteroids can be completely withdrawn. Diabetogenic agents such as tacrolimus can be replaced with nondiabetogenic immunosuppressants such as sirolimus. Ideally, glycated hemoglobin (HbA_{1c}) should be reduced to less than 7%; this results in fewer cardiovascular events and a reduction of diabetic target organ damage.[60]

MANAGEMENT OF OTHER LONG-TERM MEDICAL CONDITIONS

Musculoskeletal Conditions

Other posttransplantation problems include musculoskeletal conditions, such as osteoporosis. This condition stems from the older age of the patients receiving transplants, the presence of diabetes, poor nutritional state, and concomitant use of corticosteroids. Clinical studies suggest that the majority of bone loss occurs in the first 6 months after transplantation, when steroid use is at its highest. Although newer immunosuppressive regimens employing lower doses of steroids have reduced the frequency of avascular necrosis, osteopenia and osteoporosis remain widespread. These conditions can progress and lead to pathologic fractures, vertebral collapse, and substantial morbidity. Consequently, early identification of bone loss with dual-energy x-ray absorptiometry (DEXA) scanning and interventional therapy with calcium, vitamin D, bisphosphonates, and calcitonin are important in preventing pathologic fractures. Occasionally, hyperparathyroidism can persist after transplantation despite restoration of normal renal function. Chronic hyperparathyroidism may also lead to osteopenia and may require surgical correction.

Chronic hyperparathyroidism may require 6 to 12 months to resolve after successful transplantation. Vitamin D therapy may be useful in suppressing parathyroid activity. Patients with hyperparathyroidism that persists beyond 12 months are candidates for parathyroidectomy.

Hematologic Conditions

Hematologic conditions are usually caused by immunosuppressants or excessive blood draws. Anemia and leukopenia are not uncommon. Many of these conditions can be corrected with vitamins, iron, folate, and reduced doses of antimetabolites or reduction in the frequency of blood draws. Parvovirus infection can also cause anemia, and inadequate renal function may require concomitant use of erythropoietin. Infection with parvovirus B19 can be diagnosed by changes in serology or by detection of the parvovirus genome in sera or bone marrow by polymerase chain reaction. Leukopenia can be caused either by

infection, such as CMV, or by medications, such as azathioprine or mycophenolate mofetil. Drugs that block the renin-angiotensin system, such as ACE inhibitors or angiotensin II receptor blockers, may also cause a 10% to 20% reduction in hematocrit.

Erythrocytosis may develop in 10% to 15% of renal transplant recipients. Repeated phlebotomy or use of ACE inhibitors or angiotensin II receptor blockers can normalize the hematocrit in most patients.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XII NEPHROLITHIASIS

Fuad N. Ziyadeh, m.d.
Stanley Goldfarb, m.d.

The annual incidence of nephrolithiasis in the United States is 7 to 21 per 10,000 population (higher in the Southeast and lower in the Northwest), and the annual incidence of hospitalization for nephrolithiasis is 7 to 10 cases per 1,000 admissions.[1] As many as 5% to 10% of all cases of active stone passage may require hospitalization to manage complications such as urinary tract obstruction, infection, and severe pain.

Active Stone Passage

DIAGNOSIS

Clinical Presentation

Patients with active stone passage generally present with pain and either microscopic or macroscopic hematuria. Usually, the pain begins abruptly, is severe, is constant rather than colicky, and is either localized to the flank or radiating from the flank to the groin area. Flank pain may be associated with nausea and vomiting. Midanterior abdominal pain, however, is an uncommon clinical presentation of stone passage and should prompt a careful search for other disorders.

The site of obstruction determines the location of pain. A stone in the renal pelvis or upper part of the ureter usually causes flank pain, whereas a stone in the middle or lower ureter causes radiation of pain to the groin and genitalia. Obstruction at the terminal ureter usually results in signs and symptoms that mimic those of cystitis (urinary frequency, urgency, and dysuria), as well as pain in the lower abdomen. Occasionally, patients present with signs of extracellular volume depletion as a result of vomiting. Atypical presentation may include obstruction without pain or hematuria, progressive renal failure, urosepsis, or adynamic paralytic ileus, which may suggest a primary gastrointestinal disorder.

Passage of a sloughed papilla, clot, or fungal ball can produce renal colic and symptoms similar to those produced by the passage of a stone.

Laboratory Studies

If active stone passage is suspected, freshly voided urine should be filtered to recover stones or gravel. Microscopic examination of freshly voided, warm urine can detect diagnostically important crystalluria. Although the finding of hematuria has been considered a hallmark of acute stone passage, studies utilizing sensitive imaging techniques suggest that 20% to 25% of patients with acute stone passage may not have hematuria.[2,3] Urine specimens should be sent for culture in all cases of nephrolithiasis because the coexistence of unsuspected infection and obstruction could lead to sepsis and death. Stones are best analyzed by x-ray diffraction, but infrared spectroscopy is an acceptable alternative.

Leukocytosis may indicate concurrent infection but may also result from stress-induced demargination of leukocytes. Total serum content of CO_2 may be low in the case of acute respiratory alkalosis resulting from associated pain or anxiety or may be high in the case of metabolic alkalosis resulting from vomiting.

It is generally not useful to perform extensive biochemical screening tests of calcium metabolism during active stone passage. Serum calcium levels could be falsely elevated as a result of concurrent extracellular fluid volume depletion. Also, abnormalities in levels of urinary calcium, phosphate, and citrate, as well as pH, may be induced by acute obstruction; therefore, the values obtained would not reflect true steady-state conditions. Such metabolic evaluations should usually be delayed until at least 6 weeks after an acute stone episode.[4]

Radiologic Studies

Radiologic studies are very useful in the initial evaluation of active stone passage. A flat film of the abdomen may show the location of a radiopaque stone and may also provide evidence of ileus. Ultrasonography may detect radiolucent stones and can identify urinary tract obstruction. However, ultrasonography may fail to identify very small stones (< 5 mm in diameter) and cannot define the degree or site of obstruction. Intravenous urography (IVU) is a standard method for examining the urinary tract for obstruction in cases of renal colic [*see Figure 1*]. A meta-analysis has shown the accuracy of helical scan computed tomography to be superior to IVU in diagnosing acute nephrolithiasis.[5] This modality is now widely available and should be employed, although its higher cost must be considered.

Recommended Workup

Patients presenting with acute onset of abdominal or flank pain should be evaluated for the possibility of nephrolithiasis. If therapy is to be initiated for a presumed kidney or ureteral stone, red blood cells should be detected on urinalysis or a radiodense stone should be seen on flat abdominal film. If hematuria is absent or if a stone is not seen on a flat film of the abdomen, a helical CT scan should be performed. If a stone is not seen on helical CT scan, the diagnosis of nephrolithiasis can be ruled out.

TREATMENT

Most kidney stones less than 5 mm in diameter pass into the urine within 48 hours after the onset of an acute episode of renal colic. Up to 20% of patients with a kidney stone require some form of intervention to effect passage of the stone. Patients generally require supportive treatment for pain and for extracellular fluid volume depletion or dehydration. The majority of patients do not require hospitalization unless they have infection, obstruction, severe pain, or intractable vomiting. If a stone that causes total obstruction does not pass, active intervention is needed [*see Figure 1*]. Urgent nephrostomy relieves the obstruction and can be followed by extracorporeal shock wave lithotripsy (ESWL), percutaneous lithotripsy, retrograde basket retrieval of the stone, or, in rare instances, surgical intervention.[6]

Chronic and Recurrent Nephrolithiasis

Pursuit of extensive biochemical studies in patients who have passed a single stone is controversial, particularly when there is no evidence of continued stone formation. Although the decision to proceed with diagnostic studies and laboratory evalua-

tion should be individualized, most physicians delay evaluations until metabolic activity can be substantiated by the formation of new stones or by an increase in size in situ of a known stone. However, one study of stone-forming patients suggested that the greater the number of stones occurring before therapy is instituted, the greater the likelihood of relapse.[7]

Nephrolithiasis usually recurs; in males, there is a 40% chance of recurrence within 5 years and an almost 60% chance within 10 years after the appearance of the first stone.[6] Recurrence rates for females are about two thirds those of males.[8] A stone may remain asymptomatic and without associated metabolic activity; however, the cumulative occurrence of a symptomatic event related to stone passage over a period of 5 years is about 50%.[9]

DIAGNOSIS

Laboratory Studies

A detailed evaluation of patients should include duplicate measurements, taken at different times, of 24-hour urine levels of calcium, phosphate, uric acid, sodium, citrate, oxalate, cystine, creatinine, and urea nitrogen, as well as urine volume.[10] Patients must not deviate from their normal diet and fluid intake before testing. Modification of diet or fluid intake before the assessment may obscure the possible role of these factors in the pathogenesis of the patient's stone diathesis. Concomitant plasma determinations of calcium, phosphate, creatinine, uric acid, bicarbonate, and urea nitrogen should be obtained. Fasting urinary pH should be checked in all cases, especially in those patients with hypokalemia, hyperchloremic acidosis, or radiologic evidence of nephrocalcinosis, which are all findings characteristic of distal renal tubular acidosis. Microscopic examination of urine, which can detect crystals and signs of infection [*see Figures 2a through d*], should be performed, and specimens should be sent for urine culture to determine the type of stone [*see* Crystallographic Analysis, *below*].

Radiologic Studies

Radiologic studies can localize in situ stones, document current stone size, and assess the possible efficacy of future therapy aimed at shrinking stones and preventing new stone formation. An abdominal plain film is the initial radiologic study test because of its availability and practicality in an acute setting; however, it has limited sensitivity and specificity in the diagnosis of stones. A CT scan of the kidney is an excellent modality for identifying all radiolucent or radiopaque calculi, but cost limits its routine use. Noncontrast-enhanced spiral CT is very effective in determining the presence of urinary tract obstruction in patients with acute flank pain, and the entire test can be completed within 5 minutes.[5] Spiral CT can differentiate between a ureteral calculus and a phlebolith overlying the ureter.[11]

IVU is the previous gold standard for identifying stones and remains useful in planning therapy and confirming diagnosis. It is more sensitive and more specific than ultrasonography in identifying stones.[12] Ultrasonography is able to show a dilated renal pelvis, which indicates that obstruction is likely. IVU is able to show not only a dilated renal pelvis or dilated ureter but also the site or level of obstruction. IVU affords the additional benefit of assessing how urine flow and, consequently, kidney function are affected by the obstruction. Slow or absent urine flow proximal to the site of obstruction indicates poor kidney function.

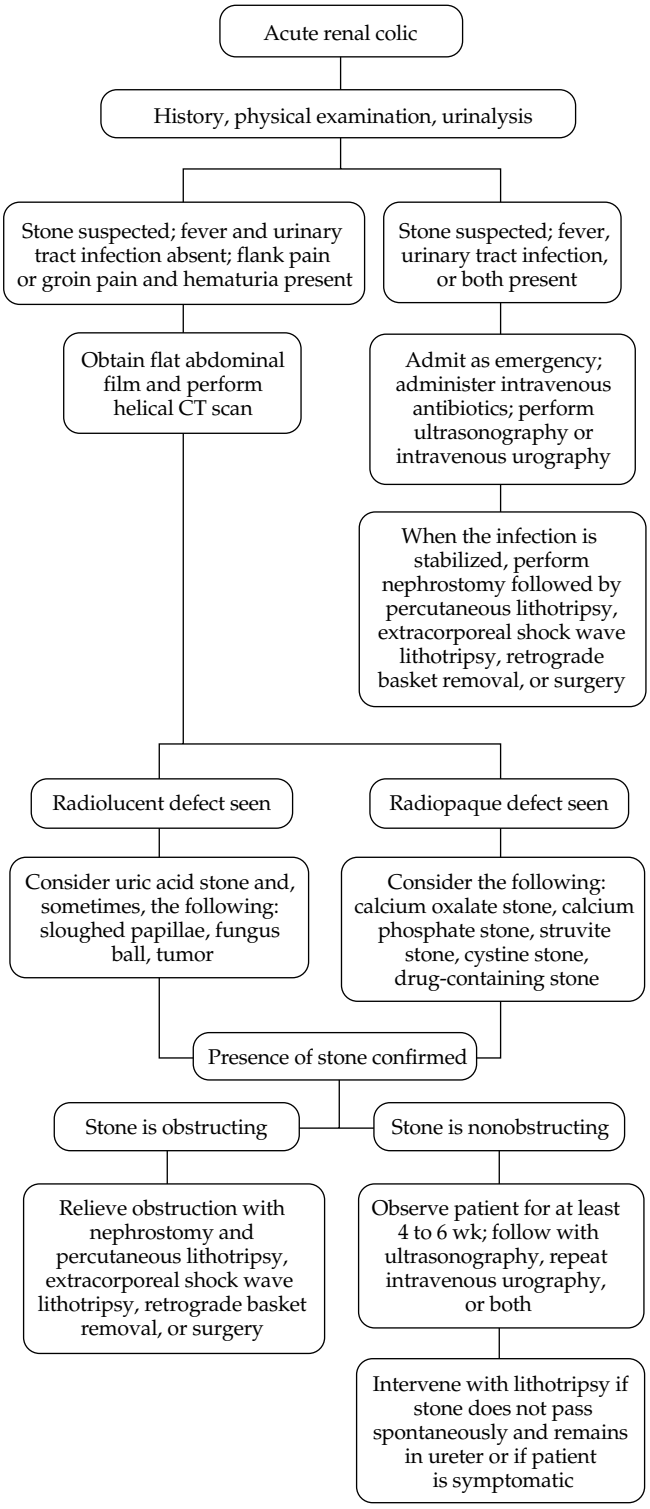

Figure 1 **This flowchart diagrams the protocol for diagnosing and treating a patient with acute renal colic.**

A follow-up flat abdominal film with or without tomography should be obtained and compared with any previous films to identify changes in the size, number, and location of stones. Quality of the plain abdominal film is improved if the patient takes a laxative the night before. Such films can be used for subsequent monitoring of in situ stones.

Crystallographic Analysis

Crystallographic analysis of renal stones serves as the basis for the diagnostic evaluation [*see Table 1*]. Stone formation is determined by the characteristics of urine, including its stone-forming constituents, volume, pH, and the various inhibitors of crystal formation, aggregation, and growth. The majority of patients with urolithiasis form calcium stones, most of which are composed of calcium oxalate or, less often, calcium phosphate. Other types of stone include uric acid, struvite, and cystine stones. In HIV patients, antiretroviral agents may induce urolithiathasis [*see* Drug-Induced Stones (Indinavir and Nelfinavir Stones), *below*]

OVERVIEW OF MANAGEMENT

The long-term treatment goal for patients with recurrent nephrolithiasis is to prevent new stone formation and growth of existing stones. Prevention of renal stone formation and growth can be accomplished by reducing the concentration of stone-forming constituents in the urine, manipulating the ionic milieu of the urine to favor solubilization of these stone-producing constituents, and correcting any mechanical or structural abnormalities that are associated with stasis in the urinary tract.

Although prevention should always be a major focus of therapy, there is an important role for stone removal in the initial evaluation. Percutaneous nephrostolithotomy and open surgery are equally effective for the management of renal stones, but percutaneous nephrostolithotomy shortens hospitalization by 60% and leads to a much more rapid return to normal activities.[13] It should be noted that percutaneous nephrostolithotomy is highly operator dependent, and published data from the highly experienced centers cannot be generalized to every urology practice. Percutaneous stone-removal procedures are currently reserved for patients with the following conditions:

1. Extremely large (> 2 cm in diameter) or complex calculi.
2. Cystine stones that are relatively resistant to ESWL.
3. Anatomic abnormalities, including horseshoe kidneys or ureteropelvic junction obstruction.
4. Stones within caliceal diverticula.

ESWL, which employs high-energy shock waves produced by an electrical discharge, is a major advance in the treatment of renal and ureteral stones, and most renal and proximal ureteral stones are currently managed by this technique. The shock waves are transmitted through water and directly focused on a renal stone, a ureteral stone, or both with the aid of biplanar fluoroscopy. The change in tissue density between the soft renal tissue and the hard stone causes a release of energy at the stone surface, which fragments the stone. Current lithotriptor technology is quite effective in fragmenting the majority of renal and ureteral calculi; data suggest that the technique is safe.[14] Recovery of stone fragments after ESWL provides important information about stone composition, which, in turn, allows the clinician to develop a management plan that minimizes recurrent stone formation.

Calcium-Containing Stones

DIAGNOSIS

Urinary calcium excretion is normally less than 300 mg/24 hr in males and less than 250 mg/24 hr in females, or less than 4 mg/kg body weight/24 hr.[15] Fasting urinary pH should be measured in all patients with calcium-containing stones to identify those patients who form hypercalciuric stones and those who form normocalciuric stones, because the management differs accordingly. If after a 12-hour fast urinary pH is greater than 6.0 in the absence of urinary tract infection (a potential cause of increased urinary pH if the infecting organism produces the ectoenzyme urease), an ammonium chloride acid loading test (100 mg/kg body weight, using a 500 mg/5 ml oral solution) should be performed. If urinary pH does not fall to less than 5.4 when serum bicarbonate falls below 20 mEq/L, classic distal renal tubular acidosis is present. In this condition, hypercalciuria occurs because acidosis enhances bone resorption and directly reduces reabsorption of calcium in the distal nephron.

RISK FACTORS FOR RECURRENT STONE FORMATION

The risk factors for calcium-containing stones include increased crystalloid concentration in the urine as a result of tubular disorders, hypercalcemia and hypercalciuria, hyperoxaluria, hyperuricosuria, reduced urine volume, abnormalities in the excretion of inhibitors of stone formation, and the presence of promoters of stone formation.[16] Calcium-containing stones may be primarily calcium oxalate or calcium phosphate [*see Table 1*]. Often, a person at risk has a family history of calcium stones.[17] Hypercalciuria is present in approximately 60% of patients with calcium-containing stones but is also detected in about 10% of people who never form stones. Studies have shown that genetic defects may underlie some forms of nephrolithiasis. Mutations in the gene encoding a chloride channel (*CLC-5*) expressed in the distal tubule may manifest themselves in a variety of phenotypic conditions, including hypercalciuria and proteinuria.[18] Various conditions increase the risk of stone formation; identification and correction of these underlying conditions is key to prevention of stone recurrence.

Specific Tubular Disorders

Distal (type 1) renal tubular acidosis contributes to stone formation in two ways: persistently high urine pH, which favors precipitation of calcium phosphate, and low levels of citrate excretion, which is normally an inhibitor of stone formation. Renal tubular acidosis should be suspected when one or more of the following are present: punctate medullary nephrocalcinosis, metabolic acidosis with a normal anion gap (hyperchloremic acidosis), alkaline urine pH, and hypokalemia. These findings, however, can be absent in so-called incomplete distal renal tubular acidosis, during which the serum bicarbonate concentration and the blood pH are within the normal range but only intracellular acidosis is present. The fasting urinary pH is not maximally acidic (pH > 5.8) and fails to fall during ammonium chloride acid loading. Intracellular acidosis is manifested by a reduction in the excretion of urinary citrate, the principal chelator of urine calcium and an inhibitor of crystallization.[19] Citrate excretion is usually reduced in states of metabolic acidosis, which stimulates the proximal reabsorption of this anion.[15]

Hypercalcemia and Hypercalciuria

Primary hyperparathyroidism accounts for 5% of calcium stones. Hypercalcemia that is caused by primary hyperparathyroidism increases the filtered and, therefore, the excreted load of calcium despite the opposing action of parathyroid hormone to enhance calcium reabsorption. Intermittent hypercalcemia may be seen in patients with mild primary hyperparathyroidism.

A particularly severe form of hypercalciuria may be caused

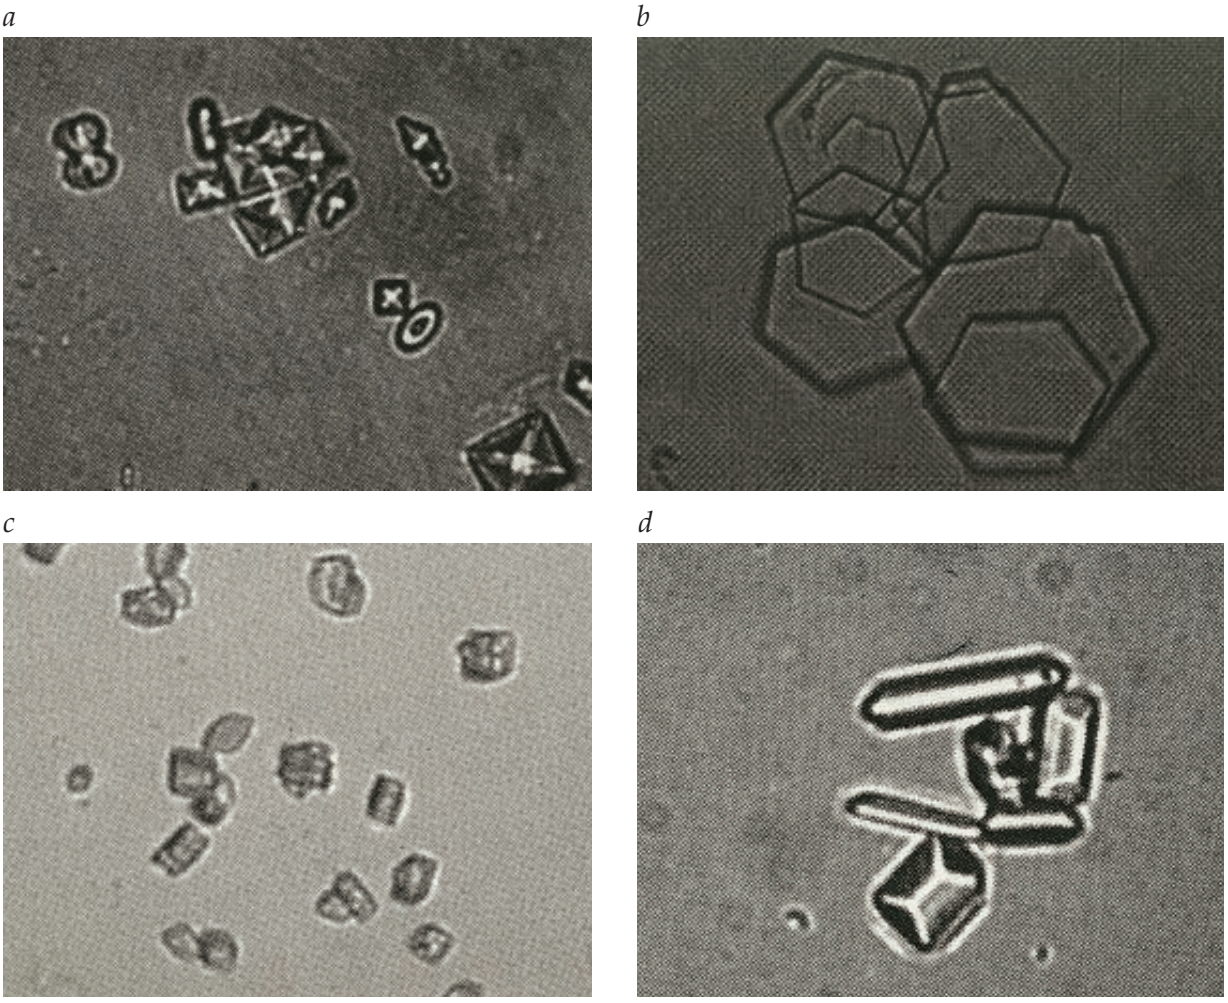

Figure 2 **In a case of chronic recurrent nephrolithiasis, microscopic examination of urine can detect and identify crystal-forming substances. Such substances include calcium oxalate (*a*), cystine (*b*), uric acid (*c*), and struvite (*d*).**

by sarcoidosis and, on rare occasions, other granulomatous conditions because a larger load of calcium is filtered and excreted (up to 600 to 700 mg/day), and secondary suppression of parathyroid hormone occurs as a result of the hypercalcemia. Circulating levels of 1,25-dihydroxyvitamin D_3 (calcitriol) may be increased in these conditions, and vitamin D intoxication may present as hypercalciuria. Patients on vitamin D therapy for osteoporosis or hypoparathyroidism may experience severe hypercalciuria and nephrolithiasis. Thyroid excess, from inappropriate hormone replacement therapy or from spontaneous disease, may also induce hypercalciuria and nephrolithiasis.

Dietary Influences

Absorptive hypercalciuria is a condition in which hypercalciuria occurs only with a high dietary intake or large oral ingestion of calcium. Renal hypercalciuria is defined by an increased urinary calcium excretion after an overnight fast. The classification of idiopathic hypercalciuria as absorptive or renal is highly dependent on the effects of dietary sodium. Renal hypercalciuria may be attributable to an intake of excess dietary sodium during the previous 24 hours in many, if not most, cases. Restriction of dietary sodium intake can produce a marked and predictable fall in urinary calcium excretion and thus cause renal hypercalciuria to be recategorized as absorptive hypercalciuria. Specific treatment of hypercalciuria on the basis of a distinction between renal and absorptive hypercalciuria is probably unwarranted.[20]

The evidence that high dietary protein intake is an important risk factor for recurrent nephrolithiasis is derived from various findings. First, population studies show a clear correlation between the societal consumption of animal protein and the prevalence of upper urinary tract stone disease.[21] Second, increased dietary protein ingestion raises urinary calcium, uric acid, and possibly oxalate excretion in normal individuals.[22] The risk has also been found in epidemiologic studies.[23] Third, high dietary protein has a hypocitraturic effect—that is, it produces a decline in the excretion of citrate, a principal factor in the chelation of urinary calcium.[24,25] Fourth, studies of dietary protein restriction have shown a beneficial effect in vegetarians and in specific therapeutic trials, particularly in persons who ingest an excessive amount of protein. Finally, some studies have found that patients with recurrent stone disease tend to be hyperresponsive to the calciuric effect of high dietary protein because they excrete larger amounts of calcium at any level of dietary protein intake than do control subjects.[26] In any event, a careful review of the literature has reaffirmed the potential role of excessive dietary protein in the pathogenesis of kidney stone formation [*see* Treatment, Dietary Modification, *below*],[27] although a

comparative trial did not find that a diet high in fiber and low in animal protein provided benefit over increased fluid intake alone.[28]

Hyperoxaluria

Normal 24-hour urinary excretion of oxalate should not exceed 40 to 45 mg/24 hr (0.7 mg/kg/24 hr) to reduce the risk of calcium oxalate stone formation. For physicochemical reasons, small increases in the urinary oxalate excretion may actually contribute more to calcium oxalate stone formation than a proportional increase in urinary calcium excretion.[29]

There are several causes of hyperoxaluria in patients with calcium oxalate stones, including hyperabsorption of oxalate, vitamin B_6 deficiency, and genetic predisposition.

Hyperabsorption of oxalate, mainly in the colon, may occur if there is a reduction in free calcium in the intestinal lumen. Calcium complexes with unabsorbed fat, which allows the dietary oxalate to be absorbed more readily; bile and long-chain fatty acids also increase oxalate permeability. The resultant increase in oxalate absorption leads to hyperoxaluria. This mechanism has been proposed to explain the hyperoxaluria commonly seen in states of GI malabsorption.[29] In some persons, marked increases in urinary oxalate excretion occur after the ingestion of 1 to 2 g of ascorbate because oxalate is an end product of ascorbate metabolism.

Vitamin B_6, or pyridoxine, is a cofactor in the interconversion of glycine and glyoxylate, which are both precursors of oxalate. A deficiency of this vitamin results in the increased formation and excretion of oxalate.[30]

Primary hyperoxaluria (type I and type II) is inherited as an autosomal recessive trait and is characterized by overproduction of oxalate. Glycolic acid excretion is increased in type I primary hyperoxaluria, whereas L-glyceric acid excretion is increased in type II primary hyperoxaluria.[31]

A deficiency of oxalate-degrading bacteria (in particular *Oxalobacter formigenes*) has been suggested as a factor in calcium oxalate stone formation.[32] By utilizing oxalate in the digestive tract, oxalate-degrading bacteria regulate oxalate homeostasis and prevent excessive enteric absorption of oxalate, thereby lowering the risk of urolithiasis; a deficiency of oxalate-degrading bacteria causes increased oxalate excretion, which in turn may increase the risk of hyperoxaluria and calcium oxalate stone formation.

Hypocitraturia

Normal 24-hour urinary excretion of citrate is approximately 300 to 900 mg, with levels substantially higher in premenopausal women, especially pregnant women, than in men. Hypocitraturia is usually profound in distal renal tubular acidosis and is perhaps the most important risk factor for calcium oxalate stone formation in patients with that disorder.[17] Hypocitraturia is caused by metabolic acidosis in distal renal tubular acidosis and by intracellular acidosis in incomplete renal tubular acidosis. Other causes of hypocitraturia include potassium depletion, presumably because of intracellular acidosis; bacteriuria, because the infecting organisms may metabolize the urinary citrate; and acidifying conditions, such as renal insufficiency and chronic diarrhea. An idiopathic variety of hypocitraturia may be associated with recurrent nephrolithiasis in many patients, partly because of excessive dietary protein intake, which leads to increased endogenous acid production and excretion. Studies have shown an important role for the enzyme citrate lyase in the hypocitraturia of metabolic acidosis. Low intracellular pH in the proximal tubule activates this enzyme and leads to increased intracellular citrate utilization, thereby enhancing citrate absorption and lowering urinary citrate in metabolic acidosis.[33]

Hyperuricosuria

Hyperuricosuria plays a role in the formation of both uric acid and calcium oxalate stones. A relation between hyperuricosuria and a particularly severe form of recurrent calcium oxalate nephrolithiasis has been observed.[34] Experimental in vitro studies using highly defined artificial solutions suggest that urate crystals, but not uric acid crystals, can act as epitaxial templates that bind calcium oxalate and promote crystal growth. Uric acid crystals, however, are the predominant form in urine; urate crystals are rarely found in urine and, furthermore, are rather poor promoters of crystal growth in the highly defined artificial urine solutions that are used in experimental studies to investigate the nature of crystal growth.

The ability of uric acid crystals to adsorb glutamic acid crystals[35] may explain why uric acid is a potent promoter of crystallization in urine, which contains various organic compounds that act as crystallization inhibitors, but not in highly defined artificial urine solutions. Hyperuricosuria in patients with calcium oxalate or uric acid stones is a function of excess dietary purine consumption rather than any intrinsic abnormality in purine metabolism.[36]

Reduced Urine Volume

Urine volume is a crucial determinant of the risk of recurrent nephrolithiasis. The risk of calcium stone formation is substantially increased if the urine output is less than 15 ml/kg/day in children[37] and less than approximately 1,500 ml/24 hr in adults.[38]

Abnormalities in the Excretion of Inhibitors of Stone Formation

Protein macromolecules account for most of the inhibition of crystal growth observed in in vitro assays of normal urine. Low-

Table 1 Crystallographic Analysis of the Stone Serves as the Basis for Diagnostic Evaluation

Stone Composition	*Incidence (%)*	*Appearance of Crystals on Urinalysis*	*Radiographic Appearance*
Calcium oxalate with or without calcium apatite	70	Octahedrons	Radiopaque
Calcium monohydrogen phosphate (brushite)	2	Amorphous crystals	Radiopaque
Ammoniomagnesium phosphate (struvite)	15–17	Coffin lids	Radiopaque
Uric acid	10	Pears and diamonds	Radiolucent
Cystine	1	Hexagons	Radiopaque

molecular-weight urinary substances, including magnesium, pyrophosphate, and citrate, also show inhibitory activity.[39] Patients who have no identifiable abnormality but who have recurrent calcium-containing stones probably lack urinary inhibitors of stone formation. Abnormalities have been reported in the structure and function of nephrocalcin isolated from the urine and stones of some patients with calcium oxalate stones.[39] Nephrocalcin is a 14 kd glycoprotein that contains γ-carboxyglutamic acid, which is a vitamin K–dependent amino acid that is also found in osteopontin (a bone glycoprotein) and its urinary analogue, uropontin.[40]

TREATMENT

The initial treatment strategy for patients with recurrent stone disease is to treat the underlying disorder. Specific therapies are obviously indicated in certain conditions implicated in the pathogenesis of calcium-containing stones; for example, patients with primary hyperparathyroidism require parathyroid surgery, those with distal renal tubular acidosis require alkali therapy, and those with sarcoidosis require steroids or other specific therapy.

Dietary Modification

Evidence supports the view that reducing the prevailing urinary concentrations of potentially insoluble constituents of kidney stones by increasing fluid intake and modifying the diet are effective in the prevention of calcium-containing stones. A prospective 5-year controlled trial of water intake in patients with a first calcium-containing stone showed that increasing urine volume to about 2.5L/day, which reduced the relative saturation of urine with respect to calcium oxalate, reduced stone recurrence to 10%; persons who did not increase water intake had a stone recurrence of 25%.[38] The type of fluid consumed may be important; grapefruit juice may enhance the risk of stone formation,[41] whereas patients who ingest one bottle of beer a day may reduce the risk of stone formation by 40%.[42]

Timed urine collections for volume, urea nitrogen, creatinine, calcium, and sodium are helpful in monitoring compliance. Patients are encouraged to reduce their calcium intake only if it is very excessive (but to maintain it at or above 1 g/day) and to reduce oxalate intake as much as possible by avoiding foods that contain high amounts of oxalate. In fact, a prospective study of 45,617 healthy men between 40 and 75 years of age who did not have a history of kidney stones led to the conclusion that a high dietary calcium intake decreases the risk of symptomatic kidney stones, presumably by reducing the gastrointestinal absorption of oxalate and hence the urinary oxalate excretion.[43,44] Curhan and colleagues showed that a higher intake of dietary calcium decreases the risk of kidney stone formation in younger women; in this patient population, supplemental calcium was not associated with increased risk of kidney stones.[23] In older women, high intake of dietary calcium appeared to decrease risk for symptomatic kidney stones; however, unlike in younger women, intake of supplemental calcium was associated with increased risk of stone formation. The reasons for this differing response to supplemental calcium are not clear.[45]

For patients with recurrent calcium-containing stones, restricted intake of animal protein and salt, combined with a normal calcium intake, reduced stone recurrence over 5 years more effectively than the traditional low-calcium diet.[29] The benefits of dietary therapy in patients with recurrent stone formation have not been rigorously tested in multiple controlled studies; in addition, there are very few clinical studies of proposed pharmacologic therapies (e.g., thiazides, phosphates, allopurinol, and citrate) for calcium-containing stone formation.[46] Evidence indicates that treatment with allopurinol, which blocks uric acid production, decreases the recurrence rate of calcium oxalate kidney stones in patients with hyperuricosuria, although allopurinol has no effect on urinary calcium or oxalate saturation.[47]

With no clear-cut advantage of any specific pharmacologic agent, it appears that many patients may benefit from dietary modification and avoid embarking on a lifelong use of medications to prevent recurrent stone formation. However, if patients are persistently hypercalciuric despite dietary modification or if they persistently form stones, pharmacologic therapy should be considered. A meta-analysis supports this concept.[48]

Treatment of Hypercalcemia and Hypercalciuria

Drugs that reduce urine calcium excretion Thiazides, most frequently hydrochlorothiazide, and longer-acting drugs such as chlorthalidone may be used to lower urine calcium excretion. Therapy with hydrochlorothiazide was highly effective in reducing new stone formation in two randomized controlled clinical trials.[49,50] Studies that failed to show a beneficial effect[51,52] were flawed because of relatively short follow-up (12 to 18 months).[53] The use of thiazide diuretics reduces the incidence of recurrent calcium nephrolithiasis by approximately 80%.[54] A total daily dose of 50 to 100 mg of hydrochlorothiazide effectively reduces calcium excretion. A daily dose of 25 mg is sometimes sufficient and avoids many of the side effects of thiazides. Failure of this therapy is usually a result of a marked increase in sodium intake (which promotes hypercalciuria) or hypokalemia. Potassium depletion leads to intracellular acidosis and causes hypocitraturia.[55]

Thiazides must reduce extracellular fluid volume to produce their full hypocalciuric action. A component of the hypocalciuric action of thiazides is also related to direct stimulation of calcium reabsorption in the distal tubule. The impact of side effects of thiazides, such as hyperlipidemia, glucose intolerance, and mild hypokalemia, has not been extensively studied in patients with nephrolithiasis. On the other hand, it has been shown that bone mineralization probably increases in persons receiving long-term thiazide therapy, thus decreasing the risk of osteoporosis.[56] Patients who have underlying disorders of calcium metabolism, such as primary hyperparathyroidism, or who are being treated with vitamin D supplements may be at risk for hypercalcemia when receiving thiazide therapy. Serum calcium levels should be monitored for 2 months after initiation of thiazide therapy.

Amiloride The hypocalciuric action of the diuretic amiloride is probably achieved through secondary stimulation of a sodium-calcium antiporter at the epithelial cell basolateral membrane that leads to stimulation of calcium transport in the distal convoluted tubule. Amiloride may be particularly useful because it retards potassium excretion and prevents thiazide-induced hypokalemia and the associated hypocitraturia. Thiazide therapy is contraindicated or ineffective in approximately 7% to 15% of patients; amiloride can be used as an adjunct or substitute.

Neutral sodium or potassium phosphate Neutral sodium or potassium phosphate (nonacidic) is an effective therapy for hypercalciuria.[57] Phosphates reduce bone resorption of calcium and promote renal calcium reabsorption. Diarrhea is the most

common short-term side effect and is a frequent problem. These agents must be administered four times a day. Acid-containing phosphate salts should not be used, because the effects of acidosis on bone and kidney (hypocitraturia and hypercalciuria) may override the beneficial effects of the phosphate salts.

Cellulose phosphate Cellulose phosphate is a nonabsorbable ion exchange resin that binds calcium in the gastrointestinal tract. Cellulose phosphate has been advocated as an effective therapy for calcium stone disease, particularly in children who have shown inadequate response to thiazide therapy, in patients with renal failure induced by sarcoid-associated nephrocalcinosis, and in patients with hypercalcemia or hypercalciuria associated with administration of calcium and vitamin D supplements after parathyroidectomy.[58,59] The increased risk of secondary hyperoxaluria may negate the beneficial action of cellulose phosphate.

Potassium citrate and potassium bicarbonate Some patients with calcium-containing stones demonstrate a marked hypocitraturia rather than hypercalciuria. This abnormality may result from a metabolic disorder or from chronic metabolic acidosis. Studies have suggested that dietary supplementation with a citrate-containing salt in a dosage of 1 mEq/kg body weight raises the level of urinary citrate excretion. This effect results from the alkali load produced by citrate supplementation rather than from the direct appearance of ingested citrate in the urine. Citrate therapy effectively reduces the frequency of new stone formation.[60,61] Equivalent sodium bicarbonate therapy may achieve the same hypocitraturic effect but is generally not well tolerated because of gastric bloating or belching. Moreover, increased intake of sodium may adversely affect response to therapy by increasing urinary calcium excretion. It has been suggested that concurrent hypercalciuria and hyperuricosuria may underlie a particularly virulent form of recurrent nephrolithiasis. The treatment of hyperuricosuria with dietary purine restriction or with allopurinol may be beneficial if the usual treatment of hypercalciuria fails to alleviate the disorder.[34]

Treatment of Hyperoxaluria

In certain patients with hyperoxaluria, particularly those with inflammatory bowel disease, additional calcium intake, as calcium carbonate (500 mg of elemental calcium four times a day), may bind intestinal oxalate and reduce its absorption. Cholestyramine, an ion exchange resin, can also reduce oxalate absorption. Cholestyramine may be administered in a dosage of 4 g two to four times a day. This resin binds bile acid, the free form of which increases colonic absorption of oxalate by increasing its permeability across the intestinal wall. Cholestyramine may also bind oxalate in the intestinal lumen. Pyridoxine alters the cellular metabolism of glycine and, in a dosage of 25 to 50 mg/day, significantly reduces the urinary excretion of oxalate.[62] A trial of pyridoxine is indicated in cases in which the dietary restriction of oxalate and increase of calcium intake are not effective in reducing hyperoxaluria. Adjunctive therapy with magnesium oxide (400 mg once or twice daily with meals) may be useful because magnesium forms a soluble complex with oxalate.

Uric Acid Stones

Although relatively uncommon, uric acid stones may recur frequently. Pure uric acid stones primarily occur in patients in whom a persistently acid urine promotes uric acid precipitation. In addition, 10% to 20% of patients with gout produce uric acid, resulting in increased risk of uric acid stone formation. Obesity resulting from dietary indiscretion and probable purine gluttony appears to have a significant role in recurrent uric acid stone formation.[63] In men, gout is a significant risk factor for uric stone formation. A large prospective study found that the prevalence of kidney stone disease was almost twofold higher in men with a history of gout, even after adjusting for age and body mass index.[64] Low urinary pH (pH < 5.5) is the most important risk factor for uric acid nephrolithiasis; in normouricosuric stone disease, the primary defect appears to be in the renal excretion of ammonia and is linked to an insulin-resistant state.[65]

DIAGNOSIS

Although typically radiolucent, uric acid stones may be slightly radiopaque when mixed with or coated by calcium crystals. Urine pH actually has greater impact on stone formation than the urinary uric acid concentration. When the urine pH decreases from 6.0 to 5.0, the concentration of undissociated uric acid (as opposed to the urate concentration) increases sixfold, leading to precipitation and uric acid stone formation. The limit of solubility for undissociated uric acid in urine is only 90 mg/L. Because total excretion values of undissociated uric acid usually range between 500 and 600 mg/day, the presence of persistently acid urine is an important cause of uric acid stone formation.

Only 10% to 20% of uric acid stones are associated with hyperuricosuria. Typically, serum uric acid levels and urinary uric acid levels are normal in patients with recurrent uric acid stones. However, the excretion of more than 1,000 mg of uric acid per 24 hours in urine that has an average pH of 5.6 is probably a risk factor for uric acid stone formation. Uric acid stones are often discrete, but they may be large and extend between minor calyxes, producing a staghorn appearance.

DIFFERENTIAL DIAGNOSIS

Xanthine and 2,8-dihydroxyadenine stones are rare forms of radiolucent stones that may be mistaken for uric acid stones. The conditions that predispose to the development of xanthine or 2,8-dihydroxyadenine stones are inherited as autosomal recessive disorders. Xanthinuria, which may lead to xanthine stone formation, may also sometimes develop in patients who receive allopurinol as therapy for excessive uric acid production. The normal urinary xanthine excretory rate is 5.1 to 8.6 mg/24 hr. An excretory rate greater than 8.6 mg/24 hr is classified as xanthinuria. The presence of 2,8-dihydroxyadenine in the urine and gross reduction of the level of adenine phosphoribosyltransferase in erythrocytes allow for the diagnosis of 2,8-dihydroxyadenine stones.[66]

These two rare forms of radiolucent stones are virtually never detected by any means other than stone analysis.

TREATMENT

In patients with increased uric acid excretion, treatment options include dietary purine restriction, urinary alkalinization, and administration of allopurinol. Urinary alkalinization, which can be achieved with sodium bicarbonate or potassium citrate (1.0 to 1.5 mEq/kg/day) or their equivalent, substantially reduces the risk of further uric acid stone formation but may increase the risk of calcium phosphate stone formation. Patients must be instructed in the measurement of urinary pH with nitrazine paper and must strive to adjust the bicarbonate dosage

to maintain the pH value between 6.0 and 6.5.

Allopurinol, given in a dosage of 200 to 300 mg/day, is the preferred treatment for reducing uric acid excretion in patients with hyperuricosuria. Allopurinol decreases the risk of further stone formation and solubilizes existent uric acid stones. The side effects include rash and other hypersensitivity reactions; allopurinol therapy must therefore be carefully monitored.

In the majority of patients with uric acid stones, uric acid excretion is quantitatively normal. Uric acid stone formation is caused by a persistently acidic pH of the urine (pH < 5.5), which fails to increase in the immediate postprandial period. Impaired production of urinary buffers (ammonia and titratable acids) may underlie this defect. In these patients, alkali therapy is more likely to be effective. Allopurinol may also be useful in such patients if alkalinization and increased fluid intake fail to dissolve the stones.

Struvite Stones

Infection of the urinary tract with organisms that secrete the ectoenzyme urease can greatly increase the urinary ammonia concentration and pH. *Proteus* is the most common cause of such infection; other organisms include *Pseudomonas, Klebsiella, Providencia, Serratia,* and staphylococci. When urea is deaminated, NH3 is formed and binds protons, thereby alkalizing the urine. These conditions dramatically increase the risk of the formation of stones composed of ammoniomagnesium phosphate (struvite).

DIAGNOSIS

Characteristically, struvite stones are very large and often have a staghorn appearance. The stones are radiopaque, but to a lesser degree than those composed of calcium. The crystals have a so-called coffin-lid shape [*see Figures 2a through d*]. Urine as well as fragments of the stone, if available, should be cultured for microorganisms. If staghorn calculi caused by struvite stones are present bilaterally, renal failure can result (about a 30% chance over 8 years).[67] Because many patients with struvite stones also have an underlying metabolic disorder, such as hypercalciuria, a complete metabolic workup should be done once these stones have been detected.

TREATMENT

Preventing recurrences of struvite stones is difficult and requires successful sterilization of the urine. Because organisms may exist in the interstices of the calculus material, all such material must be removed from the urinary tract. A combination of percutaneous lithotripsy and ESWL can achieve favorable results. The procedure involves one or more sessions of passing a nephroscope into the renal pelvis and fragmenting the stone with an ultrasonic probe or pulsed dye laser, followed 2 to 3 days later by ESWL to break up smaller fragments. All visible calculus material can be successfully removed by the combination of nonsurgical stone removal and irrigation of the urinary tract with a solution of strong organic acids, such as hemiacidrin, a 10% citric acid compound.[68] This approach, used in conjunction with organism-specific, prolonged (up to 4 weeks) antimicrobial therapy, can result in complete cure of struvite stones in approximately 90% of treated patients if all stone fragments are removed during initial therapy. CT scanning without contrast can be used to document removal of all stones and for future follow-up.

Open surgical procedures such as anatrophic nephrolithotomy are still useful in the management of struvite stones because they can achieve success rates of 90% to 100%, even with larger stones, and cure is achieved in less time than with the protracted treatment protocols of percutaneous lithotripsy plus ESWL.[69]

In rare cases in which urologic procedures cannot be attempted, the use of medical therapy is indicated as a second-line approach. Acetohydroxamic acid is an orally active bacterial urease inhibitor.[70] This agent is effective in preventing stone growth even when stone fragments and bacterial infection persist. Unfortunately, acetohydroxamic acid has several significant side effects, including hemolytic anemia, intractable headache, and, possibly, thrombophlebitis.[71]

Cystine Stones

Cystinuria is an autosomal recessive disorder in which excessive urinary excretion of the dicarboxylic amino acids (cystine, ornithine, lysine, and arginine) results from impaired transport.[72] The genetic defect in 30% of cases studied is in six missense mutations in the human *rBAT* gene, which is involved in high-affinity transport of cystine and dibasic amino acids in the kidney and intestine.[73]

DIAGNOSIS

The normal rate of cystine excretion is 30 mg/day (1.3 mmol/day). In contrast, patients with cystinuria excrete more than 400 mg/day and sometimes up to 3,600 mg/day. The sulfur atom present in cystine accounts for the moderate radiopacity of cystine stones on plain films. The stones are discrete, but staghorn calculi can occur. Urinalysis may demonstrate the pathognomonic hexagonal crystals in approximately 50% of patients, but the urine sodium nitroprusside test is more useful for screening. The nitroprusside test is positive at a cystine concentration greater than 75 mg/g creatinine. If a qualitative test is positive for cystinuria, a 24-hour quantitative urinary cystine excretion rate should be determined. Because some patients with cystinuria will not present with symptoms until their fifth or even sixth decade, a diagnosis of cystinuria should not be excluded on the basis of a patient's age.

TREATMENT

Treatment of cystine stones consists of reducing the urinary cystine concentration by hydration, increasing cystine solubility by alkalinization, and lowering the urine cystine concentration with agents such as penicillamine or α-mercaptopropionyl glycine (tiopronin). Optimal therapy not only reduces the risk of new stone formation but also causes dissolution of existing stones.[74] The limit of cystine solubility in urine is approximately 300 mg/L (1.25 mmol/L). To prevent stone formation or growth in cystinuric patients excreting more than 1,000 mg of cystine a day requires a urine volume of at least 4 L/day spread uniformly over a 24-hour interval. Fluid therapy is usually unsuccessful because patients find it difficult to drink enough fluid throughout the day and night to achieve the necessary urine volume. Adolescents and young adults, in particular, may not be conscientious in maintaining a high fluid intake. When combined with the proper fluid intake, alkali therapy is beneficial because the solubility limit of cystine can be doubled (to 600 mg/L urine) by maintaining the urinary pH at 7.5 to 7.8. Such urine pH levels are difficult to achieve but may be attempted in highly motivated patients. Unfortunately, a major side effect of alkalinization is

the increased propensity to form calcium phosphate stones. A reduction of dietary sodium intake (50 mEq/day) may be helpful by increasing renal cystine reabsorption and thereby reducing the urinary burden.[74]

In some patients, therapy with penicillamine or related drugs (e.g., tiopronin)[60] may be required. These compounds form mixed, soluble disulfides with cysteine and thereby prevent cystine stone formation. Cystine production may also decrease because of an intracellular effect of the drug. Unfortunately, penicillamine must be withdrawn in as many as 90% of patients because of an adverse reaction. A comparative study showed that serious adverse effects requiring cessation of therapy were approximately 50% less frequent with tiopronin than with penicillamine.[75] Side effects from penicillamine range from insomnia and dysgeusia to a vasculitic syndrome and Goodpasture syndrome. Insomnia and dysgeusia can be prevented with zinc supplements. Pyridoxine supplements are required to prevent pyridoxine deficiency. The therapeutic benefit attributed to captopril (also a thiol-containing compound) is based on a very limited number of patients.[76] Subsequent studies support the preliminary observations of the efficacy of captopril, but rigorous controlled trials have not yet been performed.[77] Captopril leads to the formation of captopril-cysteine complexes, but the available amounts of captopril at usual doses may not be sufficient to effectively complex large amounts of cysteine.

Fluid therapy during the day combined with penicillamine or preferably tiopronin administration at night may be an effective approach in reducing the risk of cystine stone formation while minimizing the risk of penicillamine toxicity. A lower and, thus, less toxic dose of the drug is used in this protocol.

Drug-Induced Stones (Indinavir and Nelfinavir Stones)

Components of highly active antiretroviral therapies such as nelfinavir and particularly indinavir can contribute to the formation of urinary stones. These agents are excreted as urinary crystals that may result in crystal deposition or stone formation.[78] Nephrolithiasis is an increasingly recognized complication of indinavir therapy.[79]

Indinavir urolithiasis is unique in that CT, which was once thought to be efficacious in identifying all urinary calculi, is not useful in imaging stones that are composed of pure indinavir. Ultrasonography or intravenous urography may be required to confirm the diagnosis of pure indinavir stones in patients at risk for this complication.[80]

Prevention and treatment of indinavir-induced nephrolithiasis include greatly increased water intake and possibly urinary acidification.[81] Emergency drainage may be required for patients with severe obstruction.
