V DISEASES OF THE PANCREAS

Peter Draganov, m.d.
Chris E. Forsmark, m.d., f.a.c.p.

Definitions of Disease Presentations

acute and chronic pancreatitis

Acute pancreatitis has traditionally been defined as an acute inflammatory process of the pancreas that (1) is associated with abdominal pain and elevations in serum levels of pancreatic enzymes and (2) disrupts normal pancreatic architecture and function only until the illness resolves. Chronic pancreatitis, on the other hand, is traditionally described as associated with permanent and irreversible damage to the gland. These definitions, which were developed at a series of international meetings, have limited applicability for clinicians. For example, some patients with severe acute pancreatitis develop substantial necrosis of the gland during the acute attack and sustain permanent abnormalities of both pancreatic architecture and pancreatic function. Likewise, many patients with an acute attack of alcoholic pancreatitis have already developed histologic changes of chronic pancreatitis at the onset of symptoms. Both types of patient are at risk for the complications of acute pancreatitis and are best managed as having acute pancreatitis, although they do not fit the traditional classification schemes.

In addressing these problems, the most recent consensus conference, the International Symposium on Acute Pancreatitis,[1] defined acute pancreatitis in a more clinically useful manner—that is, as an acute inflammatory process of the pancreas with variable involvement of regional tissues and remote organ systems. Because it may not be possible at the time of the attack to determine whether permanent architectural or functional changes are present or will develop, the disease may subsequently be reclassified, on the basis of additional clinical information, as chronic pancreatitis or as an acute exacerbation of chronic pancreatitis.

The International Symposium on Acute Pancreatitis also defined severe acute pancreatitis as the presence of organ failure (e.g., shock, pulmonary insufficiency, renal failure, or gastrointestinal bleeding) or pancreatic or peripancreatic complications (e.g., necrosis, abscess, or pseudocyst), or both, along with unfavorable early prognostic signs (e.g., using the Ranson criteria or the APACHE II score) [*see* Determining Disease Severity, *below*]. Although not perfect, these clinical definitions more closely fit the approach to management.

complications of pancreatitis

As part of the consensus conference on acute pancreatitis,[1] more precise definitions were developed to describe the local and systemic complications of acute pancreatitis. An acute fluid collection was defined as a collection of fluid occurring in or around the pancreas early in the course of acute pancreatitis. This collection of fluid is composed of both pancreatic juice and inflammatory fluid; it is poorly circumscribed and lacks a visible wall of fibrosis or granulation tissue. On computed tomography, these collections are seen as low-attenuation areas without a visible capsule. They are quite common in acute pancreatitis, occurring in 30% to 50% of cases.[2] Many of these acute fluid collections resolve, but some may persist and develop a visible capsule, at which time they are termed pseudocysts.

Pseudocysts are defined as collections of fluid (pancreatic juice) surrounded by a fibrous capsule. It takes at least 4 to 6 weeks for an acute fluid collection to develop a capsule and become a pseudocyst. Pseudocysts may remain sterile or may become secondarily infected.

Pancreatic necrosis is a pathologic finding but is clinically defined on contrast-enhanced CT (CECT) as areas of pancreatic parenchyma that show no enhancement with the infusion of intravenous contrast. Acute necrotizing pancreatitis (i.e., CECT findings of pancreatic necrosis) may be subclassified as sterile necrosis or infected necrosis on the basis of the presence or absence of bacteria in an aspiration or surgical sample. Acute interstitial pancreatitis is defined by the absence of CECT findings of necrosis. Finally, pancreatic abscess is defined as a circumscribed collection of pus containing little necrotic tissue. What formerly was called infected pseudocyst is now referred to as a pancreatic abscess. The term phlegmon was omitted from the report because there was no consensus on its definition.

Acute Pancreatitis

epidemiology

Estimates of the incidence of acute pancreatitis range from about 5 to 25 cases per 100,000 population. In the United States, between 166,000 and 224,000 patients are admitted each year with a primary diagnosis of acute pancreatitis.[3] The number of patients discharged from hospitals with a diagnosis of acute pancreatitis has steadily increased over the past 20 years.[4,5] Similar trends have been seen in other developed countries.[6] The reason for the increased incidence of acute pancreatitis in the United States is unclear, but the increase may be related to the increased incidence of gallstones (one of the major causes of acute pancreatitis)[5] in association with the epidemic of obesity.[7] In large series from referral hospitals, the mortality associated with acute pancreatitis has ranged from 5% to 10%; however, this range is probably high because of referral patterns, as recent estimates using more comprehensive hospital databases have documented an overall mortality of about 2%.[8] Mortality varies with etiology, the development of complications or necrosis, and the number and severity of comorbid medical conditions.[9,10] The cost of care is substantial, with estimates of total direct and indirect costs ranging from $3.6 billion to $6 billion annually.[1,5,8]

etiology

Many factors have been implicated as causes of acute pancreatitis [*see Table 1*]. Together, gallstone disease and alcohol abuse account for 70% to 80% of all cases of acute pancreatitis.[1] The prevalence of acute pancreatitis varies from population to population, depending on the relative prevalence of alcohol abuse and gallstone disease.

Gallstone Disease

The exact mechanism by which gallstone disease causes acute pancreatitis is not completely understood. It is clear that the pas-

sage of a gallstone through the ampulla of Vater is an important initiating event for gallstone pancreatitis, most likely by the gallstone's causing transient obstruction of the pancreatic duct or by edema resulting after stone passage. The association between obesity and gallstone disease is well established,[4] but abdominal obesity may be a more specific risk factor. A large prospective study indicated that abdominal adiposity in men carries a relative risk of gallstone disease of 2.29.[11]

Alcohol Abuse

The mechanism by which alcohol consumption produces acute (and chronic) pancreatitis remains obscure. In most patients, long-standing abuse of alcohol is required, and in such patients, histologic chronic pancreatitis is usually present at the onset of a clinically apparent acute attack.[12] In a minority of patients, a large alcoholic binge is the initiating event for acute pancreatitis, and no evidence is found of preexisting chronic damage to the gland.

Obstruction of the Pancreatic Duct

A number of disorders appear to cause acute pancreatitis by a process that obstructs the pancreatic duct. The most common of these is the presence of gallstones (see above). The other conditions are relatively uncommon. One such condition is sphincter of Oddi dysfunction, in which elevations of basal pancreatic sphincter pressure (more than 40 mm Hg above duodenal baseline pressures) produce pancreatic duct obstruction and acute pancreatitis. In addition, both benign and malignant strictures of the pancreatic duct can produce acute pancreatitis, as can malignancy of the ampulla of Vater. Given this, a search for underlying pancreatic or ampullary malignancy is warranted in patients at higher risk for malignancy (e.g., those older than 40 to 45 years) with unexplained pancreatitis. Less common causes of pancreatic duct obstruction and acute pancreatitis include choledochal cysts, periampullary duodenal diverticula, and worms migrating through the ampulla (*Ascaris lumbricoides*, *Clonorchis sinensis*).

Pancreas divisum, which occurs in 5% to 7% of the population, is a rare cause of acute pancreatitis.[13,14] In this congenital condition, the fetal dorsal and ventral pancreatic buds fail to fuse, and the majority of pancreatic secretions enter the duodenum through the smaller minor papilla. In a small subset of patients with pancreas divisum, the minor papilla may be inadequate to allow free drainage of pancreatic juice, creating a blockage that may lead to acute or chronic pancreatitis.[13-15]

Drugs and Toxins

Drug-induced acute pancreatitis is a relatively rare event and is usually idiosyncratic.[16,17] The antimetabolites 6-mercaptopurine and azathioprine have the highest attack rate, causing acute pancreatitis in up to 4% of patients who take these drugs. Many additional drugs have been reported to cause acute pancreatitis, the most common being pentamidine, didanosine, sulfonamides, valproic acid, furosemide, and aminosalicylates. In addition to ethyl alcohol [*see* Alcohol Abuse, a*bove*], a number of toxins may injure the pancreas and cause acute pancreatitis; these include methyl alcohol, organophosphate insecticides, and the venom from certain Central and South American scorpions. Scorpion venom and insecticides appear to cause acute pancreatitis by hyperstimulating pancreatic secretion via a cholinergic mechanism.

Table 1 Causes of Acute Pancreatitis

Gallstones and microlithiasis
Alcohol abuse
Obstruction of pancreatic duct
Sphincter of Oddi dysfunction
Pancreas divisum with stenotic minor papilla
Ampullary or pancreatic tumors
Trauma
Post-ERCP trauma
Blunt or penetrating trauma
Toxins
Methyl alcohol
Scorpion venom
Organophosphate insecticides
Drugs
Azathioprine
6-Mercaptopurine (6-MP)
Pentamidine
Didanosine
Sulfonamides
Valproic acid
Furosemide
Aminosalicylates
Infections
Viral (mumps, rubella, coxsackie B, cytomegalovirus, HIV)
Bacterial (*Klebsiella, Escherichia coli*)
Fungal (*Candida*)
Hypertriglyceridemia
Genetic mutation
Hereditary pancreatitis
Cystic fibrosis
Surgery

ERCP—endoscopic retrograde cholangiopancreatography

Infection

A number of infections have been reported to cause acute pancreatitis; among them are a variety of viral infections such as cytomegalovirus, mumps, rubella, and coxsackie B. Patients with AIDS commonly have increased serum amylase levels in the absence of acute pancreatitis and less commonly develop acute pancreatitis secondary to opportunistic infections (e.g., cytomegalovirus, *Cryptosporidium*, or *Mycobacterium* infections) or as a side effect of a medication.[18]

Metabolic Factors

Metabolic causes of acute pancreatitis include hypertriglyceridemia and hypercalcemia. Serum triglycerides generally need to be in excess of 1,000 mg/dl to produce acute pancreatitis.[19] Serum triglyceride levels in excess of 1,000 mg/dl are most commonly seen in type V hyperlipoproteinemia and are usually associated with diabetes mellitus. Acute pancreatitis can itself raise triglyceride levels but not to this degree. The use of estrogens in postmenopausal women with underlying hypertriglyceridemia is associated with increased levels of triglyceride and the induction of pancreatitis, particularly if the fasting triglyceride level before initiating estrogen treatment is more than 750 mg/dl.[20] Hypercalcemia, usually associated with hyperparathyroidism, is a very rare metabolic cause of acute pancreatitis.

Trauma

Trauma to the pancreas or pancreatic duct may cause acute

pancreatitis. Blunt trauma to the abdomen may cause contusion, laceration, or complete transection of the gland. In most cases of major trauma affecting the pancreas, damage occurs at the mid-body of the pancreas, where the pancreas is crushed against the vertebral bodies; acute pancreatitis develops rapidly in most of these patients. Patients with less extensive injuries may experience a delayed onset of symptoms up to several months or even longer after the trauma. Iatrogenic trauma during endoscopic retrograde cholangiopancreatography (ERCP) causes acute pancreatitis in about 3% to 5% of cases, although in certain subgroups (e.g., those suspected of having sphincter of Oddi dysfunction), the risk may be as high as 20% to 25%.[21] ERCP appears to cause pancreatitis as a consequence of obstruction, inflammation, and edema of the pancreatic duct orifice and by barotrauma to the acinar cells. Ischemic injury to the pancreas may occur in the setting of many surgical procedures, because the pancreatic vasculature has very limited ability for vasodilatation. In such cases, postoperative pancreatitis is often quite severe and most commonly occurs after cardiac surgery or cardiopulmonary bypass.

Genetic Factors

A number of mutations have been described in association with acute and chronic pancreatitis. These include mutations in the cationic trypsinogen (*PRSS1*), cystic fibrosis transmembrane conductance regulator (*CFTR*), and secretory trypsin inhibitor (or serine protease inhibitor Kazal type 1 [*SPINK1*]) genes.[22] These conditions are most commonly associated with chronic pancreatitis [see Chronic Pancreatitis, Etiology, below] but in some cases may also produce acute flares. A number of studies have examined polymorphisms in cytokines involved in the inflammatory response to determine whether such polymorphisms might be predictors of the severity of acute pancreatitis. To date, these studies have been unrevealing.

Autoimmune Pancreatitis

Autoimmune pancreatitis is a benign disease characterized by irregular narrowing of the pancreatic duct, swelling of the parenchyma, and lymphoplasmacytic infiltration and fibrosis. Autoimmune pancreatitis can present clinically as an attack of acute pancreatitis. Patients with autoimmune pancreatitis may have high antinuclear antibody and serum IgG4 concentrations, providing a useful means of distinguishing this disorder from other diseases of the pancreas or biliary tract.[23,24] Patients with autoimmune pancreatitis generally have a favorable response to corticosteroid treatment.

Undetermined Causes

After evaluation, about 25% of all patients with acute pancreatitis do not have a specific definable etiology. In fact, after gallstones and alcohol, idiopathic acute pancreatitis is the most common diagnosis. Some of these patients may be surreptitious alcoholics, but many more appear to have a forme fruste of gallstone disease. Two series have documented the presence of microscopic gallstones (so-called microlithiasis) in two thirds to three fourths of patients with apparent idiopathic acute pancreatitis.[25,26] The importance of microlithiasis is underscored by the fact that cholecystectomy, ERCP with sphincterotomy, and agents used to dissolve gallstones (e.g., ursodeoxycholic acid) all reduced the frequency of recurrent attacks of acute pancreatitis in patients participating in these studies. Unfortunately, there is as yet no standardized method to determine the presence of microlithiasis.

PATHOGENESIS

The pathophysiology of acute pancreatitis, irrespective of cause, remains poorly understood. All etiologies appear to converge on a final common pathway that allows the premature activation of digestive enzymes within the pancreas.[27,28] The conversion of the inactive proenzyme trypsinogen to its active form trypsin appears to be a critical early step because trypsin can then activate most of the other digestive proenzymes. The release of activated digestive enzymes into the pancreas and surrounding tissues can produce tissue damage and necrosis of the pancreas, its surrounding fat, and adjacent structures. This chemical "burn" of the retroperitoneum leads to substantial fluid loss into this area—so-called third-space fluid losses. Not all patients with acute pancreatitis develop necrosis of the pancreas itself; necrosis is most commonly seen in severe attacks of acute pancreatitis. Substantial pancreatic necrosis (acute necrotizing pancreatitis) is usually distinguished from the milder form in which necrosis is absent (interstitial pancreatitis).

The release of activated digestive enzymes into the systemic circulation can overwhelm normal protective mechanisms (e.g., antiproteases) and cause direct damage to distant organs and other systemic enzyme systems (e.g., complement and kinin systems). Finally, a number of inflammatory mediators and cytokines can be released from inflammatory cells to produce a systemic immune response syndrome (SIRS) or sepsislike syndrome.[29,30] The combination of activated digestive enzymes in the systemic circulation, the activation of other enzyme systems, and the release of inflammatory cytokines can produce the severe systemic complications associated with severe acute pancreatitis [*see Table 2*]. Recognition of the role of these inflammatory mediators has not only improved our understanding of the pathophysiology of acute pancreatitis but also provided potential new targets for therapy.

DIAGNOSIS

Clinical Findings

The diagnosis of acute pancreatitis is usually suspected on the basis of compatible signs and symptoms and confirmed by laboratory tests and radiographic imaging. Pain is the most common symptom of acute pancreatitis, occurring in up to 95% of patients. The pain of acute pancreatitis is most commonly felt in the epigastrium and radiates to the back in up to two thirds of patients. Pain may be felt more diffusely across the abdomen. The pain is usually quite severe, reaches its maximum intensity within 30 minutes, and lasts hours to days. In some cases, pain may not be the dominant symptom, particularly if it is masked by multiorgan failure, delirium, or coma; in rare cases, pain may be absent altogether. Nausea and vomiting are commonly associated with the pain of pancreatitis. No relief of the abdominal pain is achieved by vomiting.

The physical examination usually reveals epigastric or diffuse tenderness on palpation, with rebound tenderness and guarding present in the most severe cases. The abdomen is often distended and tympanic, and bowel sounds may be decreased or absent. Vital signs may be normal; more commonly, tachycardia, hypotension, tachypnea, and low-grade fever are noted. Orthostatic hypotension, tachycardia, and shock early in the course of acute pancreatitis are markers for substantial third-space fluid losses and indicate both a poor prognosis and probable need for admission to an intensive care unit. Dyspnea or tachypnea may occur because of muscular splinting secondary to abdominal

pain, pleural effusions, or a pulmonary capillary leak syndrome (i.e., acute respiratory distress syndrome [ARDS]). Generally, the presence of tachypnea, dyspnea, or oxygen desaturation merits ICU admission. Rare physical findings include ecchymoses of the flank (Grey Turner sign) and umbilicus (Cullen sign) and eruptive xanthomas in patients with hyperlipidemic pancreatitis; signs of alcoholic liver disease may be present in patients with alcoholic pancreatitis. Altered mental status may be present and usually has multiple causes (alcohol withdrawal, hypotension, electrolyte imbalance, and hypoxemia). Jaundice may be present, either from obstruction of the bile duct by a gallstone or from extrinsic compression of the bile duct by a large peripancreatic fluid collection. Purtscher retinopathy presenting as retinal hemorrhage is a very rare complication of acute pancreatitis.

Laboratory Tests

A history and physical examination suggestive of acute pancreatitis may be seen in a wide variety of intra-abdominal diseases. Therefore, the diagnosis is usually confirmed with a combination of laboratory tests and imaging studies.

Serum amylase The serum amylase level has long been the most widely used confirmatory laboratory measurement for acute pancreatitis. At least 75% of patients with acute pancreatitis will have increased levels of serum amylase at the time of initial evaluation.[31] Levels greater than three times the upper limit of normal are highly suggestive of acute pancreatitis. Amylase is cleared by the kidney; in patients with renal failure, a higher threshold of five times the upper limit of normal should be used. Normal levels of serum amylase, however, do not rule out the presence of pancreatitis. Serum amylase levels may be normal in some patients with acute alcoholic pancreatitis and in patients with hyperlipidemic pancreatitis (marked elevations in triglyceride levels can interfere with the laboratory assay for amylase). More generally, elevated levels of serum amylase may have already returned to normal if testing is delayed until several days after the onset of symptoms. In several large series of fatal pancreatitis, 10% to 30% of patients who died of acute pancreatitis were undiagnosed before autopsy.[32] The diagnosis of acute pancreatitis is generally missed in such patients for one of two reasons: serum amylase levels are normal (or are not measured) or the presenting symptoms are atypical (e.g., coma or multiorgan failure rather than abdominal pain). The true sensitivity of the serum amylase measurement as a diagnostic test for acute pancreatitis is therefore difficult to determine.

Elevations of the serum amylase level are not specific for acute pancreatitis and may be associated with a very wide variety of nonpancreatic conditions [*see Table 3*]. Although many of these other conditions would not be mistaken for acute pancreatitis, a number of intra-abdominal conditions can produce increased serum amylase levels and mimic both the signs and the symptoms of acute pancreatitis. Such disorders include intestinal ischemia and perforation, bowel obstruction, choledocholithiasis, cholelithiasis with cholecystitis, tubo-ovarian disease (ectopic pregnancy, acute salpingitis), and acute appendicitis.

Serum lipase The serum lipase level is often used as an adjunct to or in place of serum amylase testing as a confirmatory test for acute pancreatitis. Accurate measurement of serum lipase was difficult in the past, but new methods provide high levels of precision. The lipase level is in fact slightly more sensitive and somewhat more specific for acute pancreatitis than the amylase level.[31] In addition, serum lipase stays elevated longer and can confirm a diagnosis of acute pancreatitis up to 5 to 10 days after the onset of symptoms, by which time amylase levels have generally returned to normal. Like amylase, lipase may be elevated in other intra-abdominal conditions (with the exception of tubo-ovarian disease) and may be elevated in renal failure. Elevations that are more than three times the upper limit of normal have the greatest diagnostic sensitivity and specificity, but again, this threshold may need to be increased to five times the upper limit of normal in patients with renal failure. Lipase is probably preferable to amylase as a confirmatory test because in addition to its greater specificity, it is no more costly and, in most hospitals, has equally rapid availability.

Table 2 Complications of Acute Pancreatitis

- Local complications
  - Peripancreatic fluid collection
  - Pseudocyst
  - Pancreatic necrosis (sterile or infected)
  - Abscess
  - Duodenal obstruction
  - Biliary obstruction
- Systemic complications
  - Cardiovascular
    - Hypotension and shock
    - Pericardial effusion and tamponade
    - ECG changes
  - Pulmonary
    - Hypoxia
    - Atelectasis, pneumonia
    - Pleural effusion
    - Acute respiratory distress syndrome
  - Metabolic
    - Hypocalcemia
    - Hypertriglyceridemia
    - Hyperglycemia
  - Renal
    - Oliguria and azotemia
    - Acute tubular necrosis
  - Hematologic
    - Disseminated intravascular coagulation (DIC)
    - Vascular thrombosis (particularly splenic vein)
  - Gastrointestinal bleeding
  - Other
    - Encephalopathy
    - Distant fat necrosis
    - Retinopathy

Other tests Leukocytosis is frequently present in acute pancreatitis. The hematocrit may be normal, but in patients with severe pancreatitis and substantial third-space fluid loss, hemoconcentration is present. There are a number of methods to gauge the severity of pancreatitis, but the presence of hemoconcentration is a reasonably accurate marker of severe pancreatitis.[33] Hyperglycemia and hypocalcemia may also be present. Tetany is rare because ionized calcium levels are usually normal in pancreatitis despite the presence of hypocalcemia. Liver chemistries may be elevated in persons with gallstone pancreatitis or with intrinsic liver disease (e.g., alcoholic hepatitis). Elevations of alanine aminotransferase levels to three times the normal level strongly suggest gallstone disease as the etiology; however, any significant abnormality of liver chemistries should raise the suspicion of gall-

stone pancreatitis, particularly if the abnormalities rapidly return to the normal range over the course of a few days.[34] The differentiation of gallstone pancreatitis from other forms of pancreatitis is important because specific therapy may be required [*see* Removal of Common Bile Duct Stones, *below*].

Imaging Studies

Imaging studies, particularly ultrasound and CT, can be useful in confirming a diagnosis of acute pancreatitis, determining etiology, and assessing the severity of the attack.

Radiology Plain abdominal radiographs may help in the evaluation of acute abdominal pain by documenting the presence of conditions (e.g., an ileus or free intraperitoneal air) that cause acute pain, but the findings are never specific enough to confirm a diagnosis of acute pancreatitis. Similarly, barium or water-soluble contrast studies of the upper gastrointestinal tract are not helpful in confirming a diagnosis of acute pancreatitis.

Ultrasonography Abdominal ultrasonography (US) is a highly useful test in the evaluation of suspected acute pancreatitis. Diagnostic abnormalities of the pancreas, including pancreatic enlargement, changes in echotexture, and peripancreatic fluid collections, can be seen in up to two thirds of patients; in the remaining third, overlying bowel gas limits the ability of sound transmission, thus preventing adequate visualization of the pancreas.

US is the most sensitive test for detecting stones in the gallbladder in patients with gallstone pancreatitis. The presence of gallstones or a dilated bile duct visualized on US is highly predictive of gallstone disease as the etiology of acute pancreatitis. If the gallbladder and biliary tree cannot be imaged on initial ultrasonography, a repeat ultrasound several days later may prove diagnostic of gallstone pancreatitis.

Table 3 Nonpancreatic Causes of Elevated Amylase and Lipase Levels

Amylase	*Lipase*
Biliary disease Common bile duct obstruction Acute cholecystitis	Biliary disease Common bile duct obstruction Acute cholecystitis
Intestinal ischemia, obstruction, or perforation	Intestinal ischemia, obstruction, or perforation
Acute appendicitis	Acute appendicitis
Gynecologic conditions Ectopic pregnancy Acute salpingitis Ovarian cysts and malignancies	Renal insufficiency
Renal insufficiency	
Macroamylasemia	
Salivary gland disease, including mumps	
Miscellaneous causes Anorexia nervosa Diabetic ketoacidosis Lung cancer Head trauma	

Computed tomography Computed tomography is much more accurate than US in confirming the presence of acute pancreatitis, although CT is less accurate in evaluating the biliary tree and gallbladder for stones.[35-37] The two tests are therefore often used together in patients with acute pancreatitis. CT results may be normal in a small subset of patients with very mild acute pancreatitis (10% of patients), but the test is reliably diagnostic in moderate or severe disease. CT is also quite useful in assessing conditions that mimic severe acute pancreatitis. In addition, CT plays a very important role in determining severity of the attack [*see* CT Findings, *below*].

The use of a rapid bolus of intravenous contrast coupled with rapid scanning of the pancreas by use of CECT can provide a diagnosis of acute pancreatitis and, very importantly, assess the severity of disease and the extent of pancreatic necrosis. As visualized on CECT, viable pancreatic parenchyma is enhanced by uptake of the contrast medium, and necrotic areas of the gland are unenhanced. The extent of necrosis is a very important indicator of prognosis.[35-37]

CT scans are not required in every patient with acute pancreatitis, but they should be performed in patients with a first attack of pancreatitis, with moderate or severe symptoms, with systemic complications, in whom there is a suspicion of a complication (e.g., pancreatic pseudocyst), with smoldering pancreatitis that is slow to improve, or when the diagnosis is unclear.

Magnetic resonance imaging Gadolinium-enhanced dynamic magnetic resonance imaging can be used to grade the severity of acute pancreatitis if there are contraindications to intravenous contrast–enhanced CT, such as renal failure or iodine sensitivity.[38] Furthermore, magnetic resonance cholangiopancreatography (MRCP) is an accurate way to test for the presence of common bile duct stones.[39] It may be difficult, however, to perform MRI or MRCP in very sick patients.

Endoscopy ERCP and endoscopic ultrasonography (EUS) are not used as diagnostic tests for acute pancreatitis, although they may be useful in determining etiology. ERCP is accurate in evaluating many of the less common causes of acute pancreatitis, including microlithiasis, sphincter of Oddi dysfunction, pancreas divisum, and pancreatic duct strictures (benign and malignant). As a diagnostic test, ERCP is generally reserved for patients who have experienced a second attack of unexplained pancreatitis, although use of ERCP may be considered as a diagnostic option after a single attack of unexplained pancreatitis in patients at risk for malignant pancreatic duct strictures (e.g., those older than 40 to 45 years). ERCP certainly has value as a therapeutic tool (e.g., for finding and removing common bile duct stones in patients with gallstone pancreatitis).

EUS is also useful in the documentation of gallstones, microlithiasis, pancreatic tumors, and pancreas divisum. Although it is used less frequently than ERCP in patients with acute pancreatitis (primarily because it is not widely available), EUS has a significantly lower risk of complications. EUS is highly accurate in both documenting stones and visualizing tumors (more sensitive than ERCP) and will be used more commonly in the future [*see Figure 1*].

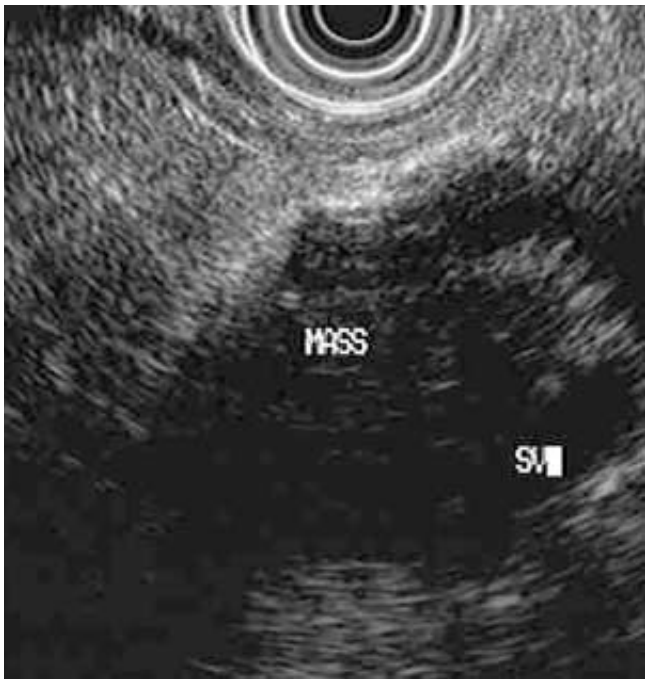

Figure 1 **An endoscopic ultrasound image of a pancreatic mass in a patient with unexplained acute pancreatitis. The mass is labeled and sits on the splenic vein (SV). The mass was not visible on computed tomography.**

Determining Disease Severity

Three quarters of patients with acute pancreatitis have a benign course and recover rapidly. The highest morbidity and mortality are in patients with necrotizing pancreatitis. The mortality associated with acute pancreatitis is 2% to 10%, with the lower estimates of mortality coming from database analyses and the higher estimates coming from more selected or referral populations. Mortality within the first week of the illness is most commonly from ARDS, multiorgan failure, or a sepsislike syndrome. Patients with persisting organ failure are at greatest risk of mortality; transient organ failure is generally not associated with mortality. Mortality after the first or second week is most commonly caused by infection of pancreatic tissue (i.e., pancreatic abscess or infected necrosis).

After making a diagnosis of acute pancreatitis, the clinician's next goal is to estimate prognosis and severity of disease. The accurate assessment of prognosis and severity allows more accurate decision making regarding ICU admission, measurement of central venous pressure or pulmonary capillary wedge pressure, and administration of prophylactic antibiotics. The assessment of severity of acute pancreatitis may be based on clinical features, laboratory tests, or imaging studies or a combination of the three. Frequently, careful evaluation by an experienced clinician is a very helpful method of gauging severity and detecting complications. The presence of delirium or coma, hypoxia, or features suggestive of massive third-space fluid loss (i.e., hypotension, tachycardia, oliguria, azotemia, or hemoconcentration) within the first 24 hours suggests a severe attack and the need for ICU admission.[40] Many patients will not develop such a dramatic illness, and a number of multiple-factor scoring systems are available to assist the clinician in determining severity and estimating prognosis.

Multiple-factor scoring systems Several multiple-factor scoring systems have been developed that use a combination of clinical and laboratory features to determine disease severity; these include the Ranson criteria [*see Table 4*], modified Glasgow criteria, and APACHE II criteria [*see Table 5*]. The most widely quoted system developed by Ranson utilizes two systems: one for gallstone pancreatitis and one for nongallstone (alcoholic) pancreatitis. In the Ranson system, the presence of one or two criteria is very specific, though not sensitive, for clinically mild pancreatitis.[40,41] The presence of three or four risk factors is associated with a mortality of 15%, although many patients with three or four criteria also recover rapidly without sequelae. The presence of a high number of criteria (e.g., six or seven Ranson criteria) is associated with a high likelihood of substantial morbidity and mortality (> 50% mortality).[40,41] All of the multiple-factor scoring systems suffer from the limitation of a high false positive rate; in other words, the presence of a moderate number of criteria is generally associated with moderate risk of morbidity and mortality, but the scoring systems do not identify whether that individual patient is likely to suffer morbidity or mortality. The APACHE II system has an advantage over the Ranson and Glasgow systems in that it can be applied at any point in the clinical illness; the Ranson and Glasgow scores require up to 48 hours before they can be calculated. Three or more Ranson criteria or eight or more APACHE II points are commonly considered an indication of an unfavorable prognosis.

CT findings CT is a useful adjunct for estimating disease severity. The initial scoring systems correlated the severity of the pancreatic and peripancreatic inflammatory processes with the prognosis. Subsequently, CT was combined with a rapidly administered bolus of intravenous contrast (CECT) to define the presence and extent of pancreatic necrosis; this technique has become widely used.[36,37,41] The lack of vascular contrast enhancement of the pancreas on CECT corresponds in a general way to the presence of necrosis. Pancreatic necrosis complicates about 25% of all cases of acute pancreatitis and is generally associated with more clinically severe disease; it is particularly associated with the development of the late complications of pancreatic abscess and infected necrosis.[37,41,42]

As with all systems used in assessing severity, CECT produces a significant number of false positive results, in that many patients who have evidence of necrosis on dynamic CT scanning have a mild clinical course.[43] Despite that, the presence of substantial pancreatic necrosis (more than one third of the gland) is a useful marker of severity because nearly all patients with a clinically severe course have necrosis and almost all cases of serious pancreatic infection occurs in this group.[42,43]

At the International Symposium on Acute Pancreatitis, an attempt was made to consolidate the various methods for determining disease severity into a unified approach.[1] The resulting system defines severe pancreatitis by a combination of clinical features (organ failure), multiple-factor scoring systems, and the presence of local pancreatic complications [*see Table 6*]. This system is useful in that it consolidates the various methods, but it does not replace frequent and experienced clinical observation.

MANAGEMENT

The treatment of acute pancreatitis has four goals: (1) provide supportive care; (2) minimize or reduce the local necrosis and the systemic inflammatory process; (3) recognize and treat complications; and (4) prevent subsequent attacks.

Supportive Care

Mild acute pancreatitis The foundations of supportive care include making the patient nil per os (NPO); providing relief from pain and nausea; replacing fluid losses; providing nutrition, if needed; and monitoring for the development of complications. This is relatively straightforward in patients with mild pancreatitis, because fluid losses are modest and complications are rare. Pain and nausea can usually be controlled by the use of moderate dosages of intravenous analgesics and antiemetics. Even in mild pancreatitis, fluid losses may be significant because of third-space fluid losses, vomiting, and insensible losses; appropriate fluid resuscitation is critical in minimizing complications. Patients can generally be fed when bowel sounds have returned and pain has resolved.

Severe acute pancreatitis When pancreatitis is severe or is predicted to be severe (based on CT or CECT findings, multiple-factor scoring systems, early evidence of significant third-space fluid losses, or early respiratory insufficiency), supportive care is more challenging and usually requires the resources of an ICU. Prompt and vigorous fluid replacement is critical in the early phases of severe acute pancreatitis and can minimize or prevent early complications, including renal failure and cardiovascular collapse.[44] The pancreas itself is prone to ischemic injury in the setting of intravascular fluid volume depletion. The pancreatic microcirculation has little capacity to respond to diminished blood supply, and intravascular volume depletion may worsen the degree of pancreatic necrosis. For all these reasons, early and vigorous fluid resuscitation is important in the management of severe pancreatitis.[40,44]

Hemoconcentration is a common and readily available marker of substantial third-space fluid losses. Measurement of central venous pressure or, if required, pulmonary capillary wedge pressure allows accurate assessment of fluid needs. Fluid needs of 5 to 10 L/day are not uncommon. Treatment with crystalloid solutions is usually appropriate, although colloid solutions (albumin or blood) may be appropriate when albumin levels are extremely low (< 2.0 mg/dl) or when the hematocrit is below 25%.

Admission to an ICU, in addition to facilitating the monitoring of fluid resuscitation, allows for intensive monitoring of respiratory and metabolic complications. Pulmonary capillary leak syndrome (i.e., ARDS) is one of the most serious complications of severe pancreatitis. Hypoxia and dyspnea are usually noted, but ARDS must be distinguished from fluid overload or congestive heart failure. This is best done with the use of a Swan-Ganz catheter. A variety of early metabolic complications (e.g., hyperglycemia, hypocalcemia, hypertriglyceridemia, and hypomagnesemia) are also most easily managed in an ICU setting.

Table 4 Ranson Prognostic Scoring System for Pancreatitis

Type	*On Admission*	*Within 48 Hours*
Nongallstone pancreatitis	Age > 55 yr WBC count > 16,000/mm^3 Glucose > 200 mg/dl LDH > 350 IU/L AST > 250 U/L	Decrease in Hct > 10 points Increase in BUN > 5 mg/dl Serum calcium < 8 mg/dl P_aO_2 < 60 mm Hg Base deficit > 4 mmol/L Fluid deficit > 6 L
Gallstone pancreatitis	Age > 70 yr WBC count > 18,000/mm^3 Glucose > 220 mg/dl LDH > 400 IU/L AST > 500 U/L	Decrease in Hct > 10 points Increase in BUN > 2 mg/dl Serum calcium < 8 mg/dl Base deficit > 5 mmol/L Fluid deficit > 4 L

AST—aspartate aminotransferase BUN—blood urea nitrogen Hct—hematocrit LDH—lactate dehydrogenase P_aO_2—arterial oxygen tension WBC—white blood cell

Nutritional support is useful for patients with severe pancreatitis and for those with milder pancreatitis who nonetheless are unable to eat for more than 5 to 7 days. The preferred route of providing exogenous nutrients has changed. For years, total parenteral nutrition (TPN) has been the standard practice. Accumulating evidence suggests that enteral feeding is comparable or superior to TPN.[45-47] Prospective, randomized trials have demonstrated that enteral feeding infused distal to the ligament of Treitz is associated with fewer complications (infection and hyperglycemia) and is cheaper than TPN.[45] Although the evidence is not definitive,[47] the accumulating data supporting this method of enteral feeding have led to a shift in the preferred method of providing nutrition to patients with acute pancreatitis. The main practical challenge in using enteral jejunal feeding is placing and maintaining position of the nasojejunal tube.

Treatment of Necrosis and Inflammation

Pancreatic rest No treatment has been proved to interrupt the inflammatory process effectively. Many early studies focused on strategies that were thought to "rest" the pancreas beyond the rest associated with maintaining the patient NPO. These have included nasogastric suction, H_2 receptor antagonists, atropine, somatostatin and its analogue octreotide, glucagon, and even fluorouracil. None of these approaches appear to have any benefit on the outcome of acute pancreatitis, although meta-analyses of somatostatin and octreotide suggest a slight trend toward benefit.[48] That is not to say that nasogastric suction is not useful if the patient has substantial nausea and vomiting or that administration of H_2 receptor antagonists does not prevent stress erosions and ulcers; however, neither of these therapies improves the overall outcome of the acute pancreatitis itself.

Protease removal or inhibition A second strategy to interrupt the inflammatory process is to remove proteases by peritoneal lavage or inhibit circulating proteases by administration of antiproteases (e.g., aprotinin or gabexate). However, neither method of protease control has been shown to be of benefit in acute pancreatitis. One potential reason for lack of efficacy is that these therapies can generally be administered only after the initiation of acute pancreatitis. In animal models, these therapies have been administered before the initiation of pancreatitis and have been shown to be nearly uniformly beneficial.[49] Pancreatitis induced by ERCP offers a unique opportunity to administer therapy in humans before the onset of acute pancreatitis. Although the data are inconclusive, meta-analyses have identified a reduction in post-ERCP pancreatitis in patients receiving the protease inhibitor gabexate or the antisecretory hormone somatostatin (but not, interestingly, its analogue octreotide).[50,51] The effect of these agents is only modest, and they are not available for clinical use in the United States. The effect of other methods, particularly the use of temporary pancreatic duct stents, appears to be far superior.

Anticytokine therapy Some studies have focused on control of the systemic immune response through the modulation of inflammatory cytokines. Because this cytokine cascade is felt to

Table 5 APACHE II Severity of Disease Classification System*

Physiologic Variable	*Physiologic Points*								
	Range

underlie the development of multiorgan failure, cytokines are attractive targets for therapy. Platelet-activating factor (PAF) has been considered to be a major proinflammatory cytokine, and several small randomized trials using an antagonist of PAF have suggested that this agent may reduce the severity of pancreatitis if administered early in the disease course. The results of these small trials, however, have not been confirmed in a large randomized trial.[52] PAF antagonists have also been tested as therapies to prevent post-ERCP pancreatitis but have not shown significant benefit. It is likely that interfering with the cytokine cascade will require multiple agents, and further testing of these and similar therapies will clarify the role they play in the treatment of severe acute pancreatitis.

Removal of common bile duct stones A therapy that has been tested as a strategy to reduce local or systemic inflammation is the removal of common bile duct stones in patients with gallstone pancreatitis. In the vast majority of patients with gallstone pancreatitis, the offending bile duct stone has already passed into the duodenum at the onset of disease. Evaluation of the common bile duct for stones early in the clinical course of gallstone pancreatitis detects the presence of stones in up to 78% of patients. This level drops to between 3% and 33% if the evaluation is undertaken later in the clinical course.[53] The vast majority of patients thus pass the stone spontaneously; however, in a small subset of patients, a persistent common bile duct stone remains, and anecdotal observations suggest that these patients seem to be at risk for more severe pancreatitis (e.g., more organ failure and a greater degree of necrosis) and concomitant cholangitis. It is well established that cholangitis complicates up to 10% of cases of gallstone pancreatitis. Furthermore, it may be difficult in some patients to distinguish the presence of concomitant cholangitis from severe pancreatitis, because the two diseases may present similar features (e.g., fever, leukocytosis, abdominal pain, and abnormal liver chemistries). Therefore, the strategy was proposed to remove common bile duct stones in patients with gallstone pancreatitis as a means to reduce severity of disease and to prevent or treat concomitant cholangitis.

Early attempts to remove persistent common bile duct stones by surgery were associated with a mortality higher than that associated with conservative management. Subsequently, endoscopic techniques (e.g., ERCP) were used to remove stones. Three randomized trials assessed the utility of early ERCP and stone removal in patients with suspected gallstone pancreatitis.[54-56]

The initial study reported that the morbidity in patients with gallstone pancreatitis who underwent ERCP and stone removal within 72 hours was lower than the morbidity in a group of patients managed conservatively.[54] This benefit included a reduction in complications (organ failure and others) and a trend (not statistically significant) toward lower mortality. These benefits were restricted to a subgroup of patients who were predicted to have a severe attack. The second randomized trial noted a reduction in biliary sepsis but no reduction in organ failure or other complications associated with severe gallstone pancreatitis.[55] One of the two studies therefore suggested that early ERCP reduced the severity of pancreatitis, whereas the other study found that ERCP had no effect on the severity of pancreatitis but merely prevented or treated concomitant cholangitis caused by common bile duct stones. A third randomized trial attempted to reconcile these results by excluding patients with cholangitis or those at high risk for cholangitis (i.e., patients with jaundice). This study demonstrated no re-

duction in morbidity or mortality in patients with gallstone pancreatitis but without jaundice.[56]

Taken together, these three studies suggest that early ERCP is indicated in patients with evidence of biliary sepsis (i.e., fever, jaundice, and right upper quadrant pain) and in those with a high likelihood of developing biliary sepsis. High risk of biliary sepsis might be clinically defined as findings highly suggestive of a persistent obstructing common bile duct stone and could be defined by the presence of a stone in the common bile duct as visualized on radiographic imaging; by persistently abnormal liver chemistries; or by radiographic evidence of a persistently dilated bile duct. Early ERCP may also be considered in patients with early and progressive organ system failure, in whom it may be difficult to determine whether the downhill course is caused by severe pancreatitis or by associated cholangitis. Undertaking ERCP in this situation can be challenging, and sedating these critically ill individuals is not without risk.

Treatment of Complications

Systemic complications Systemic complications of acute pancreatitis can occur in a wide variety of organ systems [*see Table 2*].[44,57] Systemic complications, particularly shock, ARDS, and multiorgan failure, are the most common causes of death from acute pancreatitis within the first week of the illness. In patients with severe pancreatitis, fluid losses into the retroperitoneum can be massive and can produce intravascular volume depletion, hypotension and shock, and renal failure. The development of renal failure, shock, or massive volume depletion is an indication of severe disease and is associated with increased mortality. Most substantial fluid losses occur early in the course of acute pancreatitis; hence, attention must be paid to adequate and aggressive fluid resuscitation early in the disease course.[44]

Hypoxia Hypoxia is not uncommon during the initial stages of acute pancreatitis. A subset of patients will develop more substantial or prolonged hypoxia and go on to develop ARDS. Thus, it is reasonable to monitor patients with acute pancreatitis, especially those with severe acute pancreatitis, by means of pulse oximetry to detect the development of hypox-

emia. Because patients who develop hypoxia are also at risk for MOF, persistent hypoxemia merits ICU admission. Fluid management in these patients can be difficult and is best done with monitoring of pulmonary capillary wedge pressure. Mechanical ventilation, usually with positive end-expiratory pressure (PEEP), is often necessary.

Cardiac complications A variety of cardiac complications may occur in severe acute pancreatitis, including congestive heart failure, myocardial infarction, cardiac arrhythmias, and cardiogenic shock. Hypotension is most commonly caused by third-space fluid losses and intravascular volume depletion. Cardiac dysfunction may, however, occur as part of SIRS seen in severe acute pancreatitis, which is characterized by high cardiac output and low systemic vascular resistance. Hypotension that is not responsive to fluid resuscitation may require the use of pressor agents.

Metabolic complications A number of metabolic complications may also occur in acute pancreatitis, including hypocalcemia, hyperglycemia, and hyperlipidemia. Hypocalcemia is most commonly the result of hypoalbuminemia and is uncommonly associated with a reduction in ionized calcium or symptoms of hypocalcemia. Calcium replacement is usually not needed in the absence of decreased ionized calcium or signs of neuromuscular instability (e.g., tetany, the Chvostek sign, and the Trousseau sign). Calcium should, nonetheless, be monitored carefully, as it can be a marker of severe pancreatitis.

Hyperglycemia, like hypocalcemia, is one of the Ranson criteria indicating a poor prognosis. Treatment of mild hyperglycemia is not necessary, but significant increases in blood glucose levels (i.e., levels > 200 mg/dl) should be treated with sliding-scale insulin to minimize associated fluid losses caused by glycosuria and to prevent any detrimental effect on white cell function.

Hyperlipidemia is associated with acute pancreatitis, both as an etiologic factor and as a consequence. Many patients with acute pancreatitis may develop a modest elevation in serum triglyceride levels (i.e., levels > 300 to 400 mg/dl) as a consequence of acute pancreatitis. These elevations in triglyceride levels are usually short-lived and do not require therapy. Levels above 1,000 mg/dl indicate hypertriglyceridemia as the cause, rather than a consequence, of acute pancreatitis. These levels will usually drop rapidly while the patient is NPO. Marked elevations in triglyceride levels (> 10,000 mg/dl) or failure of triglyceride levels to drop as expected may occasionally necessitate the use of plasmapheresis to rapidly clear triglycerides from the serum. After recovery from pancreatitis, patients with hyperlipidemic pancreatitis should be started on appropriate medications and dietary therapy to control lipids.

Gastrointestinal bleeding Gastrointestinal bleeding may complicate acute pancreatitis and is a marker of a severe attack.[57,58] Bleeding may occur from stress erosions, peptic ulceration, pseudoaneurysm, or varices developing as a consequence of splenic vein thrombosis. Splenic vein thrombosis, which may occur as a consequence of inflammatory and neoplastic pancreatic diseases, causes a left-sided portal hypertension characterized by gastric varices out of proportion to esophageal varices. These varices may bleed and, if they do, may be managed by splenectomy, which is curative. Bleeding from a pseudoaneurysm is usually associated with a pseudocyst [*see* Chronic Pancreatitis, Treatment of Other Complications, *below*].

Other systemic complications Rare complications of acute pancreatitis include other vascular thromboses, disseminated intravascular coagulation, distant fat necrosis in the skin (resembling erythema nodosum), encephalopathy, and sudden blindness.

Pancreatic infection and abscess Infected pancreatic necrosis, the most serious form of pancreatic infection, occurs in about 1% to 4% of patients overall with pancreatic infection and in 15% to 30% of those with pancreatic necrosis.[42,59,60] The mortality of necrotizing pancreatitis is about 10%, but this rate triples when infection supervenes. Most commonly, infection occurs during the second and third weeks of an attack of severe pancreatitis. The patient develops fever (often, temperatures > 102º F [38.9º C]), leukocytosis, and recurrent or worsening abdominal pain. The infecting organisms usually seed the necrotic area from the gut and are most commonly gram-negative rods (e.g., *Klebsiella* or *Escherichia coli*) and *Staphylococcus aureus*. *Candida*, *Enterococcus*, and anaerobic organisms are seen less commonly as causal agents of pancreatic infection. When infection is suspected, a CT scan should be obtained to evaluate the extent of necrosis and identify optimal locations for percutaneous sampling.[40,42,61] The finding of gas within the pancreatic parenchyma is highly specific but quite insensitive for serious pancreatic infection [*see Figure 2*]. However, a clinical suspicion of infection together with a finding of necrosis is an indication for percutaneous aspiration of suspicious areas, and a Gram stain and a culture of the collected tissue should be done. Experience over the past 15 years has demonstrated that percutaneous aspiration is both highly accurate and safe.[40,42,59,60] If pancreatic infection is demonstrated on percutaneous aspiration, the therapy of choice is prompt surgical debridement. Successful management of necrotic collections by percutaneous or endoscopic catheterization has also been reported,[62] but these techniques require further study because it is difficult to remove the necrotic tissue through catheters and, hence, difficult to cure the infection by this means.

Pancreatic abscess may also complicate severe acute pancreatitis, usually as a consequence of superinfection of a preexisting fluid collection or pseudocyst. Less commonly, an abscess develops secondary to superinfection of necrotic sites in the pancreas. The clinical presentation of pancreatic abscess is indistinguishable from that of infected necrosis, although therapy may differ.

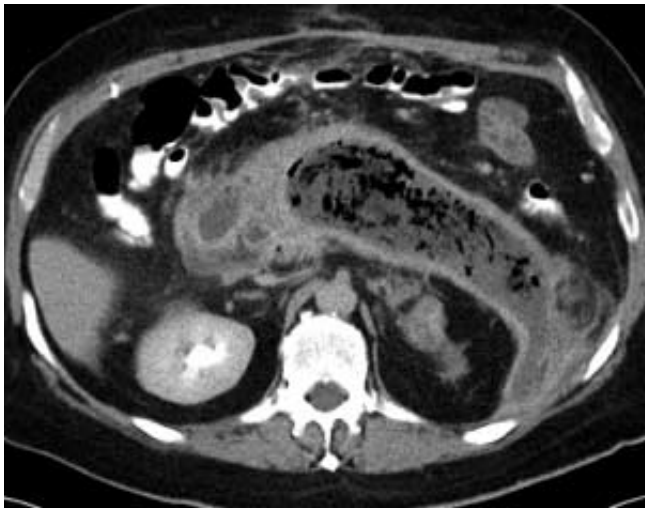

Figure 2 **A CT scan demonstrating a large amount of air within the necrotic pancreas in a patient with infected pancreatic necrosis.**

Therapy for pancreatic abscess usually consists of antibiotics and drainage. Unlike infected necrosis, which is typically treated by surgical debridement, pancreatic abscess may allow treatment by percutaneous or endoscopic tube drainage, because typically there is little solid necrotic tissue in the abscess cavity. The decision whether to treat with tube drainage or surgical exploration depends on whether the collections contain solid necrotic tissue (indicating infected necrosis, which typically necessitates open surgical drainage) or primarily pus (indicating abscess, which may allow drainage by endoscopic or percutaneous tube). However, distinguishing infected necrosis from pus may be difficult, and the most accurate picture of the collection contents is probably provided by MRI and EUS. EUS in particular is valuable because the collection not only can be assessed for the character of its contents but also can be drained safely in the same setting if appropriate. If doubt exists, it is better to err on the side of caution and opt for open surgical drainage.

Because the consequences of abscess and infected pancreatic necrosis are often severe, numerous studies have been directed toward identifying effective measures to prevent these infections. Currently, however, the role of antibiotics in the prevention of pancreatic infection is controversial. Early studies using prophylactic ampicillin demonstrated no reduction in pancreatic infections; it was later demonstrated that ampicillin does not penetrate the necrotic pancreas at adequate concentrations. More recent studies have identified agents that have adequate penetration of the necrotic pancreas; effective therapies include imipenem,[63,64] cefuroxime,[65] ofloxacin and metronidazole,[66] and ciprofloxacin and metronidazole.[67] A Cochrane Database review concluded that intravenous prophylactic antibiotic therapy for 10 to 14 days reduced the risk of superinfection of pancreatic necrosis and mortality.[68] This analysis, however, did not include the only relevant double-blind, randomized trial,[67] which demonstrated that there was no benefit with the use of prophylactic antibiotics for necrotic pancreatitis. These divergent findings have led to a difference of opinion on the overall utility of prophylactic antibiotics.

Generally, antibiotic use should be limited to patients at risk for serious pancreatic infection (i.e., if more than 30% of the gland appears necrotic on CT), and the selected antibiotic should be one that penetrates the necrotic tissue (i.e., imipenem or a fluoroquinolone plus metronidazole). Treatment should be continued for a maximum of 10 to 14 days. Patients receiving these broad-spectrum antibiotics are at risk for infection with resistant bacteria and fungal superinfection. Some researchers have advocated the concomitant use of antifungal agents such as fluconazole to reduce the risk of fungal infection, but the effectiveness of this strategy is unproved.

Fluid collections and pseudocysts Fluid collections in and around the pancreas occur commonly in patients with acute pancreatitis. Peripancreatic fluid collections are generally amorphous and not encapsulated. Most fluid collections resolve spontaneously, but some develop into pseudocysts.[57,69,70] A pseudocyst is a rounded collection of pancreatic fluid enclosed by a wall of fibrous or granulation tissue that can usually be seen on a CT scan. Most collections occur in the lesser sac or pararenal spaces, but they may develop anywhere and may even penetrate adjacent solid organs (e.g., the liver or spleen). Pseudocysts complicate 1% to 8% of all cases of acute pancreatitis.[69,70] Pseudocysts may persist, resolve, be asymptomatic, or be associated with symptoms or complications. The most common symptom associated with a pseudocyst is abdominal pain; however, other symptoms may develop if the pseudocyst obstructs an adjacent hollow viscus. For example, obstruction of the duodenum causes nausea and vomiting, whereas obstruction of the bile duct causes jaundice. Up to two thirds of all pseudocysts ultimately resolve, but spontaneous resolution is unlikely to occur with pseudocysts that are larger than 5 to 6 cm or are present for more than 6 weeks. In addition, pseudocysts larger than 6 cm are somewhat more likely to produce complications, including obstruction of an adjacent hollow viscus (e.g., duodenum or bile duct), infection, bleeding, or rupture. Infection of a pseudocyst (i.e., a pancreatic abscess) is usually relatively easy to manage with antibiotics and endoscopic or percutaneous catheter drainage; however, pseudocysts characterized by bleeding and rupture are associated with much greater morbidity and mortality. Bleeding may occur from a large artery that has formed a pseudoaneurysm from the pressure exerted by a contiguous pseudocyst, and the resulting blood flow can reach the gut through the pancreatic duct or can enter the peritoneum through a rupture of the pseudocyst. An initial bleed may be self-limited, but any unexplained drop in hemoglobin or change in pain pattern in a patient with a pseudocyst is an indication for an emergency CT scan. If any evidence of bleeding is found, emergency angiography with embolization can be lifesaving.[58]

Asymptomatic pseudocysts generally pose little risk of complications, even if they are large.[70] Symptomatic or complicated pseudocysts require therapy, and emergency surgery is required when bleeding or rupture is detected. Otherwise, elective surgical, percutaneous, or endoscopic techniques can be successful, depending on the location of the pseudocyst and the availability of expertise in these modalities. In the past, endoscopic drainage could be applied only to pseudocysts that produced a visible bulging impression in the lumen of the stomach or duodenum. Today, endoscopic pseudocyst drainage can be accomplished by using real-time endoscopic ultrasound guidance without the need of visually observing a bulge.[71] Percutaneous tube drainage can also treat pseudocysts that are farther from the gut lumen; however, tube drainage can produce a chronically draining external pancreatic fistula. Surgical treatment of pseudocysts probably has the best long-term results, but it also carries the most significant morbidity. Endoscopic ultrasound-guided transmural pseudocyst drainage appears to offer the best risk-to-benefit ratio for pseudocysts in anatomically amenable locations, but studies directly comparing surgical, endoscopic, and percutaneous drainage are lacking.

Prevention of Subsequent Attacks

Preventing subsequent attacks of acute pancreatitis requires elimination of the cause of the disease. In patients with acute alcoholic pancreatitis, cessation of alcohol consumption appears to have some benefit in reducing relapse, although unfortunately, the disease may continue to progress to symptomatic chronic pancreatitis despite abstinence. In patients with gallstone pancreatitis, cholecystectomy virtually eliminates recurrence. Similarly, the detection of microlithiasis followed by appropriate therapy (i.e., cholecystectomy, endoscopic biliary sphincterotomy, and possibly the use of ursodeoxycholic acid) can prevent recurrent pancreatitis. Aggressive control of serum lipid levels can prevent recurrent attacks of hyperlipidemic pancreatitis. In patients with a disorder that obstructs the pancreatic duct (e.g., benign or malignant pancreatic duct stricture, pancreas divisum, sphincter of Oddi dysfunction, and ampullary tumor), removal

of the obstruction by surgical or endoscopic means is generally effective in preventing relapse.

Chronic Pancreatitis

Chronic pancreatitis is characterized by irreversible damage to the pancreas and the development of histologic evidence of fibrosis and destruction of exocrine (acinar cell) and endocrine (islets of Langerhans) tissue. As with acute pancreatitis, the definition of chronic pancreatitis was developed at international symposia.[72] Several variants of chronic pancreatitis were defined, including chronic calcified pancreatitis (the most common form, which is commonly caused by excessive alcohol intake), chronic obstructive pancreatitis (caused by long-standing pancreatic duct obstruction), and chronic inflammatory pancreatitis (associated with inflammatory and, particularly, autoimmune diseases). Unfortunately, it is often not possible to make the distinction between these variants on the basis of clinical findings or imaging studies, and the distinctions are not very useful to clinicians. Recent classification schemes have focused more on etiology and are somewhat more useful to clinicians.[22]

EPIDEMIOLOGY

The prevalence of chronic pancreatitis varies with the population. Estimates of annual incidence in several studies range from three to nine cases per 100,000 population.[5,73] One study estimated an overall prevalence of 27.4 per 100,00 population. In nonfederal hospitals in the United States, this accounts for 122,000 outpatient visits and more than 20,000 hospitalizations annually.[3,4] The natural history can be quite variable and is clearly affected by the presence of ongoing alcoholism in persons with chronic alcoholic pancreatitis. In one large multicenter study,[74] the standardized mortality ratio was 3.6 (those with a diagnosis of chronic pancreatitis died at 3.6 times the rate of age-matched control subjects). Older persons and those with alcoholic chronic pancreatitis have the lowest survival. Overall, 10-year survival for patients with chronic pancreatitis has been shown to be about 70%, and 20-year survival about 45%.[5,74] Chronic pancreatitis is a strong risk factor for pancreatic adenocarcinoma, which partly explains the increased mortality associated with chronic pancreatitis.

ETIOLOGY

Alcohol Abuse

Alcohol is the cause of chronic pancreatitis in 70% to 90% of all cases. In general, at least 5 years of alcohol intake exceeding 150 g/day is required to develop symptomatic chronic pancreatitis, although some patients develop chronic pancreatitis with less alcohol intake. Only 5% to 15% of heavy drinkers ultimately develop chronic pancreatitis, suggesting that cofactors play an important role in pathogenesis.[12] Predisposing factors may include genetic abnormalities and a diet high in fat and protein. The mechanism by which alcohol causes chronic pancreatitis remains undefined, but it may be related to a change in pancreatic secretion leading to (1) protein plug formation in the pancreatic duct, (2) a direct toxic effect of alcohol or its metabolites, or (3) repeated attacks of acute alcoholic pancreatitis that eventually produce chronic irreversible damage. It has been observed that the vast majority of patients who develop an acute attack of alcoholic pancreatitis already have preexisting chronic damage to the gland.

Tropical Pancreatitis

Tropical pancreatitis is seen in certain areas of Indonesia, India, and Africa. The disease typically presents in childhood, with diabetes, abdominal pain, steatorrhea, malnutrition, and diffuse pancreatic calcifications. Malnutrition appears to be an important cofactor in this disease, as may be the presence of toxic metabolites of the dietary staple cassava. Studies also suggest a strong genetic component, with mutations in the *SPINK1* gene occurring in more than one third of patients.[75]

Genetic Factors

Hereditary pancreatitis is an autosomal dominant disease that typically presents in childhood or early adulthood and frequently is accompanied by steatorrhea, diabetes mellitus, and diffuse pancreatic calcifications. Pain and acute episodes of pancreatitis flares may also occur but are somewhat less common in hereditary pancreatitis than in alcoholic chronic pancreatitis. The initially identified genetic abnormality is a defect in the *PRSS1* gene on chromosome 7.[22,76] Multiple mutations have been described, but two are more common.[76] The two more common mutations appear to produce a trypsinogen that, once activated, is difficult or impossible to inactivate. The activated enzyme, trypsin, can in turn activate all the other pancreatic enzymes. Chronic pancreatitis appears to be caused in this situation by prolonged low-grade pancreatic injury from the activated proteases. Pancreatic adenocarcinoma frequently complicates the condition; patients with chronic pancreatitis have a 30% risk of developing pancreatic adenocarcinoma by age 70.[77] The risk may be substantially higher in patients with paternal inheritance.

Mutation of the *SPINK1* gene increases the propensity to develop chronic pancreatitis,[22,75] although mutation of this gene appears to act as a cofactor. Increased frequency of mutations in *SPINK1* is seen in patients with pancreatitis of different etiologies—namely, tropical pancreatitis (> 33% of patients), alcoholic chronic pancreatitis (about 6% of patients), hereditary pancreatitis (in a few kindreds in addition to their *PRSS1* mutation), and idiopathic chronic pancreatitis (sometimes in association with additional mutations in the *CFTR* gene). Mutations in *SPINK1* are common in the general population, but in most cases, pancreatic disease does not occur in these individuals; therefore, these mutations provide only a predisposition to chronic pancreatitis and are only some of the many factors contributing to formation of the disease.

CFTR mutations are also associated with chronic pancreatitis. Patients with classic cystic fibrosis commonly develop pancreatic insufficiency that requires supplementation of pancreatic enzyme. Several studies have also suggested that less common cystic fibrosis gene mutations, particularly when they occur as a mixed heterozygote (different mutations on the two alleles), are associated with relapsing pancreatitis and chronic pancreatitis in the absence of obvious sinopulmonary disease.[22,78] Patients with both *CFTR* and *SPINK1* mutations are at exceedingly high risk for chronic pancreatitis.

Undetermined Causes

Some patients may be misdiagnosed as having idiopathic pancreatitis if appropriate genetic studies are not performed or if a careful history of alcohol use is not obtained. Even if genetic studies are done, not all mutations may be identified (e.g., many commercially available screens look for only a few hundred of the more than 1,200 known *CFTR* mutations), and many identified *CFTR* and *SPINK1* mutations produce only a predisposition

to disease (unlike *PRSS1* mutations, which cause disease). Previous studies of patients with so-called idiopathic chronic pancreatitis that did not assess for the presence of genetic mutations appeared to identify two forms: early-onset and late-onset idiopathic chronic pancreatitis. The early-onset form presents just before or during the second decade, and it is typically associated with severe pain in the absence of diabetes, steatorrhea, or pancreatic calcification.[79] The late-onset form presents at a mean age of 56 years and is more commonly associated with exocrine or endocrine insufficiency and less commonly associated with severe pain.[79] The relative role of genetic influences on these two phenotypic variations remains to be determined.

PATHOGENESIS

The pathophysiology of chronic pancreatitis remains poorly understood. The events that occur in hereditary chronic pancreatitis suggest that one common underlying theme may be multiple subclinical episodes of acute injury that ultimately produce chronic pancreatitis.[80] A recent hypothesis (the so-called sentinel acute pancreatitis event [SAPE] hypothesis)[81] suggests that in a patient with an underlying susceptibility (e.g., genetic background), a sentinel event (e.g., alcohol exposure) can trigger the disease process, producing acute inflammation and infiltration of inflammatory cells. The acute pancreatitis may heal or, with repeated episodes, may lead to activation of pancreatic stellate cells and the development of fibrosis (i.e., chronic pancreatitis). This hypothesis, while attractive, is as yet unproved.

DIAGNOSIS

Clinical Findings

The diagnosis of chronic pancreatitis is suspected on the basis of suggestive signs and symptoms and confirmed by further tests of pancreatic structure or function. The disease is usually suspected on the basis of the presence of abdominal pain.

The vast majority of patients with chronic pancreatitis will experience pain at some point during their illness.[73,79] The pain tends to be episodic initially, but it may become more constant or continuous as the disease progresses. During acute attacks, the patient may be thought to have acute pancreatitis until the diagnosis of chronic pancreatitis can ultimately be established. Although there is no pathognomonic character of the pain, it is most commonly felt in the epigastrium, with radiation to the back. In severe episodes, nausea and vomiting are common. The natural history of the pain is quite variable, and it may worsen, stabilize, or even resolve over time. In some patients, the onset is gradual and evolves into constant abdominal pain. However, a minority of patients with chronic pancreatitis have no pain. In these patients, the disease may be suspected on the basis of the development of exocrine insufficiency (steatorrhea, weight loss, and malnutrition) or endocrine insufficiency (diabetes mellitus).

Laboratory Tests

The clinical features suggestive of chronic pancreatitis (e.g., abdominal pain, steatorrhea, weight loss, and malnutrition) are not specific for chronic pancreatitis; the diagnosis requires confirmatory tests. Diagnostic tests are usually separated into tests that detect abnormalities of pancreatic function and tests that detect abnormalities of pancreatic structure [*see Table 7*]. Chronic pancreatitis is a slowly progressive disease, and the abnormalities of pancreatic structure or function may take years to develop or may not develop at all. Hence, all of the diagnostic tests are most accurate in far-advanced disease, when obvious structural or functional abnormalities have developed.

Table 7 Diagnostic Tests for Chronic Pancreatitis*

Structural Tests	*Functional Tests*
Endoscopic ultrasonography	Direct hormonal stimulation test (secretin or secretin-CCK test)
Endoscopic retrograde pancreatography	Fecal elastase
Computed tomography	Serum trypsin
Magnetic resonance imaging/magnetic resonance cholangiopancreatography	Fecal fat
Abdominal ultrasound	Serum glucose
Plain abdominal radiograph	—

*Ranked in approximate order of decreasing sensitivity.
CCK—cholecystokinin

Structural abnormalities that can be diagnostic of chronic pancreatitis include changes in the main pancreatic duct (dilatation, strictures, irregularity, and pancreatic duct stones), side branches of the pancreatic duct (dilatation and irregularity), or pancreatic parenchyma (diffuse pancreatic calcifications). These findings can be visualized utilizing the diagnostic tests that evaluate pancreatic structure [*see Table 7*].

Functional abnormalities in chronic pancreatitis include a decrease in stimulated secretory capacity, exocrine insufficiency (malabsorption and steatorrhea), and endocrine insufficiency (diabetes mellitus).[82] Patients with alcoholic chronic pancreatitis, hereditary chronic pancreatitis, tropical pancreatitis, and late-onset idiopathic chronic pancreatitis are most likely to develop these abnormalities, although the course of development may take many years. Patients with early-onset idiopathic chronic pancreatitis may not develop these abnormalities at all. This observation has led to a general classification of chronic pancreatitis as either big-duct or small-duct disease [*see* Imaging Studies, Disease Classification, *below*].

Serum tests Serum amylase or lipase levels may be elevated during acute exacerbations of chronic pancreatitis, but these elevations are usually only modest and are neither routinely present nor diagnostic for chronic pancreatitis. Serum trypsinogen (often called serum trypsin) can also be measured. Low levels of serum trypsinogen (< 20 ng/ml) are highly specific for chronic pancreatitis,[73,83] but such low levels occur only in advanced disease (in the presence of steatorrhea). Very low levels of serum trypsinogen may also be seen occasionally in patients with pancreatic adenocarcinoma. Serum trypsinogen levels are in the normal range in most patients with less advanced chronic pancreatitis.

Stool tests A 72-hour stool collection for fat is the gold standard to detect steatorrhea but is cumbersome and unpleasant to perform. Steatorrhea is seen only in far-advanced chronic pancreatitis. More than 7 g of fat in the stool per 24 hours is considered abnormal. Of note, the patient has to be placed on a diet containing 100 g of fat a day for the results of the stool collection to be valid. At least 90% of the pancreatic enzyme secretory capacity needs to be lost before steatorrhea will develop.[84] Qualitative stool stains for fat (e.g., Sudan III) are far less accurate than a

72-hour collection but are easily performed. They should also be performed only while the patient is on a high-fat diet. Fecal levels of elastase and chymotrypsin may be reduced in patients with chronic pancreatitis, but only in cases of more advanced chronic pancreatitis.[82] Measurement of fecal elastase in a random stool sample is of reasonable accuracy[83,85] in these patients and is now available from reference laboratories in the United States. Values of fecal elastase of less than 200 μg/g of stool are seen in patients with more advanced chronic pancreatitis.

Direct pancreatic function tests The direct pancreatic function tests involve placing a tube into the duodenum to collect pancreatic juice and are complex and cumbersome. These tests directly measure pancreatic output of enzymes or bicarbonate after stimulation with a secretagogue (e.g., secretin or cholecystokinin or its analogue). Although these tests are able to detect severe decreases in pancreatic secretory output, their strength is in detecting moderate decreases in maximal stimulated secretory capacity. This decrease in maximal stimulated secretory capacity occurs before secretory failure (exocrine insufficiency) in chronic pancreatitis, and the direct function tests are felt to be the most sensitive tests available to detect chronic pancreatitis at an early stage (earlier than any other test).[73,82,86] They are particularly useful in making the diagnosis in patients with small-duct chronic pancreatitis, in whom alternative diagnostic tests (e.g., CT, ERCP) are likely to miss the diagnosis. Unfortunately, direct pancreatic function tests are available only at a few referral centers in the United States. Alternatives to cumbersome traditional pancreatic function testing have been studied. The collection of pure pancreatic juice for 15 minutes at the time of ERCP—the so-called intraductal secretin test—proved to be an inaccurate way to evaluate pancreatic function.[87] Another alternative involves administering a secretagogue (secretin) and collecting pancreatic secretions through an endoscope during upper endoscopy with sedation. Although accurate, the 1-hour collection of pancreatic secretions after secretin stimulation at the time of upper endoscopy appears to be perhaps too impractical for widespread application.[88] It is hoped that refinements will eventually allow these more sensitive tests to be used in a wider population of patients.

Imaging Studies

Radiology Simple plain abdominal radiographs may detect diffuse pancreatic calcification in very far advanced chronic pancreatitis [*see Figure 3*]. This finding is highly specific but quite insensitive.

Ultrasonography Abdominal US is most likely to detect advanced abnormalities of pancreatic structure; however, US is diagnostic in only 60% of patients.[73] The pancreas is often not well visualized on transabdominal US. New techniques of contrast-enhanced US and tissue harmonic imaging may provide better diagnostic accuracy.[89]

Computed tomography CT is much more sensitive than US (CT, 75% to 90%) because of its capacity to detect more focal abnormalities, such as calcification, a dilated pancreatic duct, fluid collections, and focal enlargements. CT may also demonstrate gland atrophy, which is seen in patients of advanced age in the absence of chronic pancreatitis. The use of multislice CT produces images of exceptional quality; this imaging technique should improve diagnostic accuracy, although it has not been adequately studied.[90] Like US, CT can be falsely negative in early or less advanced chronic pancreatitis.

Figure 3 **A plain film of the abdomen demonstrating multiple calcified stones in the pancreatic duct in a patient with advanced chronic pancreatitis.**

Magnetic resonance imaging An improvement in magnetic resonance technology has allowed more accurate imaging of both the pancreatic parenchyma and the pancreatic duct with MRCP. It is not clear whether MRI and MRCP are superior to CT, but they do appear to be at least equivalent to CT in overall accuracy.[90] The use of secretin before MRCP allows improved imaging of the pancreatic duct and, theoretically, calculation of pancreatic secretory volume.[91] Secretin-stimulated MRCP is being used at a number of centers and may improve overall accuracy of MRI for chronic pancreatitis.

Endoscopy Two endoscopic tests are used to diagnose chronic pancreatitis: ERCP and EUS. ERCP has a reported sensitivity of 75% to 90%.[73,86] With ERCP, radiographic contrast is injected into the pancreatic duct. Changes in the pancreatic duct consistent with chronic pancreatitis include ductal dilatation, strictures, irregularity, and filling defects (stones) in the pancreatic duct [*see Figures 4 and 5*]. The changes associated with chronic pancreatitis that are seen on ERCP are not specific, as they can also be seen in other clinical presentations—namely, (1) in elderly patients with pancreatic duct dilatation caused by aging, (2) in patients with resolving acute pancreatitis, (3) in some patients with pancreatic carcinoma, and (4) in patients who have previously undergone pancreatic duct stenting.[86] In addition to its diagnostic ability, ERCP may have therapeutic application in a subset of patients [*see* Management, Endoscopic and Surgical Therapy, *below*].

EUS, which allows a highly detailed examination of the pancreatic parenchyma and pancreatic duct, routinely detects abnormalities in patients with chronic pancreatitis (high sensitivity). The test is interpreted on the basis of documented changes in both the pancreatic duct and pancreatic parenchyma; a system of

grading EUS findings usually assesses nine specific features.[92,93] In addition, a normal EUS examination essentially rules out chronic pancreatitis. The specificity of the test requires some further study in that many patients without clinical chronic pancreatitis may have modest numbers of abnormalities on EUS [*see Figure 6*].[92,93]

Disease classification Depending on the findings on imaging studies, patients may be classified as having so-called big-duct or small-duct chronic pancreatitis. This distinction has both diagnostic and therapeutic implications. Big-duct disease implies substantial abnormalities of the pancreatic duct (generally, dilatation visible on US, CT, ERCP, or EUS, often with pancreatic calcifications), and small-duct disease implies the absence of these findings (e.g., a normal or near-normal US, CT, or ERCP) [*see Figures 4 and 5*]. The diagnosis of big-duct disease is much simpler; the disease usually results from alcohol abuse, and the therapeutic options include treatments aimed at decompressing the dilated pancreatic duct. The diagnosis and management of small-duct disease may prove to be more difficult than those of big-duct disease because with small-duct disease, imaging studies may be normal, disease is more commonly idiopathic, and treatment options focus on medical therapy rather than surgical or endoscopic attempts to decompress the pancreatic duct.

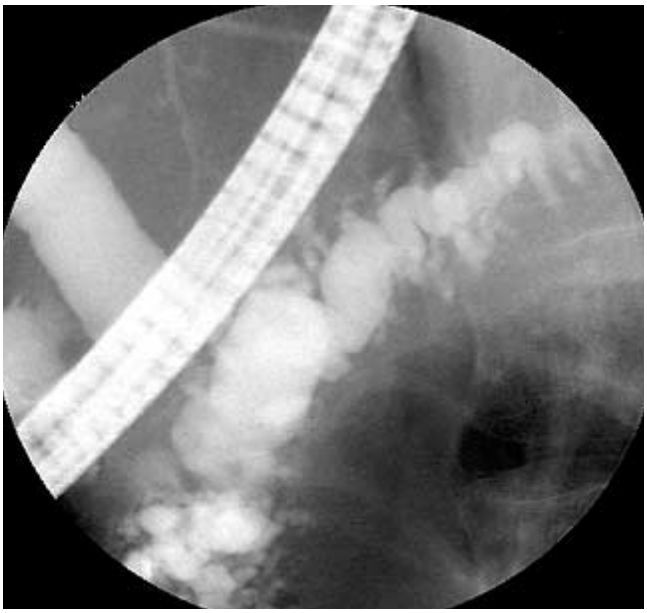

Figure 4 **An endoscopic retrograde cholangiopancreatography image demonstrating massive pancreatic duct dilatation in a patient with big-duct chronic pancreatitis.**

Figure 5 **An endoscopic retrograde cholangiopancreatography image demonstrating minimal pancreatic duct abnormalities in a patient with painful small-duct chronic pancreatitis.**

Figure 6 **An endoscopic ultrasound image demonstrating a dilated pancreatic duct (markers) in a patient with advanced chronic pancreatitis.**

Diagnostic Approach

The diagnostic approach to chronic pancreatitis should begin with tests that are safe, inexpensive, and able to detect relatively far advanced disease. Diagnostic tests that fit in this category include serum trypsinogen, fecal elastase, and abdominal US. If these tests do not lead to a diagnosis, riskier or more expensive tests will generally need to be employed (e.g., MRI/MRCP, CT, ERCP, or EUS). Direct pancreatic function testing, if available, logically should be used after the initial tests and before the more expensive or invasive tests, because direct pancreatic function tests are the most sensitive tests available and are lower in cost and less risky than the other options. Because most clinicians do not have access to pancreatic function testing, the riskier, more expensive tests are usually performed, starting with a good-quality CT using pancreatic protocol.

MANAGEMENT

Abdominal Pain

Pain is the most common symptom of chronic pancreatitis requiring medical care. There are a number of potential causes of pain in chronic pancreatitis, including inflammation of pan-

creatic nerves, pancreatic tissue ischemia, increased pressure in the gland or an associated pseudocyst, obstruction of a surrounding hollow viscus (e.g., duodenum or bile duct), and coexistent pancreatic carcinoma. The initial evaluation should focus on identifying conditions for which specific therapy exists. These conditions include pancreatic pseudocyst, duodenal or bile duct compression, and superimposed pancreatic carcinoma. This evaluation is most commonly done by performing a high-quality CT scan of the abdomen. If such a condition is identified, specific therapy is required [*see* Treatment of Other Complications, *below*].

Analgesia and cessation of alcohol use Nonspecific measures to reduce pain in chronic pancreatitis include cessation of alcohol consumption and use of analgesics. Cessation of alcohol consumption can reduce pain in some patients with alcoholic chronic pancreatitis and may prolong life by preventing other alcohol-induced diseases. Unfortunately, abstinence will not halt the progression of chronic pancreatitis, although it may slow it. Analgesics are generally needed, but it is important to start with the least potent agents first (e.g., propoxyphene napsulate or tramadol) because narcotic addiction can occur in up to 30% of patients. Many patients will require more potent narcotics. Adding an antidepressant (a selective serotonin reuptake inhibitor or a tricyclic) may allow potentiation of the narcotic effect. If these simple measures fail, further therapy utilizing medical, endoscopic, or surgical techniques can be considered.

Administration of pancreatic enzymes Several controlled trials have attempted to delineate the effectiveness of orally administered pancreatic enzymes to decrease pain. The concept behind this therapy is that proteases that are present in the duodenum may reduce the stimulus for pancreatic secretion by a negative-feedback mechanism. Only conventional (non–enteric-coated) preparations of pancreatic enzymes can deliver proteases to the duodenum; enteric-coated enzyme preparations deliver proteases too far distally to achieve a negative-feedback effect. Two studies utilizing non–enteric-coated enzymes at high dosages (8 tablets total, in four divided doses with meals and at night, coupled with an agent to suppress gastric acid to prevent premature inactivation of the enzymes) demonstrated a reduction in pain. Four other studies utilizing enteric-coated enzymes showed no effect. A meta-analysis of these studies suggested enzymes are of no benefit in treating pain.[94] In the two studies that demonstrated effectiveness, it appears that persons with less advanced disease (small-duct chronic pancreatitis) respond best, and females with idiopathic chronic pancreatitis seem to have the highest response rate. The role of enzymes in treating pain is controversial, although a consensus review advocated their use.[95] Non–enteric-coated enzyme preparations are of modest effectiveness, but they may be worth a trial in patients with less advanced disease in whom other simple medical measures have failed. A trial of enzymes for pain is generally pointless in patients with advanced or big-duct chronic pancreatitis (mainly alcoholic chronic pancreatitis). These enzyme products are inactivated by gastric acid; thus, concomitant therapy with an agent to reduce gastric acid (H_2 receptor antagonist or proton pump inhibitor) is needed.

Neurolysis Neurolysis via a celiac plexus block or thoracoscopic splanchnicectomy has been evaluated in a number of small studies. The use of percutaneous celiac plexus block has largely been abandoned in patients with chronic pancreatitis because of its transitory effectiveness. EUS-guided celiac plexus block is simpler and safer than percutaneous techniques and appears to last longer.[96] Thoracoscopic splanchnicectomy involves sectioning the splanchnic nerves at thoracoscopy. The short-term response is good (60% to 80% response), but the long-term response has been disappointing.[97]

Endoscopic and surgical therapy Endoscopic therapy and surgical therapy are most useful in patients with advanced or big-duct chronic pancreatitis. Endoscopic therapy has a general goal of relieving obstruction in the pancreatic duct by dilating or stenting a stricture or by removing an obstructing stone. Only a subset of patients with chronic pancreatitis are candidates for such therapy; generally, endoscopic therapy may be considered an option in patients with a dilated pancreatic duct (big-duct chronic pancreatitis) and an obstructing stricture or stone in the head of the gland. The results of large case series indicate that endoscopic therapy may improve pain in 70% to 80% of carefully selected patients.[73,95,98,99] The only randomized, controlled trial that compared endoscopic therapy with surgery showed that the two therapies provide equivalent short-term pain relief, but surgery provided better long-term pain relief.[100] Even if endoscopic therapy is not possible, however, an ERCP may provide useful information for planning surgical therapy.

Surgical procedures that are commonly used to treat pain include decompression of the main pancreatic duct, with or without resection of a portion of the pancreas. Surgery may also be indicated for treatment of a complication such as a pseudocyst, duodenal or common bile duct obstruction, or pancreatic fistula. For patients with intractable pain and a dilated duct, the most commonly performed procedure is the lateral pancreaticojejunostomy (i.e., modified Puestow procedure), in which the pancreatic duct is widely incised along its length and overlaid with a defunctionalized loop of small intestine for drainage of pancreatic juice directly into the small bowel. In some patients, resection of a portion of the pancreatic head may also be needed to decompress smaller-duct branches in the pancreatic head and uncinate process. Substantial pain relief is obtained in 65% to 85% of patients and appears to be relatively long lasting (in some studies, pain relief was sustained for more than 7 years); over time, the response declines to about 50%.[95,101] Mortality for these procedures is about 3% in experienced hands.

Table 8 Enzyme Supplements for Chronic Pancreatitis

Preparation	*Units of Lipase per Tablet or Capsule*
Nonenteric-coated (conventional) preparations	—
Viokase 8, 16	8,000 and 16,000, respectively
Kuzyme-HP	8,000
Generic pancrealipase	8,000
Enteric-coated preparations	—
Creon 10, 20	10,000 and 20,000, respectively
Pancrease MT 4, 10, 16	4,000, 10,000, and 16,000, respectively
Ultrase MT 6, 12, 18, 20	6,000, 12,000, 18,000, and 20,000, respectively

Steatorrhea

The pancreas possesses a 90% functional reserve for the secretion of digestive enzymes.[84] Hence, only 10% of normal maximal output of enzymes is needed to prevent malabsorption of nutrients. Steatorrhea is therefore a late complication of chronic pancreatitis requiring the presence of substantial pancreatic damage. Steatorrhea takes, on average, 13 and 26 years to develop after a diagnosis of alcoholic and idiopathic chronic pancreatitis, respectively.[79] Fat malabsorption tends to occur earlier than protein or carbohydrate malabsorption. Steatorrhea is most precisely established by measuring fecal fat excretion over 72 hours while the patient is on a diet that contains 100 g of fat a day. This test, however, is cumbersome to perform and unpleasant for both patient and staff. In practice, steatorrhea is more commonly diagnosed by identification of clinical features of oily or floating stool, diarrhea, and weight loss and is confirmed by the response to pancreatic enzyme supplementation. Unlike for the treatment of pain, enteric-coated enzyme preparations are commonly selected over non–enteric-coated preparations for the treatment of steatorrhea because of the higher potency and the need for fewer pills with the enteric-coated agents. However, non–enteric-coated enzyme preparations can be used effectively to treat steatorrhea if they are administered in sufficient doses and coadministered with an agent that reduces gastric acid. At least 30,000 units of lipase must be delivered to the small intestine during the prandial and postprandial period to reduce steatorrhea to a manageable level [*see Table 8*]. The clinical goal of this enzyme replacement therapy is to reduce the diarrhea and the losses in stool of fat, protein, and carbohydrate, thereby allowing maintenance or improvement of weight and nutritional status. In patients who do not achieve these end points, explanations for therapeutic failure need to be considered. Such explanations include patient noncompliance, inadequate dosage of enzyme therapy, destruction of exogenous enzymes by gastric acid (if non–enteric-coated preparations were prescribed), poor diet (particularly in chronic alcoholics), and the presence of a second disease causing malabsorption (e.g., small bowel bacterial overgrowth).[102]

Endocrine Insufficiency

Diabetes mellitus, like steatorrhea, is a late complication of chronic pancreatitis. Progressive destruction of the islets of Langerhans can destroy both insulin- and glucagon-secreting cells. The inadequate glucagon reserves predispose patients with this disorder to treatment-induced hypoglycemia. Complications of diabetes such as neuropathy, retinopathy, and nephropathy occur at the same rate as in other patients with diabetes mellitus.[103] Therapy is usually directed at controlling urinary losses of glucose rather than at maintaining tight control of blood glucose levels. Overvigorous attempts at tight control of blood glucose levels are often associated with disastrous complications of treatment-induced hypoglycemia.[104] However, attempts at tight control of blood glucose levels are indicated in patients with hyperlipidemic pancreatitis because in this group, the diabetes is usually a primary illness and tight control of blood glucose levels makes control of serum lipid levels possible.

Other Complications

Pancreatic pseudocyst In chronic pancreatitis, as in acute pancreatitis [*see* Acute Pancreatitis, Treatment of Complications, *above*], asymptomatic pseudocysts less than 6 cm can be safely observed. However, unlike in acute pancreatitis, most pseudocysts that occur in the setting of chronic pancreatitis are generally mature at the time of their diagnosis, and therapy therefore need not be delayed if therapy is indicated. Symptomatic, complicated, or enlarging pseudocysts require therapy by percutaneous, endoscopic, or surgical techniques. Surgical therapy usually involves cyst decompression into a loop of small bowel, and this is often coupled with a pancreatic duct drainage procedure (e.g., modified Puestow procedure). Surgical therapy has a long-term success rate of more than 90%, with an operative mortality of less than 3%.[69,70,73] Percutaneous tube drainage of pseudocysts is also a management option and is immediately successful in 95% of patients. The long-term success rate of percutaneous drainage is still unknown, but it is certainly less than that of surgical techniques. Endoscopic therapy has short-term success rates greater than 90%.[69,70] The limited number of studies that have evaluated the long-term success rate of endoscopic drainage suggest excellent results, with complete resolution of the pseudocyst observed in 90% of patients.[69,70,105]

Complicated pseudocysts may require specific types of therapy. An infected pseudocyst (pancreatic abscess) generally responds to antibiotics and drainage (e.g., endoscopic, percutaneous, or surgical). Bleeding from a pseudocyst may occur in small vessels in its wall or from an associated large arterial pseudoaneurysm. Bleeding from a pseudoaneurysm requires urgent angiography with embolization, sometimes followed by surgical therapy.[58] If no pseudoaneurysm is present on angiography, surgical therapy remains the best choice of therapy for bleeding pseudocysts. Some pseudocysts may rupture and produce a pancreatic fistula that drains into the peritoneal cavity (producing pancreatic ascites) or into the pleural space (producing a pancreatic pleural effusion). In such cases, patients may not complain of symptoms of chronic pancreatitis but may instead note abdominal distention or shortness of breath. The diagnosis can be established by documenting high levels of amylase in the leaked fluid, typically more than 4,000 U/L.[73,106] Treatment may require surgery, and ERCP is used preoperatively to delineate the location of the leak. In many patients, endoscopic therapy and placement of a stent across the fistula site will prove curative.

Other cystic lesions A number of other cystic lesions may occur in the pancreas, including true cysts and cystic neoplasms. Serous cystic neoplasms are benign, but mucin-producing cystic neoplasms may follow a more malignant course. Mucinous cystic neoplasms present as large cystic collections (cystadenomas and cystadenocarcinomas) and may be relatively asymptomatic. Most cystic neoplasms occur in middle-aged patients, particularly in women.[107] They are often mistaken for pseudocysts and inappropriately treated as such. These cystic neoplasms may follow an initially benign course; but when they undergo malignant degeneration, they have poor outcomes equivalent to those of standard adenocarcinoma.

The presence of a pancreatic cystic collection in a middle-aged person (particularly female) without a previous history of pancreatitis should immediately suggest a cystic neoplasm, not a pseudocyst. The diagnosis of a cystic neoplasm requires histologic evidence of epithelial or neoplastic tissue in the cyst wall. Analysis of the cyst fluid obtained by EUS is becoming a highly useful method of differentiating pseudocysts from cystic neoplasms.[108] When these cystic collections are mistaken for pseudocysts, they are treated with drainage, and no tissue is obtained to allow differentiation of a cystic neoplasm from a pseudocyst. Therefore, the therapy of choice for cystic neoplasms is surgical resection, not drainage.

Intraductal papillary mucinous tumors (IPMT, formerly called mucinous ductal ectasia) are characterized by superficially spreading neoplastic tissue along the wall of the pancreatic duct. This neoplastic tissue produces mucin, and patients usually present with a markedly dilated pancreatic duct filled with gelatinous mucin. The appearance is often pathognomonic on ERCP but is occasionally mistaken for chronic pancreatitis. The natural history of the lesions is variable. In general, resection is attempted if the patient is a fit surgical candidate. Depending on the extent of the neoplastic tissue along the pancreatic duct, extensive resection may be needed to eliminate the lesion.[109]

Pancreatic cancer Chronic pancreatitis is a risk factor for pancreatic carcinoma, and the two diseases can be difficult to distinguish in some patients. The risk is about 4% after 20 years of disease.[110] The cancer risk may be as high as 40% in patients with hereditary chronic pancreatitis.[77] There is no effective method of surveillance in these patients and no absolutely reliable method to distinguish cancer from chronic pancreatitis. EUS with directed biopsy, ERCP with cytologic brushings, CT scan, and tumor markers such as CA19-9 are most commonly used.

Common bile duct or duodenal obstruction Fibrosis and inflammation in the head of the pancreas may compress surrounding hollow structures, particularly the common bile duct and duodenum. Compression of the common bile duct produces jaundice, and duodenal compression produces symptoms similar to those of gastric outlet obstruction. Both duodenal compression and gastric outlet obstruction generally require surgical repair with a biliary bypass or gastrojejunostomy, respectively.

Peter Draganov, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Chris E. Forsmark, M.D., F.A.C.P., has received grants for clinical research from AstraZeneca Pharmaceuticals LP and TAP Pharmaceutical Products, Inc., and has received grants for educational activities from Cook Endoscopy and the Olympus Corporation.

Octreotide acetate and pancreatic enzymes discussed in this chapter have not been approved by the FDA for use in the treatment of chronic pancreatic pain.

VI GALLSTONES AND BILIARY TRACT DISEASE

Kimberly M. Persley, m.d.
Rajeev Jain, m.d., f.a.c.p.

Gallstone and biliary tract diseases constitute a common and costly health problem in the United States.[1] The prevalence of gallstones increases with age in all racial groups. Increased body weight, rapid weight loss, pregnancy, alcoholic cirrhosis, and a family history of gallstone disease also appear to be risk factors.[2-4]

Incidence and Prevalence of Gallstones

In one epidemiologic study of persons 30 years of age and older, new gallstones were found to develop in 2.2% of men and 2.9% of women over a 5-year period.[2] In the United States, gallstones occur in approximately 10% of persons older than 40 years, but the prevalence is significantly higher in women, increasing to 20% to 25% in women older than 50 years. Fortunately, only 20% to 30% of gallstones are symptomatic, with biliary colic being the most common symptom. A report from the Third National Health and Nutrition Examination Survey (NHANES III) stated that an estimated 6.3 million men and 14.2 million women 20 to 74 years of age had gallbladder diseases.[5]

Gallstone Formation

Two principal types of stone, the cholesterol stone and the pigment stone, form in the gallbladder and biliary tract. The cholesterol stone is composed mainly of cholesterol (> 50% of stone composition) and comprises multiple layers of cholesterol crystals and mucin glycoproteins. Mixed gallstones contain 20% to 50% cholesterol. The pigment stone contains a wide variety of organic and inorganic components, including calcium bilirubinate (40% to 50% of dry weight). In Europe and the United States, 90% of gallstones are of the cholesterol or mixed type; the remainder are pigment gallstones. Multiple risk factors for cholesterol and pigment gallstone formation have been identified [*see Table 1*]. In cholesterol gallstone formation, a genetic predisposition has been proposed on the basis of murine models and epidemiologic studies that show ethnic and geographic differences, as well as familial clustering of cholesterol gallstone disease.[6]

pigment gallstone formation

The pathogenesis of pigment gallstones is not completely understood, but bacteria may play a central role.[7] Black pigment stones are most often seen in patients with cirrhosis or hemolytic anemia and are found predominantly in the gallbladder. Brown pigment stones, which are common in Asians, are the most common stone to appear de novo in the bile duct and are associated with biliary tract infection. The prevalence of gallstones and gallbladder disease in Asians ranges from 5% to 20%.[8] Pigment stones, in contrast to cholesterol stones, are often radiopaque and can be seen on plain abdominal x-rays [*see Figure 1*].

cholesterol gallstone formation

Cholesterol is a minor but clinically significant component of bile. The other components of bile are bile salts, phospholipids, conjugated bilirubin, fatty acids, water, electrolytes, and other organic and inorganic substances. Cholesterol is a hydrophobic molecule that is relatively insoluble in water and precipitates unless it is maintained in solution by bile salts. Bile salt molecules possess hydrophilic (water-soluble) and hydrophobic (fat-soluble) regions that maintain cholesterol in a soluble state.

When bile salt molecules in water reach concentrations of 2 to 4 mM, they form spherical complexes called micelles; the concentration at which micelles form is known as the critical micellar concentration. In micelles, the negatively charged hydrophilic ends of the molecules face outward, toward the water, and the uncharged hydrophobic regions face the center of the sphere, toward one another. Cholesterol molecules are enclosed in the hydrophobic interiors.

A pure bile salt micelle must comprise at least 50 molecules to enclose a single molecule of cholesterol. The intercalation of phospholipids (principally lecithin) between bile salt molecules of a micelle improve the efficiency with which the micelle solubilizes cholesterol. Such a mixed micelle [*see Figure 2*], which is the type that exists in bile, needs only seven bile salt molecules to solubilize one cholesterol molecule. Free bile salt molecules exist in equilibrium with mixed micelles in a water solution. The combined molar concentration of bile salt and phospholipid is about 11 times that of cholesterol.

Cholesterol Saturated Bile

Cholesterol gallstone formation is potentiated by hepatic secretion of bile containing excess cholesterol relative to the concentration of bile salt.[3,9] This occurs most often because of an increase in the biliary concentration of cholesterol but may also result from decreased bile acid secretion in certain disease states. Excess cholesterol is solubilized in micelles and in vesicles composed of phospholipid bilayers. Cholesterol crystal formation seems to occur at the surface of these vesicles.

Nucleation of Crystals and Gallbladder Stasis

In addition to supersaturated bile, nucleation of crystals and gallbladder stasis are also important factors in gallstone formation. Microscopic crystals initially precipitate from a supersatu-

Table 1 Risk Factors for Cholesterol and Pigment Gallstone Formation

Cholesterol Gallstones	*Pigment Gallstones*
Increasing age	Increasing age
Female gender	Chronic hemolysis
Obesity	Alcoholic liver disease
Rapid weight loss	Biliary infection
Native-American heritage	Asian heritage
Hyperalimentation (gallbladder stasis)	Hyperalimentation (gallbladder stasis)
Elevated triglyceride levels	Duodenal diverticulum
Medications (e.g., fibric acid derivatives, estrogens, octreotide)	Truncal vagotomy
Ileal disease, resection, or bypass	Primary biliary cirrhosis

rated bile in a process called nucleation, which is influenced by several pronucleating and antinucleating proteins.[3,9] Protein mucins, which are secreted by the gallbladder, and calcium are crucial promoters of the nucleation process. Prostaglandins stimulate the synthesis and secretion of mucins. Antinucleating factors, such as certain apolipoproteins, have been less well studied. Gallbladder stasis, with concentration and acidification of bile, is also an important factor in gallstone formation, promoting the growth of cholesterol crystals into stones. Cholesterol stones rarely recur in patients after cholecystectomy.

Development of Biliary Sludge

Biliary sludge (or microlithiasis) is a term that is often applied to cholesterol crystals of sufficient number to be visualized on ultrasonography.[10] Biliary sludge, the precursor of most gallstones, is a mix of mucus, cholesterol monohydrate microcrystals, and calcium bilirubinate granules.[4] Gallbladder sludge has been shown to precipitate biliary colic, acute cholecystitis, or pancreatitis and should be regarded as part of the spectrum of gallstone disease.

Gallbladder sludge and gallstones occur in 10% of women during pregnancy and in the early postpartum period, with significant spontaneous regression.[11] Gallbladder sludge is also associated with fasting, rapid weight loss, parenteral nutrition, cirrhosis, and certain medications, such as ceftriaxone, cyclosporine, and octreotide.[10]

Choledocholithiasis

Common bile duct stones may form de novo in bile ducts (so-called primary choledocholithiasis, constituting 5% of bile duct stones) or migrate from the gallbladder to the biliary tract (secondary choledocholithiasis, constituting 95% of bile duct stones). Stones in the biliary tract usually have the same composition as those in the gallbladder, although some are softer and brownish. The brown color is a result of deposition of calcium bilirubinate and other calcium salts as a result of bacterial deconjugation of bilirubin and hydrolysis of phospholipids.

Cholecystitis and Cholelithiasis

Patients who have stones in the gallbladder or the biliary tree display syndromes that range from acute disease to chronic symptomatic or silent disease. Gallstone disease (cholelithiasis) may remain silent throughout a person's lifetime. At any stage of disease, obstruction of the cystic duct or common bile duct by a gallstone that has passed from the gallbladder may cause pain, with or without acute inflammation (cholecystitis).

SYMPTOMATIC CHOLELITHIASIS

With the exception of biliary colic, most symptoms of gallstones are not specific for gallstone disease; a meta-analysis indicated that 80% of patients with gallstones presented with other abdominal symptoms.[12] Biliary colic is a misnomer, because the pain is steady and not colicky. The pain of biliary colic is caused by functional spasm of the cystic duct obstructed by a stone. Biliary colic often develops without any precipitating events. Typically, the pain is localized to the epigastrium, has a sudden onset, and increases rapidly in intensity to a plateau that can last as long as 3 hours before subsiding. Some patients describe the pain as excruciating or lancinating, whereas others describe it as a deep ache or cramp. The pain may radiate to the interscapular region or to the right shoulder, and it may be associated with nausea or vomiting. The pain is less frequently located in the left upper quadrant, precordium, or lower abdomen. Pain lasting longer than 6 hours or pain that is associated with fever suggests acute cholecystitis. Gastrointestinal symptoms, such as dyspepsia, heartburn, bloating, and fatty-food intolerance, are common whether or not gallstones are present. Thus, the diagnosis of biliary colic is based on clinical judgment. Once an episode of biliary colic has occurred, repeated attacks of pain are common.

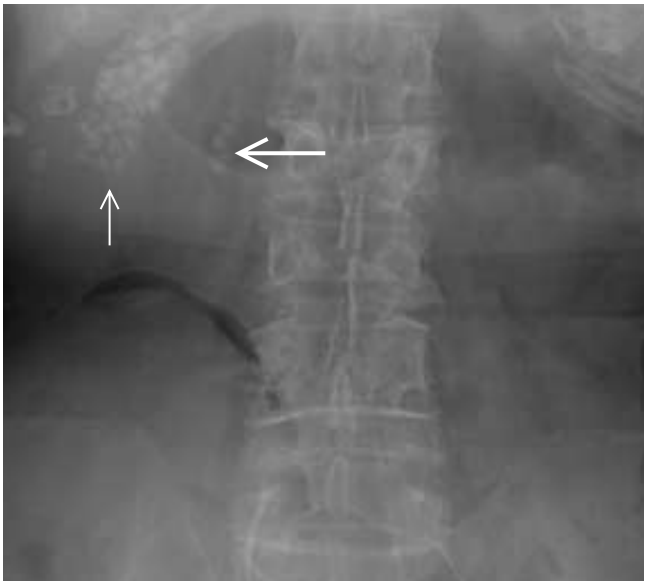

Figure 1 **Radiograph of the right upper abdominal quadrant showing radiopaque stones in the gallbladder (small arrow) and common bile duct (large arrow).**

ACUTE CHOLECYSTITIS

Acute cholecystitis refers to a syndrome of abdominal pain, fever, and leukocytosis associated with gallbladder inflammation, which is usually related to gallstone disease. Cholelithiasis is present in 90% to 95% of patients with acute cholecystitis, and most patients have had previous attacks of biliary colic. Acute cholecystitis may present as an acalculous cholecystitis in 5% to 10% of patients. It is predominantly noted in older men who are critically ill after major surgery, severe trauma, or extensive burn injury.[13] In rare cases, acute cholecystitis can result from a specific infection, such as that caused by *Salmonella* species. *Salmonella* organisms can also colonize the gallbladder epithelium without inflammation (carrier state). Cytomegalovirus and cytosporidia can infect the biliary system, resulting in cholecystitis or cholangitis in immunocompromised patients, such as those with AIDS or those who have undergone bone marrow transplantation.

Diagnosis

Clinical manifestations An episode of prolonged right upper quadrant pain (> 6 hours), especially if associated with fever, should arouse suspicion of acute cholecystitis, as opposed to simple biliary colic. Clinical features of acute cholecystitis include anorexia, nausea, vomiting, fever, and abdominal pain that initially may localize to the epigastrium before shifting to the right upper quadrant. The severe abdominal pain associated with acute cholecystitis is caused by inflammation of the gallbladder wall.[9] Most patients who present with jaundice have stones in the common bile duct. Patients are ill for several days

to a week before the acute attack completely subsides. Acalculous cholecystitis, an acute necroinflammatory disease, is clinically identical to acute cholecystitis but is not associated with gallstones.

Physical examination Physical examination may reveal upper quadrant subcostal tenderness and pain on inspiration, often with inspiratory arrest (the Murphy sign). Of all physical examination findings, the Murphy sign has the highest positive likelihood ratio (LR) for acute cholecystitis (LR, 2.8; 95% confidence interval [CI], 0.8 to 8.6).[14] The gallbladder may be palpable, especially at the time of the first attack, before fibrosis has reduced its distensibility. Tenderness, guarding, and rebound pain in the area of an inflamed gallbladder are important findings. Generalized rebound tenderness in a patient who has been ill for several days may reflect a perforation; however, localized tenderness may indicate secondary pancreatitis or an abscess in the area of the gallbladder.

Laboratory evaluation Laboratory tests frequently reveal leukocytosis and mild hyperbilirubinemia, which may occur in the absence of biliary obstruction secondary to reduced hepatic excretion of bile.[15] In one prospective study, 25% of patients with acute cholecystitis had a serum bilirubin level of 2 to 5 mg/dl and had no common bile duct abnormalities; 4% had an elevated amylase level without pancreatitis.[16] No single laboratory parameter has a sufficient positive or negative LR to establish the diagnosis of acute cholecystitis or rule it out.[14]

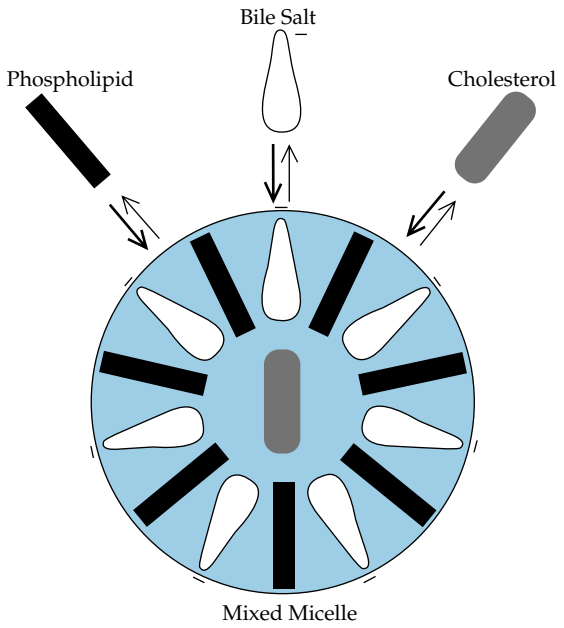

Figure 2 **Cholesterol is solubilized in bile by the formation of mixed micelles that consist predominantly of bile salt and phospholipid. Micelles form when the concentration of bile salts in water is between 2 and 4 mM, the so-called critical micellar concentration (CMC). The negatively charged hydrophilic region of the bile salt molecule faces outward into the water phase, whereas the uncharged hydrophobic region is directed inward. These three components—bile salts, phospholipids, and cholesterol—exist in equilibrium between the free state and micelle constituents. At the CMC for bile salts, the equilibrium shifts strongly in the direction of the micelle. If bile salt concentrations are insufficient, the hydrophobic cholesterol molecules will precipitate to form a nidus for a gallstone.**

Imaging studies Acute cholecystitis should be suspected when a patient presenting with certain clinical manifestations (see above) is found to have gallstones on an imaging study. However, the mere presence of gallstones is not confirmation of acute cholecystitis, because asymptomatic cholelithiasis [*see* Asymptomatic Cholelithiasis, *below*] is a common condition in the general population. Ultimately, the combination of physical findings and laboratory results suggests the diagnosis of acute cholecystitis, which can then be confirmed by diagnostic imaging.[14]

Transabdominal ultrasonography (TUS) is the diagnostic procedure of choice for a patient with suspected gallstones and acute cholecystitis. Meta-analysis indicates that TUS has a sensitivity of 88% to 90% and a specificity of 97% to 98% for the diagnosis of gallstones larger than 2 mm.[17] Gallbladder ultrasonography should ideally be preceded by an 8-hour fast, because gallstones are best visualized in a distended, bile-filled gallbladder. In addition to detecting gallstones, TUS can be used to identify other causes of right upper quadrant pain, such as hepatic abscess or malignancy, and it may reveal biliary duct obstruction. However, specific evidence of acute cholecystitis (i.e., the presence of pericholecystic fluid, edema of the gallbladder wall, or both) is found infrequently. Occasionally, a sonographic Murphy sign will be elicited when the ultrasound probe is positioned below the right costal margin.

Cholescintigraphy is the best method of confirming the clinical diagnosis of acute cholecystitis.[17] This procedure takes only 60 to 90 minutes and involves the intravenous injection of technetium-99m (^{99m}TC)–labeled hepatoiminodiacetic acid (HIDA, or lidofenin), which is selectively excreted into the biliary tree and enters the gallbladder. In the presence of acute cholecystitis, radiolabeled material enters the common bile duct and duodenum but not the gallbladder. Meta-analysis suggests that radionuclide scanning is the most accurate method of diagnosing acute cholecystitis.[17] Occasionally, the scan gives false positive results in patients who have alcoholic liver disease or who are fasting or receiving total parenteral nutrition; however, false negative results are rare. Radionuclide scanning may not be useful for patients with deep jaundice, because the labeled agent fails to enter the biliary tree.

Direct examination of bile is more sensitive than ultrasonography in the diagnosis of biliary sludge. Ideally, gallbladder bile, rather than hepatic and ductal bile, should be obtained to maximize sensitivity for detecting microlithiasis; gallbladder bile is most reliably obtained by cholecystokinin-induced stimulation of the gallbladder [*see* Chronic Cholecystitis, Bile Collection and Examination, *below*]. Bile collected at endoscopic retrograde cholangiopancreatography (ERCP) after the injection of contrast may lead to false positive findings of crystals.[18] Bile must be centrifuged and examined under polarizing or light microscopy for detection of crystals. Plain abdominal x-rays are much less useful than cholescintigraphy or ultrasonography, because only 15% to 20% of stones are radiopaque; oral cholecystography is also less useful and is now rarely performed because it requires 24 to 48 hours to perform and is less accurate than ultrasonography.

Differential Diagnosis

Because no single clinical or laboratory measurement carries sufficient weight to establish or exclude the diagnosis of acute cholecystitis,[14] the differential diagnosis is broad; it includes diseases that are characterized by severe epigastric symptoms and transient abnormal results on liver function testing.

Severe acute viral hepatitis or alcoholic hepatitis may be associated with moderately severe right upper quadrant pain, fever, and leukocytosis. A history of acute alcoholism, the finding of an enlarged liver, or markedly elevated aminotransferase levels should help distinguish one of these diagnoses from acute cholecystitis.

A patient with a penetrating or perforating ulcer may have severe epigastric pain and usually has a history of ulcer; free air may be evident on a plain abdominal x-ray if the ulcer has perforated. Early in its course, acute appendicitis may produce symptoms similar to those of acute cholecystitis, particularly if the appendix is retrocecal or the cecum is malpositioned in the subhepatic area. Acute pyelonephritis of the right kidney may produce anterior pain similar to the pain that occurs with acute cholecystitis. Pneumonia or infarction of the right lung may also cause abdominal symptoms.

Acute pancreatitis may be nearly impossible to distinguish from acute cholecystitis. Patients with either disorder may exhibit moderate signs on physical examination, with tenderness or localized rebound pain in the epigastrium. Serum amylase and lipase levels can be high in either condition, but the higher these enzyme levels are, the more likely it is that pancreatitis is present. Cholelithiasis occasionally causes pancreatitis, which further complicates the diagnosis. At times, only the clinical course distinguishes pancreatitis from cholecystitis.

Treatment

Medical therapy Patients with a clinical diagnosis of acute cholecystitis should not be fed and should be given intravenous fluids and electrolytes. It is usually necessary to give a narcotic analgesic such as morphine or meperidine to alleviate severe pain. Febrile patients who have leukocytosis or bandemia (elevated circulating band forms) should be given a broad-spectrum antibiotic, such as a third-generation cephalosporin or, for broader coverage against *Enterococcus,* ampicillin-sulbactam or piperacillin-tazobactam. Nasogastric tube decompression may be required in patients who present with vomiting or with evidence of an ileus. The usual course is one of gradual improvement for several days. Persistence of severe symptoms may indicate pericholecystic abscess or perforation.

Surgery In acute cholecystitis, laparoscopic cholecystectomy should be performed within 96 hours of onset of symptoms because the increasing inflammatory changes that occur over time have been implicated in bile duct injury; these changes may necessitate converting the procedure to an open cholecystectomy.[19,20] Early laparoscopic cholecystectomy is recommended for acute cholecystitis, because a delay in surgery does not reduce morbidity, mortality, rate of conversion to open surgery, or mean hospital stay.[21,22] In skilled hands, the laparoscopic procedure carries approximately the same risk as that of open cholecystectomy, but it is associated with much less postoperative pain and a shorter convalescence.[19] In patients with cirrhosis, laparoscopic cholecystectomy is performed for more emergent reasons and is associated with higher morbidity; however, the laparoscopic approach offers advantages of less blood loss, shorter operative time, and shorter length of hospitalization in patients with compensated cirrhosis.[23] In addition, laparoscopic cholecystectomy can be safely performed during pregnancy.[24] Laparoscopic cholecystectomy is less expensive than minilaparotomy or open cholecystectomy in high-volume surgery.[25]

In the United States, approximately 75% of all cholecystectomies are performed laparoscopically; in 5% to 10% of these patients, the procedure has to be converted to open cholecystectomy.[26] The complication rate of laparoscopic cholecystectomy is less than 5%, which is comparable to the rate reported for conventional cholecystectomy. Complications of laparoscopic cholecystectomy (bleeding and injury to the common bile duct, vasculature, and bowel) are more common when the surgeon is inexperienced.[27] Although mortality appears to be lower for laparoscopic cholecystectomy than for open cholecystectomy, the total number of cholecystectomy-related deaths has not decreased over the years, because more procedures are being performed.[28-30] This suggests that the benefits of laparoscopic cholecystectomy have expanded the indications for cholecystectomy.

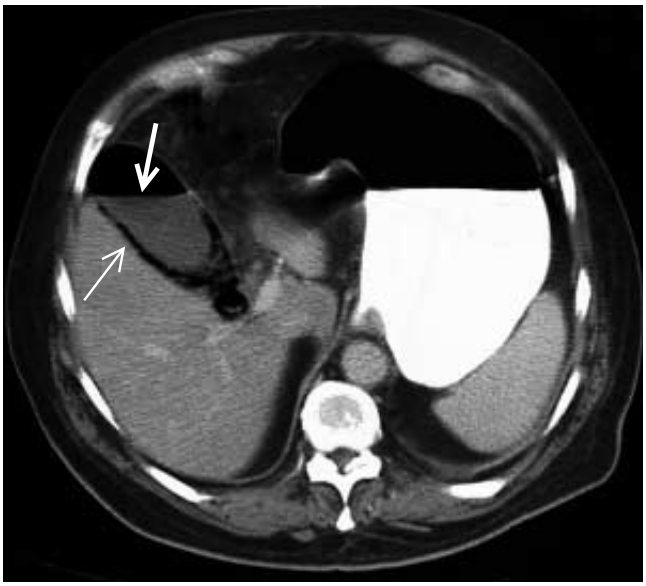

Figure 3 **CT scan from an elderly man with nausea and abdominal pain following an acute myocardial infarction, angioplasty, and stent placement. The scan shows air in the wall of the gallbladder and an air-fluid level within the gallbladder, diagnostic of emphysematous cholecystitis. The patient was treated with antibiotics and a percutaneous cholecystostomy tube; laparoscopic cholecystectomy was planned in a few months.**

Cholangiography can be performed during laparoscopic biliary surgery. However, because 10% to 15% of patients with acute cholecystitis have common duct stones, the physician should consider preoperative ERCP in patients with suspected choledocholithiasis (e.g., patients with jaundice, cholangitis, or a dilated common bile duct, as seen on ultrasonography).[31] Common duct stones can be removed endoscopically. If endoscopic common duct stone removal is not possible, the operative procedure of choice is cholecystectomy, either open or laparoscopic, for common bile duct exploration and stone removal.

Some patients (e.g., patients with septic shock, peritonitis, severe pancreatitis, portal hypertension, or marked clotting disorders) are not candidates for laparoscopic cholecystectomy. These patients should generally undergo either open cholecystectomy, if their condition permits, or simple cholecystostomy. Cholecystostomy, either operative or percutaneous under ultrasound guidance, involves extracting the stones and draining the biliary tree through a catheter left in the gallbladder. Percutaneous cholecystostomy is superior to gallbladder aspiration in severe acute cholecystitis.[32] Cholangiography can be carried out later through this drainage catheter. For patients who respond to cho-

lecystostomy and improve enough to become candidates for elective surgery, interval cholecystectomy is recommended, because the risk of recurrent symptoms is significant.[20]

Surgery is contraindicated for some patients because of the presence of other serious medical problems. In these cases, conservative medical therapy, including the use of antibiotics, may be the only possible approach for the acute attack.

Complications

The major complications of acute cholecystitis are related to severe inflammation and necrosis of gallbladder tissue.[33] Jaundice in the absence of choledocholithiasis can be noted in 15% of patients with acute cholecystitis; the stone impacted in the cystic duct results in edema and swelling, leading to extrinsic compression of the common hepatic duct, the common bile duct, or both [*see* Mirizzi Syndrome, *below*].[34]

Localized perforation and abscess Localized perforation and abscess formation are commonly found in patients who have severe symptoms that persist for many days. Such patients usually show localized right upper quadrant tenderness and rebound pain. In patients who have a delayed or subacute presentation, perforation typically occurs in the gallbladder fundus, as a consequence of ischemia that leads to gangrene and necrosis.[35] In patients who present with acute symptoms, the clinical differentiation between uncomplicated cholecystitis and gallbladder perforation is difficult; in this setting, ultrasonography should be the initial diagnostic modality.[36] These patients often have diabetes or other immuncompromising conditions; therefore, acute symptoms in diabetic or immunocompromised patients may heighten the suspicion for perforation. Free perforation extending into the peritoneum occurs in 2% to 10% of patients with acute cholecystitis; it is associated with peritonitis and a mortality of 10% to 30%.[37]

Empyema Empyema of the gallbladder occurs in 2% to 3% of patients with acute cholecystitis.[38] Typically, abdominal pain is severe and lasts for more than 7 days. The physical examination is not distinctive. Mortality approaches 25%; death often occurs as a result of septicemia.

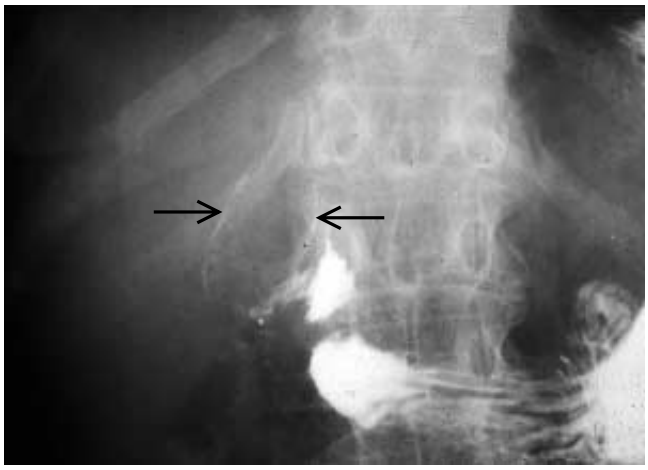

Figure 4 **Radiograph of the right upper abdominal quadrant during upper GI barium study showing a calcified wall of the gallbladder ("porcelain" gallbladder), indicating chronic cholecystitis and a high risk of gallbladder cancer.**

Emphysematous cholecystitis Emphysematous cholecystitis, which has a higher morbidity than uncomplicated acute cholecystitis, is usually caused by gas-forming bacteria, such as *Clostridium perfringens* and other clostridia, *Escherichia coli,* or anaerobic streptococci. Patients who have such infections are often very ill, and up to 50% also have diabetes.[35] Emphysematous cholecystitis occurs three times more often in men than in women.[39] Many cases of this type of cholecystitis are not associated with cholelithiasis. An ultrasound or computed tomography scan frequently reveals gas within the gallbladder; however, one study indicated that a plain abdominal x-ray is not sensitive as a diagnostic study in emphysematous cholecystitis [*see Figure 3*].[39]

Cholecystenteric fistula Another possible complication of acute cholecystitis is a cholecystenteric fistula, in which the gallbladder is connected either to the duodenum or to the hepatic flexure of the colon. In rare cases, the gallbladder communicates directly with the stomach or jejunum. A large gallstone (> 2.5 cm in diameter) will erode through the gallbladder wall into the duodenum. Subsequently, the stone may become impacted at the terminal ileum, causing small bowel obstruction, or in the duodenal bulb, resulting in gastric outlet obstruction (Bouveret syndrome). A cholecystenteric fistula is suspected when a plain abdominal x-ray shows pneumobilia, an ectopic stone, and mechanical obstruction. A barium upper gastrointestinal series can delineate a fistulous tract between the gallbladder and the intestines. CT scanning can define the site of obstruction and visualize the cholecystenteric fistula in 11% of patients.[40] Treatment of cholecystenteric fistula usually consists of one-stage cholecystectomy, exploration of the common bile duct, closure of the fistula, and extraction of the impacted stone.

Gallstones and malignancy Gallstones are present in 65% to 90% of patients with gallbladder cancer, although it is not clear whether gallstones themselves are the causal factor in oncogenesis.[41] A palpable gallbladder is usually found in malignant obstruction of the common bile duct (Courvoisier's law); however, this sign is uncommon in cases in which obstruction is caused by gallstones.

CHRONIC CHOLECYSTITIS

Chronic cholelithiasis is usually accompanied by evidence of chronic cholecystitis. The wall of the gallbladder is often thickened, fibrotic, and rigid, and the gallbladder is thus prevented from contracting and expanding normally. This condition may arise from a series of attacks of acute cholecystitis, from chronic mechanical irritation by calculi, or from both. The gallbladder wall may calcify and appear as the so-called porcelain gallbladder on plain abdominal x-ray [*see Figure 4*].

Diagnosis

Clinical manifestations It is difficult to attribute any symptom to chronic cholecystitis per se. Complaints of flatulence, heartburn, and nonspecific postprandial distress are common in patients with chronic cholecystitis, but such symptoms are also common in patients with no evidence of gallbladder disease. It is possible, however, to elicit a history of discrete attacks of abdominal pain resembling those of acute cholecystitis.

Physical examination Findings on physical examination are usually normal unless the patient is experiencing an acute attack of cholecystitis. The gallbladder is rarely palpable be-

cause scarring associated with chronic cholecystitis prevents expansion.

Laboratory evaluation Results of routine laboratory tests are usually normal; occasionally, the serum alkaline phosphatase level is modestly elevated.

Imaging studies TUS is the procedure of choice for the diagnosis of chronic gallbladder disease. In 90% to 95% of cases of cholelithiasis, ultrasonography demonstrates the echo of the calculus and the acoustic shadow behind the calculus [*see Figure 5*]. When the ultrasound is nondiagnostic, oral cholecystography may still be used to evaluate a patient with suspected gallbladder disease. If a double dose of the oral contrast agent fails to cause gallbladder opacification, cholelithiasis and chronic cholecystitis are almost certainly present. Cholescintigraphy is not helpful in diagnosing chronic cholelithiasis or chronic cholecystitis [*see* Acute Cholecystitis, *above*].

ERCP may reveal gallstones in the gallbladder of patients who have biliary tract pain and whose oral cholecystograms and gallbladder sonograms are normal. In one study, small gallstones were found with ERCP in 29 of 206 such patients (14%); the presence of these stones was confirmed during surgery.[42] CT or magnetic resonance imaging may also detect gallstones, but these techniques are unlikely to demonstrate stones not detected by ultrasonography. Endoscopic ultrasonography (EUS), with or without duodenal bile aspiration, may be a promising diagnostic approach in patients who have typical biliary symptoms but normal findings on transabdominal ultrasound.[43-45]

Bile collection and examination Gallbladder bile can be obtained by nasogastric tube or by endoscopic aspiration of the duodenum after infusing cholecystokinin intravenously to promote gallbladder emptying. In patients with biliary sludge, examination of bile under light and polarizing microscopy can show cholesterol crystals, which appear as rhomboid plates with a notch in one corner. Bile collected from the common bile duct during ERCP rarely contains precipitate, because hepatic bile transits rapidly through the biliary system,[10] and injection of contrast can lead to false positive results.[18] In one small study, EUS-guided aspiration of gallbladder bile was complicated by bile peritonitis in two of three patients.[46] Although some experts consider bile microscopy to be a gold standard in the diagnosis of biliary sludge, crystal analysis is limited by the need for invasive evaluation, meticulous sample processing, and institutional expertise.

Treatment

Surgery Elective cholecystectomy is indicated for patients who have symptomatic gallstones and chronic cholecystitis. Recurrent pain is to be expected in these patients if cholecystectomy is not performed. As many as 50% of patients with symptomatic gallstones who do not undergo cholecystectomy experience serious complications within 20 years after initial onset of symptoms.[47]

It is occasionally difficult to determine whether abdominal symptoms are secondary to documented gallbladder disease. A history of typical recurrent pain makes this determination easier. In certain cases, elective cholecystectomy is performed as a last diagnostic procedure when a thorough search for other causes of abdominal symptoms has proved negative. All too often, the symptoms recur postoperatively.

Dissolution therapy Oral bile acids, such as ursodeoxycholic acid (8 to 12 mg/kg daily) and chenodeoxycholic acid (13 to 15 mg/kg daily), can decrease biliary cholesterol levels; and when administered for months to years, ursodeoxycholic acid and chenodoxycholic acid can result in complete gallstone dissolution in 30% and 14% of patients, respectively.[48] A randomized, controlled trial found that combination therapy using these two agents was not superior to monotherapy with ursodeoxycholic acid.[49] Chenodeoxycholic acid has largely been replaced by the safer ursodeoxycholic acid; however, these drugs are effective only in patients with small cholesterol stones and a functioning gallbladder. A high rate of gallstone recurrence is noted after cessation of therapy. Infusing methyl *tert*-butyl ether through a transhepatic catheter directly into the gallbladder can rapidly dissolve cholesterol stones.[50] The rapid infusion and removal of this ether, which remains liquid at body temperature, results in the dissolution of most cholesterol gallstones within 4 to 31 hours. Dissolution therapy has limited value, except in patients who are poor candidates for surgery.

Extracorporeal biliary lithotripsy Stones in the gallbladder or common bile duct have been successfully fragmented using extracorporeal shock wave lithotripsy (ESWL), a technique widely employed for the nonsurgical fragmentation of kidney stones. Patients undergoing biliary ESWL are carefully positioned and monitored so that the shock waves are targeted at the gallstones. The highest success rates of biliary ESWL are seen in patients with a radiolucent solitary gallstone less than 2 cm in diameter; 60% to 84% of these patients are free of stones after 6 to 12 months of therapy.[51] ESWL has been associated with low rates of adverse events such as pancreatitis, biliary pain, hepatic hematoma, and hematuria. The administration of oral ursodeoxycholic acid after fragmentation of stones has been associated with an increase in the percentage of patients who are free of gallbladder stones 6 months after ESWL.[52,53] In one study, 21% of patients who received 10 to 12 mg/kg of ursodeoxycholic acid daily for 6 months after ESWL were free of gallbladder stones at the end of the treatment period; in contrast, only 9% of patients who received placebo for 6 months were free of stones.[53] Stone

Figure 5 **Ultrasound of the gallbladder showing, in the center of the image, a stone within the gallbladder with a triangular area of acoustic attenuation ("shadowing") behind the gallstone.**

fragments in the common bile duct may pass spontaneously after endoscopic sphincterotomy or can be extracted with a basket. The usefulness of biliary ESWL is limited by its high rate of gallstone recurrence and the widespread availability of laparoscopic cholecystectomy.

ASYMPTOMATIC CHOLELITHIASIS

Most gallstones are asymptomatic (silent gallstones). In one prospective study, gallstones were present or there was evidence of cholecystectomy in 291 of 1,701 persons (17%) at the time of postmortem examination.[54] Of these 291 persons, only 31 had undergone cholecystectomy, presumably because of symptomatic disease. Ten deaths were directly attributable to the gallstones; four of these deaths occurred after cholecystectomy.

Natural History

Silent gallstones seldom lead to problems. In a long-term follow-up study of patients with asymptomatic gallstones, the cumulative risk of the development of symptoms was 10% at 5 years, 15% at 10 years, and 18% at 15 years or later.[55] Nineteen percent of patients who experienced symptoms (2.5% of the patients enrolled in the study) subsequently developed acute cholecystitis or pancreatitis. No patients died of gallbladder disease during a mean follow-up period of more than 10 years.

Diagnosis

Asymptomatic gallstones are usually identified incidentally on transabdominal or pelvic ultrasonography performed for other diagnostic purposes, such as the evaluation of gynecologic symptoms or findings on physical examination.

Treatment

Patients who have asymptomatic gallstones should generally be managed conservatively without surgery. Exceptions may be made for patients at increased risk for gallbladder cancer, such as Pima Indians, patients with calcified gallbladders (porcelain gallbladder), patients with very large gallstones (> 3 cm), and patients with an associated gallbladder polyp greater than 10 mm in diameter.[56]

In the past, prophylactic cholecystectomy was recommended for diabetic patients who had asymptomatic gallstones; anecdotal reports suggested that such patients did poorly when cholecystectomy was performed as an emergency procedure. However, two well-controlled, retrospective studies of patients undergoing surgery for acute cholecystitis and a decision analysis showed that diabetes was not an independent risk factor of operative mortality or serious postoperative complications, and prophylactic cholecystectomy resulted in a shortened life span.[57,58] Thus, prophylactic cholecystectomy cannot be recommended for patients with diabetes.

CHOLEDOCHOLITHIASIS

Choledocholithiasis, a condition in which a stone lodges in the common bile duct after passage from the gallbladder through the cystic duct, develops secondary to chronic cholelithiasis in 15% to 20% of patients.[9,59] Primary common bile duct stones are more commonly seen in Asian populations than in populations of the Western world. This increased incidence of primary common bile duct stones is attributed to the increased prevalence of flukes and parasitic infections (e.g., clonorchiasis, fascioliasis, and ascariasis) in Asia, because of the prevalent use of uncooked seafood in the diet. Other risk factors for choledocholithiasis include the presence of periampullary diverticula and advancing age.[60]

Diagnosis

Clinical manifestations The signs and symptoms associated with choledocholithiasis vary. Some patients have no symptoms, whereas others may present with an acute illness. Pain is a common feature and is often located in the right upper quadrant or midepigastrium, with radiation of the pain to the interscapular region. Pain may be associated with nausea, vomiting, or both; it can be indistinguishable from biliary colic. Cholangitis may present as the Charcot triad (fever, pain, and jaundice) or the Reynold pentad (Charcot triad of symptoms, hypotension, and a change in mental status). Patients may also present with pancreatitis.

Physical examination Vital signs may reveal an elevated temperature. In more acutely ill patients, hypotension and tachycardia may occur. Physical exam may reveal tenderness and guarding in the right upper quadrant and midepigastrium. Hepatomegaly may be found when common bile duct obstruction has been present for some time. Scleral icterus may also be seen.

Laboratory evaluation Both serum bilirubin and alkaline phosphatase levels can be markedly elevated. However, when the stones do not obstruct the duct, the serum bilirubin level may be only slightly elevated or may be normal, and the alkaline phosphatase level may be substantially elevated. Typically, serum aminotransferase levels are only modestly elevated. It would be unusual to see aminotransferase levels higher than 1,000 IU/L. In some instances, aminotransferase levels rise and fall rapidly early in the course of bile duct obstruction.

Imaging studies TUS may detect only 50% of common bile duct stones[61]; however, it can often detect dilatation of common bile duct and intrahepatic ducts. The sensitivity of TUS for detecting common duct stones increases to 76% when ductal dilatation of more than 6 mm is used as the primary end point for choledocholithiasis. CT is no more sensitive or specific than TUS. Cholescintigraphy may show common bile duct obstruction, particularly when symptoms are of recent onset, but not all common bile duct stones will cause complete bile duct obstruction. Magnetic resonance cholangiopancreatography (MRCP) and EUS have similar accuracies in detecting common bile duct stones. MRCP [*see Figure 6*] is noninvasive and may be preferred in cases where the suspicion of choledocholithiasis is mild to moderate.[62,63]

ERCP allows radiographic visualization of the biliary tree [*see Figure 7*] and the option of therapeutic intervention.[64,65] EUS has greater sensitivity and specificity than ERCP in the detection of common bile duct stones but lacks the therapeutic option available with ERCP.[66] Therefore, ERCP is the technique of choice if common bile duct stones are highly suspected on the basis of the history, physical examination findings, and laboratory and imaging studies. When ERCP is unavailable or is unsuccessful in detecting bile duct stones, percutaneous transhepatic cholangiography (PTC) allows for direct imaging of bile ducts and offers the potential for therapeutic intervention. PTC involves accessing the bile ducts via a small needle.[67] The success rate of PTC in patients with dilated ducts is close to 100%; nondilated ducts are entered successfully about 70% of the time. Complica-

Figure 6 **This magnetic resonance cholangiopancreatogram shows multiple gallstones (arrows) in the common bile duct (choledocholithiasis).**

tion rates for both ERCP and PTC approach 5%. ERCP has replaced PTC as the technique of choice.

Treatment

Endoscopic sphincterotomy is the initial treatment for the patient with choledocholithiasis. In one large study, sphincterotomy was successful in 97.5% of patients with common bile duct stones, although more than one attempt was necessary in some patients. The overall rate of clearance of bile duct stones was 84.5%. The remaining patients required either surgery or permanent placement of a biliary endoprosthesis. The overall complication rate was 6.9%, and the complications included bleeding, cholangitis, pancreatitis, and perforation. The 30-day procedure-related mortality was 0.6%.[68] Follow-up studies have shown a low rate of recurrence of biliary duct problems and a low incidence of papillary stenosis.[69] Operative exploration of the common duct should be reserved for the few patients in whom endoscopic sphincterotomy is unsuccessful. Laparoscopic removal of biliary stones may be an alternative to preoperative ERCP.[70,71]

Endoscopic sphincterotomy is also the treatment of choice for patients with retained bile duct stones after gallbladder or biliary tract surgery. If sphincterotomy fails and if the patient has a T tube in place, instrumental extraction through the mature T-tube tract may be successful. Surgical exploration of the biliary tree is indicated if nonsurgical treatments fail.

MIRIZZI SYNDROME

Mirizzi syndrome refers to an obstruction of the common hepatic duct caused by a stone impacted at the neck of the gallbladder or the cystic duct. Mirizzi syndrome is classified into type I and type II.[72] In Mirizzi syndrome type I, there is only an extrinsic compression of the common hepatic duct by the gallstone and accompanying inflammation. In Mirizzi syndrome type II, a cholecystocholedochal fistula is established by the mechanism of pressure-induced necrosis from the gallstone.

Diagnosis

The clinical presentation of individuals with Mirizzi syndrome varies greatly.[73] Obstructive jaundice is commonly seen. However, 20% to 40% of patients may present without jaundice or have normal serum aminotransferase levels.[74] Biliary imaging tests often fail to demonstrate the features of Mirizzi syndrome; therefore, successful management of patients with Mirizzi syndrome is a challenge and relies heavily upon clinical suspicion and early recognition by the treating physician.

Treatment

Nonsurgical treatment of Mirizzi syndrome is limited and suboptimal. Long-term biliary stenting has a relatively high incidence of complications, including cholangitis and secondary biliary cirrhosis.[73] Nonsurgical lithotripsy and stone removal is restricted to patients with Mirizzi syndrome type II.[75] In Mirizzi syndrome type I, the offending stones are not accessible for clearance via bile ducts. Cholecystectomy is the treatment of choice. If the gallbladder is not removed, patients with Mirizzi syndrome are left at significant risk for complications from continued gallstone disease, including acute cholangitis, cholecystitis, suppurative cholangitis, liver abscess, secondary biliary cholangitis, and, perhaps, gallbladder carcinoma.[73,75,76] Nonsurgical treatment of patients with Mirizzi syndrome should be limited to those patients who are unfit for surgery or who have a shortened life expectancy.[34]

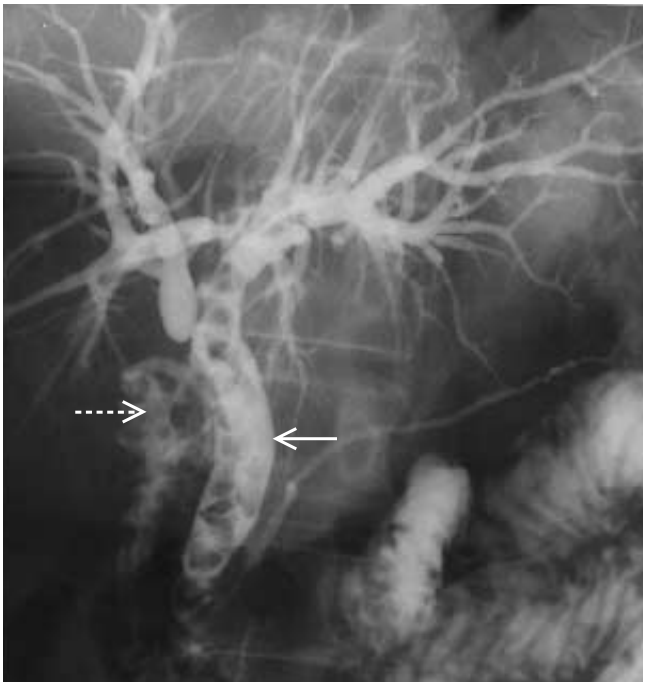

Figure 7 **Endoscopic retrograde cholangiopancreatography reveals abnormalities in a patient with gallstones. Multiple radiolucent areas establish the diagnosis of stones in the gallbladder (broken arrow) and common bile duct (solid arrow).**

Chronic Biliary Tract Disease

Chronic inflammation of biliary ducts is usually caused by partial or complete obstruction of the biliary tree. Some patients with chronic cholelithiasis or other chronic diseases of the biliary ducts will experience associated chronic inflammation or stricturing of the biliary tree.

DIAGNOSTIC OVERVIEW

Clinical Manifestations

Patients with chronic inflammation of the biliary tree may complain of fatigue, intermittent fever and chills, anorexia, pruritus, and weight loss. The physical examination may be fairly unremarkable; jaundice, excoriations of the skin related to marked pruritus, and stigmata of chronic liver disease may raise the level of suspicion.

Laboratory Evaluation

Laboratory tests will often reveal chronically elevated serum alkaline phosphatase levels and increased levels of serum 5´-nucleotidase, leucine aminopeptidase, and γ-glutamyl transpeptidase (GGT). Transient elevations of the total bilirubin level may also been seen.

Imaging Studies

Direct visualization of the biliary tree is important in determining whether the symptoms and signs result from an anatomic defect that can be corrected by endoscopic therapy or surgery. Use of MRCP or ERCP usually leads to identification of the obstructive site.

SPECIFIC PRESENTATIONS

Common Bile Duct Stricture

Benign and malignant strictures are similar in appearance, as imaged by ERCP or MRCP. Epithelial samples of biliary strictures for evaluation can be obtained by brush cytology; fine-needle aspiration; endoscopic pinch biopsy; or a combination of the three. The sensitivity of brush cytology is as high as 70% for the diagnosis of a malignant stricture of the bile duct; specificity is as high as 100%.[77] Simple bile duct aspiration alone is not as reliable. Common bile duct stricture, which may result from biliary tract surgery, can be treated endoscopically with balloon dilatation or with the placement of an endoprosthesis. If these treatments are unsuccessful, surgical intervention may prove beneficial for selected patients.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a disease of unknown etiology that is characterized by an irregular inflammatory fibrosis of both the intrahepatic and extrahepatic bile ducts [*see Figure 8*].[78] It usually occurs in men between 20 and 50 years of age.

Patients may present with jaundice, pruritus, nonspecific pain, fever, and weight loss. Approximately 75% of patients will have chronic ulcerative colitis. Liver function tests show cholestatic abnormalities.[78]

Ursodeoxycholic acid therapy will usually result in an improvement in the biochemical markers of cholestasis, but it has not been shown to increase survival.[79] Endoscopic treatment of significant ductal strictures may also improve biochemical markers of cholestasis and reduce the number of episodes of cholangitis.[80] A combined approach using therapeutic stricture dilatation and ursodeoxycholic acid therapy may benefit a select group of patients.

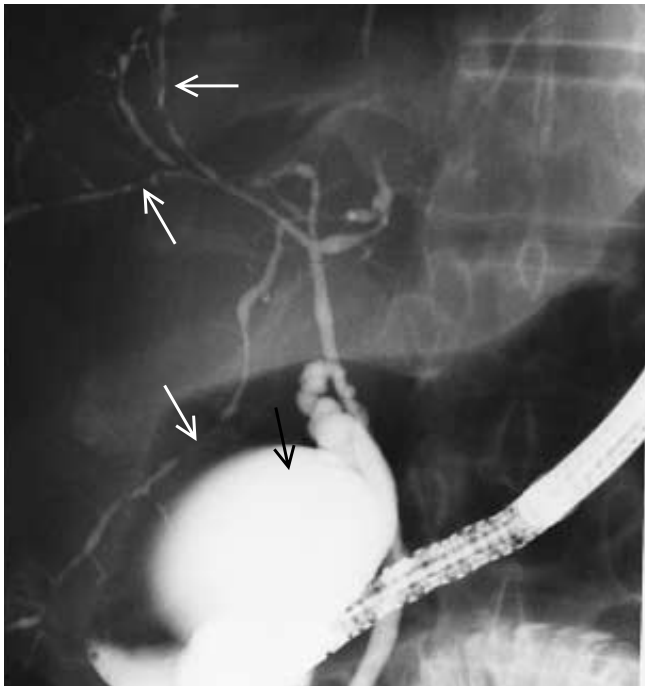

Figure 8 **This cholangiogram, obtained during endoscopic retrograde cholangiopancreatography, shows a normal gallbladder (black arrow) and a narrowed biliary tree with many areas of segmental stenosis (white arrows), diagnostic of primary sclerosing cholangitis.**

Patients with PSC are at increased risk for biliary tract cancer. The incidence of cholangiocarcinoma in patients with PSC is as high as 30%, and there is an increased risk of gallbladder and pancreatic cancer.[81] A substantial number of patients with PSC may have undetected cholangiocarcinoma at the time of liver transplantation.

Recurrent Pyogenic Cholangitis

Recurrent pyogenic cholangitis (RPC), as its name suggests, is a condition characterized by recurrent bouts of inflammation of the bile ducts. It most commonly affects patients of Asian descent. The exact etiology of RPC is unclear. Some experts propose a dietary or infectious cause. The parasites *Opisthorchis sinensis* and *Ascaris lumbricoides* are commonly found in the stools of affected patients.[82]

Patients typically present with repeated attacks of fever, chills, abdominal pain, and jaundice. Laboratory tests usually demonstrate an elevation in serum bilirubin and alkaline phosphatase levels. Elevations in serum aminotransferase levels and the prothrombin time signify hepatocyte injury, although the prothrombin time may also be prolonged because of vitamin K malabsorption.[83]

Imaging studies, such as ultrasonography, may be somewhat confusing in patients with RPC, because there may be areas of intrahepatic biliary dilatation without common bile duct dilatation. Evaluation using CT or MRCP usually defines the areas of intrahepatic and extrahepatic biliary dilatation more clearly than does ultrasonography, and these techniques also provide three-dimensional information.[84] ERCP is often required to confirm areas of stricture and dilatation. ERCP also allows for possible

therapeutic intervention. PTC provides access to peripheral ducts that may be inaccessible by ERCP.[85]

Treatment usually consists of antibiotic therapy and endoscopic or surgical stone clearance to improve biliary drainage.

Choledochal Cyst

Biliary cystic disease includes choledochal cyst disease and the less common gallbladder cysts and cystic duct cysts.[86] Choledochal cyst is an ectasia of the common bile duct that may present in late childhood or in adult life as obstructive jaundice. The cause of the disorder is not fully defined, and both congenital and acquired etiologies are postulated.[87]

Diagnosis Clinical manifestations of choledochal cyst in children include abdominal pain, cholangitis, and an abdominal mass. A palpable mass is unusual in adults, because adults tend to present with recurrent cholangitis, pancreatitis, or, rarely, portal hypertension. Choledochal cysts may involve any segment of the bile duct and are categorized according to the classification proposed by Todani and colleagues [*see Table 2*].[88] An abnormal pancreatobiliary duct junction is more common in patients with choledochal cysts and could expose the bile ducts to pancreatic juices, which could result in progressive injury to the ductal system. Type I cysts are the most common, accounting for 40% to 60% of all cases, followed by type IV. Types II, III, and V are rare.

A combination of imaging studies may establish the diagnosis. Ultrasonography may delineate the cyst and intrahepatic portions of the disease. CT and MRCP may provide useful information in regard to the extent of disease and the potential for malignancy. ERCP, PTC, and intraoperative cholangiography are important for diagnostic evaluation and surgical planning.

Table 2 Modified Classification System for Choledochal Cysts and Surgical Procedure of Choice

Classification	*Type*	*Procedure of Choice*
Type IA	Choledochal cyst	Roux-en-Y hepaticojejunostomy
Type IB	Segmented choledochal dilatation	
Type IC	Diffuse or cylindrical duct dilatation	
Type II	Extrahepatic duct diverticulum	Excision of diverticulum
Type III	Choledochocele	Endoscopic sphincterotomy
Type IVA	Multiple intrahepatic and extrahepatic duct cysts	Roux-en-Y hepaticojejunostomy
Type IVB	Multiple extrahepatic duct cysts	
Type V	Intrahepatic duct cysts (Caroli disease and Caroli syndrome)	Hepatic resection, liver transplantation

*All patients with choledochal cysts must undergo cholecystectomy to decrease the risk of malignancy, with the possible exception of patients with type III cysts. For the much rarer gallbladder and cystic duct cysts, treatment is cholecystectomy.

Table 3 Clinical Classification System for Biliary-Specific Abdominal Pain Associated with SOD*

Criteria

A. Typical biliary-type pain
B. Elevated liver enzyme levels (AST, alkaline phosphatase, or both more than two times normal on at least two occasions)
C. Delayed drainage of contrast injection during ERCP (> 45 min)
D. Dilated common bile duct (> 12 mm)

Classification Based on above Criteria

Biliary type I: criteria A through D are present; SOD is present in 80%–90% of patients
Biliary type II : criterion A plus one or two other criteria are present; SOD is present in 50% of patients
Biliary type III: only criterion A is present; SOD is uncommon

*A similar classification for SOD and pancreatic-type abdominal pain exists but is not included in this table.
AST — aspartate aminotransferase ERCP — endoscopic retrograde cholangiopancreatography SOD — sphincter of Oddi dysfunction

Treatment The initial treatment of choledochal cysts depends on the age of the patient, the presentation, and the type of the cyst. In terms of definitive treatment, pharmacologic or endoscopic management offers little benefit in that these forms of therapy do not address the well-described malignant potential of bile duct cysts.[89] Therefore, the primary role of endoscopic procedures is in the initial evaluation and diagnosis of bile duct cysts. However, endoscopic interventions such as lithotripsy, stone extraction, and laser ablation have proved successful in the treatment of intrahepatic and extrahepatic biliary stones in patients with Caroli disease, a congenital disorder associated with renal cystic disease of varying severity.[90] Endoscopic therapy, such as stone extraction, can be a definitive treatment for patients with recurrent pyogenic cholangitis. It would be the chosen therapy in elderly patients or in patients considered to be poor candidates for surgery. The current standard for surgical treatment in the patient who is a reasonable surgical risk is excision of the cyst with free biliary drainage into the gastrointestinal tract. The classical surgical reconstruction is a hepaticojejunostomy with a Roux-en-Y [*see Table 2*] reconstruction.[91]

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction (SOD) is a benign condition of intermittent or permanent obstruction of biliary drainage, pancreatic drainage, or both that is caused either by a stenosis or by smooth muscle dysfunction of the sphincter muscle.[92] Biliary SOD is classified into three types on the basis of clinical parameters using the modified Milwaukee criteria [*see Table 3*].

Diagnosis Biliary SOD is usually seen in women in the fourth to sixth decades of life. The symptoms arise typically after cholecystectomy, although SOD may occur in patients with an intact gallbladder.[93,94] The clinical presentation of biliary SOD is episodic abdominal pain in the epigastric region or the right upper quadrant that may radiate to the back or shoulders. It may be associated with nausea or vomiting that worsens with eating. Laboratory tests may reveal elevated liver function. Right upper quadrant ultrasonography and CT may reveal a dilated common bile duct.

ERCP with sphincter of Oddi manometry is the gold stan-

dard for diagnosis of SOD. A basal sphincter pressure of more than 40 mm Hg is abnormal and indicative of SOD.[95] Other tests that are noninvaive and less reliable may also indicate the presence of SOD; such tests include a provocation test with morphine (or neostigmine), which produces biliary pain and elevation of the serum aminotransferase level; ultrasound evaluation of dilatation and emptying of the common bile duct after secretin stimulation; or the kinetics of ductal emptying studied by scintigraphy.[96]

Sphincter of Oddi manometry is not required to confirm the diagnosis of type I SOD disease. However, patients classified with type II disease should undergo sphincter of Oddi manometry because only 50% of patients in this group have SOD. In patients classified as having type II disease, only patients whose SOD is confirmed by sphincter of Oddi manometry should undergo endoscopic sphincterotomy. Sphincter of Oddi manometry, endoscopic sphincterotomy, or both have low efficacy in patients with type III disease.

Treatment A low-fat diet may decrease biliary or pancreatic stimulation, although the efficacy of this approach is unknown. Endoscopic sphincterotomy is the primary treatment for patients with SOD type I disease and for patients with types II and III disease in which the presence of SOD has been confirmed by manometry. Over 90% of patients with type I disease will have a favorable response to endoscopic sphincterotomy; therefore, manometry should not be performed in these patients.

Pharmacologic therapies (i.e., calcium channel blockers and nitrates) are primarily used in patients with type III disease, because in these patients, sphincter of Oddi manometry has the greatest risk of complication and the smallest diagnostic yield. Treatment with calcium channel blockers and nitrates decreases pain by relaxing the sphincter smooth muscle.[92]

Other endoscopic therapies such as balloon dilatation, injection of botulinum toxin, temporary stent placement, and surgical sphincteroplasty are not widely used in the treatment of SOD.[97-99]

VII ACUTE VIRAL HEPATITIS

Emmet B. Keeffe, m.d.

Most cases of acute hepatitis are caused by one of the hepatotrophic viruses, but drug-induced hepatitis and hepatitis that is secondary to other viruses may at times mimic typical acute viral hepatitis. Classic acute viral hepatitis is caused by one of five etiologic agents: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), or hepatitis E virus (HEV).[1,2] In the United States in 1999, 59% of reported cases of acute viral hepatitis were caused by HAV infection and 26.5% by HBV infection; 14.5% were classified as non-A, non-B hepatitis or were unspecified.[3] HDV infection (delta hepatitis) occurs either as a superinfection in chronic HBV carriers or as a coinfection during acute HBV infection. HEV infection occurs predominantly outside the United States, but a few cases have been reported in travelers returning to the United States. All five viruses can cause acute hepatitis, but only three—HBV, HCV, and HDV—can lead to chronic infection. A new hepatitis virus, hepatitis G virus (HGV), has been identified but does not appear to be pathogenic, nor does it account for those cases that have been termed non-A–E viral hepatitis, as some investigators originally suggested. Finally, a number of viruses that cause systemic illnesses may also affect the liver—for example, cytomegalovirus (CMV) and Epstein-Barr virus (EBV).

All five types of viral hepatitis are similar and cannot be distinguished reliably by clinical features or routine laboratory tests. Infection either may occur asymptomatically or may be associated with nonspecific flulike symptoms; some patients experience jaundice. The characteristic laboratory abnormality in acute hepatitis is an elevated aminotransferase level, typically greater than 300 IU/L and, occasionally, 1,000 to 3,000 IU/L. The specific etiology of viral hepatitis is determined by serologic testing [*see Table 1*].

Classification and Pathology

hepatitis a virus

HAV is a picornavirus similar to poliovirus and rhinovirus.[4] HAV was initially discovered in stool but has also been found in the serum of patients with acute HAV infection and in the cytoplasm of liver cells and bile of animals infected with HAV.[5] It is a nonenveloped, positive-stranded RNA virus that has at least seven genotypes but only one serotype.[4] The antigenic compositions of HAV throughout the world are remarkably similar, which explains the global efficacy of immune globulin and of hepatitis A vaccine. IgM antibody to HAV is detectable at the onset of clinical illness and usually disappears within 60 to 120 days. IgG antibody reaches a high titer during convalescence, persists indefinitely, and confers immunity.

hepatitis b virus

HBV, the only member of the family Hepadnaviridae that infects humans, has a diameter of 42 nm and consists of a 28 nm core surrounded by a protein coat; the core contains protein, circular double-stranded DNA, and DNA polymerase [*see Figure 1*].[6] Immunofluorescent antibody studies have detected HBV in the nuclei of infected liver cells. The core moves through the nuclear membrane into the cytoplasm, where it acquires its surface coat. HBV is found in the serum of almost all patients early in the course of acute HBV infection.

Two additional particles appear in the liver cell cytoplasm and serum of patients with HBV: a 22 nm–diameter sphere and a rod-shaped filament of the same diameter. These particles are found at the onset of jaundice in nearly all patients with acute HBV infection. The surface coat of the hepatitis B virion and the spheres and filaments are composed of pre-S1, pre-S2, and S polypeptides, in both glycosylated and unglycosylated forms. The S polypeptide is the major hepatitis B surface antigen (HBsAg).

Although there is only one major serotype of HBV, HBsAg has five major subtype determinants, termed *a, d, y, w,* and *r,* which are primarily of epidemiologic interest. All HBsAg-positive sera contain determinant *a*; determinants *d* and *y* are mutually exclusive, as are *w* and *r*. Hence, four subtype patterns are possible: *adw, ayw, adr,* and *ayr*. The first three subtype patterns occur frequently; *ayr* is rare. Many studies have attempted to correlate subtype with clinical course. It appears, however, that the subtypes are associated with different geographic distributions of HBV rather than with different degrees of virulence. Subtype *adw* is most common in the Americas and Europe; *adr* prevails in most of the Far East.

HBV can be classified into seven genotypes (A to G) on the basis of an intergroup divergence of 8% or more in the complete nucleotide sequence.[7,8] Genotypes A (serotype *adw*) and D (*ayw*) are most common in the United States and Europe; genotypes B (*adw*) and C (*adr*) are most frequent in China and Southeast Asia.[9] There are also several variations or mutations in the nucleotide sequence of HBV. Core promoter and precore variants produce HBV virions that do not produce hepatitis B e antigen (HBeAg). These variants are most commonly seen in patients with genotypes B, C, and D. These differences in genotypes and the presence or absence of variants may account for variations in clinical manifestations of chronic HBV infection in the United States and other parts of the world.

hepatitis c virus

HCV is a single-stranded, positive-sense RNA virus that is 9.4 kb in length and accounts for most cases of non-A, non-B hepatitis.[10,11] It is most closely related to the pestiviruses and flaviviruses and is believed to be a distinct genus in the Flaviviridae family.

Table 1 Serologic Diagnosis of Acute Viral Hepatitis

Disease	*Serology*	*Comments*
Hepatitis A	IgM anti-HAV	Reasonably specific
Hepatitis B	HBsAg IgM anti-HBc	May be negative late Indicates acute hepatitis
Hepatitis C	Anti-HCV HCV RNA	Appears late Appears early
Hepatitis D	HBsAg and anti-HDV + IgM anti-HBc – IgM anti-HBc	Anti-HDV may appear late Coinfection Superinfection
Hepatitis E	Anti-HEV	Not licensed in the United States

HAV—hepatitis A virus HBc—hepatitis B virus core HBsAg—hepatitis B surface antigen HCV—hepatitis C virus HDV—hepatitis D virus HEV—hepatitis E virus

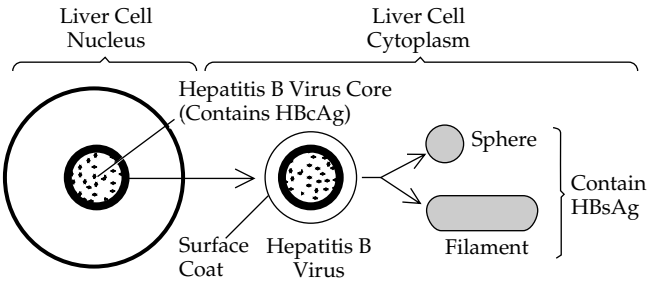

Figure 1 **The hepatitis B virus exists in the cytoplasm of parenchymal liver cells of persons with hepatitis B and constitutes the infective virus. The core of this particle is found in the nucleus of parenchymal cells (left), but as it passes through the cytoplasm, it acquires a surface coat (middle). The core contains hepatitis B core antigen (HBcAg). Spheres and filaments, also in the cytoplasm (right), appear to be excess surface coat material. They are the main source of hepatitis B surface antigen (HBsAg) in serum.**

Structural proteins are encoded at the 5′ end, which is highly conserved [*see Figure 2*]. Further downstream are the HCV core protein, the envelope proteins, and the four nonstructural proteins located at the 3′ end. On the basis of nucleic acid sequence analysis, at least six major genotypes and various subtypes have been identified worldwide. The HCV genotypes are divided into types (1, 2, 3, etc.) and more closely related subtypes (1a, 1b, 2a, etc.). Specific HCV genotypes exhibit different degrees of responsiveness to interferon therapy (e.g., genotypes 2 and 3 respond better to interferon therapy than does genotype 1). In the United States, genotype 1 is the most common, accounting for 70% to 80% of cases; genotype 2 accounts for about 15% of cases, and genotype 3 accounts for 5%. Other genotypes appear to be uncommon in the United States. Coinfection with more than one genotype may occur, particularly in patients with hemophilia or in other patient groups who have been repeatedly exposed to HCV. Quasispecies of HCV also exist. This genetic heterogeneity develops with a longer duration of infection; it may be associated with a poorer response to interferon therapy.

HEPATITIS D VIRUS

HDV, or delta agent, is a single-stranded, circular, negative-polarity, defective RNA virus that requires HBV for its expression.[12] HDV is smaller than any known animal virus and resembles certain plant viruses known as viroids. It circulates in the blood in association with hepatitis D antigen, and the RNA genome has an external coat composed of HBsAg. Although hepatitis D antigen, HDV RNA, and IgM anti–hepatitis D virus (anti-HDV) can be found in the plasma of infected persons, the only commercially available serologic marker for this infection is the total IgG antibody to hepatitis D virus antigen (anti-HDV). When anti-HDV is present in serum, markers of the HBV replication, such as HBeAg and HBV DNA, are usually absent. Although HDV infection is present worldwide, it is most prevalent in Mediterranean countries, the Middle East, and northern Africa. The virus is responsible for epidemics of fulminant hepatitis in South America. HDV infections are uncommon in the United States and northern Europe, except in I.V. drug abusers and persons frequently exposed to blood products. HDV is also uncommon in Southeast Asia and China, areas where HBV is common. Successful vaccination against HBV will prevent HDV infection.

HEPATITIS E VIRUS

HEV is a single-stranded, positive-sense RNA virus of approximately 7.5 kb that causes enterically transmitted non-A, non-B hepatitis.[13] The diagnosis of HEV infection can be made by serologic identification of anti-HEV antibodies (not yet commercially available in the United States). HEV has also been identified in the stool of patients with acute HEV infection through use of immune electron microscopy. Strain variation in HEV has been noted in different parts of the world (e.g., the HEV [B or Burma] and HEV [M or Mexico] strains have only 76% sequence similarity), but there is only one serotype. Acute HEV infection is observed in developing countries; sporadic cases in the United States have been diagnosed in travelers returning from endemic areas.

HEPATITIS F AND G VIRUSES

Between 5% and 20% of cases of acute and chronic hepatitis are not caused by the five known hepatitis viruses and have been presumed to be caused by non-A–E agents. A virus identified in stool extracts from French patients with non-A–E hepatitis was tentatively called the hepatitis F virus (HFV),[14] but the existence of this virus has not been confirmed and is doubtful. HGV was identified as a coinfection in patients with HCV infection and also in persons with non-A–E hepatitis.[15] HGV is an RNA virus closely related to but distinct from HCV. HGV appears to be similar to a GB virus (GBV).[16] Two viruses, GBV-A and GBV-B, are probably nonhuman viruses that are contaminants of serially passed human serum in tamarins. A third virus, GBV-C, is a human virus that is a closely related genotype of HGV. HGV (GBV-C) does not appear to be pathogenic or an independent cause of acute or chronic hepatitis.[17]

Epidemiology

It is particularly important to consider the epidemiology of types A, B, C, D, and E hepatitis and the special tests that may

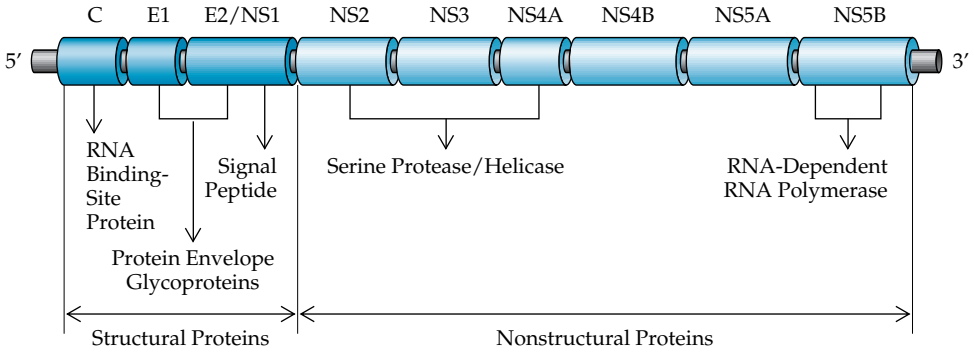

Figure 2 **The hepatitis C virus genome consists of a single, long, open reading frame. The three structural proteins (the RNA binding-site protein [C, core protein] and two envelope glycoproteins [E1 and E2]) are encoded on the 5′ end, and the nonstructural proteins (protease, helicase, and RNA-dependent RNA polymerase [NS2, NS3/NS4A, and NS5B]) are encoded on the 3′ end.**

Table 2 Features of Type A, Type B, Type C, Type D, and Type E Acute Viral Hepatitis

	Type A	*Type B*	*Type C*	*Type D*	*Type E*
Mode of transmission	Fecal-oral, sewage-contaminated shellfish	Percutaneous, sexual	Percutaneous and community	Percutaneous	Fecal-oral
Incubation period (days)	20–37 (15–49)*	60–110 (25–160)*	35–70 (21–84)*	Appears to be comparable to type B	10–56
Results of serum antigen and antibody tests	Development of IgM antibody early and IgG antibody in convalescence	Antigen (HBsAg) and antibody (anti-HBc) appear early and persist in carriers	Anti-HCV appears in 6 wk to 9 mo	Anti-HDV appears late and may be short-lived	IgM antibody usually detected within 26 days of jaundice; IgG antibody persists indefinitely
Immunity	45% of the U.S. population has hepatitis A antibodies in serum and is probably immune	5%–15% of the population has anti-HBs	Unknown	Patients immune to hepatitis B are also protected against hepatitis D	Unknown
Prevalence	Seen with increasing frequency in adults	Increasing in the United States	80%–90% of post-transfusion hepatitis; 12%–25% of sporadic acute hepatitis	Unusual in the United States but common in I.V. drug abusers	Rare in the United States
Course	Does not progress to chronic liver disease	Chronic liver disease develops in 1%–5% of adults and 80%–90% of children	Chronic liver disease develops in 85%	> 95% resolution of delta coinfection with acute hepatitis B; chronic infection common if delta superinfection is present in chronic hepatitis B carrier	Does not progress to chronic liver disease
Prevention of the disease after exposure	Pooled γ-globulin (0.02 ml/kg) decreases the occurrence of clinical disease 7- to 8-fold	Hepatitis B immune globulin and hepatitis B vaccine prevent clinical disease in adults and the carrier state in infants	The efficacy of pooled γ-globulin is uncertain	Unknown	Uncertain
Mortality	0%–0.2% with fulminant hepatitis	0.3%–1.5%	Uncertain; may approximate rate for type B	2%–20% for acute icteric hepatitis	1%–2%; may be as high as 10%–15% in pregnant women

*Usual range, with outside limits given in parentheses.

permit their differentiation, because their prognoses are considerably different [*see Tables 1 and 2*].[1,2]

HEPATITIS A VIRUS

In HAV infection, virus is shed in the stool 14 to 21 days before the onset of jaundice. Although patients may continue shedding virus for the first 1 to 2 weeks of clinical illness, they are usually no longer infectious 21 days after the illness has begun. However, virus may be detected in the stool again if the patient experiences a relapse of the acute illness. HAV is transmitted via food that has been contaminated by feces-soiled hands of infected persons. The disease is quite contagious; transmission in families is common, and several large point-source epidemics have been reported.[18] Outbreaks of HAV infection have been reported in day care centers, with young children being the most commonly infected.[19] Employees of the day care centers and household contacts and close relatives of the infected children contracted the disease with alarming frequency. Ingestion of sewage-contaminated shellfish has resulted in several epidemics of HAV,[20] as has contamination of raw produce, as in the recent outbreak of HAV infection associated with green onions.[21] The disease is sexually transmitted in men who have sex with men.[22,23] HAV is also common in I.V. drug abusers, but the method of transmission is uncertain. Viremia is present from 1 to 25 days before the onset of symptoms, but transmission by serum or blood products seldom occurs. Patients with HAV develop immunity to the disease—approximately one third of the population of the United States have serum antibodies to HAV. There is no known human or nonhuman reservoir of HAV.

HEPATITIS B VIRUS

HBV is transmitted primarily through percutaneous inoculation of infected serum or blood products. HBsAg and HBV DNA are found in a wide variety of bodily secretions, but the importance of these factors in the spread of HBV is unknown. The most common mode of transmission in men who have sex with men may be by oral or genital contact with asymptomatic bleeding lesions in the rectal mucosa. HBV may also be transmitted to the fetus during pregnancy. An appreciable segment of the population has serum antibodies to HBsAg (anti-HBs). Prevalence of anti-HBs varies among subpopulations: middle-class whites have a 5% prevalence; middle-class African Americans, 12%; Chinese Americans, 37%; and white homosexual men, 48%. This antibody confers immunity to HBV.

HEPATITIS C VIRUS

Before the advent of tests that could screen for HCV and thus help eliminate this virus from the blood supply, HCV caused most cases of posttransfusion hepatitis.[24] Since that time, the rate of HCV transmission by transfusion has declined, and the risk of posttransfusion HCV infection is estimated to be between 0.01% and 0.001% per unit transfused.[25] HCV is responsible for more than 80% of non-A, non-B hepatitis.

HCV is transmitted by parenteral means (e.g., transfusions, I.V. drug use, or occupational exposure to blood or blood products).[26] The risk of transmission from a single needle-stick accident averages 1.8% in prospective studies (range, 0% to 7%).[25] It is estimated that the risk of sexual transmission of HCV in monogamous couples is about 5%, well below the risk of sexual transmission of HBV (about 30%) or HIV (about 10% to 15%). However, the rate of HCV infection is higher in persons who have frequent sexual contact with numerous partners, and in this setting, the risk is higher for female partners of men with anti-HCV.[27] Most studies, particularly those from the United States, have failed to demonstrate any serologic or virologic evidence of HCV transmission to nonsexual partners within households. Perinatal transmission of HCV infection is unusual, except in babies born to mothers with very high levels of HCV RNA, such as mothers with concomitant HIV infection. The risk of perinatal transmission is estimated to be between 5% and 6%. There appears to be no increase in HCV infection in breast-fed babies. In summary, barrier precautions are not recommended for monogamous partners, but persons with multiple sexual partners should practice safe sex and use latex condoms. An additional commonsense precaution is to avoid shared percutaneous exposures, such as razors and toothbrushes. Finally, there is no reason to advise against pregnancy for a woman with HCV infection, because the rate of perinatal infection is low.

Recipients of organs from donors who have antibodies to HCV have a high probability of becoming infected.[28] Transplantation of an organ from an infected donor is controversial.

HEPATITIS D AND E VIRUSES

HDV occurs only in patients with HBV and is transmitted percutaneously. Simultaneous infection with HBV and HDV may produce a more severe acute hepatitis than that caused by HBV alone.[12]

HEV is a common cause of large epidemics of acute viral hepatitis in developing countries. It characteristically affects adults and may be associated with an unusually high mortality in pregnant women.[13] Epidemics have occurred in rural Mexico, with a high attack rate and with jaundice occurring in more than 5% of the local popoulation. HEV infection has also been found in immigrants to the United States and in travelers to Mexico and the Indian subcontinent.[29]

Table 3 Incidence of Symptoms in Acute Viral Hepatitis

Symptom	*Percentage of Patients*
Dark urine	94
Fatigue	91
Anorexia	90
Nausea	87
Fever	76
Emesis	71
Headache	70
Abdominal discomfort	65
Light stools	52
Myalgia	52
Drowsiness	49
Irritability	43
Itching	42
Diarrhea	25
Arthralgia	21

Diagnosis

CLINICAL MANIFESTATIONS

The onset of viral hepatitis may be gradual or sudden. The symptoms are protean [*see Table 3*].[1,2] The most common early symptoms are fatigue, lassitude, drowsiness, anorexia, nausea, and dark urine. Dehydration may result from repeated vomiting. Low-grade fever is common; shaking chills are rare. Frank pain may occur in the right upper quadrant, but vague, generalized abdominal discomfort is more common. Itching may occur but is seldom severe. Diarrhea occurs in some cases. About half of patients have myalgias or arthralgias, and some have acute arthritis with local pain, redness, swelling, and effusions. Joint symptoms are usually associated with HBV and HEV infections. Many of these early symptoms abate when jaundice develops or shortly thereafter. In the case of severe hepatitis, which is unusual, confusion, stupor, or even coma may develop. Fetor hepaticus and asterixis are usually present in these patients.

PHYSICAL EXAMINATION

The sclerae and skin may be icteric. The liver is often enlarged and tender. The spleen is palpable in about 10% of patients. Asterixis, marked peripheral edema, or ascites implies that the disease is unusually severe and suggests a poor prognosis.

LABORATORY TESTS

General Laboratory Findings

Most patients have mild anemia and relative lymphocytosis. The leukocyte count is usually normal but may be greater than 12,000/mm^3. The serum bilirubin level generally does not exceed 15 to 20 mg/dl; levels greater than 30 mg/dl imply severe disease or associated hemolysis. Serum aspartate aminotransferase (AST) and serum alanine aminotransferase (ALT) levels rise 7 to 14 days before the onset of jaundice and begin to fall shortly after jaundice occurs. The degree of aminotransferase elevation does not necessarily parallel severity, but levels less than 500 IU/L usually reflect mild illness.

The alkaline phosphatase level is slightly increased but may be markedly elevated in the few patients in whom prominent cholestasis develops later in the course of acute illness. Serum γ-globulin levels are normal or slightly elevated; concentrations greater than 3 g/dl suggest chronic active hepatitis rather than acute viral hepatitis. The serum albumin level and prothrombin time reflect the liver cells' synthetic capacity and are depressed in patients with severe, acute viral hepatitis.

Serologic and Virologic Assays

Serologic assays are used to identify each type of viral hepatitis [*see Table 1*].

Hepatitis A virus The IgM antibody to HAV (IgM anti-HAV) appears early and is quite specific for acute HAV infection. It typically persists for an average of 3 months and is then replaced by the IgG anti-HAV, which lasts throughout life and confers immunity to future infection.

Hepatitis B virus A number of serologic tests are useful to physicians who are caring for patients with acute HBV infection [*see Table 4*]. HBsAg is present on the surface of the hepatitis B virion and in the circulation as spheres and filaments [*see Figure 1*]. It appears in the serum of infected persons as early as 1 to 2

Table 4 Tests for Hepatitis B Virus Infection

Symbol	*Characteristics*
HBsAg	Hepatitis B surface antigen; present in surface coat of the hepatitis B virus and in the 22 nm diameter filaments and spheres; purified surface antigen expressed in yeast cells is used in the recombinant hepatitis B vaccines
Anti-HBs	Antibody to HBsAg; present during convalescent phase of acute hepatitis B infection and after successful hepatitis B vaccination; hepatitis B immune globulin derived from serum with high anti-HBs titers is effective in preventing clinical hepatitis B infection
Anti-HBc	Antibody to the hepatitis B virus core; present in all patients with any form of hepatitis B infection; presence of this antibody in the sera is evidence that the patient has been infected in the past or is currently infected with the hepatitis B virus
IgM anti-HBc	Antibody to the hepatitis B core antigen; present in high titers in patients with acute hepatitis B; may be the only marker of acute infection when HBsAg is no longer detectable
Anti-HDV	Antibody to hepatitis D; serologic marker of coinfection or superinfection by hepatitis D of patients with hepatitis B
HBeAg	A soluble protein derived from the hepatitis B virus core; reflects presence in the blood of circulating hepatitis B virus; sera positive for this antigen are highly infectious
Anti-HBe	Anti-HBe appears weeks to months after HBeAg (and the circulating hepatitis B virus) is no longer detectable in the blood; sera positive for this antibody are substantially less infectious

weeks after parenteral injection of infectious virus and may persist for months. If HBsAg remains in the serum of an infected person for 6 months after an episode of acute HBV infection, it will probably persist indefinitely. The antibody to HBsAg usually appears in the blood 2 to 4 months after an attack of acute HBV infection that resolves—in most cases, after HBsAg is no longer detectable. Antibody to the core antigen (anti-HBc) appears promptly in the blood of infected persons and persists indefinitely. High titers of IgM anti-HBc are found in patients with acute disease and may be the only marker of acute HBV infection if HBsAg is no longer detectable. Detection of HBeAg, a soluble protein derived from the core particle, correlates with the presence of HBV DNA and indicates that the HBV is actively replicating. Serum that is positive for HBeAg is highly infectious. A pregnant woman who is positive for HBsAg is much more likely to transmit HBV to her offspring if her blood also contains HBeAg or HBV DNA. The detection of antibody to HBeAg (anti-HBe) in association with the absence of HBV DNA is evidence that viral replication is minimal and the blood is substantially less infectious.

Hepatitis C virus Detection of antibodies to HCV (anti-HCV) remains the most practical way to diagnose acute and chronic HCV infection.[30,31] In 1992, a second-generation anti-HCV enzyme-linked immunosorbent assay (ELISA) replaced the original assay. The second-generation assay employs several viral antigens, making it more sensitive and specific than the first-generation test. The most commonly used supplemental assay for specificity is the second-generation recombinant immunoblot assay (RIBA-2), which incorporates four antigens as separate bands. Reaction of two or more of the four bands is considered a positive RIBA-2 test result; reaction of only one band is indeterminate. Third-generation ELISAs and RIBAs have been developed and should soon be available in the United States.

The detection of serum HCV RNA can be used to establish viremia and has been widely employed in the management of chronic HCV infection.[30,31] The diagnosis of acute HCV infection can also be established early, before the appearance of anti-HCV, by the use of HCV RNA assays. Assays for serum HCV RNA have recently become standardized, and serum HCV RNA can be detected by both qualitative and quantitative assays. The results of a quantitative HCV RNA assay may be useful in predicting the subsequent response to interferon therapy; patients with lower levels of viremia respond better than those with higher levels. Finally, in patients with normal serum aminotransferase levels in whom the results of RIBA-2 are positive for anti-HCV, the presence or absence of serum HCV RNA can distinguish between active infection with viremia and recovery from previous HCV infection.

Hepatitis D and E viruses HDV infection is diagnosed by the detection of anti-HDV with HBsAg. Patients with acute HDV infection will have HBsAg with IgM anti-HBc along with anti-HDV (i.e., coinfection), whereas patients with chronic HBV infection who are superinfected with HDV will have a negative IgM anti-HBc. HEV is diagnosed by the detection of antibodies to HEV (anti-HEV). Anti-HEV is found in acute and convalescent serum from patients with acute HEV infection. This assay has yet to be licensed in the United States.

Liver Biopsy

Liver biopsy is not usually performed in patients with acute viral hepatitis, because serologic tests are generally diagnostic. Spotty necrosis of liver cells and an inflammatory cell reaction that consists primarily of lymphocytes and histiocytes are the typical histologic findings. Acidophils (dying liver cells) and bile plugs are common. Biopsy performed late in the course of the disease reveals prominent evidence of hepatic cell regeneration (rosette formation and multinucleated cells) and pigment-filled histiocytes. Although usually more marked in the pericentral areas, the inflammatory reaction and cell necrosis appear throughout the parenchyma. In severe hepatitis, necrotic zones link portal areas to one another or to central areas, or they may involve whole lobules (bridging necrosis). The portal tracts contain a mild to moderate mononuclear cell inflammatory reaction, and the limiting plate, which demarcates portal areas from parenchymal cells, may be disrupted.

CLINICAL COURSE

Hepatitis typically produces symptoms for 1 to 2 weeks before the onset of dark urine and jaundice. As icterus deepens, appetite begins to return and malaise lessens. The serum bilirubin level rises for 10 to 14 days and then declines over 2 to 4 weeks. Aminotransferase levels usually begin to decline just before peak jaundice occurs and fall quite rapidly thereafter. The patient often feels much better by the time bilirubin levels have begun to decline. Usually, the clinical course is uneventful and recovery is complete, with liver function returning to normal.

In a small percentage of patients, the clinical course is atypical. Acute viral hepatitis may be protracted in elderly patients or in those infected with either HBV or HCV; the disease may last several months, and full recovery may not occur for a year. Between

6% and 15% of patients with acute viral hepatitis will have recurrent symptoms and worsening of liver function before recovery from the initial attack is complete. This relapse is usually milder than the original attack and is short-lived. In a few patients, the disease has an acute fulminant course leading to hepatic coma and even death. These events appear to be more common in pregnant women infected with HEV. HCV appears to be an unusual cause of fulminant disease.[32] In some countries, a mutant form of HBV that is incapable of encoding for e antigen is associated with fulminant disease.[9] Often, no virus can be identified, leading to speculation that other viruses may be involved—either mutant viruses or as yet unidentified viruses. Some patients do not recover completely from the initial attack, and chronic hepatitis develops. Chronic hepatitis does not occur after HAV or HEV infection. It ensues in 1% to 5% of cases of acute HBV infection and 85% of cases of acute HCV infection.[1,2]

A study in Italy has found that carriers of HBsAg who are symptom-free and whose liver function tests are normal have an excellent prognosis. In this study, the risk of hepatocellular carcinoma was low over the mean follow-up period of about 11 years.[33] The natural history of HCV infection is still being studied. The general view is that chronic HCV infection usually progresses but does so slowly over many decades.[26,34] In two histologic studies of the natural history of chronic HCV infection that resulted from blood transfusion, the times to the presence of chronic HCV infection averaged 12 years; to the presence of cirrhosis, 21 years, and to the presence of hepatocellular carcinoma, 29 years.[35,36] Both of these studies reported experiences from tertiary liver centers, however, which may have introduced referral bias. More recent studies have suggested that chronic HCV infection is more benign than originally reported and is associated with a low rate of cirrhosis.[37-40] In a large, prospective study of 568 patients with posttransfusion non-A, non-B hepatitis (mostly HCV) who were followed for an average of 18 years, there was no increase in mortality from all causes, but there was a small increase in the number of deaths related to liver disease.[39] Another large, cross-sectional study from Europe of 2,235 patients with chronic HCV infection found that the median time from infection to cirrhosis was 30 years,[40] which is about 10 years longer than the 21-year interval from infection to cirrhosis reported earlier from tertiary liver centers.[35,36] Analysis of liver biopsy specimens showed that the rate of fibrosis progression was not normally distributed, with approximately one third of persons progressing to cirrhosis in less than 20 years and another third not appearing to progress to cirrhosis for at least 50 years. Factors associated with an increase in the rate of fibrosis progression were age at which infection occurred (> 40 years of age), daily alcohol use (> 50 g), and male gender. The role of heavy alcohol abuse in exacerbating the risk of cirrhosis has been confirmed.[41] Once cirrhosis develops in patients with chronic HCV infection, the 10-year rates of decompensation of cirrhosis and development of hepatocellular carcinoma are 29% (3.9% yearly) and 14% (1.4% yearly), respectively.[42] Chronic HBV infection also predisposes the infected person to the development of primary hepatocellular carcinoma, perhaps through the integration of viral DNA into the genome of the host's hepatocytes.[43]

Unusual and sometimes fatal complications of acute viral hepatitis include aplastic anemia, hemolytic anemia, hypoglycemia, and polyarteritis. The risk appears to be higher if infection occurs at a very early age or if chronic liver disease is also present.

Differential Diagnosis

At the time of initial presentation with symptoms and elevated aminotransferase levels, before the results of serologic tests are known, it is worthwhile to consider the differential diagnosis of acute viral hepatitis.

EPSTEIN-BARR VIRUS

EBV, a herpesvirus, usually produces mild hepatitis associated with nausea and vomiting; jaundice occurs in only 10% to 20% of patients.[44] Serum aminotransferase levels are moderately elevated (300 to 500 IU/L). In most instances, the hepatitis is part of the typical clinical syndrome of infectious mononucleosis. In rare instances, hepatic dysfunction is severe and proves to be fatal, particularly in immunodeficient patients.[45] The virus appears to be transmitted during oral-oral contact through infected saliva and may be transmitted parenterally; the incubation period is about 28 days. A rise in titer of specific fluorescent antibodies to EBV or detection and quantitation of viral levels confirm the diagnosis.

CYTOMEGALOVIRUS

CMV, which is also a member of the herpesvirus group, is ubiquitous. About 80% of adults have serum complement-fixation reactivity for CMV. This virus can also produce a disease similar to infectious mononucleosis but without adenopathy or tonsillopharyngeal involvement.[46] Liver involvement may mimic that of the more common forms of viral hepatitis, but it is usually mild and does not progress to chronic liver disease. Diagnosis requires inoculation of an appropriate tissue culture with blood to demonstrate viremia. Polymerase chain reaction to assess quantitative viral loads is the best test and is becoming more widely used.

OTHER VIRUSES

Acute hepatitis caused by herpes simplex virus or varicella-zoster virus, usually accompanied by typical skin lesions, has occurred in immunocompromised patients.

DRUG-INDUCED HEPATITIS

Hundreds of drugs can cause hepatitis that may be indistinguishable from acute viral hepatitis.[47] These idiosyncratic drug reactions are infrequent, unpredictable, and not dose dependent. Clinical onset usually occurs within 2 to 6 weeks after therapy is started but may occur on the first day that the drug is administered or not until 6 months later. The disease may progress despite withdrawal of the drug; failure to withdraw the drug promptly may result in death.

One well-documented drug reaction is the hepatic necrosis that occurs in one in 9,000 to 10,000 patients given halothane. The hepatitis is often fatal and is more common in overweight women or in persons exposed a second time to the anesthetic. Fever, malaise, and elevated aminotransferase levels develop 1 to 12 days after initial exposure to the drug. Onset may be sooner after multiple exposures; the average delay is 3 days. Signs of hepatic necrosis include marked eosinophilia, marked elevation of serum aminotransferase and bilirubin levels, reduced serum albumin levels, and a prolonged prothrombin time. Other common drugs that cause hepatitis are isoniazid, methyldopa, phenytoin, and the sulfonamides. Because most drugs will injure the liver on rare occasions, hepatitis that develops shortly after initiation of a new medication should suggest a drug reaction. The treatment of choice is discontinuance of the medication.

Idiosyncratic drug reactions differ from hepatitis that results from drug overdose. Drug reactions of the latter type are rare be-

cause a clear potential for hepatotoxicity usually precludes release of the drug. Acetaminophen, however, is an exception: more than 25 g orally, usually in a suicide attempt, will cause profound hepatocellular necrosis in most persons.[48] Cell injury occurs because the liver produces a toxic metabolite that is usually rendered harmless by conjugation with glutathione. When the drug dose is high, hepatic glutathione stores are depleted and the toxic metabolite accumulates and destroys liver cells. Oral *N*-acetylcysteine, given in a loading dose of 140 mg/kg followed by 70 mg/kg every 4 hours for a total of 18 doses, reduces hepatotoxicity and mortality in cases of acetaminophen overdose.[49] The drug is most effective when given within 8 hours after the overdose but appears to have some effect as long as 24 hours after the ingestion of acetaminophen. Maximal medical support during the 1- to 2-week illness is mandatory. Acetaminophen can also cause severe hepatotoxicity when taken in ordinary doses if hepatic glutathione stores are low as a result of alcoholism with malnutrition (the so-called Tylenol-alcohol syndrome). The beneficial role of *N*-acetylcysteine in this clinical setting is less certain.

Treatment

Many treatments have been recommended for acute viral hepatitis, but it is unlikely that any of them alters the course of the disease. When the patient feels ill, it seems reasonable to reduce physical activity to a tolerable level. For some patients, bed rest may be indicated during the initial phase of illness. Once the patient feels better, there is no reason to restrict activity. Two large, controlled studies of young servicemen with viral hepatitis have shown convincingly that even heavy physical exercise in the recovery period does not result in more frequent relapse or chronic disease.[50,51]

Patients should be encouraged to eat whatever they can; there is no evidence that a low-fat diet is beneficial. At times, nausea and vomiting are so severe that hospitalization and intravenous fluid and electrolyte replacement become necessary. Abstention from alcohol is advised during the acute phase, although alcohol has not been shown to adversely affect the course of viral hepatitis.

Acute HCV infection is usually silent and thus not commonly seen in clinical practice. However, meta-analyses of published studies of interferon therapy for acute HCV infection support its efficacy in this setting.[52,53] It is generally recommended that standard doses of interferon (e.g., 3 million units of interferon alfa-2b three times a week) be administered for 3 to 6 months, which, in comparison with no therapy, increases the likelihood of sustained biochemical (normal ALT levels) and virologic (undetectable HCV RNA) responses.

Many forms of treatment have been recommended for the patient with severe acute viral hepatitis who becomes encephalopathic, but no regimen is clearly effective. In controlled clinical trials, corticosteroids,[54-57] cimetidine,[58] hyperimmune γ-globulin,[59] and exchange transfusions[60] had no effect on the course of acute hepatitis. Although no controlled trials have been completed, liver transplantation improves survival in patients with acute severe viral hepatitis and stage IV hepatic encephalopathy.[61]

Therapy for encephalopathic patients should be supportive, with evaluation for liver transplantation. Bacterial infections should be treated with suitable antibiotics. Bleeding warrants the administration of appropriate clotting factors (fresh frozen plasma, platelets, or both) and transfusions. Clotting abnormalities without bleeding do not justify massive transfusions of fresh frozen plasma, because congestive heart failure can result. Encephalopathy should be treated with oral lactulose (30 ml every 4 hours), although there is little evidence that acute encephalopathy responds to treatment.

Antiviral therapy is available for chronic HBV and chronic HCV infections [*see 4:VIII Chronic Hepatitis*].

Prevention

Prevention of viral hepatitis entails avoidance of exposure to the virus, passive immunization with globulin products, and active immunization with specific vaccines.

PASSIVE IMMUNIZATION

Immune globulin is prepared from human plasma; when given intramuscularly, it decreases the clinical attack rate for HAV by sevenfold to eightfold. The official recommendation of the U.S. Public Health Service is to administer 0.02 ml/kg to contacts as soon as possible after exposure to a confirmed case of HAV infection.[62] Administration more than 2 weeks after exposure is not protective. The usual dose for adults is 2.0 ml; for children weighing up to 25 kg (55 lb), 0.5 ml; and for children between 25 and 50 kg (110 lb), 1.0 ml. Immune globulin should be given to all persons who share a household, hospital room, or dormitory room with an HAV patient. It should also be given to staff and children in day care centers where cases of HAV infection have been identified. When a food handler with acute HAV infection has been identified, immune globulin should be given to coworkers and considered for patrons of the eating establishment if they can be identified and treated within 2 weeks after exposure. Immune globulin need not be given to all contacts at work or school unless there is clear evidence of spread. Classmates and neighborhood children who play together frequently, however, probably should be immunized. Travelers to developing countries are at risk of acquiring HAV, particularly those who plan to visit extensively or to reside in areas with poor sanitation [*see Clinical Essentials:VII Health Advice for International Travelers*]. A single dose of 0.02 ml/kg of immune globulin will be protective for as long as 2 months; a dose of 0.06 ml/kg will be protective for 5 months.[62]

Immune globulin contains anti-HBs at low titer (approximately 1:100 by radioimmunoassay), whereas HBV immune globulin has an anti-HBs titer of greater than 1:100,000. When the source is known to be HBsAg positive, persons exposed (by percutaneous or mucous membrane routes) should be given HBV immune globulin (0.06 ml/kg) and HBV vaccine within 24 hours.[63,64] When the HBsAg status of the source is unknown, the first dose of HBV vaccine should be given promptly and the series completed as recommended. If the source is subsequently found to be HBsAg positive, HBV immune globulin (0.06 ml/kg) should be administered, provided that it can be given within 7 days after exposure. Infants who are born to HBsAg-positive mothers should receive 0.5 ml of HBV immune globulin intramuscularly and 0.5 ml of HBV vaccine intramuscularly at another site within 12 hours after birth.

Prophylaxis against HCV infection with γ-globulin is more problematic. Its effect in household or casual contacts and after a needle-stick injury is unknown. The value of immune globulin in the prevention of HEV infection is also uncertain.

ACTIVE IMMUNIZATION

Two HBV vaccines that are produced by recombinant DNA techniques are available (Recombivax HB, Merck & Co., and Engerix-B, SmithKline Beecham Biologicals) [*see Table 5*].[63,64] Both

Table 5 Administration Schedules and Dosing of Hepatitis B Vaccines[63,64]

Patients	*Schedule*	*Engerix-B*	*Recombivax HB*
Infants			
HBsAg-negative mother	0–2, 1–4, and 6–18 mo	10 μg/0.5 ml	2.5 μg/0.5 ml
HBsAg-positive mother	At birth,* 1–2 mo, and 6 mo	10 μg/0.5 ml	5.0 μg/0.5 ml
Children and adolescents (0–19 yr)	0, 1–2, and 4–6 mo	10 μg/0.5 ml	5.0 μg/0.5 ml
Alternative two-dose regimen for adolescents (11–15 yr)	0 and 4–6 mo	—	10 μg/1.0 ml
Adults (≥ 20 yr)	0, 1–2, and 4–6 mo	20 μg/1.0 ml	10 μg/1.0 ml
Immunocompromised adults (hemodialysis)	0, 1, and 6 mo	40 μg/2.0 ml	40 μg/1.0 ml

*Immunization should occur within 12 hr with hepatitis B immune globulin.
HBsAg—hepatitis B surface antigen

vaccines are highly effective in inducing antibody to HBV and preventing HBV infection in infants, children, and adults. The recommendations of the Centers for Disease Control and Prevention for the use of HBV vaccine are outlined [*see Table 6*].

The vaccines are given in three I.M. doses into the deltoid muscle in young children and adults and into the anterolateral thigh muscle in infants and neonates. A suboptimal response has been observed when the vaccine was injected into the buttocks.[65] The second dose is given 1 month after the first; the third dose is usually given 6 months after the first. For healthy adults, depending on the vaccine preparation, each dose should contain 10 or 20 μg of HBsAg; for patients undergoing hemodialysis and for other immunosuppressed patients, each dose should contain 40 μg; and for infants and children younger than 10 years, each dose should contain 2.5 to 10 μg. The vaccine should be given to groups at substantial risk for HBV infection: hospital staff and other health care workers with frequent exposure to blood products, clients and staff of institutions for the mentally retarded, hemodialysis patients, homosexually active males, users of I.V. drugs, recipients of certain blood products, contacts of HBV carriers, infants born to HBsAg-positive mothers, special high-risk populations (e.g., emigrants from areas with highly endemic disease), and prisoners. It should be strongly considered for travelers who plan to reside in areas with high levels of endemic HBV infection.

Approximately 3% to 4% of healthy people have little or no antibody response to the vaccine. They appear to lack an immune response gene in the major histocompatibility complex that accounts for the ability to mount a normal antibody response to HBsAg.[66] Repeat vaccination induces a protective level of antibody in less than 50% of such people.[67] Those who do not respond to vaccine and who later become infected with HBV do not have an unusual clinical course.

After successful vaccination, titers of antibody to HBsAg begin to decline, and in 5 years, 20% to 30% of patients lack protective levels.[68] These persons will respond immediately to a booster dose of vaccine, but the need for routine booster vaccination has not been determined.[69] HBV infection may develop in a few persons when the antibody titer falls to low levels, but the infection is invariably asymptomatic and is usually identified only by the development of antibody to the core antigen. Thus, several countries and certain individuals have a policy of administering a booster injection to certain risk groups if the anti-HBs level falls below 10 mIU/ml.[70]

Vaccine is useless in HBV carriers, and it is unnecessary for those already immune to HBV; however, it has no ill effects on these groups. Therefore, the decision to screen people for susceptibility to HBV infection before vaccination is primarily based on the relative costs of the two procedures. In general, if the expected prevalence of immune persons in a particular population is high (> 20%) and the cost of screening is low (< $30 a person), screening should be done. However, it is difficult to decide which antibody (anti-HBs or anti-HBc) should be used. Anti-HBc provides definitive proof of HBV infection, but it does not discriminate between HBV carriers and noncarriers. Anti-HBs is usually not present in HBsAg carriers, but even when anti-HBs is present in the general population, it may not indicate immunity to HBV infection. Several studies have identified persons who have low serum titers of anti-HBs but who do not have anti-HBc.[71,72] This low-titer anti-HBs is predominantly of the IgM type and may not be immunoprotective.[72,73] Thus, if anti-HBs is used as the screening test, only a titer of 10 radioimmunoassay sample ratio units or higher or a positive enzyme immunoassay should be considered evidence of immunity.

Several different approaches to the development of active immunization against HAV have been attempted. A successful approach has been the preparation of inactivated HAV vaccines [*see Table 7*]. Other approaches to vaccine development, including a live attenuated and recombinant vaccine, have been slower in development because of a number of technical problems.

A large, randomized, double-blind efficacy trial demonstrating protection against HAV infection was carried out in Thailand.[74] A total of 40,119 children 1 to 16 years of age received Hav-

Table 6 Recommendations for Use of Hepatitis B Vaccine[63,64]

Routine immunization
- All infants and previously unvaccinated children and adolescents 1–18 years of age

Persons at increased risk for HBV infection
- Persons with multiple sexual partners
- Sexual partners or household contacts of HBsAg-positive persons
- Men who have sex with men
- Injecting drug users
- Travelers to regions of high HBV endemicity
- Persons with occupational exposure to blood or body fluids
- Clients and staff of institutions for developmentally disabled persons
- Patients with chronic renal failure
- Patients receiving clotting factor concentrates

HBsAg—hepatitis B surface antigen HBV—hepatitis B virus

Table 7 Administration Schedules and Dosing of Hepatitis A Vaccines

Vaccine	*Patients*	*Dosage*	*Schedule (months)*
Havrix	Children (2–18 yr) Adolescents and adults (> 18 yr)	720 ELU/0.5 ml 1,440 ELU/1.0 ml	0, 6–12 0, 6–12
VAQTA	Children (2–17 yr) Adolescents and adults (> 17 yr)	25 U/0.5 ml 50 U/1.0 ml	0, 6–18 0, 6

ELU—enzyme-linked immunosorbent assay unit

rix or a control HBV vaccine (Engerix-B) at 0, 1, and 12 months. Patients were crossed over to the alternative vaccine at 18 months. Side effects were minor. The efficacy of the HAV vaccine was 94% before the month-12 booster injection and 99% after it. In an earlier trial, researchers evaluated a different inactivated HAV vaccine.[75] They studied 1,037 children in upstate New York and also found that this HAV vaccine was safe and 100% effective in preventing HAV infection 50 to 137 days after administration of a single dose. These studies led to the licensing of a second HAV vaccine, VAQTA (Merck & Co.). Both Havrix and VAQTA are administered to adults in an initial 1 ml dose I.M. followed by a booster in 6 to 18 months.

Compared with the short-term protection afforded by immune globulin, inactivated HAV vaccine will probably induce protection lasting from 5 to 10 years and perhaps much longer.[76] In the United States, the overall incidence of HAV infection has decreased, leading to a higher proportion of adults who are susceptible. Older individuals are known to experience a more severe clinical course, and thus, the costs of HAV infection in the United States remain substantial.[77] These facts underline the importance of ensuring compliance with the current recommendations for HAV vaccination.[62] The vaccine will be particularly useful in preventing HAV infection in persons at high risk for the disease, such as travelers and immigrants to highly endemic regions. The risk of symptomatic HAV infection in travelers staying in Western-style accommodations in high-risk countries is three per 1,000 persons per month.[78] Backpackers or travelers in areas with poor hygienic conditions have a higher risk (20 per 1,000 persons per month). In unprotected travelers from the United States, the incidence of HAV infection is 10 to 100 times that of typhoid fever and 1,000 times that of cholera. Other persons at risk for HAV infection are listed [*see Table 8*].[62] Finally, patients with chronic liver disease may experience a more severe illness with acute HAV infection.[79,80] HAV vaccination has been shown to be safe and effective in patients with chronic viral liver disease.[81]

Table 8 Recommendations for Use of Hepatitis A Vaccine[62]

Routine immunization
- Children living in areas where rates of HAV infection are at least twice the national average (i.e., ≥ 20 cases per 100,000 population); vaccination should also be considered for children in areas where rates are greater than the national average, which is 10–20 cases per 100,000 population

Persons at increased risk for HAV infection
- Persons traveling to or working in countries with high or intermediate HAV endemicity, such as Mexico, the Caribbean, Southeast Asia, South and Central America, and Africa
- Men who have sex with men
- Illegal drug users
- Individuals who work with HAV-infected primates or with HAV in research laboratories
- Persons with clotting factor disorders
- Outbreaks in communities with high or intermediate rates of HAV infection

Persons at increased risk for more severe disease
- Persons with chronic liver disease

HAV—hepatitis A virus

VIII CHRONIC HEPATITIS

Peter F. Malet, m.d., f.a.c.p.

Definition

Chronic hepatitis is a term that encompasses an etiologically diverse group of clinical and pathologic diseases. Chronic hepatitis is characterized by the presence of hepatic inflammation on liver biopsy and elevation of serum liver enzymes, especially transaminases.[1] Chronic hepatitis is generally defined as disease that has lasted for 6 months or longer; in many cases, however, the diagnosis can be established earlier.

Etiology

The most important diseases that cause chronic hepatitis are (1) autoimmune hepatitis (AIH) (previously called autoimmune chronic active hepatitis), (2) chronic hepatitis B, which is caused by infection with hepatitis B virus (HBV), and (3) chronic hepatitis C, caused by hepatitis C virus (HCV) [*see Table 1*].

The hepatitis D virus (HDV) may also be present in some patients with HBV infection. Chronic overuse of alcohol may result in chronic hepatic inflammation (alcohol-induced liver disease or alcoholic hepatitis). Nonalcoholic steatohepatitis (NASH) is similar histologically to alcohol-induced liver disease and is discussed more fully elsewhere [*see 4:IX Cirrhosis of the Liver*]. Less commonly, chronic hepatitis is cryptogenic or caused by drugs. Wilson disease, α_1-antitrypsin deficiency, primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC) are also chronic liver diseases characterized by hepatocellular or bile duct inflammation, but the term chronic hepatitis is not generally used to describe these conditions. Over the past decade, international working groups have substantially modified the terminology of chronic hepatitis to reflect an etiologic basis rather than a pathologic basis.[1] As a result, previously used terms, such as chronic active hepatitis and chronic persistent hepatitis, are no longer used.

Table 1 Major Types of Autoimmune and Chronic Viral Hepatitis

Type/Subtype	*Diagnosis*
Autoimmune	
Type 1 (classic)	(+) ANA
	(+) ASMA
Type 2	(+) anti-LKM1
Type 3	(+) anti-SLA
	(+) anti-LP
Chronic hepatitis B	(+) HBsAg
	(+) anti-HBc
	(-) anti-HBs
	(+) HBV DNA > 100,000 copies/ml
(+) e antigen	(+) HBeAg
	(-) anti-HBe
(-) e antigen	(-) HBeAg
	(+) anti-HBe
Chronic hepatitis C	(+) anti-HCV
	(+) HCV RNA

ANA—antinuclear antibody ASMA—anti–smooth muscle antibody HBc—hepatitis B c antigen HBeAG—hepatitis B e antigen HBsAG—hepatitis B s antigen HBV—hepatitis B virus HCV—hepatitis C virus LKM—liver/kidney microsome LP—liver/pancreas antigen SLA —soluble liver antigen

Approach to Chronic Hepatitis

DIAGNOSIS

Clinical Manifestations

Clinical manifestations of chronic hepatitis are diverse, ranging from asymptomatic disease characterized by mildly elevated aminotransferase levels to severe, rapidly progressive illness and fulminant hepatic failure. The most common symptoms of chronic hepatitis are fatigue, malaise, and mild abdominal discomfort. Patients with mild chronic hepatitis are usually asymptomatic or have minimal symptoms with no stigma of chronic liver disease on physical examination. In more advanced cases, when hepatic synthetic function begins to diminish (a condition referred to as hepatic decompensation), the symptoms and signs may include anorexia, jaundice, spider angiomas, palmar erythema, ascites, edema, and encephalopathy. Pruritus may occur but is unusual; pruritus is more characteristic of PBC or PSC. A small proportion of patients with AIH have an acute fulminant course and are critically ill at initial presentation. Some extrahepatic manifestations of chronic hepatitis include arthralgias, arthritis, glomerulonephritis, and skin rashes.

Standard Laboratory Tests

The serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are usually elevated in patients with chronic hepatitis; however, a minority of patients, especially those who have chronic hepatitis B or C, may have either persistently or transiently normal aminotransferase levels. Therefore, even a mild elevation of aminotransferase levels (5 to 10 IU/L higher than the upper limit of normal) should lead physicians to consider the presence of chronic hepatitis. Elevations of more than 400 IU/L are not unusual in cases of AIH and may occasionally be seen with chronic hepatitis B. Aminotransferase levels that are twofold to threefold higher than the upper limit of normal are common with chronic hepatitis C. The serum bilirubin level is usually normal in chronic viral hepatitis, unless hepatic decompensation has occurred. The serum bilirubin level is higher than 3 mg/dl in patients with moderately severe AIH. A characteristic feature of AIH is an increased γ-globulin level (> 1.6 g/dl), which may sometimes be markedly increased (3 to 7 g/dl). In the most severe forms of chronic hepatitis, hepatic synthetic function is impaired; this is manifested by a decreased serum albumin level and a prolonged prothrombin time.

Imaging studies (i.e., ultrasonography and computed tomography) of the abdomen may be normal in early chronic hepatitis or may show variable degrees of hepatomegaly with or without splenomegaly. When more advanced hepatic fibrosis is present, irregularity of liver texture or contour may be seen. Evidence of portal hypertension with portal collateral vessels or ascites may be seen with advanced disease.

Liver Biopsy

The specific etiology of chronic hepatitis can usually be determined by clinical evaluation combined with serologic testing.

Table 2 METAVIR Scoring System for Grading Severity of Chronic Hepatitis

Grade/Stage	*Grade of Inflammation*	*Stage of Fibrosis*
1	Minimal	Portal
2	Mild	Periportal, rare bridging
3	Moderate	Bridging
4	Severe	Cirrhosis

Liver biopsy can confirm or exclude certain diagnoses and can establish the grade of inflammatory activity and the stage of fibrosis and cirrhosis.

The grade and stage of chronic hepatitis can be assessed with various semiquantitative scoring systems.[1,2] In the histology activity index (HAI) (also known as the Knodell score), the grades of inflammation range from 0 to 18, and the stages of fibrosis range from 0 to 4. The HAI is sometimes used in clinical research studies but is no longer commonly used in clinical practice.[2] The most popular scoring system for chronic hepatitis is the METAVIR system.[3] This system generates two scores from 0 to 4: one for the degree of inflammation and the other for the degree of fibrosis [*see Table 2*]. Other scoring systems are available but are not commonly used in clinical practice. In addition to the characterization of the degree of inflammation and fibrosis, the evaluation of a liver biopsy specimen from a patient with chronic hepatitis includes a description of all the findings present (e.g., steatosis, bile duct changes, granulomas, type of inflammatory cells, presence of iron, and Mallory hyaline) or a notation of their absence.

DIFFERENTIAL DIAGNOSIS

Primary Biliary Cirrhosis

On liver biopsy, PBC may have features similar to those of AIH but is differentiated by the presence of bile duct inflammation or ductopenia. Marked elevation of serum alkaline phosphatase and high titers of antimitochondrial antibody (AMA) (> 1:160) are useful in making the diagnosis of PBC.

Primary Sclerosing Cholangitis

PSC can sometimes mimic chronic hepatitis. Prominent elevations of the serum alkaline phosphatase level and accompanying inflammatory bowel disease will, in most cases, distinguish this disorder from other types of chronic hepatitis. The definitive diagnosis is made by endoscopic retrograde or magnetic resonance cholangiography.

Alcoholic Liver Disease

Liver enzyme elevations caused by alcohol overuse are very commonly encountered in clinical practice. When the patient admits to the overuse of alcohol, the diagnosis is straightforward; however, careful and repeated questioning of the patient and family members may sometimes be required to obtain an accurate assessment of the patient's alcohol use.

Fatty Liver and Nonalcoholic Steatohepatitis

Fatty liver and nonalcoholic steatohepatitis (NASH) are increasingly common liver diseases that are usually associated with obesity or being overweight. Fatty liver is characterized by macrovesicular and, sometimes, microvesicular steatosis without inflammation; serum transaminase levels may be normal or elevated, sometimes severalfold or more. NASH is characterized by hepatocellular inflammation, steatosis, and, usually, elevated serum transaminase levels. NASH may lead to fibrosis or to cirrhosis. Although radiologic studies are useful in the evaluation of suspected fatty liver and NASH, a definitive diagnosis may only be made with liver biopsy.

Drug-Induced Chronic Hepatitis

Drug-induced chronic hepatitis constitutes a small but important category of chronic hepatitis.[4] α-Methyldopa, nitrofurantoin, and isoniazid are well-recognized causes. In addition, cases have occasionally been reported after therapy with sulfonamides, propylthiouracil, diclofenac, terbinafine, and dantrolene; a number of other drugs have also been implicated. Thus, it is reasonable to discontinue as many medications as possible when chronic hepatitis is first diagnosed. If a patient's hepatitis is drug related, liver function abnormalities and the clinical course of disease frequently improve after the causative agent has been withdrawn, although improvement may take weeks or even months.

Wilson Disease

When neurologic abnormalities are absent, Wilson disease can present as chronic hepatitis. It is critical to establish the diagnosis of Wilson disease, because specific treatment with penicillamine, trientine, or zinc is available. In Wilson disease, the serum ceruloplasmin level is low and the 24-hour urinary copper level is elevated. Slit-lamp examination for Kayser-Fleischer rings should also be performed. Measurement of the hepatic copper content in a needle-biopsy specimen is diagnostic.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency, which is usually associated with the presence of homozygous *ZZ* alleles, is associated with progressive liver disease, which evolves into cirrhosis. Liver disease associated with α_1-antitrypsin deficiency can be distinguished from chronic hepatitis by a reduced serum α_1-antitrypsin level and by inclusions in the liver parenchyma that are positive on periodic acid–Schiff (PAS) staining.

Autoimmune Hepatitis

AIH is characterized by portal and periportal inflammation and fibrosis, autoantibodies, and hypergammaglobulinemia.[5] The early recognition of AIH is important because the condition generally responds well to treatment; if left untreated, it can progress to cirrhosis and, occasionally, liver failure and death.

DIAGNOSIS

The diagnosis of AIH rests on the presence of characteristic findings combined with the exclusion of other causes of chronic liver disease. The presentation may be acute or subacute but is more commonly chronic. Other autoimmune diseases may be present concurrently.

Elevated levels of serum transaminase and γ-globulin are typical in AIH. Aminotransferase levels may be slightly elevated or more than 10 times higher than normal. The presence of antinuclear antibody (ANA) or one of the other autoantibodies is common.

A liver biopsy is always useful to establish histologic grading

and staging; it is essential in cases in which the diagnosis is not clear on the basis of clinical and laboratory data. Interface hepatitis (formerly called piecemeal necrosis) is the histologic hallmark of AIH; however, this finding is not specific for AIH. The inflammatory component of AIH consists mainly of mononuclear cells; typically, plasma cells are present, but occasionally, they may not be a prominent feature.

In addition to its diagnostic use, liver biopsy is also an important prognostic tool. Patients with portal or mild periportal hepatitis (i.e., hepatitis that extends outside the limiting plate of the portal tract) generally respond well to therapy, whereas those with bridging necrosis (hepatitis that extends or bridges from one portal tract to another), multilobular necrosis, or cirrhosis respond less well to therapy and are at greater risk for progressive liver disease.

The International Autoimmune Hepatitis Group (IAIHG) has published a diagnostic scoring system for atypical AIH for use in adults when the diagnosis is uncertain.[6] The pretreatment score is based on 12 features, and the posttreatment score includes the response to therapy. A pretreatment score of 10 to 15 signifies probable AIH, whereas a score greater than 15 indicates definite AIH. A posttreatment score of 12 to 17 signifies probable AIH, whereas a score greater than 17 indicates definite AIH.

Disease Types

The wide spectrum of clinical and serologic manifestations of AIH has led investigators to propose several types of AIH[5,7] The distinctions in type are based on seropositive findings; however, it should be noted that in some cases of AIH, no serologic markers are present. All the proposed serologic types of AIH respond similarly to immunosuppressive therapy. Type 1, or classic, AIH is the most common form of the disease in the United States. It is characterized by hypergammaglobulinemia and the presence of ANA, anti–smooth muscle antibody (ASMA), or both. Type 2 AIH is characterized by the absence of ANA and ASMA and by the presence of antibody to liver/kidney microsome (anti-LKM1); it is much less common than type 1 and has been observed primarily in Europe. Type 3 is the least well characterized form of AIH, and it is distinguished by the presence of antibody to a soluble liver antigen (anti-SLA), to a recently characterized liver/pancreas antigen (anti-LP), or to both.

Table 3 Typical Regimens for Treatment of Autoimmune Hepatitis

	Schedule	*Dose*
Monotherapy	Initial dose	Prednisone, 60 mg p.o., q.d.
	Second week	Prednisone, 40 mg p.o., q.d.
	Third and fourth weeks	Prednisone, 30 mg p.o., q.d.
	Thereafter until end point is reached	Prednisone, 20 mg p.o., q.d.
Combination Therapy	Initial dose	Prednisone, 30 mg p.o., q.d. Azathioprine, 50 mg p.o., q.d.
	Second week	Prednisone, 20 mg p.o., q.d. Azathioprine, 50 mg p.o., q.d.
	Third and fourth weeks	Prednisone, 15 mg p.o., q.d. Azathioprine, 50 mg p.o., q.d.
	Thereafter until end point is reached	Prednisone, 10 mg p.o., q.d. Azathioprine, 50–100 mg p.o., q.d.

Overlap Syndromes

Overlap syndromes of AIH and either PBC or PSC have been recognized but are uncommon.[8,9] The term autoimmune cholangitis has been proposed to characterize patients who have biochemical or histologic cholestasis that resembles PBC. These patients test negative for AMA and have a normal IgM level; however, they have high titers of ANA and elevated levels of IgG. Results of cholangiography are normal.

TREATMENT

The standard treatment of AIH is immunosuppressive therapy. Three large randomized, controlled trials evaluated immunosuppressive treatment in patients with severe AIH[10-12]; however, data regarding treatment of patients with mild to moderate AIH are less extensive. The potential benefit of immunosuppressive therapy has to be balanced against the risks, particularly in cases of mild AIH. Most patients who have the clinical, biochemical, and histologic features of AIH should be treated,[5] but treatment may not be appropriate for some patients; for example, patients with advanced cirrhosis and relatively mild abnormalities of serum aminotransferase levels (less than twice the upper limit of normal) are probably not good candidates for such treatment.

The purpose of treatment is to relieve symptoms, decrease hepatic inflammation, and prevent the progression of hepatic fibrosis. The decision whether to initiate treatment can sometimes be problematic, particularly in cases that are atypical (e.g., when test results are negative for all autoantibodies). In such cases, the IAIHG scoring system can be useful in decision making.

Prednisone and Azathioprine Regimens

The usual regimen for most AIH patients consists of a combination of prednisone and azathioprine [*see Table 3*].[5] The starting doses are usually 30 mg of prednisone daily and 50 mg of azathioprine daily. Maintenance doses (until remission is achieved) are usually 20 mg of prednisone daily and 50 to 150 mg of azathioprine daily. Prednisone alone may be used with equal effectiveness; it is administered at a starting dose of 60 mg daily and is tapered over 4 weeks to a maintenance dose of 20 mg daily. Use of azathioprine may not be appropriate in patients who have severe cytopenia (because of the drug's bone marrow suppressive effect), who are pregnant (because of its potential to cause birth defects), or who have active malignancy (because of its potential to interfere with standard cancer treatment regimens). Azathioprine alone will not induce remission, but long-term azathioprine therapy is effective in maintaining remission.[13]

Response to Therapy

Clinical, biochemical, and histologic remission occurs in 65% of patients within 18 months and in 80% of patients within 3 years after starting treatment. In general, symptoms resolve (i.e., clinical remission) within 3 months, serum transaminase levels improve to normal or less than twice normal (i.e., biochemical remission) within 3 to 6 months, and histologic improvement (i.e., histologic remission) occurs within 18 months to 3 years. The presence of serum autoimmune markers, such as ANA, does not influence the initial response to therapy. Failure to achieve remission may represent either incomplete response to therapy or treatment failure. Patients who have an incomplete response to therapy may experience some improvement in clinical, laboratory, and histologic features when adequate therapy is administered. In cases of treatment failure, patients will expe-

rience worsening of disease despite adequate doses and compliance with therapy. Drug toxicities that necessitate the reduction of drug doses may contribute to the failure to achieve remission.

Discontinuance of Therapy

It is not clear-cut when to taper medication doses for the purpose of discontinuance of therapy. One commonly used approach is to begin tapering drugs when clinical and biochemical remissions have been achieved. Some authorities recommend a repeat liver biopsy to determine whether histologic remission has been achieved; however, this approach is not routine practice. When prednisone and azathioprine are used in combination, the dose of prednisone is usually tapered first while that of azathioprine is kept constant at 50 to 150 mg daily. Gradual tapering should occur over several months; however, there is no agreement on the rapidity of the tapering process. Once prednisone is completely discontinued, gradual tapering of azathioprine may begin.

Management of Relapse

Despite every precaution, relapse occurs within 3 to 6 months in approximately 20% to 90% of patients. Relapse is less likely if the histologic findings before tapering show that the hepatic inflammatory activity has completely resolved. If relapse occurs, medication doses should be increased in an attempt to induce remission. Once a patient has a relapse, however, the risk of future relapses is significant.

When a patient has had two or more relapses, a change in treatment approach is warranted[5]; with a change of medications, lower doses can be used to induce remission. After relapse, the aim of therapy is to keep disease activity as quiescent as possible. An acceptable therapeutic end point is a reduction of the serum transaminase level to two times normal or less. Such a serum transaminase level may be achieved with prednisone alone or in combination with azathioprine. Between 80% and 90% of patients can be maintained on a daily dosage of 10 mg of prednisone or less. When both drugs are used, the dose of prednisone can be gradually tapered while that of azathioprine is held constant at approximately 2 mg/kg/day; this combination regimen has a success rate in maintaining disease quiescence that is similar to that of prednisone alone. Limited data are available on the use of drugs such as 6-mercaptopurine and mycophenolate mofetil for the treatment of AIH.

Chronic Hepatitis B

EPIDEMIOLOGY

Chronic hepatitis B is a major global health care problem: 5% of the world's population, or approximately 350 million persons, are chronically infected.[14,15] In the United States, it is estimated that 1.25 million persons are chronically infected.[14] Approximately 0.2% to 0.5% of the United States population is positive for hepatitis B surface antigen (HBsAg); however, chronic HBV infection rates five to 10 times higher have been identified for certain groups, including Asian Americans, immigrants from endemic areas, persons who have received multiple blood transfusions or hemodialysis, intravenous drug users, men who have sex with men, and persons with HIV infection. Age at the time of initial HBV infection is the major determinant of chronicity. As many as 90% of infected neonates develop chronic infection; however, only 3% to 5% of newly infected adults develop chronic infection. Another important risk factor for chronicity is the presence of intrinsic or iatrogenic immunosuppression. Gender is also a well-established but poorly understood determinant of chronicity; women are more likely than men to clear HBsAg. As a result, men predominate in all populations with chronic HBV infection.

Table 4 Typical Serologic Findings in Hepatitis B Infection

Inactive Carrier State (low viral replication)	*Chronic Hepatitis B (high viral replication)*
(+) HBsAg	(+) HBsAg
(+) anti-HBc	(+) anti-HBc
(–) anti-HBs	(–) anti-HBs
(–) HBeAg	(+) HBeAg or (–) HBeAg
(+) anti-HBe	(+) HBeAg and (–) anti-HBe
HBV DNA < 100,000 copies/ml	HBV DNA > 100,000 copies/ml, typically in the range of 1 million to 10 million copies/ml
ALT and AST normal	ALT and AST elevated

ALT—alanine aminotransferase AST—aspartate aminotransferase

Ongoing HBV infection is an important risk factor for the development of hepatocellular carcinoma (HCC). The relative risk of HCC may be 200 times higher in patients with chronic HBV infection than in the general population. Patients with advanced fibrosis and cirrhosis are at highest risk. Evidence suggests that the use of screening tests, including ultrasonography and serum α-fetoprotein, may be useful in the early diagnosis of HCC.[14,16]

DIAGNOSIS

Chronic HBV infection can be readily diagnosed with serologic testing [*see Table 4*]. The diagnosis of chronic HBV infection is made when HBsAg remains detectable for more than 6 months. In a small percentage of patients with chronic HBV infection, mainly those who are inactive HBsAg carriers (i.e., 1% to 2% of patients a year), HBsAg clears spontaneously.

Categories of Hepatitis Infection

There are two broad categories of chronic HBV infection. The terminology to describe these states varies; the American Association for the Study of Liver Disease (AASLD) practice guidelines refer to these categories as the inactive carrier state and chronic hepatitis B.[14,15] A person who is positive for HBsAg, has normal aminotransferase levels, and has little or no necroinflammatory hepatic activity is an inactive HBsAg carrier. In inactive HBsAg carriers, the serum HBV DNA usually is relatively low ($< 10^5$ copies/ml). However, there are some inactive carriers in whom the serum HBV DNA may be much higher (often in the range of 10^7 to 10^{10} copies/ml), and this has been termed the immune-tolerant state. The immune-tolerant state is most characteristic of patients who were infected perinatally, most commonly in southern Asia.

The other broad disease category defined by AASLD practice guidelines is chronic hepatitis B. A person who is positive for HBsAg, has elevated aminotransferase levels, and has significant necroinflammatory hepatic activity is classified as having chronic hepatitis B. In patients with chronic hepatitis B, the serum HBV DNA usually is relatively high ($> 10^5$ copies/ml). In chronic hepatitis B, the HBeAg is usually positive (and anti-HBe negative); however, there is an increasing prevalence of HBeAg-negative disease. HBeAg is negative in patients with chronic he-

patitis B because of a genetic mutation in the HBV DNA genome affecting the production of HBeAg. Chronic hepatitis B is subdivided into HBeAg-positive and HBeAg-negative disease. Typically, HBV DNA levels are somewhat lower in HBeAg-negative disease, and seroconversion from HBeAg to anti-HBe cannot be used as an end point for therapy in these patients.

TREATMENT

The ultimate goal of treatment of chronic hepatitis B is to eradicate HBV infection and prevent the development of cirrhosis or HCC. Interferon, lamivudine, and adefovir dipivoxil [*see Table 5*] can suppress HBV replication and lead to improvement in the clinical, biochemical, and histologic features of chronic hepatitis B.[14,15] The two oral agents, lamivudine and adefovir, are well tolerated. Interferon has a number of potential side effects, and careful consideration must be given to its use.

All patients with chronic hepatitis B should be considered for treatment.[17] In the majority of patients who are not considered suitable candidates for therapy, the severity of disease will be deemed too mild to warrant treatment. The most severely decompensated cirrhotic patients should be treated with lamivudine because of its extremely good tolerability. For those without severely decompensated cirrhosis, the decision whether to use interferon or oral therapy with lamivudine or adefovir is based on a variety of factors, not the least of which is patient preference. Oral therapy is very well tolerated; however, it typically requires several years of treatment to achieve a seroconversion rate comparable to that which can be achieved by interferon therapy in 6 to 9 months. On the other hand, interferon therapy has many more potential side effects and is considerably more expensive. Generally, interferon treatment is appropriate for those patients able to tolerate its potentially adverse effects.

Terminology Used in Describing Response to Treatment

In HBeAg-positive chronic hepatitis B, the term seroconversion indicates the loss of HBeAg and the appearance of anti-HBe. Seroconversion from HBsAg to anti-HBs can also occur, either spontaneously or after interferon treatment. Response to treatment can be (1) biochemical, as evidenced by the normalization of ALT levels; (2) virologic, as evidenced by a marked decrease in HBV DNA levels ($< 10^5$ copies/ml); or (3) histologic, as evidenced by improvement in or resolution of hepatic necroinflammatory activity. Such responses may be seen either during therapy or after therapy has been stopped. The response to treatment is considered a sustained response if remission is maintained for at least 6 months post treatment.

Interferon Therapy

Therapy with standard interferon has been most extensively studied; however, pegylated interferon (interferon alfa-2a and alfa-2b) is being used increasingly in clinical practice because of its once-weekly administration and seroconversion rates that are as good as or better than those of standard interferon regimens.

A large number of trials have demonstrated the efficacy of interferon alfa in the treatment of HBeAg-positive chronic hepatitis B.[14] Doses of interferon alfa have been in the range of 5 million units daily to 10 million units three times a week. Treatment for 16 to 24 weeks results in seroconversion from HBeAg to anti-HBe, a low HBV DNA replicative state in about 35% of patients, and loss of HBsAg and the appearance of anti-HBs in approximately 8% of patients.[17] Predictors of a response to interferon therapy include lower pretreatment HBV DNA levels, higher ALT levels (optimally greater than five times the upper limit of normal), and short duration of infection; patients with such characteristics are optimal candidates for treatment with interferon. Relapse and reappearance of HBeAg occur in about 20% of patients. Patients who fail to seroconvert on interferon therapy should be treated with oral agents. It should be noted that interferon therapy is not equally effective in Asian patients, particularly in those whose ALT levels are only minimally elevated.

Patients with mildly decompensated cirrhosis can be treated with low, titrated doses of interferon, although the safety and tolerability of lamivudine or adefovir would make either of these drugs the first choice for treatment. One third of such patients will respond to therapy and have a sustained loss of HBV DNA and HBeAg, which may be associated with resolution of cirrhotic symptoms. These patients must be monitored closely, however, because bacterial infections and exacerbation of hepatitis are potentially serious complications.

Interferon treatment of HBeAg-negative chronic hepatitis B is less well studied. After 12 months of treatment, a sustained response (normalization of ALT levels and low levels of HBV DNA) can be achieved in about 15% to 30% of patients.[17,18]

The use of pegylated interferon has recently been examined in patients with HBeAg-positive and HBeAg-negative chronic hepatitis B.[19,20] In one study, 194 HBeAg-positive patients were randomized to receive 24 weeks of therapy with 90, 180, or 270 μg of pegylated interferon alfa-2a once a week or with standard interferon alfa-2a, 4.5 mIU three times a week.[19] At 24 weeks' follow-up, the HBeAg seroconversion rates were 37%, 35%, and 29%, respectively, for the three pegylated interferon alfa-2a treatment groups and 25% for the standard-interferon group. In another study of HBeAg-negative chronic hepatitis B, 537 patients were randomized to receive 48 weeks of therapy with 180 μg of pegylated interferon alfa-2a; lamivudine, 100 mg daily; or the two regimens combined.[20] At 24 weeks after cessation of therapy, the rates of biochemical and virologic remission were significantly higher in the groups receiving pegylated interferon; the addition of lamivudine did not improve the response rate. The combination of pegylated interferon and lamivudine continues to be studied, but it is too early to draw conclusions about the efficacy of this treatment.[21]

Table 5 Treatment of Chronic Hepatitis B

Drug	*Dose*
Lamivudine	100 mg p.o., q.d.
Adefovir dipivoxil	10 mg p.o., q.d.
Interferon alfa-2a or alfa-2b	5 million units S.C. daily or 10 million units S.C. three times weekly
Pegylated interferon alfa-2a	180 mg/wk S.C.*
Pegylated interferon alfa-2b	1.5 mg/kg/wk S.C.*

*Optimal dose and duration of treatment are under study.

Side effects of interferon therapy Interferon commonly causes side effects, but these are usually manageable. Among these are influenzalike symptoms (i.e., fever, myalgia, arthralgia, and headache), hematologic toxicity (i.e., granulocytopenia, leukopenia, and thrombocytopenia), systemic symptoms (i.e., fatigue and hair thinning), neurologic signs (i.e., decreased concentration, depression, and irritability), and thyroid dysfunction.

Contraindications to interferon therapy Patients with a history of hypersensitivity to interferon, decompensated cirrhosis,

immunosuppression associated with organ transplantation, active autoimmune disease, or severe psychiatric disease or patients who are elderly or frail are not good candidates for treatment.

Lamivudine Therapy

Lamivudine is a nucleoside analogue that inhibits HBV DNA synthesis. A dose of 100 mg/day achieves maximal suppression of HBV DNA. Lamivudine is cleared mainly in urine, and thus, dose adjustments are required for patients with significant renal failure. It has very few side effects and could be considered for use in virtually any patient with chronic hepatitis B.[14]

Lamivudine and HBeAg-positive chronic hepatitis B In three placebo-controlled studies, improved liver histology occurred in a significantly higher percentage of patients given lamivudine than in patients who received placebo.[22-24] Improvements in liver histology were similar in treatment-naive patients and patients who experienced relapse after interferon therapy or who did not respond to it; the improvements occurred independently of HBeAg seroconversion.[25,26] Serum HBV DNA levels fell rapidly and remained at least 94% below baseline values; serum ALT levels also decreased during therapy, with 50% of patients achieving and maintaining normal ALT levels 2 years post treatment. Patients receiving lamivudine for 1 year experienced a 17% rate of seroconversion from HBeAg to anti-HBe. The seroconversion rate increased progressively with additional years of lamivudine therapy, resulting in 27% seroconversion after 2 years, 33% after 3 years, 47% after 4 years, and 50% after 5 years.[27-30] The cumulative HBeAg seroconversion rate was higher in patients who had elevated baseline ALT levels before treatment. The responses to lamivudine are similar in Asian and non-Asian patients; however, the durability of HBeAg seroconversion appears to be lower in Asian patients (i.e., 60% to 80%). Patients who achieve HBeAg seroconversion can discontinue lamivudine therapy. However, on the basis of limited data, relapse rates may be lower (i.e., seroconversion is more durable) if lamivudine is continued for 3 to 6 months after initial HBeAg seroconversion is documented. The serum levels of ALT and HBV DNA return to pretreatment levels if lamivudine is discontinued before HBeAg seroconversion is achieved. After treatment, some patients may experience serum ALT levels that are transiently higher than pretreatment levels. Generally, no adverse effects have been associated with these elevations, although there are rare reports of severe flares of hepatitis B.

Lamivudine and HBeAg-negative chronic hepatitis B Lamivudine is effective in lowering ALT and HBV DNA levels and improving hepatic histology in patients with HBeAg-negative chronic hepatitis B. Several studies have demonstrated a biochemical and virologic response rate of about 70% at 1 year of therapy[14,17]; however, this response rate decreases to 50% after 2 years and 40% after 3 years. The end point for treatment is unknown, but it is the consensus that treatment beyond 1 year is warranted, provided the patient continues to exhibit a response.[15] The relapse rate after discontinuance of therapy is much higher in these patients than in patients with HBeAg-positive chronic hepatitis B.

Viral resistance to lamivudine therapy Resistant strains of HBV may appear within the first year of lamivudine therapy. The most common mutation imparting resistance occurs near the YMDD (the amino acid sequence tyrosine-methionine-aspartate-aspartate) motif of the HBV DNA polymerase. Resistance to lamivudine therapy occurs in 14% to 32% of patients after 1 year of therapy, 38% after 2 years, 49% after 3 years, 66% after 4 years, and 69% after 5 years.[30] The appearance of lamivudine resistance is manifested by rising HBV DNA and serum transaminase levels. A serologic test detecting HBV mutations imparting lamivudine resistance is available. Generally, patients experiencing lamivudine resistance can be switched to adefovir, which is effective against HBV DNA mutant strains. If patients who develop lamivudine resistance are continued on lamivudine, the initial beneficial effect of treatment on disease activity is usually lost.

Lamivudine and end-stage liver disease Lamivudine plays a role in patients with chronic hepatitis B who have end-stage liver disease. Stabilization and even improvement of biochemical and clinical features of cirrhosis may be seen in a majority of patients. Occasionally, improvement in liver function may result in deferral of liver transplantation.[17,31,32] Lamivudine therapy may serve as a bridge to transplantation for patients with decompensated cirrhosis who are awaiting a donor liver.

Lamivudine and liver transplantation Liver transplantation can be performed for liver failure associated with chronic hepatitis B, but HBV infects the allograft in 80% to 100% of cases if antiviral prophylaxis is not given, and long-term graft survival is only 45% to 50% (compared with 80% to 85% in liver transplant patients with other types of cirrhosis).[32] The HBV reinfection often is accelerated and progresses to cirrhosis. As a result, most transplant centers now implement prophylactic antiviral strategies to reduce reinfection. Before undergoing transplantation, patients should be treated with either lamivudine or adefovir to reduce the HBV viral load. Subsequently, two prophylaxis strategies are (1) the intraoperative, immediately postoperative, and long-term administration of high-dose hepatitis B immune globulin (HBIG) to maintain an anti-HBs level at 100 to 200 mIU/ml or greater, and (2) the administration of HBIG in combination with lamivudine or adefovir.[32] A number of trials suggest that these prophylaxis strategies can reduce the HBV reinfection rate to 10% to 20% and improve 1-year and 3-year graft survival rates.

Adefovir Dipivoxil Therapy

Adefovir dipivoxil is a nucleotide analogue of adenosine monophosphate. Adefovir inhibits HBV DNA polymerase and reverse transcriptase. It is effective against both wild-type and lamivudine-resistant HBV and in both HBeAg-positive and HBeAg-negative chronic hepatitis B.[14,15] Typically, adefovir therapy results in a 3 to 4 $\log_{10}$ drop in serum HBV DNA levels.

In a randomized study involving 515 patients who had HBeAg-positive chronic hepatitis B, treatment with adefovir 10 mg daily for 48 weeks resulted in a 12% HBeAg seroconversion rate.[33] As with lamivudine, the rate of treatment response is higher in patients who have higher pretreatment ALT values. Longer-term studies of adefovir are ongoing, and preliminary results indicate that the HBeAg seroconversion rate increases after 2 years. Adefovir, particularly at higher doses, may result in some renal impairment; therefore, it is prudent to periodically monitor renal function in patients receiving adefovir therapy. Adefovir has not been well studied in patients with chronic hepatitis B and decompensated cirrhosis.

Adefovir therapy in patients with HBeAg-negative chronic hepatitis B results in about a 46% biochemical and virologic response rate after 48 weeks and a 51% response rate after 96

weeks. If therapy is stopped after 48 weeks, relapse occurs in more than 90% of patients.[34,35] Development of drug resistance is much less of a problem with adefovir than with lamivudine. Resistance to adefovir is seen in about 2% of patients after 2 years and 4% of patients after 3 years.

Entecavir Therapy

Entecavir was approved by the Food and Drug Administration in early 2005 for use in the treatment of chronic hepatitis. The efficacy of entecavir is at least comparable to that of lamivudine (at a dose of 0.5 mg orally daily) in previously untreated patients. It is also effective, at a dose of 1 mg orally daily, in patients who develop lamivudine resistance.

Tenofovir Therapy

Tenofovir is related to adefovir. Tenofovir has been approved by the FDA for treatment of HIV infection. Its use in the treatment of chronic hepatitis B is being evaluated, but very limited data have been published.

MANAGEMENT OF HBV REACTIVATION

In some inactive HBsAg carriers, biochemical, clinical, and histologic exacerbations of disease activity have been noted; such exacerbations are characterized by elevated serum transaminase levels, the presence of HBV DNA, and the reversion from anti-HBe to HBeAg. These exacerbations (so-called reactivations) appear spontaneously in about 20% of inactive HBsAg carriers. Repeated reactivations, which are usually asymptomatic, may occur and may lead to progressive fibrosis. Therefore, even inactive HBsAg carriers should be periodically monitored (i.e., every 6 to 12 months) for resurgence of disease activity.

Reactivation may also occur in patients with malignancy during or after cessation of chemotherapy, especially when the chemotherapy regimens include corticosteroids. It is important to be aware of such a possibility because reactivations in these patients, although generally mild, may at times be severe and even fatal. Preemptive therapy with lamivudine in patients with malignancy has been found to decrease the incidence and severity of reactivations.[36,37] Lamivudine therapy should be strongly considered in inactive-HBsAg-carrier patients who are scheduled to have chemotherapy. Patients with chronic hepatitis B who are scheduled to have chemotherapy would presumably already be receiving lamivudine or adefovir; if not, they should be started on lamivudine therapy before initiation of chemotherapy.

Chronic Hepatitis C

EPIDEMIOLOGY

Approximately 30,000 new cases of acute HCV infection are reported annually to the Centers for Disease Control and Prevention. Of these patients, about 80% develop chronic HCV infection.[38] Approximately four million persons in the United States (1.8%) have been infected with HCV, and 74% of these individuals (1.4% of the population) are viremic. The high chronicity rate of HCV infection makes chronic hepatitis C a much more prevalent disease than chronic hepatitis B (0.2% to 0.5% of the general population).

DIAGNOSIS

The diagnosis of chronic hepatitis C is typically made by a positive anti-HCV on enzyme-linked immunosorbent assay and detectable HCV RNA.[38] Serum transaminase levels are usually elevated; about 20% of patients have persistently normal values. Most infected patients are asymptomatic. Liver biopsy may demonstrate the full spectrum of disease severity, ranging from mild portal tract inflammation and no fibrosis to cirrhosis.

Table 6 Treatment of Chronic Hepatitis C

HCV Genotypes	*Drug Regimen*
For HCV genotype 1 (48-wk regimen)	Pegylated interferon alfa-2a, 180 µg/wk S.C., plus ribavirin, 1,000-1,200 mg/day *or* Pegylated interferon alfa-2b, 1.5 µg/kg/wk S.C., plus ribavirin, 800-1,200 mg/day
For HCV genotype 2 or 3 (24-wk regimen)	Pegylated interferon alfa-2a, 180 µg/wk S.C., plus ribavirin, 800 mg/day *or* Pegylated interferon alfa-2b, 1.5 µg/kg/wk S.C., plus ribavirin, 800 mg/day

NATURAL HISTORY

After the onset of acute HCV infection, the infection resolves in 15% to 30% of patients and there is a loss of HCV RNA, although anti-HCV remains detectable. The natural history of chronic hepatitis C typically spans several decades. In general, liver disease progresses insidiously, and cirrhosis may not develop for 2 or more decades, if ever. The natural history may be more prolonged when HCV infection occurs earlier in life. In a Japanese study, the mean interval from blood transfusion to development of chronic hepatitis was 10 years; to development of cirrhosis, 21 years; and to development of HCC (a late risk), 29 years.[39] Similar results were found in a population of patients seen in a referral liver center in the United States: the mean interval from transfusion to cirrhosis was 21 years; and for progression to hepatocellular carcinoma, the mean interval was 28 years.[40]

In a European study designed to examine the natural progression of hepatic fibrosis in patients with chronic hepatitis C, the median interval from the presumed time of infection to cirrhosis, identified by liver biopsy, was 30 years.[41] The rate of progression to fibrosis and cirrhosis was not normally distributed; findings suggested at least three populations of patients with chronic hepatitis C: those with rapid progression of fibrosis (median time to cirrhosis < 30 years), those with intermediate progression, and those with no or slow progression of fibrosis. Independent factors associated with an increased rate of progression to cirrhosis are age greater than 40 years at the time of infection, daily alcohol consumption of 50 g or more, and male gender. Fibrosis progression is not related to HCV RNA level or HCV genotype.

TREATMENT

The current standard of care for chronic hepatitis C involves the use of pegylated interferon (interferon alfa-2a or alfa-2b) in combination with ribavirin [*see Table 6*].[38] Polyethylene glycol (PEG) is a water-soluble polymer that is covalently linked to interferon, which markedly increases the half-life, resulting in sustained serum levels and allowing once-weekly administration. Combination therapy with standard (nonpegylated) interferon and ribavirin is still used occasionally. In patients with certain

comorbid conditions, monotherapy with interferon (either a pegylated or standard form) is advised because of the risk of severe anemia associated with ribavirin use [*see* Side Effects of Combination Therapy, *below*].

Pegylated Interferon and Ribavirin Therapy

The persistence of undetectable HCV RNA for 6 months or more after cessation of therapy is the definition of a sustained virologic response (SVR). The major pretreatment determinant of response is HCV genotype.[38] Patients infected with HCV genotype 1 virus (the most common genotype in the United States) have lower SVR rates (in the range of 42% to 52%) than patients with HCV genotypes 2 and 3 (in the range of 76% to 84%). There are varying responses to treatment of HCV genotypes 4, 5, and 6.

Varying study designs and ribavirin doses have been used to evaluate the efficacy of pegylated interferon (interferon alfa-2a and alfa-2b) and ribavirin combination therapy. Therefore, results of treatment have been reported that often do not reflect comparable treatment regimens, particularly with regard to ribavirin doses. Some studies have used a fixed dose of ribavirin, whereas others have used doses based on weight.[38,42,43] Despite these differences, SVR rates for patients with HCV genotypes 1, 2, and 3 have been similar using either interferon alfa-2a or interferon alfa-2b plus ribavirin at varying doses.

One randomized, double-blind trial clearly addressed the issues of length of therapy and ribavirin doses.[44] In that study, 1,284 patients with HCV genotypes 1, 2, and 3 were randomized to receive pegylated interferon alfa-2a (180 μg/wk) in combination with ribavirin in either a low-dose (800 mg/day) or standard weight-based dose (1,000 or 1,200 mg/day) for 24 or 48 weeks. The SVR for HCV genotype 1 patients was 52% after 48 weeks of treatment using the regimen with 1,000 to 1,200 mg of ribavirin daily versus 41% using the 800 mg ribavirin daily dose; the SVR rates for 24 weeks of treatment were much lower. The SVRs for patients with HCV genotypes 2 and 3 were similar, ranging from 79% to 84%, regardless of which treatment regimen was used. On the basis of the study's findings, 24 weeks of treatment with pegylated interferon and ribavirin at a dosage of 800 mg daily (which resulted in an SVR of 84%) is sufficient to achieve an optimal SVR in patients with HCV genotype 2 or 3. However, patients with HCV genotype 1 must be treated for 48 weeks using pegylated interferon and ribavirin at a dosage of 1,000 to 1,200 mg daily to achieve an optimal SVR. This and other studies have led to the practice of administering treatment for 48 weeks to patients with genotype 1 and for 24 weeks to those with genotype 2 or 3 [*see Table 6*]. Among factors shown to lessen the likelihood of successful therapy are high viral load ($> 2 \times 10^6$ copies/ml), male gender, African-American ethnicity, long duration of infection, and advanced fibrosis.

Early virologic response Because pegylated interferon and ribavirin combination therapy has many side effects, strategies have been studied to determine whether continuation of treatment after an early virologic response (EVR) will likely result in an SVR.[45,46] Such studies have mostly centered on patients with HCV genotype 1, because the standard treatment length is longer and the SVR rates are lower for genotype 1 than for genotypes 2 and 3. The values of HCV RNA at two time points (12 and 24 weeks) have been closely examined. If a patient with HCV genotype 1 does not have an undetectable level of HCV RNA after 24 weeks of treatment, the chance of achieving an SVR with another 24 weeks of treatment is extremely low (i.e., in the range of 1% or less). It is strongly recommended that treatment be halted in such patients, unless individual circumstances dictate otherwise.

Recent studies have focused on the 12-week HCV RNA value and have examined the negative predictive value for achieving an SVR based on various declines in HCV RNA, as compared with baseline values. For HCV genotype 1 patients, failure to achieve a drop of 2 $\log_{10}$ or greater in HCV RNA values after 12 weeks of treatment has a negative predictive value of approximately 97% to 100% for achieving SVR after a full course of 48 weeks of treatment. Clinical judgment must be used in deciding whether to discontinue therapy after failure to achieve a 12-week SVR. The value of determining a 12-week EVR in patients who have HCV genotype 2 or 3 is unclear because virtually all these patients achieve a response at 12 weeks. The utility of determining a 4-week EVR for HCV genotype 2 or 3 patients is under study.

Side effects of combination therapy Side effects are varied and common with interferon and ribavirin combination therapy[38,47] and may necessitate discontinuance of therapy in 10% to 15% of patients. The major side effect of ribavirin is a dose-dependent hemolytic anemia, which is reversible and usually stabilizes after 6 weeks of treatment. For milder degrees of anemia, the ribavirin dose can be temporarily decreased. If the anemia is not corrected by a reduction in the ribavirin dose, epoetin can be used. If severe anemia develops, ribavirin must be discontinued, either temporarily or permanently.

Patients with preexisting moderate to severe anemia usually cannot tolerate the degree of hemolysis that occurs with ribavirin therapy, which can be dangerous. Moreover, patients with cardiovascular disease are particularly at risk should severe anemia develop during therapy, and very careful consideration would have to be given to the decision to initiate interferon monotherapy because of the drug's side effects. Patients with any degree of symptomatic cardiovascular disease are not candidates for interferon monotherapy. Patients with chronic hepatitis C and comorbid conditions preventing the use of ribavirin can be treated with interferon monotherapy, although this treatment has an SVR rate considerably lower than that of combination therapy. Ribavirin is teratogenic; therefore, patients must be advised against its use during pregnancy. Other side effects attributed to ribavirin are rash and nasal or sinus problems.

Interferon can cause or exacerbate depression and other psychiatric symptoms. Caution is warranted in using interferon therapy for patients with depression; however, these patients can often be managed with antidepressants, with or without reduction in interferon dosage. Interferon has many other potential side effects, including leukopenia and thrombocytopenia, thyroid dysfunction, insomnia, hair thinning, headaches, weight loss, various neurologic dysfunctions, and irritability. Deaths have occurred, usually because of sepsis, suicide, or cardiovascular disease.

Sustained virologic response In 5- to 10-year follow-up studies of patients who had an initial posttreatment 6-month SVR, relapse occurred in 1% to 2 % of patients.[48] Following an SVR, there is usually improvement of liver histology, including significant regression of hepatic fibrosis in about 25% of patients. Interferon therapy may delay or prevent liver decompensation resulting from cirrhosis, as well as the development of HCC, particularly in patients who show a sustained response.[49]

Relapse after Treatment

Relapse after a course of therapy is defined by detectable levels of HCV RNA, which were undetectable during treatment. Relapse usually occurs within the first 6 months after treatment. No effective treatment is available to patients in whom relapse occurs after the standard regimen of pegylated interferon and ribavirin.

Nonresponse to Therapy

Nonresponse to antiviral therapy is defined as detectable serum HCV RNA levels during therapy. A variant of nonresponse called breakthrough is characterized by an initial disappearance of HCV RNA, with subsequent reappearance of HCV RNA while the patient is still being treated. There are no effective treatments available for patients who experience a nonresponse to current therapies.

Liver Transplantation

Cirrhosis caused by chronic hepatitis C is the most common indication for liver transplantation. Although hepatitis C virus reinfects the allograft in nearly all cases, the subsequent illness is usually mild, but a small percentage of cases progress to cirrhosis and liver failure. There is no consensus of opinion regarding guidelines for treatment of chronic hepatitis C after liver transplantation.[38] Usually, posttransplant treatment is more difficult because of more severe cytopenia and complications related to immunosuppression.

The author has received grants for clinical research from Roche Pharmaceuticals and Schering-Plough Corporation.

The drugs pegylated interferon alfa-2a, pegylated interferon alfa-2b, and azathioprine have not been approved by the FDA for uses described in this chapter.

IX CIRRHOSIS OF THE LIVER

Ramón Bataller, m.d.
Pere Ginès, m.d.

Cirrhosis is the most advanced stage of most types of chronic liver disease. It is defined as a diffuse disorganization of normal hepatic structure by extensive fibrosis associated with regenerative nodules. Fibrosis is potentially reversible if the causative agent is removed. However, advanced cirrhosis comprises major alterations in the hepatic vascular bed and is usually irreversible.[1] Clinically, cirrhosis is associated with high morbidity and mortality. It leads to a wide spectrum of characteristic clinical manifestations, mainly from hepatic insufficiency and portal hypertension.[2] Major complications include ascites, renal failure, gastrointestinal bleeding, encephalopathy, bacterial infections, and coagulopathy. Cirrhosis is also a risk factor for developing hepatocellular carcinoma (HCC). Decompensated cirrhosis carries a poor prognosis, in both the short and the long term, and orthotopic liver transplantation (OLT) is often indicated.

Epidemiology

Cirrhosis is the ninth leading cause of death in the United States.[3] Chronic liver disease and cirrhosis cause 4% to 5% of deaths in persons 45 to 54 years of age and result in about 30,000 deaths each year. The incidence of newly diagnosed cases of chronic liver disease in the United States is 72.3 per 100,000 population. The prevalence of chronic liver disease and cirrhosis is 5.5 million cases. Over 60% of patients are male. Cirrhosis is more common in Hispanic whites and Native Americans; it is the sixth leading cause of death in those two populations. The economic impact of cirrhosis is considerable, with $1.5 billion in direct costs and $234 million in indirect costs in 2000.[4] In 2002, there were 421,000 hospitalizations for chronic liver disease and cirrhosis.[5]

Etiology and Genetic Factors

In the United States, the main causes of cirrhosis are hepatitis C virus (HCV) infection and alcoholic liver disease, which account for two thirds of all cirrhosis cases. Other major causes are hepatitis B virus (HBV) infection, autoimmune hepatitis, chronic cholestasis (primary biliary cirrhosis [PBC] and primary sclerosing cholangitis [PSC]), and genetic metabolic diseases (hemochromatosis and Wilson disease) [*see Table 1*]. With the current epidemic of obesity, nonalcoholic steatohepatitis (NASH) is increasingly being recognized as a major cause of cirrhosis. Many patients diagnosed with cryptogenic cirrhosis have a history of metabolic syndrome, suggesting a role for NASH in the pathogenesis of their cirrhosis.

Many genes interact with environmental factors to cause cirrhosis.[6] Nongenetic factors that influence progression to cirrhosis include age, alcohol intake, immunosuppressive therapy, and HIV infection. Genetic factors involved in the pathogenesis of cirrhosis are not well known, but they may explain the broad spectrum of responses to the same etiologic agent found in patients with chronic liver disease. Polymorphisms in genes encoding immunoregulatory proteins, inflammatory cytokines, and fibrogenic mediators influence the occurrence of conditions that may cause chronic liver injury (e.g., alcohol abuse, chronic HCV infection, and autoimmune disorders), as well as modulate the progression of chronic hepatitis to cirrhosis.

Pathogenesis

EARLY PHASE: LIVER FIBROGENESIS

Cirrhosis is the end stage of many forms of chronic liver disease that are characterized by progressive fibrosis. Hepatic fibrosis is the result of the wound-healing response of the liver to repeated injury.[7] It consists of the accumulation of extracellular matrix (ECM) proteins, mainly fibrillar collagen, from both increased ECM synthesis and decreased degradation. Myofibroblasts, mostly derived from hepatic stellate cells, are the main ECM-producing cells in the injured liver. Chronic injury promotes the activation of stellate cells into fibrogenic myofibroblasts [*see Figure 1*]. Key mediators of this process include inflammatory cytokines, transforming growth factor–1 (TGF-1), and angiotensin II. The pathogenesis of liver fibrosis varies with the underlying cause. In alcohol-induced liver disease, lipopolysaccharide levels are elevated in portal blood; the lipopolysaccharide activates Kupffer cells to release reactive oxygen species and cytokines, activating stellate cells and sensitizing hepatocytes to undergo apoptosis. The pathogenesis of HCV-induced liver fibrosis is poorly understood. HCV infects hepatocytes, causing oxidative stress and inducing the recruitment of inflammatory cells. Both factors lead to stellate cell activation. In chron-

Table 1 Main Causes of Cirrhosis

Viral diseases	Hepatitis B Hepatitis C Hepatitis D
Autoimmune diseases	Autoimmune hepatitis Primary biliary cirrhosis Primary sclerosing cholangitis Graft versus host disease
Hepatotoxic agents	Alcohol abuse Drugs (e.g., methotrexate, α-methyldopa, amiodarone) Vitamin A intoxication
Acquired metabolic diseases	Nonalcoholic steatohepatitis
Vascular diseases	Chronic right-sided heart failure Budd-Chiari syndrome Veno-occlusive disease Inferior vena cava thrombosis
Genetic diseases	Wilson disease Hemochromatosis Type IV glycogen storage disease Tyrosinemia α_1-Antitrypsin deficiency
Miscellaneous	Secondary biliary cirrhosis Cryptogenic

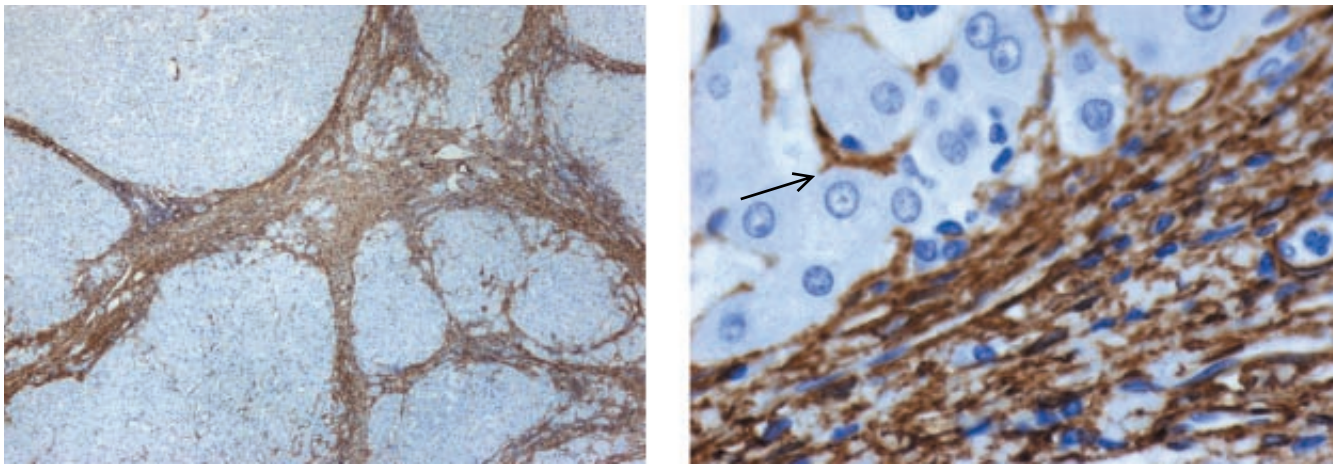

Figure 1 **Immunohistochemical analysis of accumulation of fibrogenic myofibroblasts (smooth muscle [α-actin–positive] cells) in a liver biopsy specimen from a 56-year-old man with liver cirrhosis from chronic hepatitis C infection. The patient was admitted for the study of new-onset ascites. Myofibroblasts mainly accumulate in fibrous septa. Some activated hepatic stellate cells can be observed around hepatic sinusoids (arrow). (*a*) Magnification: ×40; (*b*) magnification: ×600.**

ic cholestatic disorders, such as PBC, T cells and cytokines mediate persistent bile duct damage. Biliary cells secrete fibrogenic mediators that activate neighboring portal myofibroblasts to secrete ECM. Eventually, perisinusoidal stellate cells become activated and fibrotic bands develop. The pathogenesis of liver fibrosis in NASH is poorly understood, but a so-called two-hit model has been proposed: first, hyperglycemia and insulin resistance lead to elevated serum levels of free fatty acids, resulting in hepatic steatosis; second, oxidative stress and inflammatory cytokines promote hepatocyte apoptosis and the recruitment of inflammatory cells, leading to progressive fibrosis.

CIRRHOSIS

Bridging fibrosis is associated with profound abnormalities in hepatic microcirculation.[8] Capillarization of the hepatic sinusoids occurs, and new vessels form within the fibrous sheath. There is a local predominance of vasoconstrictors over vasodilators, resulting in a tonic contraction of perisinusoidal stellate cells that increases vascular resistance. Moreover, thrombosis in small vessels occurs and intrahepatic arterial shunts develop. Hepatocytes proliferate in ischemic areas in a disorganized manner, forming regenerative nodules. Pressure in the portal venous system progressively increases, leading to the development of portocollateral veins and esophageal varices.[9] The resulting portal hypertension leads to splanchnic vasodilatation, which increases hepatic venous blood flow. Systemic vascular resistance is decreased, and eventually, there is a marked activation of systemic vasoconstrictor systems that worsen portal hypertension and favor ascites formation. Hepatocellular function is progressively impaired, and there is decreased function of the reticuloendothelial system, leading to endotoxemia and the increased risk of bacterial infections. Eventually, hepatocellular function fails, resulting in severe coagulopathy and hepatic encephalopathy. A profound circulatory dysfunction from impaired myocardial function and decreased systemic vascular resistance is frequently seen. In very late stages of cirrhosis, renal vasoconstriction develops, leading to the hepatorenal syndrome (HRS). In this phase of the disease, most patients die unless an OLT is rapidly performed.

Diagnosis

The diagnostic process in a patient with suspected cirrhosis is intended to determine the presence, severity, and cause of the condition. Data obtained from the history, physical examination, laboratory tests, and liver biopsy are used to identify the etiology of cirrhosis [*see Table 2*].

CLINICAL MANIFESTATIONS

Cirrhosis can be clinically silent, and some cases are discovered incidentally at laparotomy or autopsy. In many patients, symptoms are insidious in onset and include generalized weakness, anorexia, malaise, and weight loss. Skeletal muscle mass is frequently reduced. So-called compensated cirrhosis is defined by the absence of symptoms or the presence of only minor symptoms. Eventually, most patients exhibit the clinical manifestations of hepatocellular dysfunction and portal hypertension, including progressive jaundice, bleeding from gastroesophageal varices, ascites, and neuropsychiatric symptoms. The abrupt onset of one of these complications may be the first manifestation of cirrhosis. Coagulopathy and subsequent mucosal bleeding typically occur in patients with advanced cirrhosis. Progressive obstruction to bile flow, which is especially common in patients with PBC and PSC, leads to skin hyperpigmentation, jaundice, pruritus, and xanthelasmas. Patients who have progressed to such conditions often experience malnutrition secondary to anorexia, fat malabsorption, and increased catabolism. Deficiency of fat-soluble vitamins is also frequently found in patients with cirrhosis. In patients with alcohol-induced liver disease, extrahepatic symptoms related to the nervous system, the heart, and the pancreas can also be present.

PHYSICAL EXAMINATION FINDINGS

Physical examination can be normal in patients with early cirrhosis. More commonly, the liver is enlarged initially and is palpable. In advanced cirrhosis, liver size usually decreases. Splenomegaly is a common finding. Ascites, peripheral edema, or both may be present, and collateral venous circulation can be observed in the abdomen. Patients with hepatic encephalopathy have altered mental status, decreased consciousness, and asterix-

is. Other signs typical of cirrhosis include muscle wasting, palmar erythema, vascular spiders, gynecomastia, axillary hair loss, testicular atrophy, and fetor hepaticus. In alcoholic patients, Dupuytren contractures, parotid gland enlargement, and peripheral neuropathy can be noted. Skin hyperpigmentation is typical of patients with cholestatic disorders (e.g., PBC) or hemochromatosis. Advanced cirrhosis is commonly marked by severe malnourishment, prominent ascites, and neuropsychiatric symptoms [*see Figure 2*].

LABORATORY STUDIES

Blood Tests

Liver function test results are commonly abnormal in patients with cirrhosis. Serum aspartate aminotransferase (AST) levels are frequently elevated, but levels above 300 U/L are uncommon. Serum levels of alanine aminotransferase (ALT) may be relatively low (AST/ALT ratio greater than 2). Serum prothrombin time is frequently prolonged, reflecting reduced synthesis of clotting proteins, most notably the vitamin K–dependent factors. Serum albumin levels are decreased, mainly because of poor hepatocellular synthesis. Total serum globulin concentration increases in advanced cirrhosis, as a result of poor reticuloendothelial function and increased blood levels of bacterial products. The alkaline phosphatase concentration is usually only moderately increased, except in patients with biliary diseases (i.e., PBC or PSC), who show markedly increased levels of alkaline phosphatase and γ-glutamyl transpeptidase, which in some cases are associated with increased bilirubin levels. Anemia is fairly common; it is usually normocytic, but it may be microcytic, hypochromic from chronic GI bleeding, macrocytic from folate deficiency (in alcoholism), or hemolytic. Hypersplenism can lead to leukopenia and thrombocytopenia. Cholesterol and triglyceride levels may be increased in patients with biliary obstruction, whereas they are low in patients with advanced cirrhosis of nonbiliary origin. Cirrhotic patients may develop glucose intolerance and diabetes mellitus, mainly because of insulin resistance. Central hyperventilation may lead to respiratory alkalosis. Dietary deficiency and increased urinary losses cause hypomagnesemia and hypophosphatemia. Renal failure, as indicated by elevated creatinine and blood urea nitrogen levels, and hyponatremia can be observed in cirrhotic patients with ascites.

Table 2 Identification of the Main Causes of Cirrhosis

Cause	*Diagnostic Method*
Alcohol-related	Medical history (also obtained from relatives), urinary alcohol levels, histologic findings
Hepatitis C virus (HCV)	Anti-HCV antibodies, HCV RNA assay
Hepatitis B virus (HBV)	HBsAg, HBV DNA assay
Hepatitis D virus (HDV)	Anti-delta IgM or IgG
Autoimmune disease	Antitissue antibodies (ANA, LKM, ASMA), hypergammaglobulinemia, histologic findings
Primary biliary cirrhosis	AMA, histologic findings
Primary sclerosing cholangitis	Severe cholestasis; detection of biliary tract abnormalities by magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) or ERCP; ANCA; presence of inflammatory bowel disease; histologic findings
Wilson disease	Serum ceruloplasmin levels, Kayser-Fleischer rings, copper content in the liver, genetic studies
Hemochromatosis	Serum ferritin levels, total iron binding capacity, iron content in the liver, genetic studies
Nonalcoholic steatohepatitis	Metabolic syndrome, histologic findings (may be absent in cirrhosis), absence of alcohol abuse

AMA—antimitochondrial antibodies ANA—antinuclear antibody ANCA—antineutrophil cytoplasmic autoantibodies ASMA—anti–smooth muscle antibodies ERCP—endoscopic retrograde cholangiopancreatography HBsAg—hepatitis B surface antigen LKM—liver/kidney microsomal antibody

Figure 2 **Photograph of a 45-year-old patient with advanced cirrhosis from alcohol-induced liver disease. The patient was admitted because of tense ascites, and a superimposed acute alcoholic hepatitis was diagnosed. A large-volume paracentesis followed by albumin administration was performed.**

Imaging Studies

Real-time ultrasonography, in combination with color flow Doppler, is the most useful tool in the evaluation of patients with cirrhosis.[10] Ultrasonography is useful for demonstrating the morphologic characteristics of cirrhosis, including irregular or nodular liver edges, altered structure, and signs of portal hypertension such as portocollateral veins. It is also useful to detect hepatic steatosis, ascites, splenomegaly, and portal vein thrombosis. In patients with cholestasis, ultrasonography helps rule out extrahepatic causes of jaundice. Doppler ultrasonography provides useful information on portal hemodynamics and can detect reversal of portal blood flow [*see Figure 3*]. Ultrasound examination is particularly helpful for detecting hepatic tumors such as HCC. Demonstration of tumor vascularization by Doppler ultrasonography, with or without injection of ultrasound contrast, is valuable in the differentiation of regenerating nodules from HCC. Dynamic studies using computed tomography and magnetic resonance imaging are also useful in the assessment of cirrhosis and the diagnosis of hepatic tumors previously detected by ultrasonography. The use of CT or MRI to screen for HCC in patients with cirrhosis is limited by the high cost of these techniques.

Liver Biopsy

Liver biopsy can unequivocally establish the presence of cir-

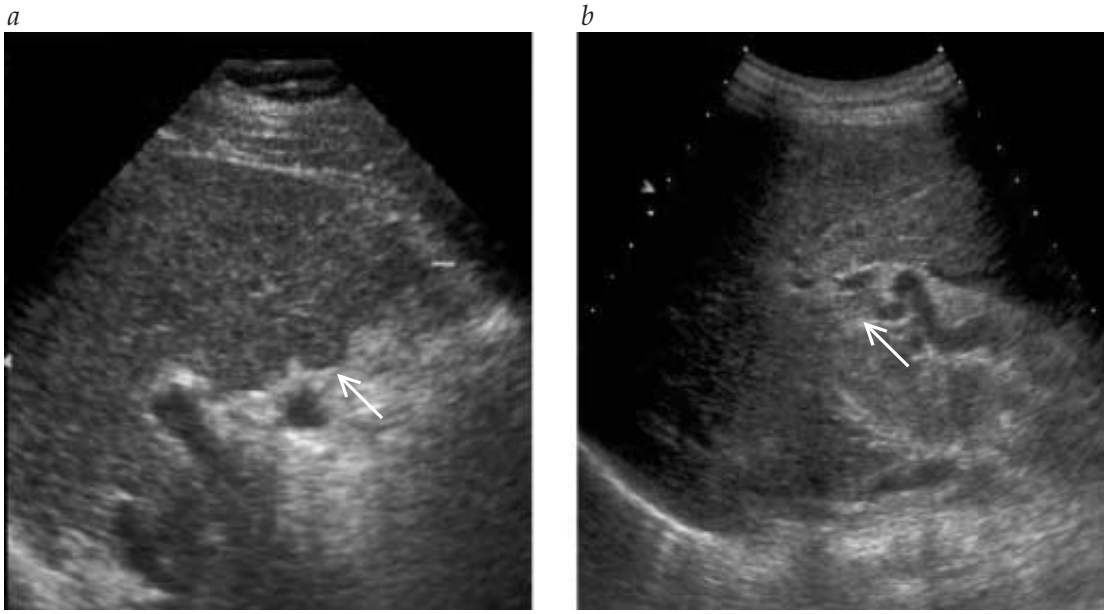

Figure 3 **Real-time ultrasound images of a 56-year-old man with liver cirrhosis from chronic hepatitis C. The patient had a compensated cirrhosis and was undergoing liver ultrasonography plus determination of α-fetoprotein serum levels every 6 months to screen for hepatocellular carcinoma. (*a*) The liver showed irregular edges (arrow) and an altered structure. (*b*) A patent portal vein thrombosis was detected (arrow).**

rhosis.[11] Liver biopsy helps determine the cause of cirrhosis, as well as provides information on the extent of liver damage. The biopsy is usually performed using a percutaneous approach, but percutaneous biopsy should not be used in patients with severe coagulopathy (i.e., those with an international normalized ratio [INR] greater than 1.5 or a platelet count less than 50,000/μl), and it must be used with caution in patients with ascites or severe obesity. Limitations of liver biopsy are that it is an invasive procedure and that sampling error can occur (i.e., false negative results), especially in patients with macronodular cirrhosis.

Transjugular liver biopsy offers an alternative to percutaneous biopsy. Transjugular liver biopsy can be used in patients with ascites; is indicated in patients with severe coagulopathy; and allows the measurement of portal pressure.[12] However, the amount of tissue obtained is limited, and often, the diagnosis of cirrhosis cannot be made. In selected cases, liver biopsy can be performed during laparoscopy. This approach is generally reserved for the staging of cancer or for ascites of unknown origin.

Histologic findings that define cirrhosis include extensive fibrosis and regenerative nodules. The degree of infiltration of inflammatory cells depends on the activity of the underlying disease. Micronodular cirrhosis is characterized by the presence of uniformly small nodules (diameter < 3 mm), whereas in macronodular cirrhosis, nodules vary in size (diameter 3 mm to 5 cm) and contain some normal lobular structure (e.g., portal tracts or terminal hepatic venules).

In some cases, histologic findings help identify the causative agent of cirrhosis, such as periportal lymphocyte infiltration in HCV-induced cirrhosis; Mallory bodies, polymorphonuclear leukocyte (PMN) infiltration, and steatosis in alcohol-induced cirrhosis and NASH; biliary involvement in PBC; and massive iron deposition in hemochromatosis. In advanced cirrhosis, however, different underlying diseases may have similar histologic findings.

Management

GENERAL MEASURES

Cirrhotic patients should undergo regular follow-up. Patients with compensated cirrhosis should be seen two or three times a year. At diagnosis, an extensive medical history should be taken and laboratory tests, including viral serologies, performed to identify the causative agent. Endoscopic examination should be done to assess the presence and size of esophageal varices. Abdominal ultrasonography and α-fetoprotein serum measurements should be performed at diagnosis and every 6 months thereafter to detect early HCC. Criteria for OLT should be reviewed periodically, and major clinical complications (i.e., bacterial infections, renal impairment, and GI bleeding) should be actively prevented.[13] Many patients complain of anorexia, and care should be taken to ensure that patients take in adequate calories and protein. Nutritional supplements are often beneficial. Zinc deficiency is common and should be treated. Zinc sulfate (50 to 200 mg/day) may be effective in the treatment of muscle cramps and is adjunctive therapy for hepatic encephalopathy. Pruritus is a common complaint in cirrhotic patients, especially in those with chronic cholestasis (i.e., PBC and PSC). Drugs that may provide relief for pruritus include cholestyramine, ursodeoxycholic acid, naltrexone, rifampicin, and ondansetron. Some men suffer from hypogonadism; those with severe symptoms can be treated with topical testosterone preparations, although their safety and efficacy are not well studied. Patients with cirrhosis may develop osteoporosis. Supplementation with calcium and vitamin D is important in patients at high risk for osteoporosis, especially patients with chronic cholestasis and those receiving corticosteroids for autoimmune hepatitis. Evidence of decreased bone mineralization from bone densitometry studies also may prompt institution of therapy with a bisphosphonate (e.g., alendronate). Mild exercise, including walking or swimming, should be encouraged in patients with compensated cirrhosis. Debilitated patients frequently benefit from formal exercise programs su-

pervised by a physical therapist. Patients with cirrhosis should be vaccinated against hepatitis A. Other protective measures include vaccination against hepatitis B, pneumococcal infection, and influenza. Potential hepatotoxic medications should be avoided. Patients with ascites should not receive nonsteroidal anti-inflammatory drugs (NSAIDs) or nephrotoxic antibiotics (e.g., aminoglycosides). NSAID use may predispose patients with cirrhosis to development of renal failure or GI bleeding. Surgery and general anesthesia carry increased risks in patients with cirrhosis, particularly those with portal hypertension, and may lead to hepatic decompensation.

COMPENSATED CIRRHOSIS

Specific medical therapies may be applied to different liver diseases to diminish disease progression. However, these therapies may become progressively less effective if chronic liver disease evolves into cirrhosis. In patients with compensated cirrhosis, specific therapies prevent the development of clinical complications and therefore delay the need for liver transplantation. Treatment with pegylated interferon plus ribavirin should be considered in patients with compensated cirrhosis from HCV infection, although the rate of sustained response is lower than in noncirrhotic patients.[14] Moreover, antiviral treatment may worsen existing anemia or thrombocytopenia, and drug discontinuance is frequent. In patients with HBV-related cirrhosis, lamivudine appears to be a safe and effective antiviral agent, which may improve or stabilize liver disease in selected patients with advanced cirrhosis and active HBV replication.[15] However, viral resistance can develop with prolonged treatment. Adefovir and entecavir are newer antiviral agents that have activity against both wild-type and lamivudine-resistant HBV. The most effective measure for patients with alcohol-induced cirrhosis is to stop drinking.[16] Abstinence can stabilize and may dramatically improve liver function. Psychological support is highly recommended to help patients achieve prolonged alcohol abstinence. Nutritional support is advisable in all alcoholic patients. Although small clinical trials have shown improvement in survival and reversal of cirrhosis with colchicine treatment, a randomized, controlled trial found that in patients with advanced alcoholic cirrhosis, there was no reduction in overall or liver-specific mortality with colchicine; although liver histology improved to septal fibrosis in a minority of patients after 24 months of treatment, rates of improvement were similar with placebo and colchicine.[17]

In cases of superimposed alcoholic hepatitis, treatment with glucocorticoids (40 mg/day for 4 weeks followed by tapering of therapy for 1 or 2 weeks) or pentoxifylline (400 mg three times daily) increases short-term survival.[18] In patients with PBC, ursodiol (13 to 15 mg/kg/day) relieves pruritus and improves blood chemistry test results.[19] Although ursodiol may decrease the need for OLT, its usefulness in cirrhotic patients is limited. Other treatments (e.g., glucocorticoids, colchicine, azathioprine) are not indicated, because they are associated with severe side effects. No specific therapy improves the outcome of patients with PSC, but ursodiol does have beneficial effects on biochemical parameters. In patients with cirrhosis from autoimmune hepatitis, immunosuppressant therapy (e.g., glucocorticoids) should be used with caution because it may favor infections, and necroinflammatory injury at this stage of the disease is usually mild. Patients with cirrhosis resulting from hemochromatosis benefit from phlebotomies to reduce iron stores [*see 5:II Red Blood Cell Function and Disorders of Iron Metabolism*]; those with Wilson disease benefit from treatment with copper chelators (i.e., D-penicillamine or trientine) or zinc [*see 11:XV Parkinson Disease and Other Movement Disorders*].

DECOMPENSATED CIRRHOSIS

Ascites

Ascites is the most frequent complication of cirrhosis.[20] It impairs quality of life and increases the risk of bacterial infections. It is caused primarily by splanchnic vasodilatation from increased synthesis of vasodilators (e.g., nitric oxide). Severe splanchnic vasodilatation decreases effective arterial blood volume, which activates systemic vasoconstrictor and sodium-retaining factors. In advanced cirrhosis, solute-free water excretion is also impaired and renal vasoconstriction develops, leading to dilutional hyponatremia and HRS, respectively. Ascites can be graded into three groups: grade 1 ascites is clinically silent and detectable only by ultrasonography; grade 2 ascites is moderate, with patent distention of the abdomen; and grade 3 ascites is tense, with marked abdominal distention.

The first step in the evaluation of patients with new-onset ascites is to rule out extrahepatic causes (e.g., tuberculosis and malignancies). Besides serum tests, ultrasonography is useful to confirm signs of cirrhosis, rule out HCC, and detect portal vein thrombosis. Ascitic fluid should be examined in patients with new-onset ascites, suspected spontaneous bacterial peritonitis (SBP), encephalopathy, or GI bleeding. Measurements should be done of cell counts, albumin and total protein concentrations, and culture in blood culture bottles. Renal function and circulatory status should also be assessed in all patients.

The initial management of ascites includes reduction of sodium intake to 60 to 90 mEq/day. In patients with dilutional hyponatremia (i.e., a serum sodium concentration of 130 mmol/L in the presence of ascites or edema), fluid intake should be restricted to less than 1,000 ml/day, although compliance is problematic. Patients with moderate-volume ascites can achieve a negative sodium balance and loss of ascitic fluid with spironolactone (50 to 200 mg/day) or amiloride (5 to 10 mg/day). Low doses of furosemide (20 to 40 mg/day) may be also added; however, patients should be followed closely to avoid excessive diuresis. The recommended weight loss to prevent renal failure is 300 to 500 g/day in patients without peripheral edema and 800 to 1,000 g/day in those with peripheral edema. Patients with large-volume ascites should be treated initially with large-volume paracentesis. Plasma expanders should be given to prevent paracentesis-induced circulatory dysfunction and renal failure.[21] Albumin is the plasma expander of choice if more than 5 L of ascitic fluid is removed (8 g of I.V. albumin for each 1 L of ascitic fluid removed). Spironolactone (100 to 400 mg/day), with or without furosemide (40 to 160 mg/day), can be given to prevent recurrence of ascites. Doses of diuretics should be adjusted according to diuretic response.

Refractory ascites, which is defined as a lack of response to high doses of diuretics or the occurrence of side effects (e.g., renal failure, encephalopathy, hyponatremia, or hyperkalemia) that preclude the use of diuretics, occurs in 5% to 10% of patients with ascites. Current therapeutic strategies for patients with refractory ascites include repeated large-volume paracentesis with plasma expanders and transjugular intrahepatic portosystemic shunting (TIPS) [*see Figure 4*]. TIPS is effective in preventing ascites recurrence, but it does not improve survival.[22] The principal drawbacks of TIPS are the high rates of shunt stenosis and hepatic en-

cephalopathy. The use of polytetrafluoroethylene-covered prostheses for TIPS can improve patency rates and decrease clinical relapses and the need for reintervention, without increasing the risk of encephalopathy.[23] TIPS is indicated for patients without severe liver failure or encephalopathy who have loculated fluid that cannot be treated with paracentesis and for those who do not tolerate repeated paracentesis. Patients with ascites should be evaluated for OLT, because their 5-year survival rate is only 30% to 40%. Patients with refractory ascites, SBP, or HRS have a worse prognosis, and prioritization in the waiting list should be considered.

Dilutional hyponatremia is present in 30% to 35% of hospitalized patients with cirrhosis and ascites.[24] It reflects impaired excretion of renal solute free water caused by nonosmotic hypersecretion of antidiuretic hormone. Although dilutional hyponatremia is commonly asymptomatic, it may favor the development of hepatic encephalopathy. Management consists of fluid restriction (1,000 ml/day) and discontinuance of diuretics; however, these measures do not correct hyponatremia in many cases. Vasopressin type 2 receptor antagonists are being evaluated for the management of hyponatremia, but they are not available in the United States.

Hepatorenal Syndrome

HRS is the most severe complication of patients with cirrhosis.[25] It is a functional renal failure resulting from extreme renal vasoconstriction [*see 10:VI Acute Renal Failure*]. HRS may occur spontaneously or after precipitating conditions such as SBP, acute alcoholic hepatitis, or large-volume paracentesis without plasma expansion. Diagnostic criteria for HRS have been established [*see Table 3*].[26]

There are two clinical types of HRS. Type 1 is characterized by progressive oliguria and a rapid rise of the serum creatinine concentration to more than 2.5 mg/dl. Survival of patients with type 1 HRS is extremely poor. Type 2 is defined by a moderate and stable increase in the serum creatinine concentration and is frequently associated with refractory ascites.

In type 1 HRS, the use of vasoconstrictors (e.g., terlipressin, midrodine, and norepinephrine) plus intravenous albumin improves renal function in more than half of patients.[27] TIPS is effective for patients with HRS, but its use is not recommended for patients with severe liver dysfunction. These treatments may serve as a bridge to OLT. Liver transplantation is the treatment of choice, but its applicability is limited by the poor survival of these patients.

Spontaneous Bacterial Peritonitis

SBP is a severe infection found in 15% to 25% of cirrhotic patients hospitalized with ascites.[28] Predisposing factors include severe liver insufficiency and low protein content in ascitic fluid (< 1 g/dl). SBP appears to be related to the translocation of GI tract bacteria from the mesenteric lymph nodes. Clinical manifestations are variable, ranging from no symptoms to a severe picture of peritonitis [*see 7:XXI Peritonitis and Intra-abdominal Abscesses*]. SBP should also be suspected in cirrhotic patients with impairment of renal or liver function that has no apparent cause.

The most common causative organisms are *Escherichia coli, Streptococcus pneumoniae, Klebsiella* species, and other gram-negative enteric organisms. SBP is diagnosed when the ascitic fluid has more than 250 PMNs/μl or is positive for leukocyte esterase (3+ or 4+) on urine dipstick testing. Culture results of ascitic fluid are positive in fewer than 50% of patients.

SBP should be treated empirically. The most commonly used regimen is a 5- to 7-day course of a third-generation cephalosporin (e.g., cefotaxime, 2 g every 8 to 12 hours, or ceftriaxone, 1 g/day).[29] Alternatives include oral ofloxacin and other intravenous antibiotics with activity against gram-negative enteric organisms. Development of renal failure during SBP is common and is the most important predictor of mortality. Administration of albumin at a dose of 1.5 g/kg at diagnosis and 1 g/kg 48 hours later prevents renal failure and reduces mortality from 30% to 10%.[30] Response to therapy is indicated by decreases in the signs of infection and in the PMN count in ascitic fluid. After SBP resolution, patients have a 70% chance of recurrence within 1 year. Prophylactic antibiotic therapy can reduce the recurrence rate of SBP to 20%.[31] Current prophylactic regimens include norfloxacin, 400 mg/day, and trimethoprim-sulfamethoxazole, one double-strength tablet 5 days a week. The 1-year survival probability after an episode of SBP is only 40%. Accordingly, eligible patients should be evaluated for OLT after resolution of SBP.

Figure 4 **Transjugular intrahepatic portosystemic shunting is basically indicated for patients with variceal bleeding and refractory ascites. It consists of (*a*) an autoexpandable stent, which is inserted using a transjugular approach. (*b*) The stent (arrow) creates a shunt between a portal vein branch and the inferior vena cava.**

Table 3 Diagnostic Criteria for Hepatorenal Syndrome*

Major Criteria
Low glomerular filtration rate, as indicated by serum creatinine level > 1.5 mg/dl or 24-hr creatinine clearance < 40 ml/min
Absence of shock, ongoing bacterial infection, fluid losses, and current treatment with nephrotoxic drugs
No sustained improvement in renal function (decrease in serum creatinine to ≤ 1.5 mg/dl or increase in creatinine clearance to ≥ 40 ml/min) after diuretic withdrawal and expansion of plasma volume with 1.5 L of a plasma expander
Proteinuria < 500 mg/day and no ultrasound evidence of obstructive uropathy or parenchymal renal disease
Additional Criteria
Urinary volume < 500 ml/day
Urinary sodium level < 10 mEq/L
Urinary osmolality > plasma osmolality
Urinary red blood cells < 50 cells/high-power field
Serum sodium concentration < 130 mEq/L

*According to the International Ascites Club.[26]

Variceal Bleeding

Rupture of gastroesophageal varices because of portal hypertension is a severe and frequent complication of cirrhosis.[32] Portal hypertension is caused by increased intrahepatic vascular resistance, as well as increased portal blood flow secondary to splanchnic vasodilatation. It is recommended that all patients with cirrhosis be screened for gastroesophageal varices and that those with large varices be offered primary prophylaxis. If esophageal varices are very small or absent, it is recommended that an endoscopic examination be performed every 2 years.

Primary prophylaxis of variceal bleeding should be initiated in patients with medium-size to large varices. Nonselective beta blockers (e.g., nadolol or propranolol) are the treatment of choice. They should be given in a stepwise fashion, with the dose being increased until the resting heart rate decreases by 25% of the baseline value. However, there are a number of limitations to the use of beta blockers in such patients (e.g., hypotension).[33] Alternatively, varices can be eradicated by repeated sessions of endoscopic variceal band ligation, although this is more commonly done in Europe than in the United States. Pharmacologic therapy and endoscopic therapy are similarly effective; both reduce the risk of bleeding by 40% to 50%.[34] Endoscopic treatment should be offered to cirrhotic patients in whom the use of beta blockers is contraindicated. The combination of variceal band ligation and beta blockers seems to be more effective than beta blockers alone and is being evaluated in large clinical trials.[35]

Acute variceal bleeding Initial therapy for acute variceal bleeding should be directed at correcting hypovolemia, achieving hemostasis, and preventing severe complications (e.g., renal failure, bacterial infections, and hepatic encephalopathy).[32] Volume replacement, as well as the need for blood transfusion, should be considered. Excessive transfusion should be avoided, because it may increase portal pressure and favor variceal rebleeding. In patients with hepatic encephalopathy and those requiring aggressive sedation for endoscopic examination, endotracheal intubation should be considered. Antibiotics (norfloxacin, 400 mg/day, or cefotaxime, 2 g every 12 hours; both for 7 days) decrease the rate of bacterial infections and improve outcome.[28] Hemostatic treatments include vasoactive drugs, endoscopic band ligation, and surgical portosystemic shunts or TIPS. Vasoactive drugs that are effective in controlling variceal bleeding include octreotide (100 μg bolus, followed by 50 μg/hr for 5 days); alternatives currently unavailable in the United States are terlipressin (2 mg every 4 hours for the first 48 hours, then 1 mg every 4 hours for up to 5 days) and somatostatin (bolus of 250 μg, followed by an infusion of 250 μg/hr for 5 days).[36]

Pharmacologic therapy controls variceal bleeding in 75% to 80% of cases. Cirrhotic patients with upper gastrointestinal bleeding should be initially treated with a vasoactive drug. If the endoscopic examination confirms that esophageal varices are the source of the hemorrhage, variceal band ligation should be performed and drug therapy maintained for 5 days to prevent early variceal rebleeding. This approach controls bleeding in most patients. In patients with massive bleeding, balloon tamponade may temporarily help in controlling the hemorrhage. A repeat session of therapeutic endoscopy can be performed in patients who rebleed. In patients who are hemodynamically unstable or who experience several rebleeding episodes, TIPS or surgical portosystemic shunts or both should be considered.[37,38] TIPS controls bleeding in more than 90% of cases and is preferred over shunt surgery because it is associated with lower morbidity and mortality. However, TIPS can impair liver function in patients with advanced cirrhosis. Patients with preserved liver function (Child-Pugh class A) may also benefit from shunt surgery (i.e., H-graft portacaval shunt or mesocaval shunt).

Because of the high rate of rebleeding (60%), secondary prophylaxis is recommended. Drug therapy with nonselective beta blockers and repeated sessions of variceal band ligation are similarly effective.[39] The beneficial effect of beta blockers should be confirmed by the hepatic venous pressure portal gradient (HVPG), if this is available. A reduction of HVPG to less than 12 mm Hg or by 20% protects patients from variceal rebleeding.[40] The combination of beta blockers and endoscopic band ligation seems to be more effective than either treatment used alone; this combined approach is being evaluated. TIPS, surgical portosystemic shunting, or both should be considered for patients who rebleed despite drug therapy and endoscopic treatment.

Hepatopulmonary Syndrome

The hepatopulmonary syndrome (HPS), which is characterized by hypoxemia from intrapulmonary shunting, a ventilation-perfusion mismatch, or both, develops in some patients with cirrhosis.[41] Patients with HPS have no apparent parenchymal lung disease but have orthodeoxia, the unusual finding of increased hypoxemia with the change from a supine to a standing position. Other typical manifestations include exertional dyspnea, platypnea, and digital clubbing.[42] The diagnostic workup includes arterial blood gas measurements, contrast-enhanced echocardiography, and scanning with technetium-99m–labeled macroaggregated albumin. Pulmonary angiography may be necessary to detect discrete arteriovenous communications. Pharmacologic agents, such as almitrine bismesylate, prostaglandin $F_{2\alpha}$, indomethacin, somatostatin, and methylene blue, have been used to treat HPS, but results have been disappointing. Although TIPS may improve oxygenation, OLT is the only curative treatment; by 6 months after OLT, about 80% of patients with HPS have improved oxygenation.[43]

Hepatic Encephalopathy

Hepatic encephalopathy is a syndrome observed in patients

with advanced cirrhosis that is marked by personality changes, intellectual impairment, neuromuscular dysfunction, and a depressed level of consciousness.[44] The pathogenesis involves altered brain-energy metabolism and increased permeability of the blood-brain barrier, facilitating the passage of neurotoxins.[45] Putative neurotoxins include short-chain fatty acids, mercaptans, false neurotransmitters (e.g., tyramine, octopamine, and β-phenylethanolamines), ammonia, and γ-aminobutyric acid.[46]

The diagnosis of hepatic encephalopathy is made on the basis of altered mental status and neuromuscular signs in the absence of any specific mental or neurologic disease. Hepatic encephalopathy is classified into five grades, according to clinical severity [*see Table 4*]. In addition, hepatic encephalopathy can be classified as episodic, persistent, or minimal. Minimal encephalopathy refers to patients with subtle manifestations of hepatic encephalopathy that cannot be detected by standard clinical examination.[47]

Typical findings on physical examination include asterixis and fetor hepaticus. The serum ammonia level (arterial or free venous) is commonly elevated. Electroencephalography usually shows high-amplitude low-frequency waves and triphasic waves. CT scan and MRI studies of the brain may be important in ruling out neurologic diseases.

Common precipitating factors of hepatic encephalopathy include diuretic therapy, renal failure, GI bleeding, bacterial infections, and constipation. Dietary protein overload is an infrequent cause of worsening encephalopathy. Medications—notably opiates, benzodiazepines, antidepressants, and antipsychotic agents—also may worsen encephalopathy symptoms. Surgical portosystemic shunts and TIPS favor the development of encephalopathy. The differential diagnosis for hepatic encephalopathy includes intracranial lesions, central nervous system infections, metabolic encephalopathy, toxic encephalopathy from alcohol or drugs, organic brain syndrome, and postseizure encephalopathy. In the initial management of hepatic encephalopathy, precipitants should be identified and corrected.[48] Lactulose, lactitol (not available in the United States), or both are helpful in patients with the acute onset of severe encephalopathy symptoms and in patients with milder, chronic symptoms.[49] Lactulose stimulates the passage of ammonia from tissues into the gut lumen and inhibits intestinal ammonia production. The initial lactulose dosage is 30 ml orally once or twice a day. The dose is increased until the patient has two to four loose stools a day. The dose should be reduced if the patient complains of diarrhea, abdominal cramping, or bloating. In hospitalized patients with severe encephalopathy, higher doses of lactulose may be administered via either a nasogastric tube or a rectal tube.[50] Neomycin (2 to 6 g/day), metronidazole (250 mg/day), rifaximin (1,200 mg/day), and other antibiotics (e.g., oral vancomycin, paromomycin, and oral quinolones) serve as second-line agents.[51] Antibiotics work by decreasing the colonic concentration of ammoniagenic bacteria. Other chemicals capable of decreasing blood ammonia levels are L-ornithine–L-aspartate (available in Europe) and sodium benzoate. Low-protein diets are not recommended, because they worsen the catabolic status of these patients and may cause malnutrition. In patients with portosystemic shunts, including TIPS, shunt-diameter reduction can be considered when hepatic encephalopathy is severe and does not respond to medical therapy. Because hepatic encephalopathy carries a poor prognosis, patients with episodic or permanent encephalopathy should be evaluated for OLT. The specific prognosis of patients with minimal encephalopathy is still unknown.

Table 4 Grading of Hepatic Encephalopathy

Grade	*Clinical Manifestations*
0 (subclinical)	Normal mental status, but minimal changes in memory, concentration, intellectual function, and coordination
1	Mild confusion, euphoria or depression, decreased attention, slowing of ability to perform mental tasks, irritability, disorder of sleep pattern (i.e., inverted sleep cycle)
2	Drowsiness, lethargy, gross deficits in ability to perform mental tasks, obvious personality changes, inappropriate behavior, intermittent disorientation (usually for time)
3	Somnolent but arousable, unable to perform mental tasks, disorientation to time and place, marked confusion, amnesia, occasional fits of rage, speech is present but incomprehensible
4	Coma, with or without response to painful stimuli

Hepatocellular Carcinoma

HCC is currently the main cause of mortality in cirrhotic patients.[52] The annual incidence of HCC in cirrhosis from HCV is 3% to 5%. Surveillance to detect early HCC involves the use of ultrasound examination and serum α-fetoprotein measurement every 6 months. In patients with nodules smaller than 1 cm, which are malignant in less than 50% of cases, close follow-up is recommended. HCC diagnosis is based on elevated serum α-fetoprotein levels, ultrasonography, helical CT and MRI findings, and positive cytohistology. The prognosis in patients with early-stage HCC depends on tumor status, liver function, and the treatment applied. Different staging systems (e.g., Barcelona Clinic Liver Cancer [BCLC] or Okuda) use tumor characteristics and liver function to classify patients with HCC.[53] Unfortunately, many HCC patients are diagnosed at advanced stages of disease that preclude the use of curative treatments. The 3-year survival rates of patients at intermediate and advanced stages of HCC are 65% and 16%, respectively. Curative treatments for HCC include surgical resection, OLT, and percutaneous ablation. In well-se-

Table 5 Indications for Liver Transplantation

Disease	*Criteria*
Hepatocellular liver disease	Serum bilirubin > 3 mg/dl Serum albumin < 2.5 g/dl Prothrombin time > 5 sec above control
Cholestatic liver disease	Serum bilirubin > 5 mg/dl Intractable pruritus Progressive bone disease Recurrent bacterial cholangitis
Both hepatocellular and cholestatic liver disease	Recurrent or severe hepatic encephalopathy Refractory ascites Spontaneous bacterial peritonitis Recurrent portal hypertensive bleeding Progressive malnutrition
Hepatocellular carcinoma	< 3 nodules No nodule > 5 cm No portal invasion

lected patients, resection and OLT achieve the best outcomes, with 5-year survival rates of 60% to 70%, whereas 5-year survival rates with percutaneous treatments are only 40% to 50%. Transplantation is the ideal treatment for patients with one tumor and decompensated cirrhosis or multicentric small tumors.[54] Arterial embolization may improve quality of life and, in some cases, even increase survival. Tamoxifen does not seem to have a significant beneficial effect.

Indications for Liver Transplantation

OLT is a central tool for the management of advanced cirrhosis.[55] In the United States, more than 3,000 liver transplants are performed each year. However, because there are many more candidates for transplantation than there are available donor livers, the selection and timing of patient referral are critical. The general indications for OLT are broadly categorized as clinical and biochemical [*see Table 5*]. Biochemical indexes vary, depending on whether liver disease is caused by hepatocellular conditions or chronic cholestatic disorders. Patients should be referred for transplant workup if the serum bilirubin level is greater than 3 mg/dl in noncholestatic disease or greater than 5 mg/dl in cholestatic disorders; if the prothrombin time is prolonged by more than 5 seconds; or if the serum albumin level is below 2.5 g/dl. Clinical criteria include HCC, hepatic encephalopathy, refractory ascites, recurrent variceal bleeding, SBP, and intractable pruritus. The clinical complications of cholestatic liver disease, such as intractable pruritus, recurrent bacterial cholangitis, and progressive bone disease, often warrant liver transplantation before hepatic encephalopathy or variceal hemorrhage develops. HCV-infected patients with decompensated cirrhosis awaiting OLT can be treated with pegylated interferon plus ribavirin; in these patients, treatment can be initiated several months before OLT to prevent graft reinfection.[56]

Contraindications for OLT include severe cardiovascular or pulmonary disease, active drug or alcohol abuse, malignancy outside the liver, sepsis, or psychosocial problems that may jeopardize a patient's ability to follow medical regimens after transplantation. The presence of HIV infection was considered a contraindication to transplantation, but successful liver transplantations are now being performed in patients in whom antiretroviral therapy has eliminated any detectable HIV viral load. Additional clinical study is required before OLT can be offered routinely to such patients.

In the United States, the Model for End-Stage Liver Disease (MELD) is the scoring system used by most liver transplant centers for determining priority for OLT.[57] MELD relies primarily on the bilirubin level, INR, and creatinine level to determine a patient's risk of dying within 3 months if OLT is not performed.[58] Patients' scores are calculated continuously while they are on the waiting list for OLT. Scores typically range from 6 (less ill) to 40 (gravely ill). A MELD calculator is available on the Internet (http://www.unos.org/resources/MeldPeldCalculator.asp?index=98).

Advances in surgical technique, organ preservation, and immunosuppression have resulted in dramatic improvements in postoperative survival over the past 2 decades.[59] In the early 1980s, 1-year and 5-year survival after liver transplantation were only 70% and 15%, respectively; the current rates are 85% and more than 70%. In most cases, patients can anticipate a good quality of life after liver transplantation.

Approximately 15% of patients listed as candidates for liver transplantation die before a donor organ becomes available. Strategies to improve the current donor organ shortage include programs to increase public awareness of the importance of organ donation, increased utilization of living-donor liver transplantation for pediatric recipients, and exploration of the efficacy and safety of living-donor liver transplantation in adults.[60]

Prognosis

The prognosis of patients with cirrhosis depends on the underlying disease, the occurrence of major complications (i.e., ascites, GI bleeding, encephalopathy, HRS, or bacterial infections), the degree of liver insufficiency, and the existence of HCC. In patients with compensated cirrhosis, the 10-year probability of major clinical complications is 58% and that of survival is 47%. For patients with decompensated cirrhosis, prognosis can be estimated by the older Child-Pugh classification and by the MELD score.[61] The variables included in the Child-Pugh score reflect the synthetic (albumin and prothrombin time) and elimination (bilirubin) functions of the liver, as well as major complications (ascites and encephalopathy). In contrast, the MELD score includes only numeric variables that reflect liver function (INR and bilirubin level) and renal function (creatinine level). The principal advantages of the MELD score are that it is based on objective variables selected for their influence on prognosis and that continuous recalculation helps in scoring individuals more precisely among large populations.[58] However, the MELD score has not been validated in some clinical situations. For example, in patients with type 1 HRS, the MELD score may underestimate survival.[62]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

X GASTROINTESTINAL BLEEDING

Elizabeth Rajan, m.d.
David A. Ahlquist, m.d.

Gastrointestinal (GI) bleeding occurs commonly, has many causes, and ranges from trivial to torrential and life-threatening in severity. Practical classification of GI bleeding—based on the presentation, site, and mechanism of the bleed—aids the clinician in selecting an appropriate management algorithm.

GI bleeding is defined as overt when visible red or altered blood is noted in emesis or feces. Overt bleeding is considered major when accompanied by hemodynamic instability and considered minor when not. Occult bleeding is visibly inapparent but is detected directly by stool testing or suggested indirectly by iron deficiency anemia.

GI bleeding occurs when a pathologic process such as ulceration, inflammation, or neoplasia causes erosion of a blood vessel. The size of the eroded artery is an important determinant of the rate of bleeding, the risk of rebleeding, and the clinical outcome. Blood flow and, thus, rate of blood loss vary directly with the diameter of the vessel; small changes in vessel diameter have dramatic effects on bleeding rates. Most GI bleeds result from erosion into small vessels and are trivial and self-limited. Erosion of larger vessels can produce lesions that exceed the capacity of normal hemostasis and result in overt major bleeding. A study of the external diameter of arteries in gastric ulcers that bled recurrently showed a range of 0.1 to 1.8 mm, with a mean of 0.7 mm.[1] Deep, large ulcers are more likely to erode into large blood vessels. Recurrent or persistent bleeding may result from inadequate vasoconstriction because of large vessel size or inflammatory necrosis of the vessel wall, from pseudoaneurysm formation at the bleeding site, or from systemic coagulopathies.

Overt Bleeding

EPIDEMIOLOGY

The reported incidence of GI bleeding varies widely, in part because of varying definitions. Overt minor bleeding, such as from anorectal hemorrhoids, is exceedingly common. Most major bleeding arises from upper GI lesions, and the estimated annual incidence ranges from 40 to 150 episodes per 100,000 population.[2,3] Mortality from upper GI bleeding has remained at 8% to 10% over the past 50 years.[4,5] The fact that, over this period, mortality has failed to decrease substantially despite advances in patient care and technology may reflect the increasing number of elderly patients with complicated comorbidities. Cases in individuals older than 60 years account for 35% to 45% of all cases of acute upper GI bleeding but nearly all of the associated mortality.[6] Lower GI sources account for an estimated 15% to 20% of all major GI bleeds. The incidence of lower GI bleeds increases with age.[7,8]

ETIOLOGY

The causes of GI bleeding are protean [*see Table 1*]. The most common etiologies are briefly elaborated in this subsection.

Upper GI Bleeding

Upper GI bleeding is arbitrarily defined as hemorrhage from a source proximal to the ligament of Treitz (i.e., the esophagus, stomach, or duodenum). Hematemesis essentially always reflects upper GI bleeding, and stools may range from black (melena) to bright red (hematochezia), depending on rates of bleeding and intestinal transit.

Peptic ulcer disease (PUD) The most common cause of upper GI bleeding is PUD, accounting for 60% of cases found at emergency endoscopy.[9] About 50% of cases have a clean-based ulcer with a low probability of rebleeding, so that only pharmacologic intervention is required.[10] Adherent clots, visible vessels, or active bleeding [*see Figure 1*] portend progressively less favorable outcomes unless endoscopic or surgical treatment is applied. Although nonsteroidal anti-inflammatory drug (NSAID) use and *Helicobacter pylori* infection are the two most important risk factors for bleeding in PUD, heavy alcohol ingestion and smoking are also associated with increased risk.[11-13]

Drugs Aspirin and other NSAIDs are responsible for most drug-induced GI bleeding. In the United States, more than 30 billion NSAID tablets are consumed annually. Except for sodium salicylate, all NSAIDs can cause bleeding. Acetaminophen is not associated with GI bleeding.

The elderly are especially susceptible to NSAID-induced GI bleeding.[14] NSAIDs may cause bleeding at any level of the GI tract, but they most commonly do so in the stomach or duodenum. Although the bleeding risk increases in proportion to NSAID dose, any amount (including low-dose aspirin taken for

cardiovascular prophylaxis) may cause bleeding. Use of selective serotonin reuptake inhibitors (SSRIs) has recently been found to be associated with a higher risk of upper GI bleeding, especially in patients who are also taking NSAIDs or low-dose aspirin.[15] Anticoagulants do not cause GI bleeding per se, but they can unmask or aggravate hemorrhage from preexisting lesions.

Variceal bleeding Gastroesophageal variceal bleeding accounts for 10% to 30% of all upper GI hemorrhage. Patients present with overt major bleeding that is sudden in onset. Variceal bleeding is distinctive, with large-volume hematemesis of bright-red blood or clots and associated severe hemodynamic instability [*see Figure 2*]. Because of the cathartic nature of blood, patients may also present with hematochezia. A prospective review found that the distribution of bleeding varices was 75% esophageal and 25% gastric.[16] The most common site of bleeding is the distal 5 cm of the esophagus, because of relatively greater variceal distention and thinner supporting tissue surrounding the veins in this region, compared with the upper and the middle esophagus. Varices are present in 40% to 60% of patients with cirrhosis, and hemorrhage occurs in 25% to 35% of them.[17-19] Approximately one third of first variceal bleeds are fatal.[19] Physicians should bear in mind that up to half of patients with portal hypertension bleed from a nonvariceal cause.[16]

Mallory-Weiss tear Mallory-Weiss tear is a longitudinal mucosal laceration at the gastroesophageal junction or gastric cardia caused by forceful retching or vomiting. Most tears occur within 2 cm of the gastroesophageal junction on the lesser curvature aspect of the cardia. Mallory-Weiss tears account for 5% to 11% of all major upper GI hemorrhages.[20] Most patients present with hematemesis, often associated with alcohol use. Typically, overt bleeding is minor and bleeding ceases spontaneously. Mallory-Weiss tears can also occur with upper GI endoscopy when a patient struggles or retches during the procedure.

Figure 1 **High-risk posterior duodenal bulb ulcer with nonbleeding visible vessel (arrow).**

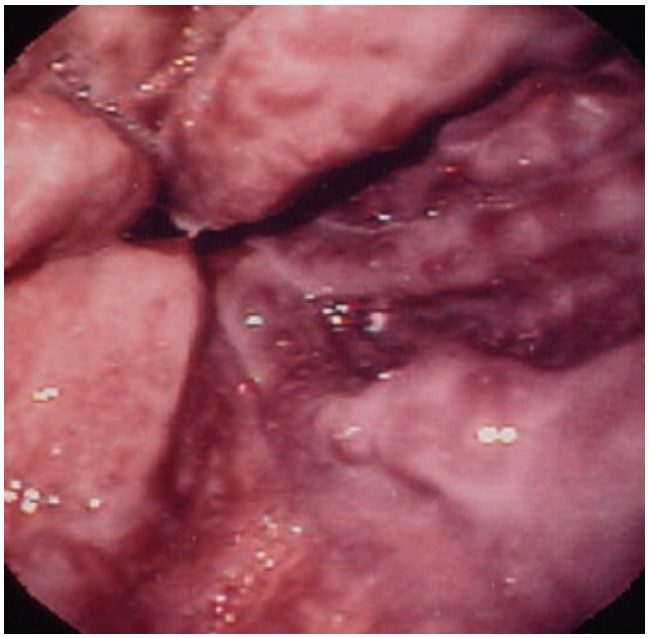

Figure 2 **High-risk esophageal varices with red wale marking.**

Dieulafoy lesions Dieulafoy lesions account for approximately 5% of cases of major upper GI bleeding.[21] Their characteristic feature is the presence of a large-caliber, tortuous artery in the submucosa close to the mucosal surface, which bleeds upon erosion of the overlying mucosa and artery wall [*see Figure 3*]. They can be extremely difficult to detect endoscopically unless actively bleeding. Dieulafoy lesions are usually single lesions located in the proximal stomach. However, these lesions can occur anywhere throughout the GI tract. A review of 90 Dieulafoy lesions identified 34% of lesions as extragastric.[22]

Lower GI Bleeding

Diverticulosis Diverticular disease is one of the most common causes of lower GI bleeding, particularly in the elderly. Diverticulosis is uncommon in persons younger than 40 years, but it affects roughly two thirds of persons older than 80 years.[23,24] The mean age period for diverticular hemorrhage is the sixth decade of life. The true incidence of diverticular bleeding is difficult to ascertain, given the different definitions and evaluations used in various studies. Bleeding occurs from an arteriole at either the dome or neck of a diverticulum. Typically, there is no associated diverticulitis. Diverticula are most commonly found in the left colon, but many bleeds arise from diverticula in the right colon. Patients typically present with painless, large-volume hematochezia. Because diverticular bleeding tends to stop spontaneously, the diagnosis is often presumptive and based on exclusion of other sources of bleeding in a patient with diverticulosis.[25]

Angiodysplasia Angiodysplasia is an acquired vascular ectasia that is considered to be degenerative in origin, given its propensity to occur in the elderly. Typically, patients present between 60 and 80 years of age. The pathogenesis of angiodysplasia remains unclear, but a proposed cause is chronic, intermittent, low-grade obstruction of submucosal veins, leading to dilatation of mucosal capillaries [*see Figure 4*]. The lesions of angiodysplasia are usually small (2 to 5 mm in diameter) and can be single or multiple. These lesions can occur anywhere

Figure 3 **Dieulafoy lesion in gastric fundus (arrow).**

along the GI tract but are most commonly found in the proximal colon (approximately 80%), particularly the cecum.[26] Angiodysplasia is an incidental finding at colonoscopy in 2% of nonbleeding patients older than 65 years.[27,28] Fewer than 10% of patients with angiodysplasia will bleed.[27] Bleeding stops spontaneously in the majority of patients, but rebleeding is common.

Polypectomy Colonoscopic polypectomy is generally considered a safe procedure, but hemorrhage is reported to occur in 0.3% to 6.0% of cases.[29] A retrospective study of 83 patients and 274 polypectomy sites found that bleeding occurred at a median of 5 days (range, 0 to 17 days) after the procedure.[30] Bleeding was associated with advanced age, polyps greater than 1 cm in diameter, sessile polyps, and polyps in the cecum. The prognosis for these patients is favorable. Most cases are managed with observation or endoscopic hemostasis.

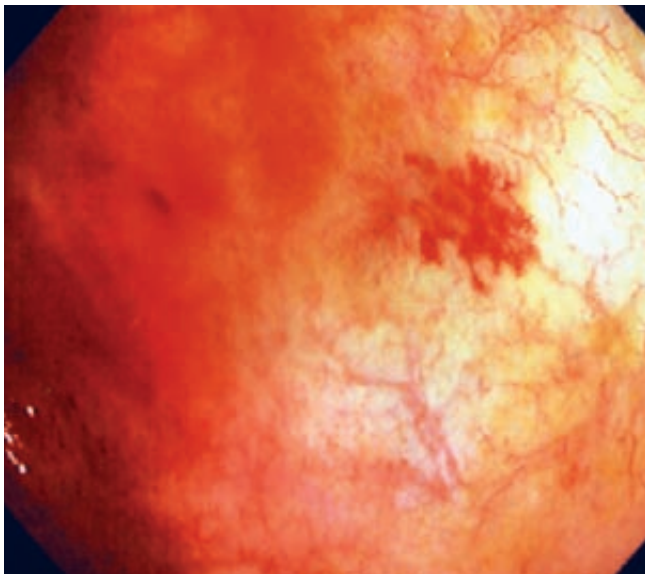

Figure 4 **The lesions of angiodysplasia are usually small (2 to 5 mm in diameter) and can be single or multiple. These lesions can occur anywhere along the GI tract but are most commonly found in the proximal colon, particularly the cecum.**

Diagnosis

EMERGENT EVALUATION AND MANAGEMENT

Management of GI bleeding is determined by the severity of the bleed; algorithms differ with major bleeding [*see Figure 5*] and minor bleeding [*see Figure 6*]. Patients with overt major bleeding require immediate hospitalization with intensive monitoring. Patients are initially stabilized with fluid and blood component replacement and with correction of any coagulopathy or electrolyte imbalances. Endotracheal intubation may be necessary. Stabilization is followed by immediate endoscopic evaluation and therapy as indicated. If hemorrhage control is ineffective and the patient continues to be hemodynamically unstable, radiologic or surgical interventions are considered.

CLINICAL AND LABORATORY ASSESSMENT

The history and physical examination provide vital information on the location, severity, and duration of bleeding and can help identify patients at increased risk of exsanguination and rebleeding [*see Table 2*]. It is important to remember that patients with overt major bleeding from an upper GI source can present

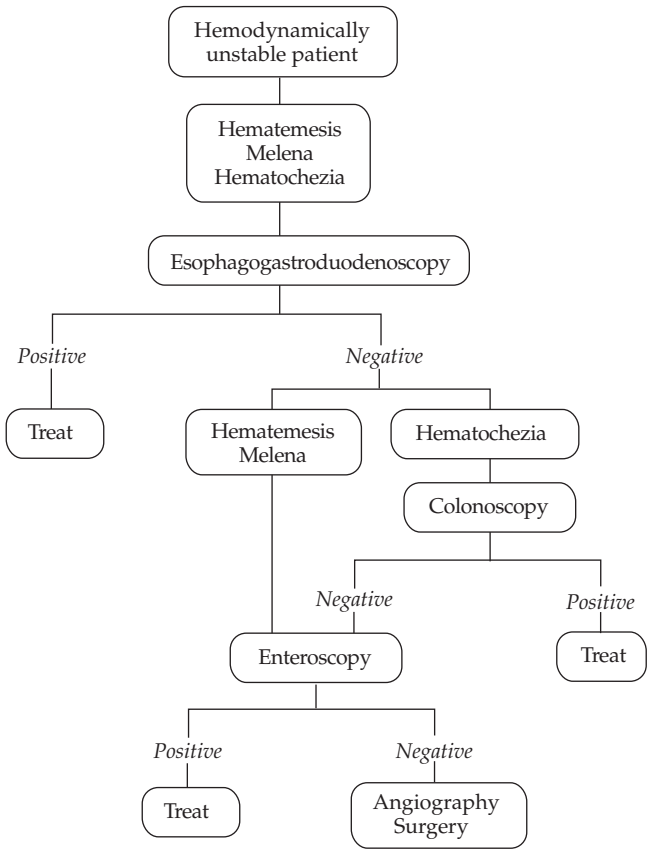

Figure 5 **Evaluation and management of overt major gastrointestinal bleeding.**

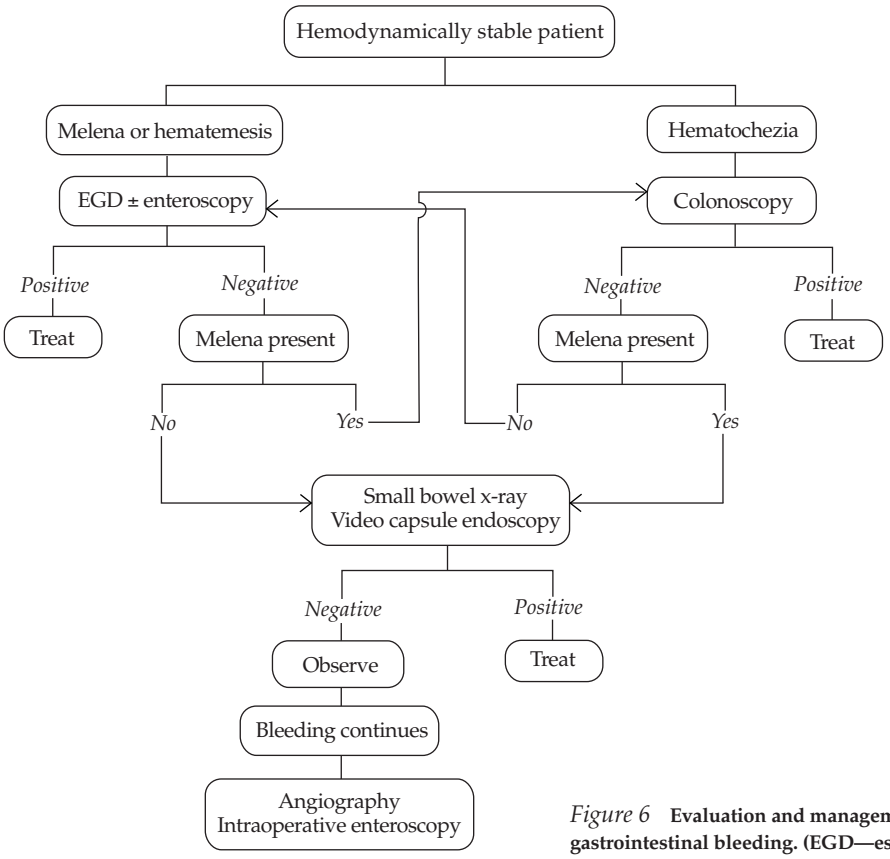

Figure 6 **Evaluation and management of overt minor gastrointestinal bleeding. (EGD—esophagogastroduodenoscopy)**

with hematochezia. These patients can experience visceral discomfort and orthostatic symptoms shortly after the onset of bleeding. Abdominal pain—especially periumbilical cramping and gaseous distention—usually indicates rapid intestinal transit of blood and suggests a major bleed.

The physician should look for evidence of liver disease, PUD, coagulopathy, previous abdominal aortic aneurysm repair, and significant comorbidities such as heart disease and diabetes mellitus. A history of drug or alcohol ingestion may suggest a diagnosis.

After cessation of active upper GI bleeding, patients may experience melena for 2 to 3 days. This does not indicate rebleeding, especially if the hemoglobin level does not decrease.

Serial recording of vital signs is crucial in determining whether an overt major bleed has occurred. Significant volume loss is indicated by hypotension (systolic blood pressure less than 100 mm Hg), orthostasis (a decrease in systolic pressure of more than 20 mm Hg or an increase in heart rate of more than 20 beats/min), tachycardia (heart rate greater than 100 beats/min), or a drop in hemoglobin of more than 2 g/dl. Further assessment of skin pallor, features of liver disease or portal hypertension, and stool color from rectal examination can also help with diagnosis or management.

A nasogastric tube can be placed if there is uncertainty about the location of the bleed in a patient with hematochezia or if bleeding persists in a patient with hematemesis. Aspiration of blood indicates a recent upper GI bleed, but absence of blood in the aspirate does not exclude a recent bleed.

The most important laboratory measurement to assess severity of the initial bleed and to monitor rebleeding is the hemoglobin level. An abrupt drop of more than 2 g/dl indicates a significant bleeding episode. An increase in the ratio of blood urea nitrogen to creatinine to more than 25:1 strongly suggests an upper GI source. Measurement of serum electrolyte concentrations, coagulation indices, platelet count, and liver enzyme levels aids in the diagnosis and guides management.

ENDOSCOPY

In most patients, the location of the bleed is identified by upper GI endoscopy or colonoscopy. Endoscopy also provides therapeutic options and essential information on the risk of rebleeding [*see Table 3*]. There are established visual criteria, based on stigmata of recent hemorrhage, that the endoscopist can use to identify patients at high or low risk for rebleeding.

During upper GI endoscopy, if massive active bleeding is encountered, it is prudent to discontinue the procedure and protect the airway by endotracheal intubation before proceeding. If vi-

Table 2 Clinical High-Risk Criteria for Rebleeding and Mortality

Advanced age (≥ 70 yr)
Major organ comorbidities
In-hospital bleed
Bright-red hematemesis in patient with liver cirrhosis
Hypotension (systolic blood pressure < 100 mm Hg)
Tachycardia (heart rate >100 bpm)
Orthostasis (BP drop > 20 mm Hg; HR rise > 20 bpm)
Hemoglobin < 10 g/dl or drop of ≥ 2 g/dl
≥ 4 units of blood transfused in 24 hr

Table 3 Endoscopic High-Risk Stigmata for Rebleeding and Indications for Endoscopic Therapy

Nonvariceal bleeding	Arterial spurting Oozing bleed Nonbleeding visible vessel Adherent clot
Variceal bleeding	Large varices (> 5 mm esophageal, > 1 cm gastric) Red wale marks (longitudinal dilated venules resembling whip marks) Cherry-red spots (< 2 mm diameter) Hematocystic spots (> 4 mm diameter)

sualization is impaired, use of large-bore orogastric lavage or a jumbo-channel (6 mm) therapeutic endoscope to evacuate blood and clots may be effective. Erythromycin lactobionate (125 mg intravenously) can also be used to promote quick intestinal transit of blood when active bleeding has stopped.

Before colonoscopy, whenever possible, patients should receive a rapid colonic lavage with 2 to 3 L of a nonabsorbable polyethylene glycol solution administered through a nasogastric tube over 2 hours to cleanse the colon and facilitate adequate visualization.

RADIOLOGY

Selective visceral angiography is considered when endoscopic therapy for an established lesion has failed and surgery is not an option or when the site of an active bleed remains obscure after endoscopy. An optimal examination with a high positive yield is best obtained when there is active bleeding at rates exceeding 0.5 to 1 ml/min. Significant complications—including contrast reaction, acute renal failure, and femoral artery thrombosis—have been reported in approximately 9% of cases.[31,32] The reported sensitivity of angiography varies from 22% to 87%. The specificity approaches 100%.[33]

Radionuclide Technetium Scan

A technetium-99m–labeled red cell scan should be considered when active bleeding is suspected but endoscopy has been negative. Nuclear scans can detect bleeding at rates that exceed 0.1 ml/min. On scans, however, pooled blood may sometimes be mistaken for active bleeding, which contributes to a reported false positive rate of about 22%.[34] Upper GI bleeding may be misdiagnosed as lower because of pooling in the distal ileum or right colon. A positive result is more reliable when the scan is done early rather than delayed (several hours later).

Other Measures

Endoscopic techniques that are currently available for examination of the small bowel include push enteroscopy, wireless capsule endoscopy, and intraoperative enteroscopy. Push enteroscopy typically reaches into the proximal jejunum only, whereas wireless capsule enteroscopy and intraoperative enteroscopy reach the entire small bowel.

Enteroscopy is currently performed using a pediatric colonoscope with or without an overtube. In one study, the diagnostic yield of enteroscopy in overt GI bleeding was 46%; the most common lesions seen were angiodysplasia and ulcers.[35]

Wireless capsule endoscopy represents a new technology involving an easily swallowed 11 × 30 mm capsule. No sedation is required. The capsule contains a color video chip, light source, and transmitter. The patient wears an antenna array on a belt. While transiting through the intestine by peristalsis, the capsule takes color photos and sends them to the antenna array. These images are then downloaded onto a computer after the examination. There is a total of 6 to 8 hours of recording time. This technique may be beneficial in patients with recurrent or occult GI bleeding of obscure origin, but it is not appropriate in unstable patients with major active bleeding.

Intraoperative enteroscopy, performed during exploratory laparotomy, through single or multiple enterotomy sites, is indicated for the occasional patient with active or recurrent major bleeding of obscure origin. Complications include mucosal laceration, intramural hematoma, mesenteric hemorrhage, and intestinal ischemia.[36]

Treatment

NONVARICEAL BLEEDING

Endoscopic Therapy

A variety of endoscopic modalities are currently available for the management of GI bleeding. These can be categorized into thermal, mechanical, and injection devices. Thermal devices are either contact (e.g., heater probe, multipolar electrocautery) or noncontact (e.g., argon plasma coagulator, laser). These devices generate sufficient heat to create a hemostatic bond through tissue desiccation. The heater probe consists of a Teflon-coated hollow aluminum cylinder with a heating coil. Only heat (no electrical current) is delivered to the tissue. Multipolar or bipolar cautery works by completion of an electrical circuit between two electrodes on the probe tip. The argon plasma coagulator utilizes high-frequency monopolar alternating current delivered to target tissue through ionized argon gas. The conduit of argon gas is called the argon plasma. Electrons flow through a channel of electrically activated, ionized argon gas from the probe electrode to the tissue, causing a thermal effect at the interface. In laser photocoagulation, which is less frequently used, the conversion of light to heat results in coagulation or vaporization of tissue. The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is the one most commonly used. Mechanical devices for hemostasis include metallic clips and rubber-band ligators. An injection solution that is generally used to achieve hemostasis is saline mixed with epinephrine at a 1:10,000 concentration.

These therapeutic modalities are used alone or in combination. A common practice is to start by injecting epinephrine and saline submucosally in the region of active bleeding so as to stop or slow hemorrhaging and therefore allow for adequate inspection. Thermal or mechanical modalities are then used to achieve definitive hemostasis. Prospective, controlled studies have confirmed the benefit of endoscopic intervention in achieving initial hemostasis and in prevention of rebleeding.[37] Combination therapy (i.e., injection plus thermal therapy) has been demonstrated to reduce rebleeding rates more successfully than single therapy.[38,39] Currently, combination therapy using injection followed by either a thermal or a mechanical intervention is the most effective approach. Rebleeding after endoscopic therapy occurs in approximately 20% of cases, typically within 48 to 72 hours after treatment. However, rebleeding can occur as late as 7 days after therapy.

Pharmacotherapy

Initial drug therapy for major nonvariceal upper GI bleeding is directed at gastric acid suppression. In a randomized, double-blind study of high-dose omeprazole versus placebo, rebleeding after endoscopic therapy occurred less frequently in the omeprazole group (7% versus 23%).[40] In general, proton pump inhibitors are administered in doses that reduce gastric acidity. Blood clot stability depends on intragastric pH, with optimum stability at a pH of 6 or higher.[41]

In patients with PUD, long-term acid suppression and eradication of *H. pylori* infection after endoscopic intervention promote ulcer healing, including ulceration at the treatment site, and reduce rebleeding substantially. GI bleeding from NSAIDs is best prevented by avoiding these drugs or by using a cyclooxygenase-2 (COX-2) inhibitor plus a proton pump inhibitor.

Radiologic Intervention

Selective arterial embolization and selective vasoconstriction with intra-arterial infusion of vasopressin are the methods currently available for the control of major nonvariceal GI bleeding. The proponents of embolization favor this form of therapy because it reduces the need for intensive care observation and it eliminates indwelling arterial lines, the risk of catheter dislodgement, and problematic systemic side effects of intravenous vasopressin [*see* Pharmacotherapy, *below*]. Advances in catheter design have allowed for superselective embolization of vasa recta; in experienced units, this modality is probably the treatment of choice. A study of superselective embolization in 48 patients with lower GI bleeding showed that embolization was the definitive treatment in 44% of patients, with a 27% technical failure rate.[42] The risks associated with embolization include misplacement of embolic material, inadvertent distal reflux of embolic agent, and excessive devascularization of an organ leading to ischemia and eventual luminal stenosis. Endoscopy can be helpful in determining ischemic injury if suspected. Microcoils (e.g., stainless steel, platinum), gelfoam pledgets, polyvinyl alcohol particles, and collagen suspensions have been used for embolization.

Intra-arterial vasopressin is the drug of choice for selective vasoconstrictive therapy and is generally infused for a minimum of 24 hours. It is associated with a 70% rate of bleeding control and an 18% rate of rebleeding.[43-45] Vasopressin may be ineffective when bleeding arises from large arteries that do not constrict in response to therapy. A study comparing embolization with vasopressin showed similar initial hemostasis rates but a higher rebleeding rate with vasopressin.[2] The use of intra-arterial provocative mesenteric angiography with heparin and tissue plasminogen activator (t-PA) to aid in diagnosis has been described but is still in the experimental stage.

Surgery

Despite the high overall success rate of endoscopic therapy in the treatment of major GI bleeding, surgery is still indicated when (1) initial hemostatic control cannot be achieved, (2) rebleeding occurs despite repeated endoscopic sessions, (3) a large (> 2 cm) penetrating ulcer is present, (4) a vessel larger than 2 mm in diameter is visible within the culprit lesion, (5) the ulcer is located in the posterior duodenal bulb (this location is associated with the large gastroduodenal artery), and (6) the patient requires substantial transfusion (i.e., four or more units of blood over 24 hours). The choice of surgery depends on the location of the bleed and the presence of comorbidities. Localization of the site of bleeding is critical for surgical planning.

VARICEAL BLEEDING

Endoscopic Therapy

With variceal bleeding, endoscopic treatment is used primarily for esophageal varices, and the techniques include sclerotherapy and band ligation. Sclerotherapy utilizes a variety of sclerosants to induce variceal thrombosis, with sodium tetradecyl sulfate and ethanolamine oleate used most frequently. Intravariceal injections are more effective than paraesophageal injections in controlling bleeding. Compared with a sham injection, sclerotherapy is significantly more likely to stop bleeding (91% versus 60%), reduce mortality during hospitalization (mortality, 25% versus 49%), reduce rebleeding rates (rebleeding, 20% versus 51%), and reduce transfusion need (four versus eight units).[46] Complications of sclerotherapy include retrosternal chest pain, fever, ulceration (usually deep ulcers that heal within 3 weeks), dysphagia, delayed perforation (1 to 4 weeks later), and stricture formation. Complication rates vary from 19% to 35%.[47-49] The popularity of sclerotherapy has diminished as a result of these complications.

Band ligation is now considered the first-line endoscopic therapy for esophageal varices. The band ligator is readily attached to the distal end of the endoscope, which is advanced to the varix; the endoscopist then suctions the varix into the ligator cap and deploys a rubber band around the varix. This results in the plication of the varices and surrounding submucosal tissue, with fibrosis and eventual obliteration of varices. Comparative studies report a better initial control of bleeding (control rates, 91% versus 77%) and lower rebleeding rates (rebleeding, 24% versus 47%) with band ligation than with sclerotherapy.[47] Complications of banding include retrosternal chest pain, dysphagia from compromise of the esophageal lumen, band ulceration (usually superficial ulcers that heal within 2 weeks), esophageal injury from the overtube, or esophageal perforation. Complication rates vary from 2% to 19%.[50,51]

If bleeding continues despite endoscopic therapy or if endoscopic therapy cannot be initiated, then a modified Sengstaken-Blakemore (Minnesota) tube should be inserted. However, this is only a temporary measure until more definitive treatment—endoscopic, radiologic, or surgical—can be undertaken.

Preventive measures may be indicated in patients with esophageal varices. Preventive measures are generally offered to patients who have a history of a bleed and to those who have large esophageal varices without a prior bleeding event. Currently, the accepted preventive measures for variceal bleeding include endoscopic band ligation, beta-blocker therapy, or a combination of both. Ligation is performed every 14 to 21 days until varices are completely eradicated, which typically requires three or four sessions.

Pharmacotherapy

In acute variceal bleeding, splanchnic blood flow and portal pressure can be reduced by intravenous infusion of vasoconstrictors such as vasopressin, terlipressin, somatostatin, and octreotide. Vasopressin is a potent vasoconstrictor that has a reported overall success rate of 50% but a high rebleeding rate when treatment is discontinued.[52] It has a short half-life and therefore is given as a continuous infusion. Vasopressin-induced hypertension and bradycardia have the potential to confound hemodynamic monitoring and may give false reassurance in the face of active bleeding. Because the systemic vasoconstrictive side effects associated with vasopressin may lead to myocardial

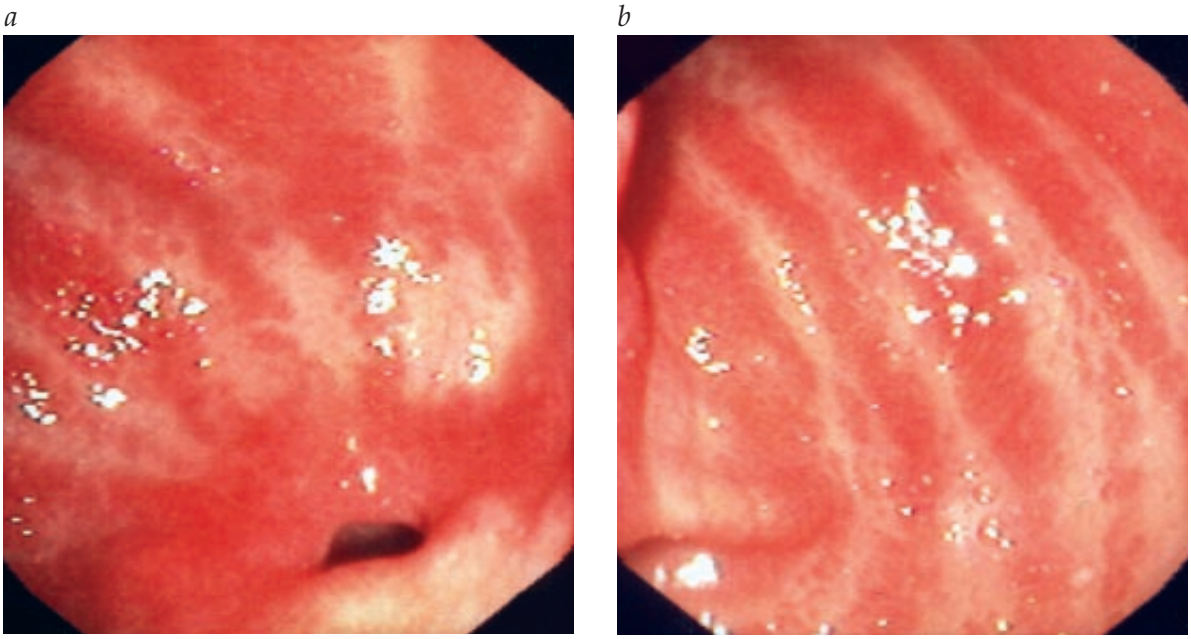

Figure 7 **Watermelon stomach with (*a*) typical spokes of vascular ectasia radiating from the pylorus into the antrum and (*b*) close-up view.**

or mesenteric ischemia, it is rarely used alone. To minimize these side effects, it is given in conjunction with nitroglycerin. The nitroglycerin can be administered as a continuous infusion, sublingually, or by transdermal patch. Terlipressin is a synthetic analogue of vasopressin that has fewer side effects and a longer half-life and is given in bolus injections; however, terlipressin has not yet been approved for use in the United States.

Somatostatin, a naturally occurring peptide, is reported to stop variceal bleeding in 80% of patients.[17,53] Side effects are few and include hyperglycemia and abdominal pain. Octreotide is a synthetic analogue of somatostatin that is preferred because of its longer half-life. The combination of pharmacologic treatment (e.g., octreotide for 5 days) and endoscopic therapy appear to offer better control of acute bleeding than either alone.

The role of beta blockers is primarily prophylactic. These agents are not used in the acute management of variceal bleeding. The use of isosorbide mononitrate with beta-blocker therapy does not offer a survival advantage and in fact reduces the tolerability of therapy.

Radiologic Intervention

The radiologic intervention available for variceal bleeding is transjugular intrahepatic portosystemic shunt (TIPS). The accepted indications for TIPS are bleeding or rebleeding that cannot be controlled by either pharmacologic or endoscopic therapy. TIPS is contraindicated in patients with severe hepatic failure, chronic heart failure, hepatic encephalopathy, bile duct obstruction, or cholangitis. TIPS is reported to control bleeding in at least 90% of patients, with rebleeding rates of 12% to 26% at 1 year and 16% to 44% at 2 years.[54,55] Patients require close surveillance for shunt dysfunction (evidenced by reduced flow by Doppler ultrasound or reappearance of varices) because primary shunt patency rates are poor (reported cumulative patency rates of 50% at 1 year and 21% at 3 years) but cumulative secondary shunt patency rates can be as satisfactory as 85% and 55% at 1 and 3 years, respectively.[55] TIPS should not be undertaken lightly, because the overall procedure-related mortality can be as high as 1% to 2%,[54] largely from intraperitoneal hemorrhage. Other complications include hepatic encephalopathy, portal vein thrombosis, renal failure, sepsis, and stent migration or stenosis.

Surgical Intervention

Surgical intervention is rarely used for variceal bleeding; it is considered when other measures have proved ineffective. Surgical treatments include portosystemic venous shunt operations and esophageal devascularization. A variety of surgical shunts are available. These are generally classified as total, partial, or selective, depending on the intended impact of portal flow diversion. The end-to-side portacaval shunt is a total shunt that diverts all portal blood flow into the inferior vena cava. The side-to-side portacaval shunt diverts only a part of the portal blood flow. Selective shunts decompress variceal flow while preserving portal blood flow. The distal splenorenal shunt is a selective shunt designed to prevent encephalopathy, which is often seen with total shunts. Surgical shunts are used for both esophageal and gastric varices. Encephalopathy, accelerated progression of liver failure, and perioperative morbidity can occur with surgical intervention. Esophageal devascularization may be an effective means of controlling acute variceal bleeding, but bleeding can recur as additional varices develop.

Occult Bleeding

The critical metabolic sequela of occult GI bleeding is iron deficiency.[56] Occult GI bleeding causes most cases of iron deficiency in adults, especially in men and postmenopausal women.

ETIOLOGY

Most of the many lesions that cause overt bleeding can also produce occult blood loss. However, variceal and diverticular hemorrhage invariably bleed overtly, whereas lesions such as watermelon stomach (gastric antral vascular ectasia) and diaphragmat-

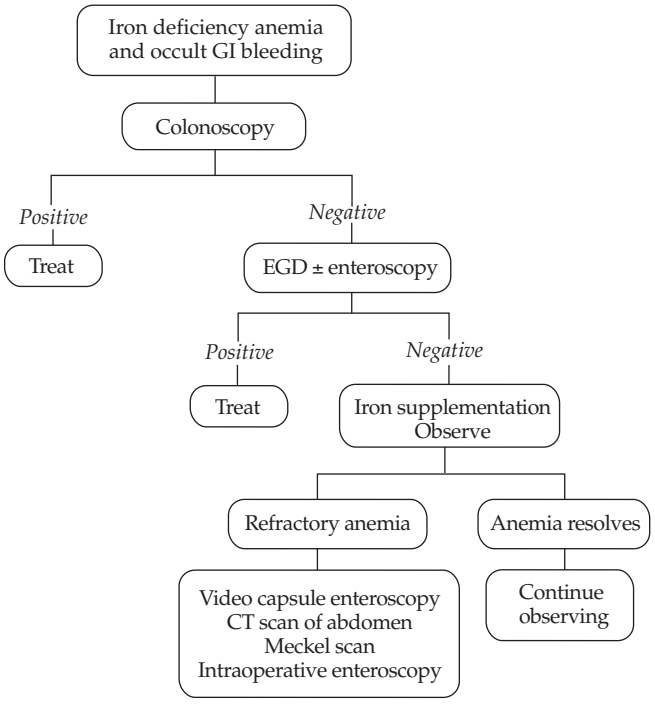

Figure 8 **Evaluation and management of occult gastrointestinal bleeding.**

ic hernia with Cameron erosions tend to bleed occultly. Occult GI bleeding in most patients is suspected only when manifested by fatigue, pallor, or the finding of iron deficiency.

Inflammation

In Western countries, erosive or ulcerative diseases of the esophagus, stomach, and duodenum are the most common GI lesions associated with occult bleeding and iron deficiency anemia. Most peptic disease is caused by either *H. pylori* infection or use of drugs such as aspirin or other NSAIDs. The association between large diaphragmatic hernias and iron deficiency anemia has long been known. A large diaphragmatic hernia is found in about 10% of iron-deficient patients.[57] Blood loss in these patients is generally caused by longitudinal mucosal erosions (Cameron erosions) located proximally in the hernia and believed to be secondary to repeated mechanical trauma from respiration.

Cancers and Neoplasms

In adults from Western countries, GI tumors are second only to PUD as a cause of occult bleeding leading to iron deficiency anemia.[58] Colorectal cancer is currently the most common source of occult bleeding from GI tract malignancies.

Vascular Causes

Vascular malformations are found in approximately 6% of adults with iron deficiency anemia.[59,60] This may be acquired or hereditary (hereditary hemorrhagic telangiectasia). An increasingly recognized and endoscopically treatable vascular lesion is watermelon stomach [*see Figure 7*], which typically presents as iron deficiency anemia in older women.

TREATMENT

When a patient is found to have iron deficiency and occult GI bleeding, it is critical to conduct a thorough GI investigation. Such an evaluation may disclose a health-threatening lesion, in which case specific therapy can be given to prevent associated morbidity and further iron loss. Only after a specific lesion has been treated or has been ruled out, is it appropriate to place patients on iron therapy and monitor them [*see Figure 8*].

Whatever the culpable lesion, treatment with iron supplementation is important to correct iron deficiency. With conditions such as Cameron erosions, iron supplementation is the mainstay of treatment. Most patients can be managed as outpatients. Oral iron therapy with ferrous sulfate is preferred because it is inexpensive, effective, and, in most cases, well tolerated [*see 5:II Red Blood Cell Function and Disorders of Iron Metabolism*]. A maximal adult dose of ferrous sulfate is 325 mg three times a day. Absorption is not appreciably increased with higher doses. Oral iron is as effective as parenteral iron in repleting iron stores, except in patients with a malabsorption syndrome, and is safer.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XI DISEASES PRODUCING MALABSORPTION AND MALDIGESTION

Charles M. Mansbach II , m.d.

Definition

Malabsorption refers to the impaired intestinal absorption of nutrients. It can result from congenital defects in the transport of nutrients or from acquired defects in the absorptive surface of the intestinal epithelium. Maldigestion, another factor in nutrient absorption, refers to the impaired digestion of nutrients within the intestinal lumen. Although these two processes are pathophysiologically distinct, they are interdependent; and in clinical practice, malabsorption has come to signify derangements in both processes.

Overview of Diseases Producing Malabsorption

Malabsorption is clinically defined as impaired absorption of fat (steatorrhea), because measuring fat absorption is the best indicator of the normality of the overall process of nutrient absorption. Under certain conditions, however, fat absorption may be normal but other substances may be poorly absorbed, such as iron, calcium, bile salts, or, in certain hereditary conditions, specific amino acids, disaccharides, or monosaccharides.

etiology

Generally, there are three possible causes of fat malabsorption: small bowel disease, liver or biliary tract disease, and pancreatic exocrine insufficiency [*see Table 1*].

Small Bowel Disease

Small bowel disease can result in moderate amounts of fat in the stool (7 to 30 g/day on a diet containing 100 g of fat). Patients with small bowel disease may leak protein (protein-losing enteropathy) through a diseased intestinal mucosa, which results in a reduced serum albumin concentration. Deficiencies of fat-soluble vitamins (i.e., vitamins A, D, E, and K) may be present in small bowel disease. Patients may malabsorb vitamin B_{12} because of a very diseased or previously resected (usually over 60 cm) terminal ileum. Folic acid may also be malabsorbed, and hypocalcemia and hypomagnesemia may also be present.

Liver or Biliary Tract Disease

Patients with liver or biliary tract disease usually have only small increases in fat in the stool (7 to 15 g/day) and may also malabsorb fat-soluble vitamins. The association of cholestatic liver disease, especially primary biliary cirrhosis, with osteoporosis is well known. Osteoporosis may be the presenting symptom of the liver disease. Vitamin K deficiency, as shown by a prolonged prothrombin time, may also occur. Administration of vitamin K corrects the clotting defect in cases where the extent of the liver disease is not severe enough to impede clotting factor synthesis.

Pancreatic Exocrine Insufficiency

Patients with pancreatic exocrine insufficiency may have up to 80 g of fat/day in the stool. That they absorb fat at all is the result of the action of gastric lipases. Gastric lipase is present in the chief cells of the human stomach[1] and is thought to account for any lipid absorbed in the setting of chronic pancreatitis as exemplified by cystic fibrosis. Indeed, in cystic fibrosis, an increase in gastric lipase has been reported.[2]

clinical manifestations

The symptoms of malabsorption are protean. In the most obvious case, the patient complains of weight loss despite a good appetite. In these cases, there is a clear change in the quality of the stool and usually an increase in stool number. The consistency of the stool softens, and in the presence of excess fat, the stool becomes more malodorous and is difficult to flush down the toilet. Oil drops or a lipid sheen may appear on the water. Excess gas in the stool causes the stool to float.[3]

Depending on other dietary constituents that are malabsorbed, patients may experience a distended abdomen, borborygmi, abdominal cramps (lactose intolerance), easy bruising (vitamin K deficiency), osteopenia or tetany (vitamin D deficiency and calcium malabsorption), iron deficiency, or night blindness (vitamin A deficiency). The most challenging cases are those in which the question of malabsorption is not raised because of lack of change in the quality of the stools.

The diarrhea of malabsorption is classified as an osmotic diarrhea and usually stops during fasting. In fat malabsorption, the diarrhea is caused not only by the excessive osmotically active

Table 1 Causes of Malabsorptive Syndromes

Diseases of the small intestine	Gluten-sensitive enteropathy Tropical sprue Collagenous sprue Eosinophilic enteritis Radiation enteritis Amyloidosis Mastocytosis Abetalipoproteinemia Whipple disease Intestinal lymphangiectasia Immunoproliferative small intestinal disease Ischemic bowel disease *Giardia lamblia* infection AIDS Short bowel syndrome Ileal resection Ileitis (e.g., Crohn disease)
Diseases of the liver and biliary tract	Cirrhosis/parenchymal liver disease Intrahepatic cholestasis syndrome Cholestasis due to extrahepatic obstruction
Diseases of the pancreas	Chronic pancreatitis Cystic fibrosis Cancer
Combined or multiple defects in digestion and absorption	Hyperthyroidism Diabetes mellitus Carcinoid syndrome Zollinger-Ellison syndrome Postgastrectomy (Billroth II type)

Table 2 Tests of Digestive-Absorptive Function

	Characteristics	*Clinical Use*
Fecal fat analysis		
Qualitative	Simple microscopic study for increase in fat globules	A good screening test for moderate increase in stool fat, but quantitative fecal fat analysis is preferable
Quantitative	Chemical analysis for fat excretion during a 72 hr period by titration with NaOH; most sensitive test for malassimilation of fat; normal is < 6 g/day; does not distinguish between small intestine, pancreatic, or luminal abnormalities	The most important test to identify maldigestion or malabsorption; indicated in all patients suspected of having malassimilation
Xylose absorption	As a pentose not requiring luminal or intestinal surface digestion, xylose allows assessment of small intestine function; normally, > 4 g/5 hr is excreted in urine after ingestion of 25 g; plasma xylose should be 10–20 mg/dl/1.73 m^2 of body surface area at 60–75 min	Indicated whenever quantitative fecal fat is abnormal; not as sensitive as fat analysis but localizes the abnormality to the small intestine
Small intestine x-ray	Allows analysis of continuity of small intestine and identification of diverticula or alteration of mucosa; diseased pancreas may impinge on duodenum	Indicated when quantitative fecal fat excretion is increased
Small intestine peroral biopsy	Permits direct histologic examination of mucosa; characteristic alterations occur in several diseases producing malabsorption	Indicated when fecal fat excretion is increased, particularly if the xylose test or small intestine x-ray is abnormal; a portion of biopsy may be assayed for disaccharidases
Bile acid breath test	In small intestine bacterial overgrowth or ileal disease that produces malabsorption, ^{14}C–glycocholic acid (5 μCi) will be deconjugated, metabolized, and excreted via the lungs as $^{14}CO_2$	Indicated in patients with documented steatorrhea caused by suspected bacterial overgrowth or ileal dysfunction
Bentiromide test	The peptide bond in this nonabsorbable arylamine is cleaved specifically by intraluminal chymotrypsin to yield PABA, which is then readily absorbed and excreted by the intestine	Indicated when fecal fat excretion is increased; less sensitive than quantitative fat analysis but, when positive, establishes insufficiency of intraduodenal pancreatic digestive enzyme levels Not available in U. S.

particles but also by fatty acids, which stimulate cyclic adenosine monophosphate (cAMP)–dependent Cl^- secretion.

Specific physical findings of various diseases may accompany the malabsorptive state and assist in making the diagnosis. For example, the skin changes of scleroderma or dermatitis herpetiformis may be present. Signs of diabetic neuropathy may be disclosed. Although thyrotoxicosis may be associated with excessive fat in the stool, patients with thyrotoxicosis usually eat gluttonously but absorb a normal percentage of dietary fat eaten (95%) and therefore do not malabsorb in the true sense.

TESTS FOR SUSPECTED MALABSORPTION

The tests for malabsorption involve determining whether there is excessive fecal fat excretion [*see Table 2*]. Protein is produced in large quantities by the digestive tract, especially the pancreas, making creatorrhea difficult to interpret. Malabsorbed carbohydrate delivered to the colon may be metabolized by colonic bacteria to short-chain fatty acids, which are in part absorbed by the colon. Thus, the quantitative measurement of carbohydrate absorption is inaccurate, although a fall in stool pH occurs, which is indicative of excessive amounts of the short-chain fatty acids that are excreted under these conditions.

Measurement of Fecal Fat

Fecal fat can be measured qualitatively and quantitatively. The qualitative measurement of fecal fat using Sudan III staining has been shown to be surprisingly accurate,[4] especially if clinically significant amounts of fat are being excreted. One group reported that counting and measuring the size of fat globules present in the stool significantly improved the sensitivity and specificity of the Sudan assay.[4] As with many qualitative tests, however, accuracy varies with test performance and interpretation, making the skill of the observer crucial to success.

The quantitative measurement of fecal fat is the benchmark by which all other tests are ranked. It is important to remember that the test cannot be performed unless the patient is able to eat at least 80 g, preferably 100 g, of fat a day.

Xylose Absorption Test

The absorptive surface area of the intestine is measured by the ability of the patient to absorb xylose, a sugar. Unlike glucose, xylose is not actively absorbed by the intestine but is absorbed by the slower process of passive diffusion. In the xylose absorption test, 25 g of xylose is given by mouth and the urine is collected for 5 hours. The normal urinary excretion of xylose is greater than 4 g over 5 hours. For an adequate urinary flow to be ensured, the patient should drink 500 ml of water after drinking the xylose. This intake should result in a urine volume of at least 300 ml during the collection period. Xylose excretion can be falsely low in patients with reduced renal function or in patients with ascites in which the xylose is diluted in the ascitic fluid. To avoid falsely low results, it is advisable to measure the concentration of xylose in blood [*see Table 2*]. Malabsorbed xylose reaches the colon and can be metabolized by the resident bacteria to hydrogen. Hydrogen may be quantitated in the breath; this test is reported to be as accurate as the measurement of xylose in the serum or urine.

Imaging Studies

A plain film or ultrasonogram of the abdomen is usually not helpful in most cases of malabsorption. However, 30% of cases of chronic pancreatitis have visible calcifications on an abdominal plain film. Detection of pancreatic calcification can be increased if computed tomography or ultrasonography is used. CT or ultrasonography also can identify dilatated pancreatic ducts, another characteristic sign of chronic pancreatitis. Endoscopic retrograde pancreatography (ERP) can also be helpful when ductular changes indicative of chronic pancreatitis are seen [*see 4:V Diseases of the Pancreas*].

Radiographic studies of the small intestine after oral ingestion of barium can aid in the diagnosis of several abnormalities. The

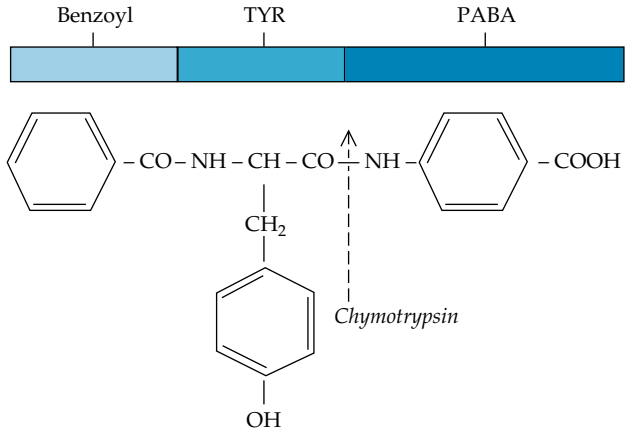

Figure 1 **Cleavage of the bentiromide molecule by the intraduodenal enzyme chymotrypsin yields two fragments, benzoyl-tyrosine and aminobenzoic acid (PABA). Bentiromide is composed of benzoyl (light blue), tyrosine (TYR) (blue), and PABA (dark blue). The released PABA is absorbed across the intestine and excreted in significant quantities in the urine. Absence of chymotrypsin, as a result of pancreatic disease or duct obstruction, will result in failure of release, absorption, and urinary excretion of PABA.**

presence of diverticula of the small intestine or of impaired peristalsis, as seen in scleroderma or idiopathic intestinal dysmotility, can be an indicator of bacterial overgrowth. A careful examination of the terminal ileum can identify Crohn disease. Stricturing may be identified in some patients with radiation injury or injury caused by nonsteroidal anti-inflammatory drugs. Hypoalbuminemia affecting the small intestine may lead to the so-called stack-of-coins sign.

Small Bowel Biopsy

An experienced pathologist can be helpful in supporting the diagnoses of gluten-sensitive enteropathy (with or without dermatitis herpetiformis), hypogammaglobulinemic sprue, tropical sprue, Whipple disease, *Mycobacterium avium* complex disease, stasis syndrome, amyloidosis, and intestinal lymphangiectasia.

Assessment of Pancreatic Exocrine Function

More than 90% of pancreatic exocrine function needs to be destroyed before symptomatic malabsorption results [*see 4:V Diseases of the Pancreas*].[5] The most sensitive test of pancreatic exocrine function requires the passage of a double-lumen tube.[6] Cholecystokinin (CCK) or secretin is administered intravenously, and gastric and duodenal secretions are collected separately. However, secretin became unavailable in the United States when the manufacturer discontinued production in 1999. If CCK is given, lipase or trypsin activity is determined using appropriate substrates. When secretin is administered, duodenal fluid volume and bicarbonate concentration are measured.

The noninvasive bentiromide test is based on the action of trypsin on bentiromide to yield *p*-aminobenzoic acid (PABA) and benzoyl-tyrosine [*see Figure 1*]. PABA is readily absorbed by the intestine and excreted into the urine. In healthy persons, when 500 mg of bentiromide is ingested, 57% or more of the PABA appears in the urine within 6 hours. In patients with chronic pancreatitis, the amount of PABA excreted is significantly less, averaging 42%. Using the 57% excretion as a cutoff, the sensitivity of the bentiromide test is 67% to 80% and the specificity is 95%.[7] PABA may also be measured in the plasma 120 minutes after ingestion of bentiromide, which may enhance the sensitivity of the test.[8] Plasma measurements are helpful in cases of impaired renal excretion, which may be seen in the elderly. PABA is identified colorimetrically, and thus, other arylamines can interfere with its determination (e.g., acetaminophen, lidocaine, procainamide, sulfonamides, and thiazide diuretics).[9] In cases in which intestinal absorption is impaired, such as with sprue, the absorption of released PABA may be reduced, leading to a falsely low urinary recovery. Unfortunately, the bentiromide test becomes positive only when the pancreatic gland is more than 90% destroyed. Nevertheless, in considering the workup of a patient with steatorrhea, the test may be useful because it takes an equal amount of glandular destruction to generate steatorrhea.

Although the vast majority of pancreatic proteases and lipases are stored in zymogen granules and are released from the apical portion of the pancreatic exocrine cell into the pancreatic duct, a small percentage leaks into the interstitium of the gland, is carried into the circulation, and can be measured by the serum trypsinogen assay. Because the activation peptide of trypsin is not yet released and any active trypsin is quickly bound by α_1-antitrypsin, the free-circulating form of trypsin is trypsinogen. In patients who have chronic pancreatitis with exocrine insufficiency, the serum concentration of trypsinogen is lower than that in healthy persons (2 to 18 ng/ml, compared with 29 to 79 ng/ml in healthy persons).[10] A low serum trypsinogen level appears to have a high degree of specificity for chronic pancreatitis but is only modestly sensitive.

Bile Acid Absorption Tests

Bile acids are synthesized from cholesterol in the liver and require conjugation by either glycine or taurine before they are excreted into the intestine via the common bile duct. The bile acid conjugates solubilize the products of triacylglycerol hydrolysis into complex micelles, which facilitate the rapid absorption of dietary lipid. Bile acids are not absorbed in the proximal intestine with dietary lipid but in the distal ileum. The bile acid pool recirculates six times a day. About 95% of bile acids are reabsorbed and recirculate in the enterohepatic circulation each day; approximately 0.5 g of bile acids appears in the stool daily, which equals the hepatic synthetic rate under steady-state conditions. If bile acids are not adequately absorbed, diarrhea results (choleretic enteropathy). In the complete absence of bile salts, fatty acids are less efficiently absorbed, with up to 25% to 50% of ingested lipid appearing in the stool. In patients with idiopathic diarrhea or with diarrhea after ileal resection (≥ 30 cm), the malabsorption of bile acids is an etiologic possibility. Also, children who have unexplained diarrhea may have a congenital defect of the sodium-dependent bile salt transporter in the terminal ileum.[11]

To test for the presence of bile acid malabsorption, two methods are available, although not widely used. The first is the ^{14}C-glycocholic acid breath test, and the second is the selenium-75–labeled homocholic acid–taurine (^{75}SeHCAT) absorption test. In the former test [*see Figure 2*], a trace amount of ^{14}C-glycocholic acid is given by mouth. Many bacteria are capable of hydrolyzing the amide bond and releasing the ^{14}C-glycine; either it is absorbed and $^{14}CO_2$ is produced in the liver or it is further metabolized in the intestinal lumen to $^{14}CO_2$. In either event, the $^{14}CO_2$ appears in the breath in measurable amounts. The percentage of the ingested dose excreted in the breath increases if the intestinal lumen contains more bacteria than normal or if an excess of bile acids is delivered to the colon (ileal dysfunction). A gastric anti-

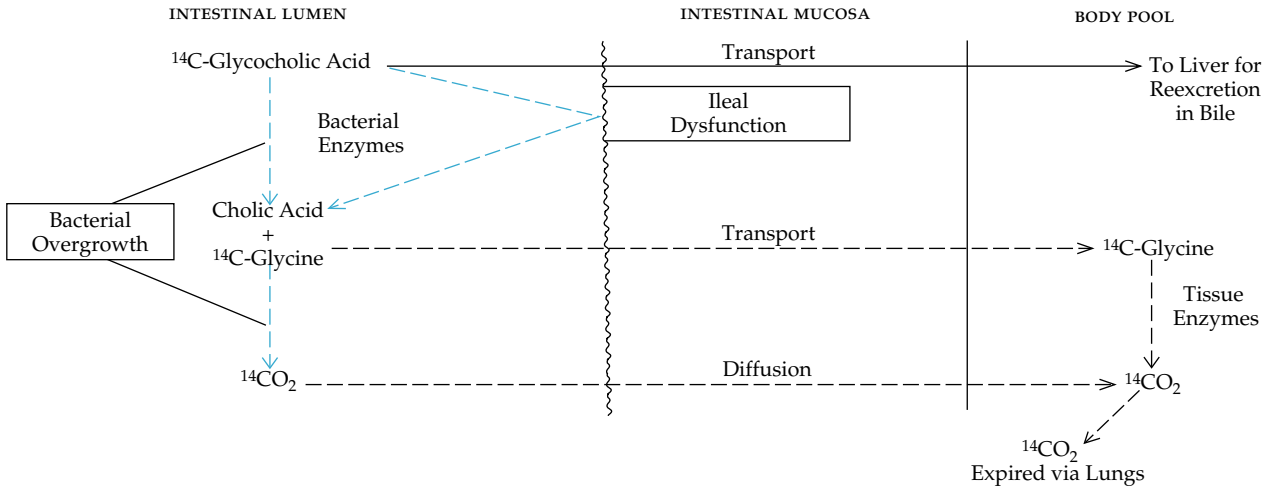

Figure 2 **In the bile acid breath test, a small dose of ^{14}C–glycocholic acid is ingested and its fate determined by measurement of $^{14}CO_2$ excretion in breath. In a normal person, little of the ^{14}C–glycocholic acid is metabolized for excretion in breath because it passes intact to the ileum for absorption and return to the enterohepatic circulation. If there is either intestinal bacterial overgrowth or ileal dysfunction, however, bacterial enzymes will deconjugate the bile acid (broken blue lines), releasing cholic acid and ^{14}C-glycine. The radioactive glycine may be transported across the intestinal mucosa (upper broken gray line) and subsequently degraded to $^{14}CO_2$ by tissue enzymes; alternatively, the ^{14}C-glycine may be metabolized within the intestinal lumen to $^{14}CO_2$, which then diffuses (lower broken gray line) into the circulation and is carried to the lungs. Consequently, $^{14}CO_2$ excretion is 10 times greater in either intestinal bacterial overgrowth or ileal dysfunction than it is in the normal state.**

secretory drug may also increase the resident population of bacteria in the intestine to a level that results in an abnormal breath test.[12] The usefulness of this test as an indicator of bile acid malabsorption is therefore limited. The ^{75}SeHCAT test has more potential clinical usefulness because of its strong correlation with cholate excretion and the ease of measurement of ^{75}Se retention by the whole-body gamma camera. Normal persons retain greater than 19% of an orally administered dose of ^{75}Se after 7 days, whereas patients with significant ileal dysfunction or resection retain less than 12%.[13]

Now that the human sodium-dependent bile acid transporter has been cloned, congenital defects are being discovered that lead to bile acid malabsorption resulting in diarrhea.[11] Such defects may be the cause of primary bile acid malabsorption.

Diseases Producing Malabsorption

GLUTEN-SENSITIVE ENTEROPATHY

Gluten-sensitive enteropathy (GSE) was once called celiac disease in children and idiopathic or nontropical sprue in adults. In 1960, it was recognized that the diseases were the same, caused by the major wheat protein gluten and, more specifically, its alcohol-soluble component, gliadin.[14]

GSE is generally considered less common in the United States than in Western Europe. However, a recent large multicenter study indicated that the prevalence of GSE in the United States in symptomatic patients (1 in 56) and in not-at-risk persons (1 in 133) is similar to that reported in Europe.[15]

Genetic and Etiologic Factors

GSE is associated with haplotypes HLA-DQ2 (DQA1*501, DQB1* 201) and HLA-DQ8 (DQA1*031, DQB1*302). In sets of monozygotic twins, 30% of the opposite twins from the incidence case do not have GSE. This condition leads to the belief that there is another, unknown (nongenetic) factor that is important in disease causation. A 33-amino-acid peptide part of gliadin has been shown to be poorly digested by proteases and to cause T cell activation in GSE patients.[16]

Pathogenesis

GSE is associated with impaired cholecystokinin release. CCK cells are either reduced in number or so defective that the amount of CCK present in the duodenal mucosa is greatly reduced.[14] This CCK deficiency leads to a reduced amount of pancreatic lipase and bile acids delivered to the intestinal lumen in response to dietary lipid. The intestinal crypt cells are the major fluid-secreting cells of the intestine, via their cAMP-dependent Cl^- secretion with attendant water secretion. In GSE, the cryptal portion of the villous complex is greatly expanded, leading to increased water secretion. Because the villous tip cells, which normally absorb the water, are diseased and reduced in number, water and electrolyte absorption is not as effective as normal, and the intestine becomes secretory.[14] Thus, the concentration of bile acids in the intestinal lumen is reduced below that expected simply from the impaired CCK release. The ability of bile acids to solubilize the products of lipolysis depends on the presence of bile salts at a concentration greater than their critical micellar concentration (CMC) of 1.4 mM.[17] Normally, the intestine has a postprandial bile salt concentration of 10 mM.[18] The brush borders at the surface of mature enterocytes are severely affected in GSE. Further, the villous structures are flattened. These two conditions lead to a severely reduced surface area that limits lipid absorption. The amount of reduction in surface area can be estimated by the D-xylose absorption test. The enterocytes that are at the surface of the intestine are not as mature as normal enterocytes, because their turnover rate is greatly increased, which probably results in a reduced capacity to process absorbed lipid.

Diagnosis

Clinical manifestations Although GSE may start in childhood and respond to gluten withdrawal, children with the dis-

ease undergo a remission in their teenage years even if they ingest a diet containing gluten. As adults, these patients, 25% or more of whom were symptomatic in childhood, may present with a variety of complaints; usually, weight loss, fatigue, abdominal cramps, distention, bloating, and diarrhea (steatorrhea) are prominent, although there may be no loss of appetite. In some patients, the disease is insidious in onset and the symptoms are mild. It is only after these patients have been treated that they realize, in retrospect, how ill they were. In population studies in which the presence of disease was determined by intestinal biopsy, people with a biopsy consistent with GSE were often asymptomatic but sometimes of shorter stature than unaffected siblings. Because nothing specifically leads to the diagnosis, especially in the absence of clinically evident steatorrhea, the realization that the patient has GSE may be delayed. This problem is most likely to occur with patients who do not have steatorrhea but do have osteoporosis, easy bruising as a result of vitamin K deficiency, or unexplained iron deficiency anemia. Iron deficiency anemia is common in adult patients with GSE,[19] and one study suggested that fractures may be the only sign of malabsorption in patients with undetected GSE.[20]

Laboratory tests In a patient in whom the suspicion of GSE is high (e.g., a first-degree relative of a known GSE patient; a patient who has a history of a childhood disease that caused diarrhea, was evaluated by a specialist, and was treated with a special diet; or a patient with malabsorption who is not an alcoholic and does not have another obvious reason for malabsorbing fat), a positive tissue transglutaminase antibody test makes the diagnosis almost certain [*see Figure 3*].[21] Alternatively, the diagnosis might rest on small bowel biopsy findings [*see Figure 4*]. Classic features include partial or complete villous atrophy, abnormal-appearing enterocytes at the villous tips, an increase in intraepithelial lymphocytes, a lamina propria infiltrate consisting predominantly of lymphocytes and macrophages, an increase in the size of the crypts both vertically and horizontally, and an increase in the number of mitotic figures.[14] These features, although typical, are not pathognomonic. For the diagnosis to be definitive, the patient must respond to dietary therapy. Symptomatic improvement can be expected in 80% of patients within 1 month, but histologic improvement lags behind considerably. Another 10% of patients do not respond until after 2 months, and the remainder may take up to 2 years. Even under the strictest dietary control, the biopsy findings might not return to normal. Most often, the patient remains under good control because of the symptomatic improvement while on the diet, but many patients will eventually either test whether they are cured or be in a situation that forces them to commit a dietary indiscretion. This lapse inevitably results in recurrence of symptoms, further securing the diagnosis.

Another helpful test is the identification of an antiendomysial antibody. This antibody is present in up to 95% of cases and is rarely present in control subjects.[22] Other tests of malabsorption, such as the D-xylose absorption test or stool fat studies, may be abnormal. Low clotting factors, the presence of anemia caused by folate or iron deficiency, or osteoporosis may also be present. None of these conditions are specific for GSE, however.

Treatment

The treatment of GSE is a strict gluten-free diet. Because a gluten-free diet is a lifelong commitment, is more expensive than a normal diet, and may carry social limitations, it should not be recommended until the diagnosis of GSE is firmly established. A gluten-free diet prohibits the intake of wheat, rye, and barley. Oats are thought to be safe but are usually avoided during the early stage, when the clinical response to the diet is being judged. Keeping the patient on the diet is sometimes difficult because many foods have hidden gluten content. Maintaining a gluten-free diet is important because intestinal lymphomas are more likely to develop in patients who do not follow such a diet.[23]

Support groups, such as those organized by the Celiac Society of America, can be helpful, especially when the disease is newly diagnosed. Information such as what to look for on package labels and interesting recipes can be very instrumental in helping the patient maintain the gluten-free diet. During the trial period, beer, ale, and whiskey, which may contain enough gluten to sensitize the patient, should not be consumed. After the dietary response is clear, these drinks may be tried, if desired, to determine whether the patient is sensitive. Other products that are not usually thought of as containing gluten, but often do, are ice

a *b*

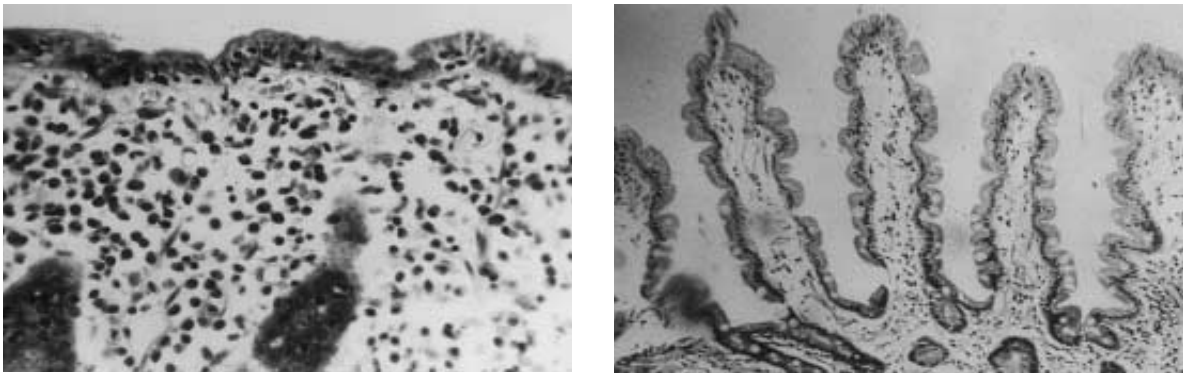

Figure 4 **Biopsy specimen from the small intestine of a patient with untreated celiac sprue (*a*) demonstrates a flat surface with plasmocytic infiltration of the subepithelial region (magnification: 400×). In contrast, a biopsy sample taken from a patient with pancreatic exocrine insufficiency (*b*) is indistinguishable from a normal specimen and shows tall, scalloped villi and minimal subepithelial mononuclear infiltration (magnification: 100×).**

cream, communion wafers, and even some drugs (as a filler). Despite the restrictions, many dietary options are open to the patient, including certain breakfast cereals, milk, cheese, eggs, meat, chicken, fish, chocolate, and products made from corn, rice, or potato flour.

If the patient does not respond, the most likely reason is that the patient is not accurately following the diet. In such cases, it is helpful to have a dietitian carefully go over the patient's dietary history.[14] Less often, the patient will have an intestinal stasis syndrome or pancreatic insufficiency. When these subsidiary problems are diagnosed and successfully treated, the patient usually shows a response to the diet. However, a minority of patients who do not respond to a gluten-free diet have what is called refractory sprue.[24] Patients with refractory sprue may require treatment with corticosteroids and other immunosuppressants, including azathioprine.[25]

GSE-Associated Disorders

Dermatitis herpetiformis Many patients with dermatitis herpetiformis have GSE.[21] The intensely pruritic, blistering lesions appear on the knees, elbows, shoulders, and buttocks [*see 2:I Cutaneous Manifestations of Systemic Diseases*]. Skin biopsies of dermatitis herpetiformis lesions have characteristic immunoglobulin A (IgA) deposits. On a gluten-exclusion diet, both the dermatologic and the intestinal lesions improve, indicating a linkage between the two. However, the skin lesions respond to dapsone treatment and the intestinal lesions do not, which indicates that there are differences between the two diseases as well.

Type 1 diabetes mellitus Patients with type 1 diabetes mellitus are at increased risk of developing GSE. With the use of antiendomysial antibodies as a screen, gluten-sensitive enteropathy has been found in three of 47 diabetic patients (6%), a much higher incidence than would be expected by chance.[26] Even when patients with type 1 diabetes mellitus show no apparent signs of malabsorption, they are at risk for developing celiac disease; screening for celiac disease in these patients therefore may be advisable.[27] One study reported a 5.7% prevalence of celiac sprue in patients with type 1 diabetes and noted a finding of increased autoimmune diseases in these patients.[28] The prevalence of autoimmune disorders in patients with celiac disease seems related to duration of gluten exposure, which provides further rationale for the early diagnosis and treatment of GSE.[29]

OTHER SPRUELIKE DISORDERS

Tropical Sprue

Tropical sprue is a malabsorptive illness that appears in certain areas of the world, especially the tropics, in both the indigenous populations and tourists. In two carefully studied populations, 5% to 13% of North Americans living in Puerto Rico for 6 months or longer experienced symptoms of tropical sprue. Expatriates from the United States who return from the tropics or other areas endemic for tropical sprue may experience symptoms of tropical sprue more than 10 years after their return.[30] Peace Corps volunteers from the United States who spent time in Pakistan had demonstrable small bowel lesions and functional abnormalities that reverted to normal over several months after returning home.[31] Indians and Pakistanis living in the United States may take a longer time (up to 4 years) to excrete normal amounts of D-xylose.[32] Exactly what causes these changes in the small bowel is not clear, but the tropical sprue syndrome is thought to be caused by one or more species of coliform bacteria, such as *Klebsiella* species,[33] which colonize the upper intestinal tract.

Diagnosis The symptoms of tropical sprue differ from those of GSE. Weight loss caused mostly by anorexia is very prominent, as is diarrhea. A sore tongue (70% of patients), pedal edema (25%), folate and vitamin B_{12} deficiency (75% to 100%), or an abnormal result on the Schilling test (96% to 100%) is much more common in tropical sprue than in nontropical sprue.[33] The symptoms can be quite severe, sometimes leading to death in endemic areas. However, the prognosis, in general, is excellent for patients either remaining in the tropics or returning to the United States.

The diagnosis of tropical sprue is made by performing a small bowel biopsy in patients with a compatible clinical presentation and travel history. Villi are leaflike or blunt, and the lamina propria are packed with inflammatory cells [*see Figure 5*]. Thin villous structures are seen in North Americans and Europeans [*see Figure 4*]. In considering this disease, it should be noted that intestinal biopsy results in residents of endemic areas or in tourists who do not stay in mainstream hotels in endemic areas would be classified as abnormal in persons living in the United States or Europe.

Treatment Treatment of tropical sprue should begin with folic acid (5 mg/day).[33] This therapy is associated with rapid improvement in appetite, and it eliminates most of the clinical

symptoms. In patients with a short duration of symptoms (< 4 months), folate given for 6 months to 1 year may suffice. For patients with a longer duration of symptoms (> 4 months), antibiotics, such as tetracycline (2 g/day for 1 year), should be added. Most patients returning to the United States gain weight quickly even if the results of absorption tests or intestinal biopsies are not normalized.

Collagenous Sprue

Collagenous sprue is a rare, devastating disease in which there is a layer of collagen underneath the enterocytes of the small bowel. The relation of collagenous sprue to collagenous colitis is unclear, but the basic histologic feature of subepithelial collagen deposition is the same. The origin of collagenous colitis is unknown, but it develops in approximately half the patients who have refractory celiac disease (those unresponsive to the gluten-exclusion diet).[34] Although it is known that type 6 collagen is deposited in the more commonly diagnosed collagenous colitis, the type of collagen laid down in the small bowel in collagenous sprue is unknown. In collagenous colitis, the symptoms (primarily diarrhea) are usually modest, but in collagenous sprue, symptoms are more severe and include obvious malabsorption. This severity of symptoms is probably caused by the diffusion barrier presented by the collagen, which prevents nutrients from diffusing either into the portal capillaries or into the lymphatics.

Diagnosis The diagnosis of collagenous sprue is made by the classic histologic picture of villous atrophy and subepithelial collagen deposition. If the diagnosis is missed, however, and the patient is thought to have GSE on the basis of the flat villous structure, the patient will usually not be responsive to the gluten-free diet.

Treatment Therapy for collagenous sprue is uncertain. The most common problem is the osmotic diarrhea caused by the gross malabsorptive state induced by the disease process. In this event, the patient is treated as if he or she had the short bowel syndrome. Some patients respond to steroid therapy. A few respond to steroids and a gluten-exclusion diet, with the patient's improved condition eventually making it possible to taper the steroid dosage.[35]

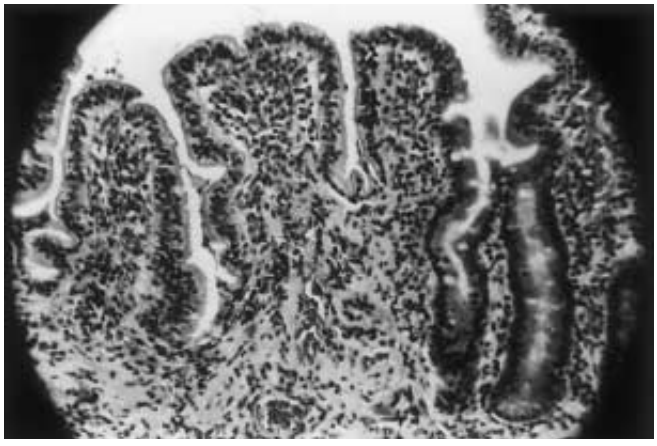

Figure 5 **In a biopsy specimen from the small intestine of a patient with tropical sprue, villi are broadened and shortened and the crypts are deepened; these changes yield a villus-to-crypt ratio of 1:1 (magnification: 100×).**

Hypogammaglobulinemic Sprue

The gastrointestinal tract is the largest lymphoid organ in the body. The environment to which this immune system is exposed is filled with foreign antigens that must be sorted, identified, and, if necessary, reacted to. Thus, it is not surprising that intestinal dysfunction may develop in patients who are immune deficient, particularly those with IgA deficiency, because IgA is the most important immunoglobulin of the intestine. Some patients who have one of the hypogammaglobulinemic syndromes may experience malabsorption.[36] Patients with IgA deficiency also usually have a history of recurrent respiratory infections,[36] which further distinguishes them from patients who have gluten-sensitive enteropathy. The most common cause of malabsorption seen in this condition is giardiasis.

Diagnosis The diagnosis of hypogammaglobulinemic sprue is suspected if the patient has signs and symptoms of malabsorption and low levels of serum immunoglobulins, especially IgA. Intestinal biopsy specimens lack plasma cells and thus are easily distinguishable from those of patients with gluten-sensitive enteropathy, in which plasma cell types are abundant. Plasma cells are readily seen in normal biopsy specimens as well. *Giardia lamblia* organisms may also be present in hypogammaglobulinemic sprue.

Treatment Frequently, the intestinal symptoms associated with hypogammaglobulinemic sprue improve if metronidazole is given at 750 mg/day for 10 days to treat giardiasis.

SMALL BOWEL DISEASE SECONDARY TO SURGERY AND RADIATION

Short Bowel Syndrome

Massive small bowel resection is used to treat various diseases, including mesenteric ischemia, volvulus, and Crohn disease. Because the intestine requires a certain surface area over which absorption can occur, reducing the area below a critical value results in malabsorption. Depending on the amount of bowel resected, the results can range from mildly inconvenient to catastrophic. Retention of the ileocecal valve lessens symptoms. The ileum responds to jejunal resection by hyperplasia much more effectively than the jejunum responds to an ileal resection. There are also specialized mechanisms present in the ileum that are not available to the jejunum, such as bile salt and vitamin B transporters. The maintenance of an adequate bile acid pool is important for fat absorption because the reduced absorptive surface area in patients who have undergone bowel resection makes it necessary for fat absorption to be as efficient as possible. Alternatively, the ileum can perform most of the functions of the jejunum except for folic acid, Ca^{2+}, and Fe^{2+} absorption. However, these can be replenished by appropriate medication.

Diagnosis The diagnosis of short bowel syndrome is made by a history of bowel resection in combination with clinical manifestations of the syndrome, such as diarrhea, steatorrhea, weight loss, trace-element deficiencies, hyponatremia, and hypokalemia.

Treatment Treatment of patients with short bowel syndrome depends on the part and the amount of the bowel that has been resected. Protein requires the greatest surface area for absorption.[37] Thus, achieving adequate assimilation may become

problematic, despite the water solubility of proteins and their hydrolytic products. Vitamins and minerals also need to be added to any therapeutic regimen, depending on what part of the bowel is missing. Treatment can include eating multiple small meals each day, eating quickly absorbed foods such as canned caloric supplements, having food finely chopped or ground, and eating foods containing medium-chain triglycerides, which can be absorbed in the absence of bile salts.[37] Foods rich in polyunsaturated fatty acids, such as vegetable oils, are more easily absorbed than meats, which have more saturated fat. Finally, completely hydrolyzed dietary supplements are rapidly absorbed. To slow bowel transit, diphenoxylate-atropine, loperamide, or deodorized tincture of opium can be used effectively. An alternative method is to have the patient drink a small amount of safflower oil just before a meal. The lipid quickly goes to the ileum (if present), the colon, or both[38] and elaborates peptide YY (PYY),[39] which is the putative ileal break, slowing gastric emptying. Having patients try different diets will often enable them to ingest food orally rather than receive total parenteral nutrition (TPN), which is less desired.

Radiation Enteritis

Injury of the intestine is an all too common result of delivery of ionizing radiation as oncologic treatment. Injury to the small bowel is more common if the patient has had previous abdominal surgery, which may restrict the movement of the small bowel. The terminal ileum may become involved during pelvic irradiation. To prevent radiation injury, it may be advisable to irradiate patients on a turntable so that more than one part of the intestine receives the maximal amount of radiation.

WHIPPLE DISEASE

Whipple disease is a rare multisystem disease caused by the bacterium *Tropheryma whippelii*.[40] The pathogenesis is obscure. The bacillus may be widespread throughout the body, but the sites of invasion show little sign of inflammation, suggesting that an autoimmune deficiency may create a predisposition to the disease.[41] Accurate diagnosis is imperative because mortality approaches 100% without antibiotic treatment.

Diagnosis

Clinical manifestations Classically, Whipple disease begins in a middle-aged male with a nondeforming arthritis that usually starts years before the onset of the intestinal symptoms. Arthralgias, diarrhea, abdominal pain, and weight loss are the cardinal manifestations of Whipple disease. Other complaints include fever, abdominal distention, lymphadenopathy, hyperpigmentation of the skin, and steatorrhea.[42] Many patients express the HLA-B27 isotype. Occasionally, intestinal symptoms are absent, even in some patients with central nervous system involvement.[43] In a well-documented but unusual case, intestinal involvement was not identified, even after extensive biopsies in two laboratories, despite the fact that the patient otherwise had typical symptoms of the disease.[44] Cardiac and pulmonary involvement may also be found.[45]

Laboratory tests The recognition of Whipple disease in patients without intestinal symptoms or involvement by the disease has been increasing since the advent of polymerase chain reaction techniques that identify the unique 16S ribosomal RNA of *T. whippelii*.[46]

The diagnosis rests on identifying the classic periodic acid–Schiff (PAS)–positive macrophages, which contain sickle-form particles.[42] By far the most common site of biopsy that yields positive results is the intestine. The histologic lesion shows distended villi (clubbed villi) filled with the foamy, PAS-positive macrophages and lymphatic dilatation. A flat villous surface can be seen in extreme cases. These findings need to be differentiated in the appropriate clinical setting from those of *M. avium* complex disease, in which PAS-positive macrophages are also found. A stain for acid-fast bacilli should differentiate between them. Central nervous system involvement, occasionally associated with typical macrophages in the cerebrospinal fluid as substantiated by the more sensitive PCR technique, may be present in the absence of neurologic symptoms,[47] and a negative result on PCR may predict a low likelihood of clinical relapse.[48] Occasionally, a brain biopsy is required, which can be guided by magnetic resonance imaging.

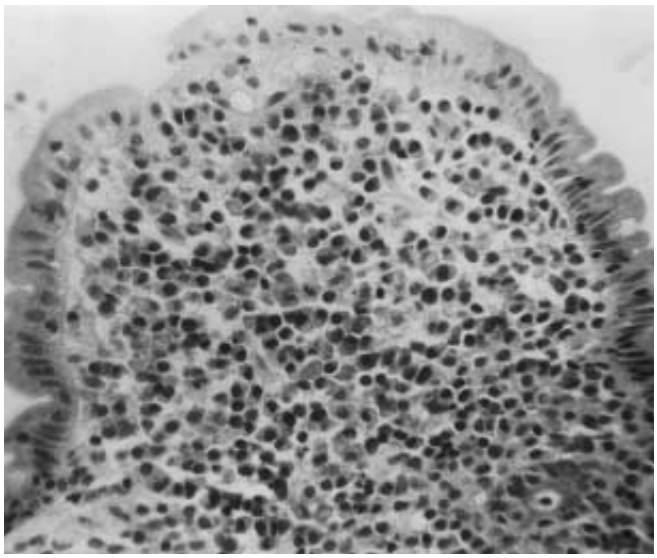

Figure 6 **Small intestinal biopsy specimen from a patient with primary intestinal lymphoma shows a single broadened villus (magnification: 400×). The epithelium is composed of normal columnar cells, but the lamina propria is packed with plasma cells and other mononuclear cells. Surgical biopsies in this patient revealed evidence of generalized subepithelial histiocytic lymphoma.**

Treatment Because Whipple disease is so uncommon, a well-defined treatment plan is difficult to establish. The originally proposed treatment was penicillin (250 mg q.i.d.) and streptomycin (1 g I.M.) for 2 weeks, followed by tetracycline (1 g) for 1 year. Typically today, trimethoprim-sulfamethoxazole (one double-strength tablet b.i.d.) is given for 1 year. All antimicrobial agents are used in customary doses.

Although the intestinal and systemic symptoms respond readily to either treatment, the major concern is treatment of CNS manifestations. Usually, in those patients who do not have CNS involvement initially, CNS symptoms appear a year or more after treatment of the systemic and intestinal symptoms, especially if an antibiotic is administered that does not cross the blood-brain barrier. A progressive dementia may be seen, but the pathognomonic signs of CNS disease, when present, are oculomasticatory myorhythmia and oculofacial-skeletal myorhythmia.[49] Antibiotics that cross the blood-brain barrier are therefore required. Interestingly, the short period of penicillin-streptomycin administration is enough to block CNS symptoms, whereas even long-

term trimethoprim-sulfamethoxazole therapy occasionally may not prevent CNS manifestations of Whipple disease.[50] Tetracycline alone does not eradicate CNS disease and should not be given by itself, even though it is effective in treating the intestinal and systemic symptoms. An important aspect to keep in mind is that in 50% of patients, the CSF may contain Whipple disease macrophages or PCR-positive material even in the absence of CNS symptoms.[46] Once CNS involvement occurs, treatment is usually not helpful, although with treatment, some improvement may be noted and the disease may not progress.

IMMUNOPROLIFERATIVE SMALL INTESTINAL DISEASE

Immunoproliferative small intestinal disease (IPSID), previously known as primary intestinal lymphoma, is a condition in which the lamina propria of the small bowel is intensely infiltrated with lymphocytes and the overlying enterocytes are normal morphologically [*see Figure 6*]. It is a B cell disorder involving the mucosa-associated lymphoid tissue (MALT). The disease is rare in developed nations and more common in underprivileged populations, primarily in persons in the second and third decades of life, with a male predominance. In a series of Chinese patients, six of 45 patients with intestinal lymphoma had IPSID.[51] These patients presented with severe malabsorption. Among the lymphoma patients without IPSID, 65% had abdominal pain, weight loss, abdominal masses, obstruction, and perforation. IPSID is associated with heavy chains (from IgA), with paraprotein present in the serum, urine, or jejunal fluid. Duodenography shows thickened folds and many nodular elevations without ulceration. The diagnosis may be made by small bowel biopsy in 85% of cases.[52] Early in its course, the disease appears to be treatable with antibiotics. If allowed to progress, however, it may develop into more aggressive forms of lymphoma.[53]

INTESTINAL LYMPHANGIECTASIA

Intestinal lymphangiectasia is often a congenital condition in which deformed lymphatics impair the transport of chylomicrons from the enterocytes to the mesenteric lymph duct. A similar pathophysiologic picture occurs in certain cases of IPSID, granulomatous enteritis, tuberculous enteritis, or Whipple disease in which normal lymphatic drainage is blocked.

Diagnosis

The blockage of lymphatic drainage may result in chylous ascites, chyluria, or chylometrorrhea.[54] Protein-losing enteropathy and lymphopenia are prominent features. Modest steatorrhea is also present, with fat excretion commonly reaching 20 g/day. In the congenital form of the disease, lymphedema of the legs or of one leg and one arm is seen. With endoscopic examination, white villi, white nodules, and submucosal elevations may be noted.[55] The white appearance of the mucosa is undoubtedly caused by retained chylomicron triacylglycerol. Double-contrast barium x-ray examination shows smooth nodular protrusions and thick mucosal folds without ulceration.[56] On histologic examination, dilated lymphatics with club-shaped villi are seen, sometimes in asymptomatic patients, in whom the outcome is benign.

Treatment

Treatment is directed toward any identified causative process. In patients with the congenital condition, in whom improvement of the lymphatics is not expected, a low-fat diet supplemented with medium-chain triglycerides is usually helpful. Surgery can be used to remove isolated areas of lymphatic dysfunction if these areas can be identified or to anastomose a lymph duct to the venous system. Sometimes a peritoneovenous (LeVeen) shunt is helpful.

ABETALIPOPROTEINEMIA

In the rare congenital condition of abetalipoproteinemia, postprandial chylomicronemia does not develop in patients, because they are unable to adequately couple apolipoprotein B to the developing chylomicron. Because lipid and lipid-soluble vitamins are transported from the intestine in chylomicrons, the consequent reduction in lipid and lipid-soluble vitamin absorption results in symptomatic steatorrhea, neurologic abnormalities, a variant of retinitis pigmentosa, and spiculated red cells. In contrast to earlier theories about the etiology of abetalipoproteinemia, patients with this disease have normally transcribed apolipoprotein B messenger RNA (mRNA) from which the protein is adequately translated. Nevertheless, apolipoprotein B is not secreted from the intestinal cell. The defect in this condition is in various mutations in the gene that encodes the M component of the microsomal triglyceride transport protein.[57] This chaperonelike protein complex consisting of a 97 kd M component and a 55 kd P component (protein disulfide isomerase) helps translocate the apolipoprotein across the membrane of the endoplasmic reticulum.[58] Without this step, the apolipoprotein is degraded by cytosolic and microsomal peptidases. The result of this defect is that both the intestine and the liver are unable to produce and secrete their triacylglycerol-rich lipoproteins, chylomicrons, and very low density lipoproteins. Because chylomicrons cannot transport the fat out of the enterocyte, it is presumed, but not proved, that the 80% of the lipid that is absorbed is absorbed via the portal vein.[59]

Diagnosis

In addition to having intestinal symptoms, patients with abetalipoproteinemia have severe neurologic problems. These neurologic problems may be caused in part by essential fatty acid deficiency and in part by either the impaired delivery of lipid to nerves or an interference with the local synthesis of lipids. The result is a demyelinating condition that causes a sensory ataxia because of the loss of position and vibratory sensations. The symptoms are similar to but less severe than those of Friedreich ataxia.[60] Patients may have muscle weakness and athetoid movements. Patients also experience retinitis pigmentosa, usually with mild loss of visual acuity but preservation of central vision. In addition to having neurologic abnormalities, patients have acanthocytes in their blood. Acanthocytes are spiculated red cells that have a near-normal life span but that demonstrate an increased susceptibility to mechanical trauma on in vitro testing.

These patients have low plasma triacylglycerol and cholesterol levels. On histologic examination, the enterocytes are seen to be laden with fat. Despite this phenotype, the amount of steatorrhea is modest (about 20 g/day).

Abetalipoproteinemia is usually discovered in childhood because patients with the disease fail to thrive and have steatorrhea. In adults, the disease can be recognized by the combination of neurologic and ophthalmologic findings, the red cell morphology, the very low levels of plasma lipids, and the modest steatorrhea. On small bowel biopsy, the enterocytes are seen to be stuffed with lipid even after an overnight fast, indicating that the absorbed lipid cannot exit the enterocytes.[61]

Treatment

Treatment should include vitamin E as well as the other fat-soluble vitamins and medium-chain triglycerides to reduce the steatorrhea, if required.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis is a rare disease that is characterized by the presence of eosinophilic infiltration of one or more portions of the gastrointestinal tract, anywhere from the esophagus to the colon, in conjunction with gastrointestinal symptoms. No identifiable cause of the eosinophilic infiltrate, such as parasitic infestation, is present. Many patients have an underlying allergic diathesis (e.g., hay fever, asthma, atopic dermatitis, or drug allergies).

It is not known why eosinophils congregate in the GI tract in eosinophilic gastroenteritis, but evidence suggests that eosinophils, once activated, can produce cytokines that self-perpetuate the accumulation of additional eosinophils. These cytokines are interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF), which have been identified in eosinophils of patients but not in control subjects with irritable bowel syndrome. Local production of these cytokines is suggested by the finding that serum levels of IL-5 are normal in patients with eosinophilic gastroenteritis, in contrast to patients with the hypereosinophilic syndrome, who have increased levels of IL-5 in their blood.[62]

Diagnosis

Although eosinophils are a normal constituent of the GI tract, in eosinophilic gastroenteritis the eosinophils appear more numerous than normal and are more invasive. For example, eosinophilic invasion of the crypts in the small intestine is a hallmark of eosinophilic gastroenteritis. A peripheral eosinophilia is often seen but is not always present.

Eosinophilic gastroenteritis can be divided into two basic forms: a tumorous mass of eosinophils producing a granulomatous-type lesion and a more diffusely infiltrative form. In the former case, the lesions are most often in the distal stomach, which may produce obstructive symptoms, or the masses may be found in the more proximal stomach, small bowel, or colon. When lesions are in the small bowel or colon, the condition needs to be differentiated from a lymphoma or Crohn disease.[63] In the case of diffuse disease involving the small bowel, the infiltration can be mucosal, with symptoms of protein-losing enteropathy or malabsorption. If the infiltration is primarily in the muscle layers of the intestine, obstructive symptoms are common. Finally, the disease may be found in the subserosal area of the intestine, with resultant eosinophilic ascites.[64]

Treatment

Most patients respond to conservative measures and steroids. Surgery should be avoided unless it is needed to relieve persistent or small bowel obstruction.

Prednisone, 40 mg orally every morning and tapered slowly over 2 weeks, is the most effective therapy for patients with obstructive symptoms and ascites. If high-dose steroids are needed to maintain remission, azathioprine can be added for its steroid-sparing effect.

Diet elimination therapy may be beneficial in patients with mucosal layer involvement.

CROHN DISEASE

The prevalence of Crohn disease in North America ranges from 26.0 to 198.5 cases per 100,000 persons, with a maximal incidence in people of Jewish decent.[65,66]

Pathogenesis

Crohn disease, a stenosing, fistulizing disease of the intestine, may impair intestinal absorption by at least two mechanisms, ileal dysfunction and the stasis syndrome [*see* Stasis (Bacterial Overgrowth) Syndrome, *below*]. In the case of either ileal resection or severe ileal involvement with Crohn disease, the ileum cannot absorb bile salts normally. In that event, postprandial bile salt deficiency occurs in the upper intestine; this condition may become more severe the later in the day a meal is eaten.[67] Postprandial bile salt deficiency occurs despite the liver's response to bile acid loss from the enterohepatic circulation, which is to increase bile acid synthesis. The increase in bile salt synthesis is not adequate, because each time the gallbladder contracts in response to a meal, most of the bile salt pool is lost to the colon[68] if significant amounts of the ileum have been resected. Thus, the liver does not have time to generate enough replacement bile salts for the complete absorption of the meal just eaten or the next one. The colonic perfusion of bile acids may result in diarrhea. This condition has been termed choleretic enteropathy and may occur when more than 30 cm of the terminal ileum is resected. The excess fluid in the colon is caused by cAMP-driven Cl^- secretion, specifically by the dihydroxylated bile acids, chenodeoxycholate and deoxycholate, not trihydroxylated cholic acid.[69]

Diagnosis

Crohn disease with malabsorption is suggested by the history (e.g., a prior ileal resection); by physical examination in which thickened, tender bowel may be felt; or by imaging studies (e.g., a small bowel barium study showing the absence of the terminal ileum and the presence of strictures, stellate ulcers, or cobblestoning of the mucosa). Ileal dysfunction secondary to ileal resection is suggested by the presence of diarrhea without steatorrhrea, but it may difficult to differentiate this presentation from the stasis syndrome. Lipid malabsorption would be suggested by an increase in fat in the stool.

The loss of bile acids to the colon and thus to the enterohepatic circulation can be associated with no or minimal steatorrhea.[70]

With more extensive (100 cm or greater) ileal resection, however, the diarrhea is caused not only by bile acids but also by malabsorbed fatty acids (steatorrhea).[71] Thus, the diarrhea associated with Crohn disease may be caused not by active disease but by the results of ileal resection. This scenario is suggested by the finding that the diarrhea occurs when the patient first eats after surgery, a time when disease activity may be low secondary to active disease resection, or by the fact that the patient had no or minimal diarrhea before surgery, with diarrhea becoming more prominent afterward.

Because of the stenosis present in some patients with Crohn disease, the stasis syndrome can develop [*see* Stasis (Bacterial Overgrowth) Syndrome, *below*].

Treatment

When the diarrhea is caused by bile acid loss, the treatment is cholestyramine (4 g a.c. and h.s.).[71] This resin preferentially binds the dihydroxylated bile acids, reducing their aqueous concentration and reducing their proportion in the total bile acid pool.

Both effects are beneficial. In the case of larger ileal resections in which steatorrhea is prominent, cholestyramine may actually provoke more diarrhea and malabsorption because it reduces the aqueous bile acid concentration in the upper intestine when taken before meals. In this case, medium-chain fatty acids are used as a replacement for the long-chain fatty acids. The results of this strategy are often not as good as desired. Vitamin B_{12} absorption should also be evaluated in all patients with ileal resection, and if absorption is found to be abnormal, vitamin B_{12} should be given parenterally.

Some patients with severe Crohn disease undergo extensive intestinal resection, resulting effectively in short bowel syndrome. Similarly, patients who have numerous enteroenteric fistulas also have symptoms of short bowel syndrome because the fistulas cause the chyme to bypass large sections of the small intestine. Both types of patients should be treated as if they had short bowel syndrome [*see* Short Bowel Syndrome, *above*].

STASIS (BACTERIAL OVERGROWTH) SYNDROME

The stasis (bacterial overgrowth) syndrome occurs when intestinal stasis leads to the opportunity for bacteria to proliferate locally. This condition has a multiplicity of causes. The most prominent causes are diabetes, scleroderma, intestinal diverticulosis, afferent loop of a gastrojejunostomy, and intestinal obstruction caused by strictures, adhesions, or cancer. These disorders may be present years before the development of symptoms. Symptoms may appear in an otherwise stable patient because of the administration of a proton pump inhibitor that reduces gastric acid production, allowing gastric and small bowel overgrowth, or the administration of an opiate that further reduces intestinal motility.

Intestinal dysfunction in the stasis syndrome is probably caused by bacterial glycosidases that hydrolyze the carbohydrate moieties that form the extensive glycosylation of the apical brush-border proteins.[72] Although bile acid deconjugation occurs in the stasis syndrome, which may theoretically lead to impaired solubilization of the products of triglyceride hydrolysis, studies have shown that in fact the fatty acid concentration in the aqueous phase of postprandial intestinal content is normal.[73] Electron micrographs, however, show that there is damage to the enterocytes, in that absorbed lipid collects in the endoplasmic reticulum and does not progress normally to the Golgi apparatus.[73]

Diagnosis

Clinical manifestations Symptoms of the stasis syndrome are similar to those of other malabsorptive states and include steatorrhea and anemia. The patient may have vitamin B_{12} deficiency, which has several causes, including binding of the vitamin to bacteria[74,75] and bacterial metabolism of the vitamin to metabolically ineffective metabolites. Folic acid levels are usually high secondary to bacterial production of folate.[76] Serum albumin levels may be low secondary to protein-losing enteropathy and remain low for months after adequate treatment. The diagnosis is usually made in a patient with malabsorption in the appropriate clinical setting. Intestinal (usually jejunal) diverticulosis is most often unsuspected until a small bowel x-ray is performed.

Laboratory tests Establishing the diagnosis of the stasis syndrome is not simple. The most accurate way is to pass an aspiration tube into the intestine. The fluid must be quantitatively cultured both aerobically and anaerobically. In most cases, more than 10^5 anaerobes will be found. Alternatively, the noninvasive hydrogen breath test may be used. A high resting hydrogen level or a quick increase in the breath hydrogen in response to a fermentable substrate, such as glucose or lactulose, can be used. Another breath test is the 1 g (^{14}C)-D-xylose test, in which the breath $^{14}CO_2$ is measured.

Treatment

The first choice of treatment for the stasis syndrome is surgical correction of defects, such as an afferent loop that is harboring bacteria, or a jejunocolic fistula. If the surgical option is not available, then recurrent dosing of an antibiotic is required. Tetracycline, at a dosage of 1 to 2 g/day for a 7- to 10-day course, gives good results, or another antibiotic that is active against anaerobic bacteria may be used (e.g., trimethoprim-sulfamethoxazole, one double-strength tablet b.i.d.). The patient will need to be re-treated if clinical symptoms reappear, or the patient can receive treatment for 1 week every month.

AMYLOIDOSIS

The intestine is often involved in patients with systemic amyloidosis, especially if they have polyneuropathy. In patients older than 85 years, 36% have intestinal involvement with amyloidosis,[77] although most are asymptomatic. Endoscopically, mucosal erosion, friability, or polypoid protrusions can be seen.[78] The diagnosis is made by either full-thickness or peroral intestinal biopsies. If a peroral biopsy is performed, it must be deep enough to have arteries visible, so that amyloid, if present, can be demonstrated. Congo red–stained arterioles that become apple green under polarized light confirm the diagnosis. Small bowel follow-through x-rays may show swollen intestinal plicae, possibly with separated loops of bowel. If steatorrhea is present, it may be the result either of bacterial overgrowth caused by intestinal dysmotility or of impaired bile acid absorption.[79] No specific effective therapy is available. If bacterial overgrowth is present, then appropriate antibiotics should be given.

SYSTEMIC MASTOCYTOSIS

In this rare condition, the skin (99% of cases), bones (9%), liver (12%), spleen (11%), lymph nodes, and GI tract are involved with proliferating mast cells. Diarrhea or abdominal pain or both (23% of cases), peptic ulceration (4%), and itching and flushing (36%) may be seen. Headache, fatigue, and malaise are seen in 12% of cases. There may also be cognitive dysfunction. Eosinophilia is seen in 12% to 50% of cases.[69] Many of these manifestations of the disease are secondary to histamine, which is released from the mast cells. Histamine release may be precipitated by alcohol, aspirin, narcotics, and nonsteroidal anti-inflammatory drugs, causing episodic disturbances of flushing, diarrhea, abdominal pain, and hypotension that may progress to syncope.[80]

Excess histamine is excreted into the urine in excess in approximately 75% of patients, making the urinary excretion test useful for diagnostic purposes.[80] The urinary excretion of a metabolite of prostaglandin D_2 from mast cells may be an even better test.[81] X-ray studies of the small intestine may show thickened folds or nodulation. These findings are not diagnostic but may point to a diseased small bowel.

Histamine-mediated overproduction of gastric acid may lead to peptic ulceration. In that event, H_2 receptor blockers or proton pump inhibitors are effective in controlling symptoms. In the skin, urticaria pigmentosa may be effectively treated with H_1 re-

ceptor antagonists such as diphenhydramine (25 μg every 6 to 8 hours). If diarrhea persists, cromolyn sodium may be given at a dosage of 100 mg orally four times a day.

CHRONIC PANCREATITIS WITH EXOCRINE INSUFFICIENCY

Most chronic pancreatitis is caused by alcoholism. In rare cases, the disease is inherited. Patients experience weight loss resulting from malabsorption of food. Malabsorption caused by pancreatitis is discussed elsewhere [*see 4:5 Diseases of the Pancreas*].

POSTGASTRECTOMY STEATORRHEA

One of the consequences of gastric surgery is steatorrhea, primarily in patients who have the Billroth II gastric resection with a gastrojejunostomy. In this operation, the antrum and a variable portion of the body of the stomach are resected, the stomach is sutured closed, and a gastrojejunostomy is created. Thus, food bypasses the duodenum and most proximal jejunum, which are the sites of maximal cholecystokinin and secretin concentrations and the active sites for folate, calcium, and iron absorption. Approximately one half of patients who have undergone the Billroth II procedure have steatorrhea of 10 to 15 g of fat/day. This condition is thought to result from food entering the jejunum without the hormone-sensitive sites in the duodenum receiving the appropriate signals for hormone release. Thus, there is poor gallbladder contraction and reduced release of pancreatic digestive enzymes to the intestine resulting in poor admixing of the chyme with pancreatic enzymes and bile acids. The afferent loop, which drains the duodenum and proximal jejunum, may become blocked or atonic and harbor bacteria. The stasis syndrome may occur if enough bacteria are present. Because of their small stomachs, the affected patients cannot eat as much as they previously could. This decrease in food consumption, in combination with steatorrhea, causes many patients who undergo the Billroth II procedure to stabilize at a lower weight than they were before surgery. Osteopenia and iron deficiency anemia are also found. Constant small amounts of blood loss from the gastric ostomy site combined with impaired iron absorption contribute to the iron-deficient state, which is the most common form of anemia. Folate deficiency secondary to the inability to generate absorbable monoglutamyl folate from nonabsorbable heptaglutamyl folate (the common form of folate found in the diet) is also found.[82] Least commonly seen is vitamin B_{12} deficiency caused by hypochlorhydria and resection of intrinsic factor–containing gastric parietal cells. Treatment of the steatorrhea is usually not necessary, because it is not clinically significant. Iron, calcium, or vitamin B_{12} and folic acid must be replaced as indicated. If the patient has early satiety, multiple small meals may be efficacious.

Symptoms of GSE may develop in patients after gastric surgery.[83] It is likely that these patients had clinically silent GSE before the operation. The operation itself causes modest steatorrhea (10 to 15 g fat/day) in 50% of cases, even in patients whose intestine is otherwise normal. In the previously compensated GSE patient, however, surgery is enough to cause clinical symptomatology. Therefore, if postgastrectomy patients exhibit excessive steatorrhea, an evaluation for GSE is warranted. Inflammatory bowel disease that develops in patients after gastrectomy may likewise be an indication of the presence of previously silent GSE.[84]

XII DIVERTICULOSIS, DIVERTICULITIS, AND APPENDICITIS

WILLIAM V. HARFORD, M.D., F.A.C.P.

Colonic Diverticular Disease

Colonic diverticula are herniations of colonic mucosa and submucosa that extend through the muscularis propria. They occur where perforating arteries traverse the circular muscle layer and form parallel rows between the mesenteric and antimesenteric taenia. Diverticulosis describes the presence of diverticula, whereas diverticulitis refers to the inflammation of diverticula. Diverticulosis is a common condition; of persons with known diverticulosis, about 10% to 20% will develop diverticulitis or diverticular bleeding.[1]

DIVERTICULOSIS

Epidemiology

There are no population-based studies of the prevalence of diverticulosis. About 1% of the United States population reported having diverticulosis in the 1983–1987 National Health Interview Survey (NHIS). Women were two to three times more likely than men to report having diverticulosis, and whites were more likely than African Americans. The prevalence of self-reported diverticulosis increased with age. It was 0.1% at 45 years of age or younger and 4.4% at 75 years of age or older. Unrecognized diverticulosis is more common than known diverticulosis. It is estimated that 10% to 20% of persons older than 50 years have diverticulosis.[2] In Western countries, diverticula occur predominantly in the left colon, particularly the sigmoid colon, which is involved in 95% of cases. In the Orient, including Japan, diverticula occur predominantly in the right colon.[3,4]

About 85% of persons with self-reported diverticulosis in the NHIS were asymptomatic or reported no limitations resulting from diverticulosis. Patients who are asymptomatic at the time of diagnosis are unlikely to develop diverticulitis. In the First National Health and Nutrition Examination Survey (NHANES I) Epidemiologic Follow-up Study, a cohort of physicians with asymptomatic diverticulosis were followed for a 10-year period. The probability of hospitalization for diverticular disease was less than 1% for physicians who were 25 to 44 years of age at the beginning of the follow-up period and was about 5% for those who were 65 to 74 years of age.[2] In English and Finnish populations, the risk of acute diverticulitis was about four per 100,000 population per year.[5,6] The risk of diverticulitis increases with age and with the use of nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and opioids.[1,5,7]

Pathogenesis

Reduced colonic diameter and reduced colonic wall compliance are felt to predispose persons to diverticulosis. A reduced colonic diameter causes the formation of closed segments during colonic contractions, thereby increasing intraluminal pressure. Diverticulosis is common in countries where a low-fiber diet is consumed, because a low-fiber diet leads to reduced stool volume and colonic diameter, particularly in the sigmoid colon. A high-fiber diet reduces the risk of diverticular disease.[8,9] Patients with diverticulosis have an age-related increase in elastin deposition and collagen cross-linking.[10] Increased proline absorption from Western diets may be a factor contributing to increased elastin deposition.[11] Changes in elastin and collagen lead to thickening and shortening of the taenia and circular muscle layers (myochosis) in many patients with diverticulosis, increasing the possibility of segmentation. These elastin and collagen changes also result in reduced compliance of the colonic wall, so that for any colonic diameter, intraluminal pressure is higher than it is in patients with normal compliance.[12] Increased intraluminal pressure leads to herniation of mucosa through the defects in the muscularis of the colon associated with perforating arteries.

Only mucosa and submucosa separate the lumen of diverticula from the colonic serosa. Diverticulitis may result from abrasion of the mucosa by inspissated stool. Changes in bacterial colonic microflora have been reported in patients with diverticulosis. It has been proposed that these changes may lead to low-grade chronic inflammation, predisposing to the development of diverticulitis.[13,14] Chronic intermittent use of oral rifaximin, a poorly absorbed antibiotic, and mesalazine, an anti-inflammatory agent, appears to reduce the risk of diverticulitis.[15,16]

Diverticula form where medium-sized perforating arteries penetrate the muscularis propria to enter the submucosa. Pathologic examination has been reported to reveal evidence of chronic injury to the internal elastic lamina and media of these arteries. This injury can cause arterial rupture into the lumen of the colon. Diverticular bleeding is rarely associated with acute diverticulitis.

DIVERTICULITIS

Diagnosis

Diverticula are most often discovered incidentally during investigation of another condition. Diverticulitis varies in presentation and severity. The diagnosis of acute diverticulitis is often made on the basis of the history and physical examination, which includes abdominal, rectal, and pelvic examinations; imaging studies are used to confirm the diagnosis. Computed tomography has become the optimal method of investigation for patients suspected of having diverticulitis. The modified Hinchey classification, which takes into account both clinical and CT findings, is useful for prognosis and management [*see Table 1*].[17]

Clinical presentation Patients with mild diverticulitis (Hinchey stage 0 or 1a) have limited inflammation or phlegmon in the area of the involved diverticulum. They typically present with left-sided lower abdominal pain and localized tenderness, low-grade fever, anorexia, and nausea without vomiting. They may have mild leukocytosis. Patients with mild diverticulitis can often be managed without hospitalization.[4] Patients with more severe diverticulitis usually must be hospitalized. They often have a diverticular abscess (stage 1b or 2), which is usually contained in the pericolic fat, mesentery, or pelvis but may extend beyond the pelvis. Patients with an abscess (or large phlegmon) commonly have systemic toxicity, high fever, severe localized abdominal tenderness, and leukocytosis. The phlegmon or abscess may be palpable. Rupture of a diverticular abscess results

in purulent peritonitis (stage 3), which usually leads to diffuse abdominal tenderness. Free perforation of a diverticulum with fecal soiling of the abdominal cavity leads to feculent peritonitis (stage 4). Feculent peritonitis causes severe acute generalized peritonitis and sepsis.

Colonic inflammation associated with diverticulitis may cause either diarrhea or constipation. Acute diverticulitis may lead to colonic or small bowel obstruction. Repeated episodes of diverticulitis with fibrosis may cause colonic stricture.

Diverticulitis may cause fistula formation, most commonly from the sigmoid colon to the bladder. Inflammation adjacent to the bladder may lead to dysuria even if no fistula is present. Overt lower gastrointestinal bleeding is rarely associated with acute diverticulitis. Other causes of bleeding (e.g., angiodysplasia, a neoplasm, or inflammatory bowel disease) must be excluded in patients with diverticulitis who present with overt bleeding or who have positive fecal occult blood tests.

In a large retrospective study of patients who required hospitalization for acute diverticulitis, 72% of patients had no abscess (Hinchey stage 0 or 1a); 19%, an abscess (Hinchey stage 1b or 2); 5%, prurulent peritonitis (Hinchey stage 3); 1%, feculent peritonitis (Hinchey stage 4); 1%, obstruction; and 2%, fistula. Overall, surgery was required in 26% of patients.[17] Comparable distribution of stages has been reported in other studies.[18-20]

Diverticulitis in areas other than the sigmoid colon is uncommon in Western countries. In such cases, clinical presentation may be atypical and confusing. Cases of right-sided colonic and cecal diverticulitis are often clinically indistinguishable from appendicitis.[21-23]

Diverticulitis may lead to episodic abdominal pain. In a study of patients previously hospitalized for acute diverticulitis, 70% subsequently experienced new, recurrent episodes of abdominal pain, usually lasting less than 4 hours.[24] After the first episode of diverticulitis, 30% to 50% of patients have subsequent episodes. About 20% to 25% of patients have subsequent episodes of complicated diverticulitis within the first several years of follow-up.[18,19] Patients who initially have a large diverticular abscess have an increased risk of recurrence of diverticulitis, even if the abscess is treated by antibiotics and drainage by interventional radiology.[17]

Table 1 Modified Hinchey Classification of Acute Diverticulitis[17]

Stage	*Characteristic Symptoms*
0	Mild clinical diverticulitis (left lower quadrant abdominal pain, low-grade fever, leukocytosis, no imaging information)
1a	Confined pericolic inflammation, no abscess
1b	Confined pericolic abscess (abscess or phlegmon may be palpable; fever; severe, localized abdominal pain)
2	Pelvic, retroperitoneal, or distant intraperitoneal abscess (abscess or phlegmon may be palpable, fever, systemic toxicity)
3	Generalized purulent peritonitis, no communication with bowel lumen
4	Feculent peritonitis, open communication with bowel lumen
Complications	Fistula, obstruction (large bowel or small bowel)

Imaging studies Patients with symptoms and signs of mild, uncomplicated diverticulitis who respond promptly to outpatient medical treatment do not necessarily require an imaging study immediately. Confirmation of the diagnosis can be delayed for 4 to 6 weeks, when active inflammation has resolved. If there is uncertainty about the diagnosis, outpatient CT is performed to exclude conditions that mimic diverticulitis [*see* Differential Diagnosis, *below*].

On CT, diverticula are seen as collections of gas or contrast measuring 5 to 10 mm and protruding from the wall of the colon. Symmetrical thickening of the colonic wall may be noted. In diverticulitis, a phlegmon is marked by streaky enhancement of pericolic or perirectal soft tissue and the mesentery [*see Figure 1*]. Perforation and fistula may be visualized by air or contrast. Abscess is seen as one or more discrete fluid collections.[25] If the abscess communicates with the colonic lumen, contrast may enter the abscess cavity. CT readily detects remote abscess. When abscess is detected, the feasibility of CT-guided drainage can be determined.[8,26,27]

Diagnostic tests The objectives of diagnostic testing in suspected acute diverticulitis are to exclude other important conditions, to confirm the diagnosis of diverticulitis, to determine if complications have occurred, and to plan treatment.

Leukocytosis is usually present in acute diverticulitis. The urine may contain a modest number of white cells or red blood cells. Recurrent or polymicrobial urinary tract infections should suggest the possibility of a colovesical fistula. Plain abdominal x-rays are most useful to exclude other abdominal conditions, such as intestinal obstruction. Occasionally, an inflammatory mass with gas may be noted, confirming the presence of an abscess. Free air in the abdominal cavity is unusual in diverticulitis.

Colonoscopy is generally not required for diagnosis in suspected acute diverticulitis, and air insufflation caused by introduction of air may worsen a contained perforation. Colonoscopy can be performed with relative safety if no fluid or free air is noted on abdominal CT.[28] After treatment and resolution of an acute epsisode of diverticulitis, patients should have an elective examination either by colonoscopy or by fiberoptic sigmoidoscopy after barium enema ; the purpose of elective colonoscopy is to exclude the presence of colon cancer and inflammatory bowel disease.[29] Barium enema should be avoided in suspected acute diverticulitis because of the risk of barium contamination of the peritoneum if a perforation is present.

Differential Diagnosis

A number of conditions may mimic acute diverticulitis [*see Table 2*]; among the differential diagnoses less frequently considered are epiploic appendagitis and omental torsion/infarction, which may be distinguished from diverticulitis by CT. Epiploic appendices are small peritoneal pouches filled with fat that are situated along the margin of the colon. These structures can become inflamed, resulting in acute epiploic appendagitis, which may mimic diverticulitis or appendicitis. The clinical presentation consists of acute abdominal pain and tenderness. Peritoneal signs sometimes occur, as do low-grade fever and mild leukocytosis. On CT scan, epiploic appendagitis has a characteristic appearance: an oval, fatty mass surrounded by mesenteric stranding, and mural thickening of adjacent colon is typically present.[30-32]

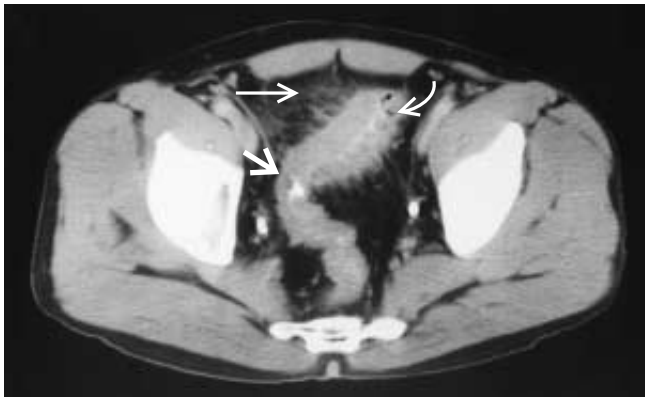

Figure 1 **CT diverticulitis. The wall of the sigmoid colon is thickened (broad arrow). Air is seen within a diverticulum (curved arrow). Streaky enhancement of pericolis fat (horizontal arrow) is caused by inflammation.**

In rare cases, the omentum may undergo spontaneous torsion, causing ischemia or infarction. The clinical presentation may mimic acute diverticulitis, appendicitis, or cholecystitis. The diagnosis of omental torsion may be determined preoperatively by the use of abdominal CT.[33,34]

Diverticulitis in Specific Patient Groups

Immunocompromised patients Immunocompromised patients, such as those on glucocorticoids or those who have had an organ transplant, may not manifest the usual signs of diverticulitis, and diagnosis in these patients may therefore be delayed. The severity of diverticulitis may also be underestimated. The threshold for diagnostic evaluation should be low in such patients.

Abdominal CT with rapid helical technique is the most useful diagnostic study when complicated acute diverticulitis is suspected or when the diagnosis is not clear. Specificity and sensitivity are reported to be over 95%.[35] The colon should be filled with water-soluble contrast given either orally (most commonly) or by gentle enema. CT can confirm the diagnosis, identify complications, and aid in planning of treatment. If the patient does not have acute diverticulitis, abdominal CT will usually lead to the correct diagnosis. Conditions other than diverticulitis are found in up to 25% of CT studies.[35]

Women suspected of gynecologic conditions Abdominal ultrasonography may be most useful for women when gynecologic conditions are part of the differential diagnosis. Abdominal ultrasonography may be an alternative test when CT is not readily available or is contraindicated. On ultrasound, diverticula are echogenic and produce acoustic shadowing. On a graded compression ultrasound, the colonic wall in diverticulitis is thickened, noncompressible, and hypoechoic. The involved segment is hypoperistaltic. A phlegmon causes irregular enhancement of pericolic soft tissue, whereas an abscess appears as a fluid collection, within which gas is readily appreciated, if present. When an abscess is identified on ultrasound, a CT scan should be performed to evaluate the potential for radiographic drainage.[26,36]

Magnetic resonance imaging has been reported to be useful in the diagnosis of acute diverticulitis in pregnant women. MRI has the advantage over CT of avoiding fetal exposure to radiation.[37]

Table 2 Differential Diagnosis of Acute Diverticulitis

Inflammatory bowel disease: Crohn disease, ulcerative colitis
Perforated colon cancer
Ischemic colitis
Infectious colitis
Mesenteric appendagitis, omental torsion
Gynecologic conditions: pelvic inflammatory disease; ovarian torsion, ruptured follicle or cyst; endometriosis
Appendicitis (situs inversus)

TREATMENT

Outpatient Management

Fewer than 20% of patients with acute diverticulitis require hospitalization.[38] Patients who present with mild diverticulitis should be placed on a regimen of oral fluid/electrolyte solution (e.g., a sports drink) and oral antibiotics. Patients should eat no solid foods during this period. The antibiotic regimen should provide coverage against gram-negative and anaerobic bacteria. For example, amoxicillin–clavulanic acid at a dosage of 875/125 mg twice daily is acceptable monotherapy; a suitable combination therapy is a quinolone (e.g., levofloxacin, 750 mg once daily) combined with metronidazole (500 mg twice daily).[39] The patient should be instructed to report back at once if symptoms worsen. Reevaluation is scheduled for 48 to 72 hours after the office visit. If improvement is satisfactory, the diet is advanced to full liquids, antibiotics are continued, and another office visit is scheduled at 7 days. If improvement is evident at 7 days, the patient can resume a regular diet and discontinue antibiotics.[4] Patients whose symptoms worsen or who do not have a favorable response within 48 to 72 hours should be hospitalized. If there is uncertainty about the diagnosis, outpatient CT is performed. An elective colonoscopy or sigmoidoscopy and barium enema exam is scheduled for 6 weeks after the acute illness, unless such a study was performed within the past 5 years.

Inpatient Management

Patients should be hospitalized if there are signs of severe or complicated diverticulitis, such as systemic toxicity, temperature exceeding 101° F (38.3° C), vomiting, an abdominal mass, or signs of peritonitis; patients should also be hospitalized if they fail to respond within 2 to 3 days to outpatient management. Hospitalized patients should be placed on bowel rest and given intravenous fluids and antibiotics. Antibiotic coverage must include both aerobic and anaerobic gram-negative bacteria. An example of a suitable monotherapy regimen is ampicillin-sulbactam (1.5 to 3.0 g every 6 hours); an acceptable combination therapy regimen is levofloxacin (750 mg I.V. once daily) combined with metronidazole (1 g I.V. every 12 hours).[39] A surgical consultation should be obtained upon admission. CT scanning should be done promptly. If a phlegmon or small abscess (< 3 cm) is found, antibiotic treatment alone may suffice. Abscesses larger than 5 cm should be drained by interventional radiology, unless radiologic drainage is contraindicated by the location of the abscess or the presence of multiple abscesses.[27] Antibiotic treatment and radiologic abscess drainage often allow control of infection in cases of complicated diverticulitis. Control of infection im-

proves the possibility of elective single-stage resection and reanastomosis. Urgent surgery should be considered for patients with large abscesses that are not amenable to radiologic drainage or with multiple abscesses; for patients failing to respond within 48 to 72 hours; and for patients with evidence of free rupture of an abscess or a large perforation with fecal spillage. About 20% to 30% of patients hospitalized for the first time with acute diverticulitis require either urgent or elective surgery.[17]

Surgical Treatment

Open resection The optimal surgical treatment of acute diverticulitis involves resection of the involved segment at the initial operation whenever this is technically possible. Leaving the diseased colon in place and performing only a diverting colostomy is associated with a higher rate of complications than primary resection. Primary reanastomosis is generally possible.[40] If there is concern that the anastomosis is at undue risk of disruption, a temporary diverting ileostomy may be performed. Alternatively, the distal rectal segment can be closed (Hartmann procedure) and a descending colostomy created. Patients undergoing surgery for diverticulitis should be informed about the possibility that an ostomy, if created, may be permanent. Because of comorbidities and other issues, about 35% of ostomies performed for diverticulitis will still be in place 4 years after surgery.[41] In the case of sigmoid diverticulitis, it is important to extend the resection to the rectum—to include the entire segment involved with diverticula—because failure to do so markedly increases the probability of recurrent diverticulitis.[42,43]

Laparoscopic surgery Laparoscopic surgical techniques are increasingly being used for diverticular disease. Results of laparoscopic resection for diverticulitis are the same as those of open resection if the resection extends to the rectum and no sigmoid colon is left in place.[44,45] Laparoscopic resection is safe and effective; its advantages over open surgery include decreased blood loss, faster recovery of bowel function, and shorter hospital stay. There are no differences in operative time or mortality with the two procedures.[45] Less than 10% of cases require conversion from laparoscopic to open resection.[44]

Elective surgery Factors considered in the recommendation of elective surgery for diverticulitis include the general health of the patient, the number and severity of episodes, and the degree to which symptoms resolve between episodes. As mentioned, about 20% to 25% of patients will have a subsequent episode of complicated diverticulitis within several years after their first episode.[18,20] Surgery is often recommended after one episode of complicated diverticulitis or two episodes of uncomplicated diverticulitis; however, a recent decision analysis study suggested that the best overall outcome—taking into account mortality, morbidity, the number of surgical procedures, and the number of ostomies—may be achieved if elective colectomy is recommended after the fourth episode of uncomplicated diverticulitis, which is a more conservative recommendation than is generally practiced.[46]

Young, overweight men have been reported in some series to have a higher risk of complicated diverticulitis and recurrent diverticulitis than other patients. Some surgeons therefore recommend surgery after the first episode of diverticulitis in such patients[29,47,48]; however, this increased risk has not been confirmed in other series, and some surgeons have suggested that the recommendation for surgery after the first episode be tempered.[20,49,50]

Preventive Treatment

A diet high in insoluble fiber and low in fat and red meat appears to reduce the risk of diverticular disease. Higher levels of physical activity are also associated with reduced risk of diverticulitis.[8,9]

The intermittent use of rifaximin, a poorly absorbed oral antibiotic, has been reported to provide a greater reduction of symptoms of diverticular disease and risk of recurrence than the use of fiber alone.[15] Rifaximin is given in a dosage of 400 mg by mouth twice daily for 1 week of each month. Mesalamine has been used for the same purpose in a dosage of 800 mg by mouth twice daily for 1 week of each month. The combination of rifaximin and mesalamine has been reported to be more effective than mesalamine alone.[16]

It is prudent to advise patients with a history of diverticular disease to avoid NSAIDs if possible, as these medications have been associated with an increased risk of complications.[5,7]

COMPLICATIONS OF DIVERTICULAR DISEASE

Fistula

Fistula is the presenting complication in 10% to 15% of patients who require surgery for diverticular disease. There is often no history of acute diverticulitis. Patients may present with symptoms related primarily to the organ involved with the diverticular fistula, which is the bladder in most cases. Diverticular disease is the most common cause of colovesical fistula, followed by colon cancer and Crohn disease. Colovesical fistulas are much less common in women than in men, presumably because the uterus is interposed between the sigmoid colon and the bladder. Patients with colovesical fistulas usually present with recurrent polymicrobial bladder infections, pneumaturia, or both. Fistulas may also connect with other parts of the colon, the small bowel, the uterus, or the vagina. Colocutaneous fistulas are unusual and generally occur after surgery for diverticulitis.[51]

Colovesical fistulas are difficult to visualize. CT scanning may be the most useful single study. Even though fistulas are rarely directly visualized, CT is very sensitive for detection of air in the bladder, which is virtually diagnostic of an enterovesical fistula in the absence of prior bladder catheterization. CT demonstrates the presence of diverticula, and thickening of the bladder wall adjacent to an area of diverticulitis supports the diagnosis.[52] Colovesical fistulas are often not identified by a barium enema study, although secondary changes of diverticulitis are usually apparent. Cystoscopy often reveals focal mucosal inflammation in the area of a fistula, even though the opening is not apparent. Fistulas may be visualized by contrast cystography.[53] Colonoscopy should be done at some point to exclude cancer or inflammatory bowel disease, but it rarely reveals the fistula. CT, barium enema, cystoscopy, and colonoscopy are complementary studies for the evaluation of a suspected colovesical fistula.[52] Patients with a diverticular fistula should have elective surgical resection of the involved segment of colon once the acute inflammatory process has been controlled. In the case of colovesical fistulas, the adherent colon can usually be dissected off the bladder and the involved bladder oversewn, rather than resected.[54]

Obstruction and Stricture

Acute obstruction during an episode of diverticulitis is often self-limited. It may be caused by a large phlegmon or abscess. Secondary ileus may mimic obstruction. Chronic stricture is an uncommon presentation of diverticular disease. It usually occurs

after repeated episodes of diverticulitis. A diverticular stricture may be difficult to distinguish from a malignant stricture, particularly by CT or a barium enema study. Colonoscopy with biopsies is the best means of making this distinction, although visualization may be limited even with colonoscopy.

Segmental Colitis Associated with Diverticular Disease

In about 1% of cases, chronic diverticular disease is associated with patchy mucosal hemorrhage, congestion, and granularity in the sigmoid colon. On microscopic examination, a lymphocytic infiltrate, lymphoglandular complexes, mucin depletion, mild cryptitis, crypt distortion, Paneth cell metaplasia, and ulceration can be seen. These changes may mimic Crohn colitis, ulcerative colitis, or ischemic colitis. However, in segmental colitis associated with diverticular disease (SCAD), the changes are limited to areas of diverticulosis.[55,56]

Risk of Colon Cancer in Diverticular Disease

Some studies have shown an increased risk of sigmoid colon cancer in patients with a history of diverticulitis, but other studies have not confirmed this finding.[57-59] In addition to the difficulty in distinguishing a diverticular stricture from a malignant stricture, perforated colon cancer can mimic acute diverticulitis accompanied by a phlegmon or abscess. Thus, it seems prudent to recommend elective colonoscopy to patients with diverticular disease.

DIVERTICULAR BLEEDING

Diverticular bleeding is less frequent than diverticulitis as a complication of diverticulosis. It is difficult to arrive at a firm estimate of what proportion of major lower gastrointestinal bleeding is caused by colonic diverticula. Estimates have ranged from 15% to 56%.[60-62] In many cases, the source is presumed to be diverticular when no other cause is found.

Diverticular bleeding is usually sudden and painless. Typically, moderate to large amounts of bright-red blood, clots, or maroon stool are passed. Bleeding stops spontaneously in 70% to 80% of cases; bleeding eventually recurs in 25% to 35% of cases.[63,64] Lower gastrointestinal bleeding (occult bleeding in particular) should not be attributed to diverticulosis unless other causes have been excluded. The most common causes of lower gastrointestinal bleeding in adults are diverticulosis, inflammatory bowel disease, neoplasm, angioectasias, benign anorectal disease, and upper gastrointestinal sources.[65]

Practice guidelines for the evaluation and management of lower gastrointestinal bleeding have been published.[64]

Emergent Management and Evaluation

The first priority in lower gastrointestinal bleeding is volume restoration with intravenous fluids and blood. During resuscitation, a directed history is taken and a physical examination is performed; the physical examination includes anoscopy and proctoscopy to exclude an anorectal source. A nasogastric aspirate should be obtained, because about 10% to 15% of apparent major lower gastrointestinal bleeding is, in actuality, from an upper gastrointestinal source.[61] Lack of blood in the nasogastric aspirate, however, is not conclusive proof of a lower gastrointestinal source. Bleeding from an upper gastrointestinal source may have stopped, and the stomach may have evacuated residual blood. Blood from a duodenal source may not reflux into the stomach. Some clinicians perform an upper gastrointestinal endoscopy before colonoscopy even if the nasogastric aspirate is negative for blood, particularly for apparent major lower gastrointestinal bleeding.

Colonoscopy Many clinicians consider colonoscopy to be the most useful initial study for the evaluation of patients presenting with major lower gastrointestinal bleeding of unknown cause.[66] Lower gastrointestinal bleeding is usually intermittent and often stops before hospital admission or shortly thereafter. Adequate colonic purging followed by colonoscopy is almost always possible even in spite of moderate active lower gastrointestinal bleeding.[61,66] The most important contribution of colonoscopy is to establish a presumptive diagnosis of diverticular bleeding by excluding other causes and to determine the distribution of diverticula, which is important if colonic resection becomes necessary. Some authors recommend urgent colonoscopy and report a high success rate in localizing and treating diverticula responsible for bleeding.[66] In another report, however, there was no correlation between the timing of colonoscopy and success in localizing the bleeding diverticulum over an interval of 7 to 29 hours.[67] If active bleeding or an adherent clot is found at the time of colonoscopy, endoscopic therapy can be performed with epinephrine injection, cautery, hemostatic clips, or banding.[68,69]

Labeled blood cell scintigraphy Technetium-99m (^{99m}Tc)–labeled red blood cell scintigraphy is another tool for the evaluation of acute lower gastrointestinal bleeding. After injection with ^{99m}Tc, imaging is done continuously for 60 to 120 minutes. Dynamic scans are viewed in a computer-generated cinematic format. Continuous scanning improves the probability of detecting intermittent bleeding.[70] The radioactive label remains active for over 24 hours; thus, if the scan is not positive initially, scanning can be repeated at any time during the first day if there are indications of recurrent bleeding. A scan is considered positive if there is a focus of increased activity that changes in location and intensity over time [*see Figure 2*]. ^{99m}Tc-labeled red blood cell scanning is the most sensitive study for detection of acute gastrointestinal bleeding. It can theoretically detect bleeding rates as low as 0.5 ml/min. Localization of bleeding to the small bowel, right colon, or left colon is generally possible, but reports of the accuracy of ^{99m}Tc-labeled red blood cell scanning have been inconsistent.[70-72] False positive readings may occur with vascular neoplasms, inflammatory conditions, vascular grafts, varices, splenosis, and bladder or penile activity.

^{99m}Tc scanning does not elucidate the cause of bleeding; rather, it demonstrates active bleeding and the approximate location of its source. Colonoscopy is still necessary to determine the presence of diverticula and exclude other potential colonic sources. Once diverticula have been established as the probable cause of bleeding, scanning has a role in detecting recurrent bleeding. A positive ^{99m}Tc scan also provides prognostic information; patients with positive scans are much more likely to have positive arteriograms and are more likely to require surgery than those with negative scans.[72]

Treatment

Visceral angiography and vasopressin infusion Visceral angiography may be useful in persistent moderate to severe lower gastrointestinal bleeding, particularly when the site has not been discovered by colonoscopy and upper gastrointestinal endoscopy or when colonoscopy is not feasible. Angiography can provide precise localization of bleeding in patients who have a positive bleeding scan. If active bleeding is detected and local-

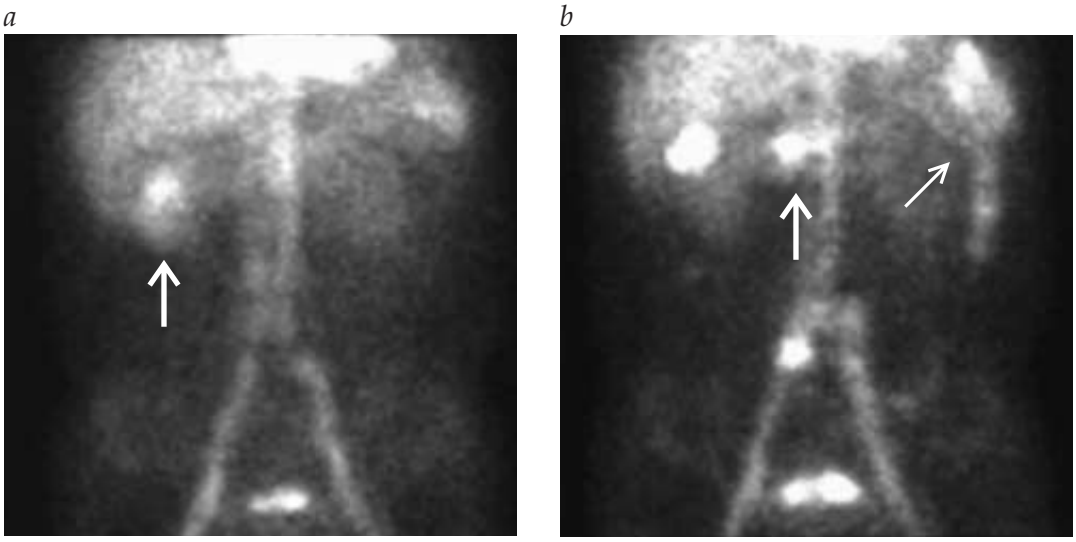

Figure 2 ***(a)*** **Technetium-99m red cell scanning shows increased tracer activity in the area of the hepatic flexure (arrow).** ***(b)*** **Later, tracer activity has progressed to the transverse colon (broad arrow), as well as the splenic flexure and descending colon (small arrow), confirming that the right colon is the source of the bleeding.**

ized, it may then be treated with intra-arterial vasopressin infusion. Rebleeding occurs in 25% of patients when the vasopressin infusion is stopped. Even temporary control may provide time to stabilize the patient and prepare for elective surgery.[64,71]

Arterial embolization Arterial embolization of the bleeding artery has been reported, but it is associated with a substantial risk of intestinal infarction, particularly if followed by vasopressin infusion.[71] Bowel or myocardial ischemia, as well as other complications inherent to contrast arteriography, may complicate both vasopressin infusion and embolization.

Surgery About 20% of patients hospitalized for diverticular bleeding require surgery during that hospitalization.[63] Patients who initially require four units or more of blood have a 50% risk of continued bleeding, as compared with a 2% risk of continued bleeding for patients who require two or more units of blood. Persistent instability despite aggressive resuscitation demands surgical intervention.[63]

Elective surgery for recurrent bleeding The risk of recurrent diverticular bleeding after the first episode is about 10% after 2 years and 25% after 4 years.[60] The risk is higher after a second episode. Elective surgery is usually recommended after two or more episodes of bleeding. If diverticula are limited to the left side of the colon, left hemicolectomy is appropriate. The decision regarding the extent of resection is more difficult when diverticula are distributed throughout the colon. If all previous episodes of diverticular bleeding have been localized to either the right or the left side by scintigraphy or angiography, some clinicians would advocate a corresponding hemicolectomy. The risk of recurrent bleeding from diverticula in the remaining colon is not known. Other clinicians would recommend a subtotal colectomy. Occasionally, persistent or recurrent severe lower gastrointestinal bleeding cannot be localized. Blind segmental resection is associated with an unacceptable recurrence rate, and subtotal colectomy is the favored procedure.[61]

Appendicitis

EPIDEMIOLOGY

The lifetime risk of appendicitis is about 9% for males and 7% for females.[73] Appendicitis rarely occurs in infants; it increases in frequency between the ages of 2 and 4; and it reaches a peak between the ages of 10 and 20. About 80% of cases occur before the age of 45. Nevertheless, there is a steady low incidence in older individuals. The mortality associated with acute appendicitis declined between 1945 and 1960, coincident with advances in antibiotic treatment. In 1990, the mortality associated with acute uncomplicated appendicitis was approximately equal to that associated with general anesthesia. However, the mortality associated with gangrenous appendicitis is about 0.5 %, and that of perforated appendicitis is 5%. Most deaths from acute appendicitis occur in persons older than 65 years.[73]

ANATOMY AND PATHOGENESIS

The adult appendix is a tubular structure that is 4 to 25 cm long and arises from the medial posterior wall of the cecum several centimeters below the ileocecal valve. Its location in the peritoneal cavity varies. Atypical locations, such as the pelvis, retrocecal area, and right upper quadrant, lead to atypical clinical presentations [*see* Atypical Presentations, *below*].

Appendicitis is generally caused by obstruction of the lumen of the appendix, followed by infection. The appendix has abundant lymphoid tissue. Appendicitis increases in frequency during the period of lymphoid hyperplasia in childhood. During periods of childhood enteric infection, lymphoid tissue may obstruct the appendiceal lumen. About one third of cases of appendicitis are associated with obstruction by fecaliths. Foreign bodies, tumor (e.g., carcinoid or cecal adenocarcinoma), barium, and adhesions may also cause obstruction. Obstruction leads to bacterial overgrowth. Mucus accumulates in the lumen proximal to the obstruction, and intraluminal pressure increases. Impairment of lymphatic and venous drainage leads to mucosal ulceration, bacterial invasion, transmural inflammation, and ischemia. During the first 24 hours after obstruction, most patients

have only inflammation. The incidence of necrosis and perforation increases markedly after that. Patients who present with a history of symptoms for 48 hours should be strongly suspected of having perforation and abscess. Free perforation causes generalized peritonitis.

DIAGNOSIS

Clinical Presentation

Appendicitis usually causes a distinctive sequence of symptoms and signs. More than 90% of patients with appendicitis complain of pain. The pain of appendicitis is initially caused by obstruction of the appendiceal lumen. It has the qualities of midgut visceral pain and is referred to the periumbilical or epigastric areas. It may be cramping or aching in nature, but it is often difficult for patients to describe. Within 12 to 24 hours, inflammation becomes transmural, involving the adjacent parietal peritoneum. Pain then becomes somatic in quality: sharper and more localized. At this time, patients may note exacerbation of pain by coughing, sneezing, or movement.

Anorexia is present in 80% to 90% of patients. Vomiting, when it occurs, does not occur initially but follows the onset of pain. Prominent vomiting is unusual and suggests the possibility of another diagnosis, such as gastroenteritis or small bowel obstruction. Fever is usually low grade. High fever or rigors suggest perforation.

Tenderness in the right lower quadrant can be elicited in more than 90% of patients. Proximity of the inflammatory process to the retroperitoneal muscles produces the psoas and obturator signs. The psoas sign is present when pain occurs as the patient raises the right leg against resistance or, alternatively, when the physician passively extends the right hip with the patient lying on the left side. The obturator sign is present when pain occurs upon internal rotation of the hip. Local hyperesthesia of the skin in the right lower quadrant may be noted. Voluntary guarding progresses to involuntary muscle rigidity as the inflammatory process worsens. Diffuse abdominal tenderness and rigidity suggest perforation. An abdominal mass suggests phlegmon or abscess formation.

The presentation of appendicitis may mimic a broad range of diseases [*see Table 3*].

There is evidence that appendicitis may resolve spontaneously and recur. Occasionally, the patient history includes previous episodes of acute appendicitis that resolved without treatment. Examination of appendixes removed incidentally at surgery or at autopsy sometimes show fibrosis and obliteration of a portion of the lumen, suggesting previous episodes of appendicitis.[74,75]

Atypical presentations Atypical presentations of appendicitis are as common as the classic presentation. Atypical location of the appendix leads to atypical symptoms and signs. An inflamed retrocecal appendix is relatively shielded from the parietal peritoneum. Pain may be less severe and abdominal tenderness less pronounced. The characteristic shift in pain location to the right lower quadrant may be delayed. A pelvic appendix may cause symptoms resulting from inflammation of the bladder or rectum, such as dysuria or tenesmus. In such cases, tenderness may be best elicited on pelvic or rectal examination. Incomplete intestinal rotation and third-trimester pregnancy displace the appendix toward the right upper quadrant, causing confusion with cholecystitis or perforated peptic ulcer.

Tip appendicitis and stump appendicitis In appendicitis that involves only the tip of the appendix, inflammation may be less severe and may resolve spontaneously; cases of recurrent appendicitis may involve such a pathophysiology. Partial visualization of the appendix on CT may be mistaken for complete filling and lead to a false negative reading.[76] Appendicitis has been reported to occur in the stump of the appendix that is left behind after a previous appendectomy; this can lead to confusion and a delay in diagnosis.[77]

Appendicitis and appendiceal tumors Tumor of the appendix, such as carcinoids, may obstruct the lumen and lead to appendicitis. In elderly men with appendicitis, there is a relatively high incidence of appendiceal tumors.[13,69]

Appendicitis in special groups of patients The diagnosis of appendicitis is difficult in certain groups of patients. Young children, for example, often do not express their symptoms clearly; they may present with only lethargy, irritability, and anorexia.[78] Elderly patients may have a reduced inflammatory reaction; in such cases, pain may be vague, and there may be less fever or abdominal tenderness.[79] Consideration of other diagnoses, such as diverticulitis, may delay surgery. Delayed diagnosis of appendicitis contributes to an incidence of perforation that is close to 20% in the elderly and small children.[80]

In women of childbearing age, gynecologic conditions and pregnancy cause difficulty in diagnosing appendicitis.[81] In one study, the preoperative diagnosis was incorrect in 25% of cases.[82] Complications of pregnancy attributable to appendicitis are considerable. Appendicitis in pregnancy has been reported to result in fetal loss in 33% of first-trimester cases and 14% of second-trimester cases.[82]

Diagnosis of appendicitis may also be difficult in immunosuppressed patients; for example, patients on glucocorticoids often have attenuated symptoms, leading to delay in presentation and a high incidence of complications. In patients with AIDS, symptoms may be typical, but concerns about a multiplicity of other diagnoses may delay surgery.

Diagnostic Evaluation

In the management of suspected appendicitis, it is important to minimize the delay to surgery—and thus reduce the risk of perforation—while at the same time minimizing the number of

Table 3 Differential Diagnosis of Appendicitis

Crohn disease
Gynecologic conditions: ovarian torsion (especially during pregnancy), ovarian vein thrombosis, endometriosis
Perforated right-sided colon cancer
Cecal diverticulitis
Foreign-body perforation of right colon
Meckel diverticulitis
Omental torsion
Epiploic appendagitis
Infections (particularly those involving the ileum): yersinosis, brucellosis, salmonellosis, tuberculosis, amebiasis
Vasculitis
Appendiceal tumors
Psoas abscess

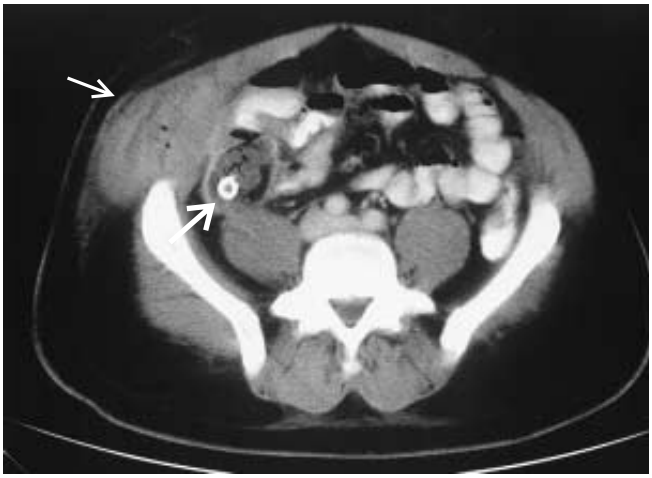

Figure 3 **CT of appendicitis. A calcified appendicolith is noted within a complex abscess containing fluid and air (broad arrow). The abscess involves the soft tissues of the abdominal wall (small arrow).**

unnecessary appendectomies. Taking into account the serious consequences of progression to perforation and the relatively low morbidity of appendectomy, most surgeons adopt a relatively aggressive approach to early surgery, accepting a 10% to 15% rate of negative appendectomies (i.e., negative exploration in patients with clinically suspected acute appendicitis).

Some factors that lead to a delay in diagnosis are not under physician control, such as a patient's delay in seeking medical care. Factors that are under physician control include decisions to perform additional diagnostic studies or to observe the patient for the purpose of improving diagnostic accuracy and reducing the number of unnecessary appendectomies. Clinical scoring systems have generally not been found to improve preoperative diagnostic accuracy.[83]

Abdominal examination The abdominal examination is very important for the diagnosis of appendicitis. This has led some physicians to delay the administration of narcotic analgesics until a surgeon has had the opportunity to examine the patient. It has been proved that this practice is unnecessary: morphine does not change the physical examination in acute appendicitis, and early pain relief does not affect the decision for surgery in adults.[84,85]

Diagnostic Tests

The role of diagnostic studies for suspected appendicitis depends on the particular clinical presentation. In cases characterized by a classic presentation, it is standard practice to base the decision to operate primarily on the history and physical examination. A complete blood count, a urinalysis, and plain x-rays of the chest and abdomen may be obtained, but these serve the purpose of excluding other conditions rather than confirming the diagnosis of appendicitis. The total white blood cell count, the differential count, or both are abnormal in more than 90% of cases, but the decision to perform surgery should not be delayed if the white blood cell count is not elevated.[86]

In women of childbearing age, a pregnancy test is mandatory. In many cases, no further diagnostic studies are performed. Among women of childbearing age, the rate of negative appendectomy can be as high as 40%.[81] In other patients, particularly young children or the elderly, the presentation may be atypical and the diagnosis uncertain. In such patients, additional diagnostic studies may be appropriate and helpful.

Abdominal ultrasound Examination by transabdominal or transvaginal ultrasound or both is useful in pregnant and nonpregnant women of childbearing age to exclude a gynecologic cause of symptoms.[81,87] Ultrasound examination is also useful for evaluation of children in cases in which the diagnosis is doubtful. Sonography is widely available, fast, safe, and inexpensive.

On graded compression ultrasonography, the inflamed appendix is a noncompressible, aperistaltic tubular structure that is greater than 6 mm in diameter and located in the right lower quadrant. It has a target appearance, and the lumen is filled with anechoic or hyperechoic material. An appendicolith may be visualized in up to 30% of cases. Pericecal inflammation or phlegmon is seen as prominent fat; abscess appears as loculated fluid. In experienced hands, the sensitivity and specificity for the diagnosis of appendicitis are 85% and 95%, respectively.[88] Despite abdominal tenderness, most patients find the examination tolerable if it is performed gently. Marked peritonitis or abdominal gas may compromise the examination.

Abdominal ultrasound is not as accurate as CT for the diagnosis of appendicitis in adults and adolescents; in addition, it is not as useful as CT for the evaluation of phlegmon or abscess.[89]

Abdominal CT Abdominal CT scanning can increase diagnostic accuracy in many cases of suspected appendicitis. The development of rapid scanning techniques has made CT readily available and practical even in emergency room settings. CT is useful when the diagnosis is unclear, as in elderly patients in whom diverticulitis and perforated colon cancer are important considerations. Abdominal CT may be helpful in women if pregnancy has been ruled out.[90] The routine use of appendiceal CT in the emergency room setting has been reported to reduce both the number of unnecessary appendectomies and delays before necessary appendectomies.[91] CT is helpful when an appendiceal abscess is suspected. It provides information about the size, location, and number of abscesses, as well as the feasibility of percutaneous drainage under radiologic guidance.[92]

CT for suspected appendicitis has been reported to have an accuracy of about 95%.[93,94] CT scan for appendicitis is best done using thin collimation helical scanning. The terminal ileum and cecum must be opacified with contrast that is administered by mouth or by rectum. Rectal administration of contrast has been reported to have advantages over oral contrast for assessing appendiceal filling.[84] The diagnosis of appendicitis is established when pericecal inflammation , phlegmon, or abscess is seen with either an appendicolith or an abnormal appendix. In appendicitis, the appendix is enlarged to more than 6 mm in diameter and fails to fill with contrast. If intravenous contrast has been given, the inflamed appendix will also show enhancement.[71] CT is useful for the evaluation of the degree and extent of periappendiceal inflammation [see *Figure 3*]. Inflammation may cause thickening of the adjacent cecum or ileum. Streakiness of periappendiceal fat is seen with phlegmon. Loculated fluid and, sometimes, gas bubbles are seen with abscess; if gas bubbles are not present, an air-fluid level may be apparent.

Barium enema Since the advent of abdominal ultrasound and CT examination, barium enema has had little place in the evaluation of suspected appendicitis. Appendicitis is most likely to be discovered on barium enema exam when the study is done

for determination of another diagnosis. In acute appendicitis, the appendix fails to fill with contrast on barium enema exam; this finding is more valuable in children than in adults, because the appendix fails to fill with contrast in 15% to 20% of normal adults. Partial filling of the appendix is often difficult to distinguish from complete filling, given the marked anatomic variations in the length of the appendix. Appendicitis may produce a mass effect or inflammatory changes in the adjacent cecum or ileum that can be appreciated by barium enema, but CT provides much more information than barium enema in this regard. Barium enema exam may be helpful in the evaluation of chronic or recurrent right lower quadrant abdominal conditions that mimic "chronic" appendicitis, such as Crohn disease.

TREATMENT

Preoperative Management

The treatment of appendicitis is prompt appendectomy. Preoperative preparation consists of intravenous volume repletion and antibiotics. For simple appendicitis, one dose of a broad-spectrum antibiotic given before surgery and one dose given postoperatively is sufficient.[95] One example of an appropriate regimen for adults is cefazolin (1.5 g I.V.) preoperatively and metronidazole (500 mg I.V.) postoperatively.[39]

If perforated appendicitis is suspected, antibiotic coverage should be broadened. An example of an acceptable regimen for adults is levofloxacin (750 mg I.V. once daily) combined with metronidazole (1 g I.V. every 12 hours).[39] If the presence of a phlegmon or abscess is confirmed, antibiotics are customarily continued for 7 to 14 days postoperatively. However, a prospective, randomized study found that adding a 7-day regimen of oral antibiotics after a course of intravenous antibiotics made no difference in outcome, either in complicated or uncomplicated appendicitis.[96]

Patients with free, unconfined perforation should have abdominal saline lavage during surgery. A prolonged ileus should be anticipated.

Appendectomy

Appendectomy can be performed by a traditional open incision or by laparoscopy. Compared to open appendectomy, laparoscopic appendectomy results in decreased wound infections but slightly increased intra-abdominal infections. Postoperative pain is reduced in laparoscopic appendectomy, and patients return to normal activity sooner. Overall, the benefits of laparoscopic appendectomy over open appendectomy are modest; the greatest benefits occur in women and obese patients.[97-99] The laparoscopic approach is useful in women because it allows for accurate diagnosis of gynecologic conditions if appendicitis is not responsible for the symptoms.[100,101]

Complications occur in fewer than 5% of cases of simple appendicitis but can be anticipated in 30% to 50% of cases of appendicitis after perforation. The most common complications are wound infections, intra-abdominal abscess, intestinal obstruction, and prolonged ileus. Postoperative abscesses are heralded by recurrent malaise, anorexia, and fever, and they are best evaluated by CT.

Interval Appendectomy

Some patients with a contained perforation can be managed by interval appendectomy after treatment with antibiotics or CT-guided percutaneous drainage. The information from preoperative CT or sonography is useful in planning therapy. If imaging shows a phlegmon or small abscess and the patient responds to antibiotic treatment within 48 hours, appendectomy may be postponed for 6 weeks, until the inflammatory process has subsided. If the abscess is large but well circumscribed and accessible, CT-guided percutaneous catheter drainage may be used to reduce the abscess before surgery. The catheter is placed in the abscess and left until drainage from the abscess becomes minimal.[92] If drainage is successful, appendectomy can be postponed for 6 weeks. However, if a patient with a contained perforation does not respond promptly to antibiotic treatment or drainage, surgery should not be delayed. Catheter drainage is not possible if imaging shows a poorly defined or multilocular abscess or if the abscess is not accessible to percutaneous drainage.

If a patient is operated on for suspected appendicitis and the appendix is found to be normal at surgery, it should be removed to prevent future confusion. The cecum and terminal ileum should be examined for evidence of Crohn disease or other acute inflammatory bowel disease, for tumor, or for Meckel diverticulitis. Lymph nodes in the area should be inspected for evidence of mesenteric adenitis, and biopsies should be performed if the lymph nodes appear abnormal. The gallbladder and duodenum should be palpated. If necessary, the incision should be extended to permit wider exposure. Before closing, the surgeon must feel confident that the cause of the clinical presentation has been explained and that there is no other acute abdominal condition.

Incidental Appendectomy

Incidental appendectomy, performed during surgery for another cause, may be justified in individuals younger than 30 years if the primary surgery would not be compromised. Appendectomy does not increase morbidity when performed under these circumstances.[102]

XIII ENTERAL AND PARENTERAL NUTRITION

Khursheed N. Jeejeebhoy m.b.b.s., ph.d.

Definitions

Enteral nutrition is the process of nourishing a patient with a liquid diet of defined composition, usually given through a nasogastric, nasointestinal, gastrostomy, or jejunostomy tube. Parenteral nutrition is the administration of nutrients directly into the bloodstream through a central venous catheter or by peripheral infusion. When the only source of nutrient intake is via the parenteral route, it is called total parenteral nutrition (TPN). The term nutritional support refers to the use of enteral or parenteral nutrition rather than to an oral diet, with or without supplements.

Etiology of Malnutrition

In circumstances in which food is available, malnutrition has three main causes: (1) insufficient intake of food, as a result of conditions such as anorexia, coma, dysphagia, gastric lesions, and psychological factors; (2) heightened metabolic requirements, as may occur in burns, trauma, sepsis, and neoplasia; and (3) intestinal failure, which comprises all conditions that prevent the proper intake, digestion, or absorption of a normal oral diet. Malnutrition from reduced food intake or gastrointestinal failure is most amenable to treatment or prevention with nutritional support. Although nutritional support may overcome some of the effects of trauma, burns, sepsis, or cancer, nutritional support alone may be unable to prevent the development of critical malnutrition in such cases.

Effects of Malnutrition

Even in the absence of disease, malnutrition adversely influences function and survival. A study of Irish hunger strikers found a 30% mortality in strikers who lost 35% to 40% of their body weight.[1] Similarly, in patients with cancer, weight loss of about 30% preceded death.[2] In 12 human volunteers, semistarvation (with a 15% to 20% weight loss over 24 weeks) led to a 60% decrease in function on the basis of a fitness score.[1] Even after 20 weeks of refeeding, the fitness score and handgrip strength in these individuals did not return to normal. Other studies have shown that lack of food intake results in substantial loss of muscle function in addition to loss of body mass.[3] Surgical patients who had weight loss greater than 10% and clinical evidence of dysfunction of two or more organ systems (including skeletal and respiratory muscles) preoperatively had significantly more postoperative complications than did normal patients or those with weight loss but no physiologic dysfunction.[4]

The presence of various diseases compounds the effects of malnutrition. In ill patients, malnutrition results in nutritionally associated complications such as poor wound healing, increased infections, delayed rehabilitation, and increased mortality.

Evidence Regarding Nutritional Support

Well-nourished patients are unlikely to benefit from nutritional support. However, in patients with initial malnutrition and poor function who have continued inability to eat or to absorb ingested food, randomized controlled trials have demonstrated that nutritional support favorably influences outcome by reducing nutritionally associated complications.

parenteral nutrition

Three large meta-analyses of parenteral nutrition have given inconsistent results. In a comparison of parenteral nutrition with standard care in 26 trials, Heyland and colleagues[5] found that parenteral nutrition did not influence overall mortality but did reduce complications in malnourished patients. Benefit from TPN was observed in studies performed before 1988, in studies deemed to be of less statistical quality, and in patients who did not receive lipid. These researchers found only six trials of parenteral nutrition in critical illness; in these trials, complications and mortality were significantly higher than in trials done in surgical patients. Another meta-analysis showed that in malnourished patients, standard care, compared with parenteral nutrition, was associated with increased mortality and a trend toward increased infectious complications; in well-nourished patients, infections were more frequent with parenteral nutrition than with standard care or enteral nutrition.[6] These authors speculated that the increased infectious complications in patients on parenteral nutrition were attributable to hyperglycemia. Not all the studies included in this meta-analysis mentioned blood glucose, but of the seven that did, six found both hyperglycemia and increased infectious complications.

Koretz and colleagues[7] have done a technical review and made recommendations to the American Gastroenterological Association about parenteral nutrition. They found that overall, mortality with parenteral nutrition was no lower than mortality with standard care. In contrast to the meta-analysis by Heyland and colleagues,[5] this analysis showed that total complications and length of stay were lower only in studies in which lipid was a component of TPN. Infectious complications were increased with TPN, especially in cancer patients. Benefit from parenteral nutrition was seen only in patients with upper GI cancer, who had significantly fewer complications when given perioperative parenteral nutrition.

enteral nutrition

Enteral nutrition has not been compared with standard care in the same systematic way as has parenteral nutrition. However, comparisons of enteral nutrition with parenteral nutrition have consistently shown fewer infectious complications with enteral nutrition than with parenteral nutrition.[6] Data from a large controlled trial in intensive care unit patients showed that keeping blood glucose levels below 127 mg/dl (7 mmol/L) significantly reduced mortality from sepsis-related multisystem organ failure.[8] Hyperglycemia probably was more frequent with parenteral nutrition because patients randomized to parenteral nutrition received more calories than those on enteral nutrition,[9]

despite the intent to make both groups isocaloric. None of these studies prove that enteral nutrition is better than standard therapy; rather, they show that enteral nutrition is less likely than parenteral nutrition to cause infection. In a 562-patient trial of enteral nutrition versus TPN that mirrored the conventional practice of nutritional support, Woodcock and colleagues[10] concluded that TPN did not increase sepsis, enteral nutrition delivered less than the target nutritional intake, and procedure-related complications were greater with enteral nutrition.

Determining the Need for Nutritional Support

Unfortunately, for many clinical situations there are no data from randomized, controlled trials to help clinicians determine how to identify patients who are likely to progress to critical weight loss and to determine when to start nutritional support in patients who are at risk. In the absence of reliable data, clinicians have to make decisions about nutritional support at the bedside. Obviously, a previously healthy person who does not eat for 1 or 2 days does not need nutritional support. On the other hand, if inadequate nutritional intake persists for weeks, weight loss will continue; the loss will accelerate if there is added trauma or sepsis; and when loss of body weight exceeds 30%, there is an increased likelihood of death.

The risk of malnutrition can be assessed with a clinical tool called the Subjective Global Assessment (SGA).[11] The SGA, which can be used by physicians, dietitians, or nurses after brief training, is based on a focused history and physical examination that includes the degree and progression of any weight loss, dietary intake, ability to take and absorb food (state of the GI tract), the degree of stress from comorbidity, and functional status.[12] This information is used to classify the patient into one of three groups: A (normally nourished and unlikely to progress to a malnourished state), B (normally nourished but likely to progress to a malnourished state), or C (malnourished and progressing to increasing malnutrition).

The SGA not only provides an assessment of the patient's current nutritional status but also predicts the possible nutritional outcome if nutritional support is not instituted. More important, it allows the clinician to weigh the role of disease severity versus limited nutrient intake as the cause of malnutrition.

Two controlled studies of the SGA have shown that the likelihood of nutritionally associated complications progressively increased from grades A to C. Patients who are classified as SGA C are very likely to develop nutritionally associated complications and therefore should benefit from nutritional support. These studies also found that the SGA grade correlated with other objective measures of nutritional status but was more likely to predict nutritionally associated complications than several of the objective measures taken individually.[13] SGA has been shown to be a valid predictor of nutritionally associated complications in general surgical patients, patients on dialysis, and liver transplant patients. In two large studies, SGA independently identified increased mortality and morbidity from malnutrition, even when the data were adjusted for other factors influencing survival and complications.[14,15]

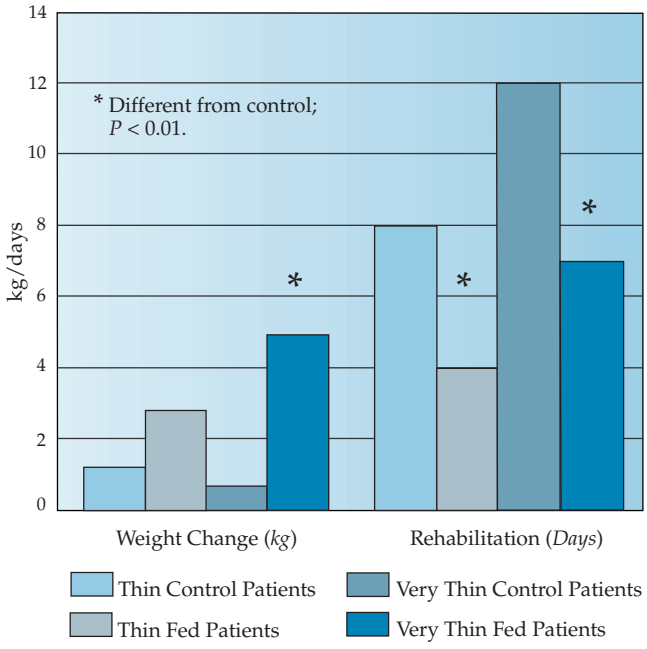

Figure 1 **In elderly women with femoral neck fractures, weight increase was greater and rehabilitation time was shorter in those who received overnight supplementary enteral feeding than in control subjects, who were given a normal hospital diet. The effect was evident in thin patients and was particularly marked in very thin patients.[22]**

Nutritional Support in Specific Clinical Conditions

INSUFFICIENT ORAL INTAKE DESPITE A NORMAL GUT

Well-nourished Patients

In general, most patients with serious illness have reduced food intake, partly from the illness itself and partly as a result of iatrogenic factors. Most hospital inpatients eat insufficient food or are prevented from eating. Several studies have indicated that a significant number of hospital patients have signs of malnutrition. Patients likely to have an inadequate intake of food are those with critical illness (e.g., trauma, burns, severe sepsis, respiratory failure); coma and neurologic diseases; or major psychiatric illnesses. Although many hospital patients fit these categories, there are no controlled trials to provide guidelines that can be confidently used to guide nutritional support in such patients and to confirm that nutritional support can reduce the occurrence of nutritionally associated complications. Clinically, it is a common practice to start nutritional support if the period of reduced intake exceeds 7 to 10 days or weight loss exceeds 10%.[16] Unfortunately, this practice has no supporting data except consensus and expert opinion.

Early enteral feeding has been recommended on the basis of a randomized trial in trauma patients who were to undergo a laparotomy and had an abdominal trauma index greater than 15.[17] This subset constituted 20% of all trauma patients admitted during the period of study. These patients, who were well nourished on admission, were randomized to a group who received early (12 to 18 hours after surgery) institution of enteral feeding through a jejunostomy tube inserted at surgery or to a control group in whom TPN was started 5 days after surgery if the patient was not yet on a regular oral diet. There was no difference in overall complications between the groups, but septic complications were significantly lower in the early-fed group (4%, versus 26% in the TPN group). Such data are subject to the criticism that there was no control group receiving standard care. However, there are other reasons to support early feeding. In a randomized trial of postoperative supplemental sip

feeding of a liquid formulation, grip strength significantly improved and the occurrence of serious infections was reduced.[18] In a trial of 501 hospitalized elderly patients randomized to oral supplements or a ward diet, Larsson and colleagues[19] showed that irrespective of their initial nutritional status, the supplemented patients had lower mortality, better mobility, and a shorter hospital stay. The difference between ward diet and supplementation was even more pronounced in a secondary analysis of patients with weight loss.

Recommendations The available data suggest that well-nourished patients who are admitted with major trauma should receive enteral nutrition. Elderly patients should receive supplemental feeding or enteral nutrition if they are incapable of eating adequately. However, all hospitalized patients should have their SGA assessed so that possible future outcome without nutritional support can be documented and considered. For example, if a previously healthy patient has a severe head injury and is likely to remain comatose (and therefore unable to eat) for an indefinite period, it is easy to predict that malnutrition will occur in the absence of nutritional support. Such a patient should be started on enteral nutrition. Similarly, major burns, the hypermetabolic state, anorexia, and ileus all result in rapid weight loss unless nutritional support is given. Each case needs to be assessed individually, however. Repeated evaluation of the SGA allows the clinician to determine any impediment to the intake of food, the presence of GI dysfunction, and progressive functional loss and weight loss, which signal the need to start nutritional support.

The purely scientific approach would be to avoid nutritional support in all situations for which proof of benefit from randomized, controlled studies is lacking; however, in patients without adequate oral intake, this approach could in some cases result in starvation and death. The pragmatic approach is to evaluate the patient, using the SGA, and start nutritional support if the clinical evidence shows that otherwise the patient is likely to progress to critical malnutrition.[20]

Malnourished Patients

There are no controlled trials to show that nutritional support will reduce complications in all patients classified as SGA C. However, there are several indirect lines of evidence suggesting that nutritional support in such patients will reduce complications and improve outcome.

A multicenter, randomized, controlled trial undertaken by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group[21] stratified patients into three nutritional groups. In the group of severely malnourished patients, the rate of major noninfectious complications was significantly lower in patients randomized to TPN than in control subjects (5.3% versus 42.9%). Overall rates of complications and infectious complications in TPN-treated patients in this trial were not different from those in control patients, however.

Other studies have shown that nutritional supplementation can significantly reduce rehabilitation time in patients with hip fractures who had severe weight loss [*see Figure 1*][22] and that elderly patients with hip fractures, especially those with weight loss, benefit the most from supplemental feeding.[19]

Recommendations Elderly patients, especially those with weight loss, should receive nutritional supplements in the hospital. Despite the lack of data from well-designed controlled trials, patients who are classified as SGA C should be given nutritional support.

SURGERY

In a meta-analysis of perioperative parenteral nutrition, Detsky and colleagues[23] combined the results of 14 randomized or quasi-randomized trials and showed that absolute morbidity was reduced by 5.2% and the relative risk reduction was 20.7%. These differences were not statistically significant, however ($P = 0.21$). Of the 14 studies, only one showed a significant reduction in complication and fatality rates with TPN. These authors concluded that perioperative TPN did not influence outcome. On the other hand, only three of the 14 trials were limited to malnourished patients (who were the most likely to benefit from TPN), so the negative result may simply reflect the fact that the trials were weighted by patients who were unlikely to benefit from nutritional support. In contrast, Twomey[24] concluded that the pooled estimate in malnourished surgical patients shows a 7.1% reduction in morbidity with TPN. In the VA trial,[21] secondary analysis showed that the severely malnourished patients had a reduction in overall morbidity from 47% to 26% with perioperative TPN.

Fan and colleagues[25] conducted a controlled trial of perioperative nutritional support in 124 patients undergoing major hepatic resection for hepatocellular carcinoma. The patients were randomized to parenteral nutrition plus oral diet or to diet only. Patients in the treatment arm received 1.5 g/kg of amino acids, of which 35% were branched-chain amino acids (BCAA), with 30 kcal/kg of a glucose-lipid mixture for energy. Medium-chain triglycerides (MCT) constituted 50% of the lipid infused. The parenteral formulation was given for 14 days. At least 20% of the patients had a preoperative weight loss of greater than 10% and therefore were likely to be malnourished, but 80% did not have weight loss. Overall morbidity, morbidity from sepsis, and diuretic use for ascites all were lower in patients who received nutritional support.

Although the benefits of parenteral nutrition in the perioperative state are controversial, randomized trials of postoperative enteral feeding have shown improved outcome. In hip fracture patients,[22] supplemental feeding of a liquid formula diet reduced recovery time. In general surgical patients,[26] the rate of infectious complications with early enteral feeding was lower than that with nil per os (NPO).

Recommendations

Postoperatively, patients who have undergone major surgery should receive supplemental liquid formula feeding. The data do not support the routine use of parenteral nutrition for perioperative nutritional support, but parenteral nutrition clearly reduces complications in patients undergoing hepatic resection. It is not clear whether standard parenteral formulations will reduce complications in patients undergoing hepatic resection or whether it is necessary to give BCAA or MCT. Patients with hip fracture and weight loss will benefit from enteral feeding. Despite the lack of proven benefit, other severely malnourished patients (i.e., those classified as SGA C) should receive perioperative nutritional support.

SERIOUS COMPROMISE OF BOWEL FUNCTION

In patients with massive small bowel resection (i.e., less than 60 cm remaining), chronic bowel obstruction, extensive bowel disease, severe radiation enteritis, or end jejunostomy in which

oral feeding results in uncontrolled fluid and electrolyte losses, parenteral nutrition is needed because oral feeding is very unlikely to provide sufficient nourishment. An economic analysis of such patients showed that provision of parenteral nutrition at home was associated with improved quality of life and was cost-effective.[27] The outlook was especially good for those with chronic intestinal failure from benign disease.[28]

Recommendations

Initially, all patients with a short bowel (see above) need parenteral nutrition. Later, about 30% (especially those with an intact or partially intact colon) can be treated with oral diet and supplements. Enteral nutrition is not necessary in these patients; controlled studies have shown that enteral nutrition was no better than an oral diet in patients with a short bowel and end jejunostomy.[29] Patients with a massive resection can absorb 50% to 60% of an oral diet.[30] By using oral rehydration solution, supplements, and a high-calorie oral diet, about 30% of such patients can reduce or stop home parenteral nutrition. The remaining patients will require supplemental fluid and electrolytes or parenteral nutrition to maintain a normal weight and electrolyte-fluid status.

BOWEL REST

Parenteral Nutrition

Bowel rest is widely used in pancreatitis, intestinal fistulas, and inflammatory bowel disease. The bowel is rested by keeping the patient NPO. Malnutrition is avoided by instituting parenteral nutrition.

Parenteral nutrition is used in pancreatitis because eating often induces pain in such cases. The only controlled trial of parenteral nutrition versus oral diet in patients with mild pancreatitis showed that TPN did not influence recovery.[31] In two trials comparing parenteral nutrition with enteral nutrition in patients with mild or acute pancreatitis, the trial of patients with mild pancreatitis[32] found no difference in septic complications, whereas the trial of patients with severe pancreatitis[33] found less sepsis with enteral nutrition. However, in the latter trial, twice the number of patients on parenteral nutrition were hyperglycemic, a factor known to increase septic complications.[8] Again, these trials do not prove that enteral nutrition is better than standard care.

Parenteral nutrition is useful in patients with intestinal fistulas, in whom eating increases output and fasting reduces output by 30% to 50%. However, there are no controlled trials comparing the effect of bowel rest plus parenteral nutrition with that of oral intake in the healing of fistulas.

In inflammatory bowel disease, bowel rest reduces abdominal discomfort and diarrhea. Controlled trials have not shown that bowel rest aids recovery in these patients, however.[34]

Recommendations Because pancreatitis, intestinal fistulas, and inflammatory bowel disease may prevent the ingestion or absorption of oral nutrients and result in malnutrition, the use of bowel rest and parenteral nutrition is a reasonable strategy in some of these cases, despite the lack of evidence that bowel rest alters the course of the disease. Specifically, enteral or parenteral nutrition should be given to prevent or treat malnutrition when a patient cannot take in or absorb nutrients for 7 to 10 days, when a patient loses nutrients because of a fistula for 7 to 10 days, or when a patient is clearly malnourished (SGA C). The route of administration selected should be capable of delivering the ideal nutrient intake successfully. For example, enteral nutrition is unlikely to be successful in a patient with a high jejunal fistula who is putting out large volumes of intestinal contents.

Enteral Nutrition in Crohn Disease

Controlled trials in Crohn disease have shown that enteral nutrition reduces the activity of the disease and, in children, promotes growth.[35] However, a recent meta-analysis of eight randomized, controlled trials of 413 patients with Crohn disease showed that enteral nutrition was not as effective as corticosteroids in inducing a remission (odds ratio of enteral nutrition/corticosteroids, 0.35; confidence interval, 0.23–0.53). In addition, there was no difference between elemental and polymeric diets in inducing clinical remission.[36] Regrettably, there are no placebo-controlled trials to show whether enteral nutrition is an effective modality for treatment of active Crohn disease.

Recommendations Enteral nutrition is not a replacement for routine drug treatment of active Crohn disease, but under certain circumstances it has definite benefits. Enteral nutrition is especially useful in promoting growth and reducing disease activity in children with growth failure. In such children, enteral nutrition can be given on a long-term basis at home, along with other treatment to promote growth.

In line with other recommendations for nutritional support, patients with active Crohn disease who are SGA C should be treated with enteral nutrition and other modalities as required. However, if they are SGA C and are unable to tolerate enteral nutrition, parenteral nutrition should be used until they can tolerate adequate nutrition by the oral route. Nutritional support is also necessary when serial SGA determinations show evidence of poor intake and the patient has severe GI symptoms and continued functional impairment that could lead to critical malnutrition. The route used depends on the capacity of the GI tract to absorb nutrients.

CANCER MALNUTRITION

Malnutrition in metastatic cancer has been used as an indication for parenteral nutrition. Controlled trials have failed to substantiate that nutritional support is beneficial in patients with metastatic cancer,[37] however, and in fact have suggested that parenteral nutrition may have adverse effects. On the other hand, parenteral nutrition has been shown to favorably influence graft survival in patients receiving a bone marrow transplant.[38]

Recommendations

In cancer patients, nutritional support with enteral or parenteral nutrition is appropriate for preventing or treating malnutrition that is not caused by the tumor per se. For example, patients whose colon cancer has been eradicated but who suffer from short bowel because of extensive radiation enteritis should respond to parenteral nutrition. Criteria for nutritional support in cancer patients are as follows: (1) there is no evidence of tumor or its progression; (2) the patient has a GI complication, such as radiation enteritis or resection; and (3) as a result of this GI complication, critical malnutrition has occurred or will predictably occur (i.e., the patient is SGA C, or serial evaluation of SGA indicates progression toward SGA C).

The most difficult ethical question concerns the use of parenteral nutrition for patients in whom tumor progression causes intestinal obstruction or cachexia. Parenteral nutrition is being increasingly used for this indication [*see* Home Parenteral Nutrition, *below*].

RENAL FAILURE

Because patients with renal disease cannot excrete nitrogen normally, parenteral nutrition in which the source of nitrogen is limited to essential amino acids (EAA) has been used to reduce urea production. A meta-analysis has concluded that parenteral nutrition with EAA does not improve survival to discharge; when the trials were adjusted for quality, there was no effect of EAA.[39]

Recommendations

Patients with renal failure who cannot meet their nutritional requirements by the oral route should be given nutritional support and have fluid, electrolytes, and nitrogenous metabolites removed by dialysis or continuous arteriovenous hemofiltration. Fluid intake is minimized by using enteral nutrition with a calorie density of 2 kcal/ml or parenteral nutrition containing 35% dextrose or 20% lipid as the source of energy. Sodium intake should be restricted to 40 to 70 mmol/day, and other electrolytes should be added if their plasma levels fall. Acidosis should be controlled by appropriate dialysis. Trace elements and vitamin supplements need not be curtailed.

HEPATIC FAILURE AND ALCOHOLIC LIVER DISEASE

The discovery that hepatic encephalopathy is associated with reduced BCAAs and increased aromatic amino acids in plasma has led to the use of parenteral nutrition formulas enriched in BCAAs and reduced in aromatic amino acids. Meta-analysis of trials comparing BCAA-enriched mixtures with standard therapy has shown significant improvement in encephalopathy and, possibly, in short-term mortality.[40] On the other hand, there is no evidence that standard amino acid mixtures or enteral nutrition providing 0.8 to 1 g/kg/day of protein or amino acids has precipitated encephalopathy. In fact, 75 g/day of supplementary amino acids with 400 kcal/day of dextrose improved liver function and was tolerated by patients with severe alcoholic hepatitis.[41]

Recommendations

Patients with hepatic failure who are unable to be on a normal diet need enteral or parenteral nutrition. The protein intake should be about 0.8 to 1 g/kg/day of a high-quality protein or balanced amino acids. Carbohydrates and fat should be given in equal proportions because these patients are carbohydrate intolerant but utilize fat well, and fat infusions increase the levels of BCAA in plasma.[42] Because these patients are sodium and water overloaded, they should receive a total of about 1,500 ml of water daily, and their sodium intake should be restricted to 20 mmol/day. Supplemental potassium, vitamins (A, D, and B complex), and zinc should be given.

Practice of Nutritional Support

GENERAL PRINCIPLES OF NUTRITIONAL CARE

At hospital admission, all patients should be interviewed by a dietitian and have their SGA calculated to determine whether they can be maintained on a normal or modified oral diet (with supplements) in sufficient quantities or whether nutritional support is indicated and, if so, how urgently. In patients requiring nutritional support, the physician and the dietitian should define nutrient intake, route of administration, and goals. The most important objective is maintenance of uninterrupted nutrient intake, to avoid weeks of starvation followed by the urgent institution of parenteral nutrition to an iatrogenically malnourished patient.

Table 1 Procedure for Nasogastric or Nasoenteral Tube Placement

1. Explain the procedure to the patient, to obtain cooperation.
2. Seat the patient comfortably at the edge of the bed, sitting upright.
3. Check nostrils for painful lesions and obstruction.
4. Insert stylet into tube and lubricate.
5. Measure approximate length of tube to be passed by the distance between the tip of the nose to the ear and down to the midepigastrium. Add about 25 cm to this distance.
6. Flex neck slightly.
7. Pass tube through an unobstructed nostril. If the patient finds this very uncomfortable, spray nostril with lidocaine 4% topical solution.
8. Ask the patient to swallow water as the tube is passed.
9. If the patient coughs or chokes, withdraw tube into the pharynx and reinsert.
10. Aspirate gastric contents to confirm position of tube.
11. Air may be injected into the tube while auscultating to determine the intragastric location of the tube.
12. For nasogastric feeding, confirm the tube position by x-ray before infusing.
13. For nasoenteral feeding, place the patient in right lateral position and gradually advance tube. Metoclopramide, 10 mg I.V., may be used to propel the tube.
14. If tube has not passed into the bowel by 24 hours, endoscopic or fluoroscopic guidance may be used.

Oral Nutrition

In patients who can eat, close attention to maintenance of oral dietary intake—and use of supplements, where required—should be the standard of care. Enteral nutrition should be considered if it becomes clear that this approach does not permit sufficient intake to meet requirements.

Enteral Nutrition

Enteral nutrition is applicable to all patients, but it should be used with caution in patients with (1) clinically significant gastroesophageal reflux; (2) intestinal obstruction; (3) GI fistula or recent surgical anastomosis, unless the tube can be inserted distal to the area in question or threaded at operation past the area; and (4) cardiovascular instability with shock. Gastric retention is a relative contraindication. In patients who accumulate secretions in the stomach and then aspirate, it may be possible to pass a feeding tube into the small intestine and aspirate the stomach with a second tube. However, in such cases the relative discomfort of two tubes versus parenteral nutrition should be considered. A recent survey showed that patients preferred parenteral nutrition over enteral nutrition.[43]

Short-term enteral access Nasogastric or nasoenteric placement of a feeding tube provides short-term enteral access. The tube should be small bore (9 to 12 French) and 105 to 110 cm long [*see Table 1*]. These tubes are usually made of Silastic or

polyurethane. The latter become very slippery when wet, thus aiding insertion. I prefer intestinal placement of the tube, because controlled trials have shown better achievement of nutrient intake[44] and, possibly, reduced risk of aspiration when the tube is placed beyond the ligament of Treitz.

Long-term feeding The definition of long-term feeding is arbitrary. Children with Crohn disease have been fed for months by teaching them to pass a nasogastric tube each night, receive a nocturnal feeding, and then remove the tube in the morning before going to school. However, in many instances nasal tubes become uncomfortable, and a gastrostomy tube can be placed endoscopically by a gastroenterologist or an interventional radiologist. This method has been shown to be safer and more cost-effective than a surgically placed gastrostomy. There are two methods of percutaneous endoscopic gastrostomy (PEG): the pull (Ponsky-Gauderer) method and the push (Russell) method.

Feeding into the small bowel can be performed after the insertion of a percutaneous endoscopic jejunostomy (PEJ). After the tract of the PEG tube is established, a PEJ tube with two arms can replace the tube. One arm remains in the stomach and can be used to drain this organ; the other arm is advanced under endoscopic guidance through the pylorus into the small intestine. In this way, the stomach can be decompressed, and simultaneously, the patient can be fed into the small bowel.

To eliminate the inconvenience of the bulky feeding tube, patients with long-term gastrostomies can be fitted with a so-called button device, which lies flush with the abdominal wall. Between feedings, a valve in the device closes off access to the stomach; during feedings, the feeding tube is inserted past the valve, permitting access to the stomach.

Parenteral Nutrition

The intravenous route is used as a supplement to oral or enteral nutrition or is used as the sole source of nutrition (TPN) when it becomes clear that the patient is not receiving sufficient nutrients by the other routes. Regular evaluation of SGA should be performed during TPN to ensure that the patient's nutrient requirements are being met.

Short-term parenteral feeding Short-term infusions are best given through a peripherally inserted central catheter (PICC). These catheters are inserted into an arm or forearm vein and advanced into the superior vena cava. PICCs are comfortable and avoid the risks of subclavian puncture or the difficulties of maintaining sterility of the exit sites of jugular catheters. In addition, full TPN with hypertonic mixtures can be given through these catheters without risk of thrombosis. Despite the designation "short term," these catheters can be used for months.

Long-term parenteral feeding Patients with intestinal failure often require parenteral feeding for years. To permit long-term parenteral feeding, an interventional radiologist advances a specially designed catheter through a subcutaneous tunnel via the jugular vein to the superior vena cava. The tip of this catheter should lie just above the right atrium, to avoid thrombotic complications. Near the exit site, within the subcutaneous tunnel, the catheter is surrounded by a Dacron cuff. Fibroblasts will grow into the cuff, sealing and anchoring the skin exit site.

NUTRIENT REQUIREMENTS

Protein

Protein requirements are met by giving whole proteins, peptides, or amino acids in enteral nutrition and by infusing an amino acid mixture in parenteral nutrition. The goal is to promote nitrogen retention and protein synthesis. Although limiting glucose and lipid (energy) intake will maximize nitrogen retention, dietary protein has an anabolic effect independent of energy intake, and will reduce nitrogen losses when infused alone.[45] Thus, the amount of amino acids given appears to be a very important determinant of nitrogen balance.

About 1 to 1.5 g/kg of ideal body weight of protein or amino acids will be sufficient for most patients with normal renal function. Additional amounts should be added for losses from prior depletion or current hypercatabolism. In patients with hepatic failure, protein intake should be restricted to 0.8 to 1.0 g/kg a day.

Glutamine

Glutamine is an amino acid released by muscle and used by immune cells and enteral cells for energy. In malnutrition and after trauma, muscle glutamine and muscle protein synthesis are reduced. The infusion of glutamine normalizes muscle glutamine and restores protein synthesis.[46] Clinically, bone marrow transplant patients were noted to have fewer episodes of sepsis and a shorter hospital stay if they received a glutamine-supplemented amino acid solution.[47] Because glutamine does not have a long shelf-life in solution, dipeptides containing glutamine have been used as a substitute. Infusion of solutions containing such dipeptides has been found to increase muscle glutamine and improve protein synthesis.[46]

Immunonutrition

Enteral formulations enriched in arginine, omega-3 fatty acids, and glutamine nucleotides are considered to enhance the immune response; treatment with these formulations is referred to as immunonutrition. These formulations vary in composition, but they are distinguished by high (12 to 15 g/L) or low (4 to 6 g/L) arginine content, presence or absence of glutamine and nucleotides, and different concentrations of omega-3 fatty acids. A recent summit on immune-enhancing enteral therapy[48] concluded, on the basis of published literature, that immunonutrition should be given to malnourished patients undergoing elective GI surgery and to trauma patients with an injury severity score of 18 or greater or an abdominal trauma index of 20 or greater. Immunonutrition was also recommended, despite lack of evidence, in patients undergoing head and neck surgery or aortic reconstruction, as well as in patients with severe head injury or burns, and in ventilator-dependent nonseptic patients. It was not recommended for patients with splanchnic hypoperfusion or bowel obstruction distal to the access site or after major upper GI hemorrhage.

A systematic review of immunonutrition by Heyland and colleagues[49] showed that it reduced septic complications but did not reduce mortality. Their analysis of 22 randomized, controlled trials covering 2,419 critically ill or surgical patients indicated that only high-arginine formulations reduced infectious complications and length of stay. These authors concluded that in patients undergoing elective surgery, immunonutrition may reduce complications and reduce length of stay. Pending further studies, however, immunonutrition was not recommend-

ed in patients with critical illness. Because many trauma and septic patients may be critically ill, these authors' recommendations are at variance with those of the immunonutrition summit (see above). The finding that benefit is seen only with the formulation containing higher amounts of arginine raises the question whether arginine per se or the higher nitrogen intake is responsible for the benefit.

Energy (Glucose and Lipids)

In healthy persons, basal energy expenditure (BEE), or basal metabolic rate (BMR), in kilocalories a day can be predicted with the Harris-Benedict equation:

$$\text{BEE in males} = 66.5 + (13.8 \times \text{weight in kg}) + (5.0 \times \text{height in cm}) - (6.8 \times \text{age in yr})$$

$$\text{BEE in females} = 655.1 + (9.6 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in yr})$$

A calculator for determining BEE according to the Harris-Benedict equation can be found on the Internet, at www-users.med.cornell.edu/~spon/picu/calc/beecalc.htm.

For patients substantially on bed rest, about 30% should be added to the BEE to meet their metabolic requirements. In practice, this calculates as a daily expenditure of about 31 kcal/kg. An expert group has suggested a daily intake of 25 kcal/kg in ICU patients.[50] Therefore, 25 to 30 kcal/kg/day will meet the needs of most patients, except those with burns. Malnutrition reduces the expected BEE by as much as 35%; injury, sepsis, and, especially, burns increase requirements.[51] Baker and colleagues[52] found that in critically sick patients in respiratory failure, the maximal degree of hypermetabolism was about 30%.

Energy requirements during TPN can be met by infusing glucose or lipid emulsions. These nonprotein energy sources enhance nitrogen retention. The most striking increase in nitrogen balance has been found to occur when energy was increased from 0 kcal/kg to 30 kcal/kg of ideal body weight. Increases above that provided only slight improvement. In obese persons, a high-protein formulation with only about 14 kcal/kg/day meets nitrogen requirements[53] and is associated with satisfactory wound healing.[54]

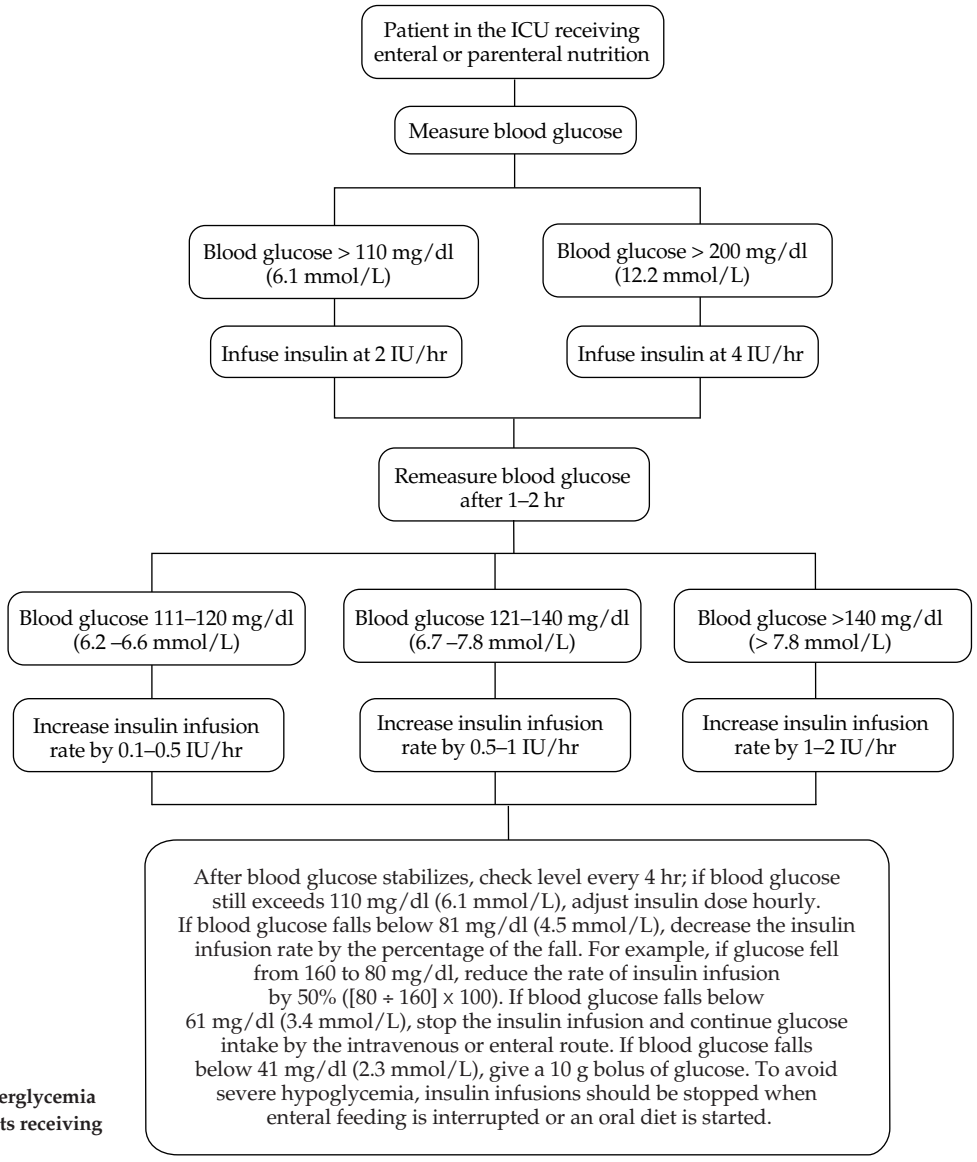

Figure 2 **Controlling hyperglycemia in intensive care unit patients receiving nutritional support.**

Table 2 Daily Electrolyte and Trace Element Requirements for Adults on Total Parenteral Nutrition

Element	*Normal*	*Increased GI Losses*	*Renal Failure*	*Comments*
Sodium (mmol)	80–120	Meet losses	20–40	Reduce in heart failure
Potassium (mmol)	40–-80	80–120	0–20	Correct hypokalemia before starting nutrition
Magnesium (mmol)	5–10	10–20	0–5	Correct hypomagnesemia before starting nutrition
Phosphorus (mmol)	10–15	10–15	0–5	Risk of dangerously low serum levels when feeding patients with severe malnutrition
Zinc (mg)	TPN: 3–4 Enteral: 15–20	TPN: 12–25 Enteral: 50–100	No change	—
Copper (mg)	TPN: 0.25–0.3 Enteral: 2–4	TPN: 0.5–0.7 Enteral: 4–8	No change	Reduce to 0.1 in hepatic failure

Because glucose spares nitrogen in fasting persons, it has been advocated as the main source of energy for parenteral nutrition. However, recent studies have shown that in malnourished patients and septic patients, lipids can promote nitrogen retention and increase total body nitrogen to the same extent as glucose, provided amino acids are given.[55] Fats constitute about 30% of total energy in most enteral formulas. Furthermore, glucose-lipid mixtures facilitate the control of severe hyperglycemia in septic patients with insulin resistance.[50]

Infusion of glucose at rates that exceed energy requirements elevates O_2 consumption, CO_2 production, resting energy expenditure, and urinary norepinephrine excretion. However, the magnitude of increased CO_2 production is small if total calories infused conform to levels recommended for the patient's clinical situation.[51]

The exact amount of lipid to include in the parenteral nutrition regimen is controversial. In a randomized, controlled trial of 512 bone marrow transplant patients receiving TPN, sepsis was no more frequent in patients who received 30% of energy as lipid than in those who received only sufficient lipids to meet essential fatty acid (EFA) needs (6% to 8% of energy intake).[56] In addition, EFA deficiency developed in some of the latter patients, and in some, this small amount of lipid was insufficient to meet energy requirements without induction of hyperglycemia from the glucose component. These authors recommend giving 25% to 30% of energy as long-chain triglycerides (LCTs). In contrast, a study in 57 trauma patients found that TPN with added lipid increased sepsis and hospital stay.[57] It was not clear whether the adverse effect was from the lipid per se or the increased energy intake while on lipid.

Because of their glucose content, both enteral nutrition and TPN enhance the risk of sepsis if the blood glucose level is allowed to rise above 127 mg/dl (7 mmol/L).[8] Therefore, insulin should be infused in patients receiving nutritional support to keep them as close to normoglycemia as possible [*see Figure 2*].

Whereas the major concern with glucose-based formulations is hyperglycemia, the key concern with lipid emulsions is hypertriglyceridemia, which may induce pancreatitis. Lipid particles also reduce gas diffusion in the lungs and inhibit the reticuloendothelial system. Provided that lipid emulsions are infused continuously at a rate that does not exceed 110 mg/kg/hr, hypertriglyceridemia does not occur. When these principles are followed, 30% to 50% of nonprotein calories can be given as fat, especially in glucose-intolerant patients.

Electrolytes, Trace Elements, and Vitamins

In patients receiving nutritional support, levels of electrolytes and trace elements should be adjusted to fit the clinical circumstances [*see Table 2*]. Carbohydrate feeding induces sodium retention, resulting in refeeding edema. In malnourished patients, great care should be taken to prevent salt and water overload.

Body potassium is disproportionately reduced relative to nitrogen in malnourished patients. Positive nitrogen balance does not occur unless potassium, phosphorus, and magnesium are given.[58,59] During enteral and parenteral nutrition, serum phosphorus may drop precipitously and cause dangerous neurologic symptoms.[60]

Micronutrients comprise vitamins and trace elements. The former are complex organic compounds; the latter are inorganic elements. Trace elements important to nutritional support include zinc, copper, chromium, and selenium. Diarrhea increases zinc requirements markedly and copper requirements modestly [*see Table 2*]. Oral chromium requirements have not been precisely determined, but deficiency occurs in patients receiving TPN; in one of my patients, the daily chromium needs were increased to 10 to 20 μg. Patients receiving parenteral nutrition may develop selenium deficiency, with muscle pains and cardiomyopathy. Increased losses of selenium can occur from the GI tract and from wounds. The recommended dose of selenium for stable patients is 40 μg/day. Patients depleted of selenium may require as much a 120 μg/day to regain normal levels.

The current recommendations for vitamins [*see Table 3*] specify the amounts required to maintain normal plasma or blood levels in patients on long-term home parenteral nutrition. There are no clearly defined recommendations for critically sick or septic patients.

HOME PARENTERAL NUTRITION

Patients with intestinal failure from a short bowel, chronic bowel obstruction, radiation enteritis, or untreatable malabsorption can be nourished by parenteral nutrition given at home. Arteriovenous shunts were initially used for long-term venous access in these patients, but success was limited because of clotting or disruption of the shunt. Long-term success has been achieved with a tunneled silicone rubber catheter or an implanted reservoir. Premixed nutrients are infused overnight. The catheter is then disconnected and a heparin lock applied, leaving the patient free to attend to daily activities. We have used home parenteral nutrition for more than 20 years in

Table 3 Recommendations for Vitamins in Adults on Total Parenteral Nutrition

Vitamin	*Recommended Daily Dose*
A	3,300 IU
D_2	200 IU
E	10 IU
K_1	150 mg
Ascorbate	200 mg
Thiamin	6 mg
Riboflavin	3.6 mg
Pyridoxine	6 mg
Niacin	40 mg
Pantothenate	15 mg
Biotin	60 μg
Folate	600 μg
Cobalamin	5 μg

two patients with total jejunoileal resection; one continues to receive it after 30 years. Survival of patients with short bowel from treatment for Crohn disease or pseudo-obstruction is excellent. Home parenteral nutrition increases quality-adjusted years of life in these patients and is cost-effective. On the other hand, mean survival in AIDS patients or those with metastatic cancer who receive home parenteral nutrition is about 3 months. There is no evidence that home parenteral nutrition prolongs their survival or enhances their quality of life. Trials are urgently required to justify the use of home parenteral nutrition in terminal cancer and AIDS.

Complications of Long-term Home Parenteral Nutrition

At the start of nutritional support, patients are vulnerable to complications related to venous and enteral access and to metabolic complications. Careful and frequent monitoring and adjusting of nutrient intake will prevent these complications. Over the longer term, patients receiving TPN are vulnerable to three organ-specific complications: hepatic disease, bone disease, and gallstones.

Hepatic disease The most serious form of hepatic disease related to TPN is chronic cholestasis with fibrosis. This condition is most common in patients with a very short bowel. The exact cause is unknown, but absorption of endotoxin or alteration in bile salts by bacterial dehydroxylation are possible factors. Successful treatment with metronidazole and with ursodeoxycholic acid has been reported. In some patients, carnitine infusions have corrected cholestasis.

Bone disease Bone loss during long-term TPN is a complex issue. In a prospective longitudinal study, patients were noted to have a high bone turnover before the institution of home parenteral nutrition, but during TPN this changed to osteomalacia and slow bone turnover. This process has been attributed to aluminum toxicity but occurs in its absence[61] and seems to respond to withdrawal of vitamin D from the TPN formula. In a prospective 4-year study of patients on home parenteral nutrition, withdrawal of vitamin D increased spinal bone mass.[62] On the other hand, patients on home parenteral nutrition can lose bone mass as a result of factors such as active inflammatory bowel disease, corticosteroid therapy, and inactivity. Some clinicians are treating reduced bone mineral density in these patients with intravenous bisphosphonates such as pamidronate and clodronate (the latter is not available in the United States). Although there are no controlled trials of bisphosphonates in patients receiving home parenteral nutrition, there are anecdotal reports of improvement of bone mass with this therapy.

Gallstones The short bowel state results in bile salt deficiency and increased biliary cholesterol secretion. In addition, sludge composed of bilirubin and calcium forms in the gallbladder. Consequently, the incidence of gallstones is high in these patients. These stones are mixed cholesterol and pigment.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XIV GASTROINTESTINAL MOTILITY DISORDERS

Michael Camilleri, m.d.

Motility disorders of the stomach, small intestine, and colon are characterized by the acute, recurrent, or chronic presentation of symptoms of stasis or rapid transit in the absence of mucosal disease or any obstruction within the lumen of the gut.[1]

The most common syndromes associated with disorders of motility are nonulcer dyspepsia,[2] irritable bowel syndrome (IBS), functional constipation,[3] and outlet obstruction to defecation (evacuation disorders)[4]; the prevalence of gastroparesis and chronic intestinal pseudo-obstruction[1] is far lower. These disorders result from impaired neurologic or muscular control of the gut or from incoordination of defecation dynamics. Motility disorders are sometimes caused by a process that influences the extrinsic autonomic nerves that supply the gut. Other disorders infiltrate the GI smooth muscle and extraintestinal organs, particularly the urinary bladder.[1]

Physiology

GASTRIC, SMALL BOWEL, AND COLONIC MOTILITY

GI motor functions are characterized by distinct patterns of contractile activity in the fasting and postprandial periods. The fasting period is characterized by a cyclic motor phenomenon called the interdigestive migrating motor complex [*see Figure 1*]. In healthy people, it occurs approximately once every 60 to 90 minutes and comprises a period of quiescence (phase I), a period of intermittent pressure activity (phase II), and an activity front, during which the stomach and small intestine contract at their highest frequency (phase III). These contraction frequencies reach three a minute in the stomach and 11 or 12 a minute in the proximal small intestine. The interdigestive activity front migrates a variable distance down the small intestine; there is a gradient in the frequency of contractions during phase III, from 11 or 12 a minute in the duodenum to as low as five a minute in the ileum. The distal small intestine also demonstrates another characteristic motor pattern—a propagated prolonged contraction, or power contraction, that serves to empty residue from the ileum to the colon in bolus transfers.

In the postprandial period, the fasting cyclic activity of the stomach and small intestine is replaced by irregular, fairly frequent contractions in those regions of the stomach and small bowel that come in contact with food [*see Figure 1*]. The caloric content of the meal is the major determinant of the duration of this so-called fed pattern. The maximum frequency of contractions is below that noted during phase III of the interdigestive migrating motor complex. After meals, segments of the small intestine that are not exposed to digesta may still show the interdigestive complex. Thus, there may be simultaneous patterns of interdigestive activity in the distal small bowel at a time when the proximal small bowel is in contact with intraluminal digesta and is responding with the irregular contractile activity that characterizes the fed pattern.

Solid and liquid food empty from the stomach at different rates. Liquids empty from the stomach in an exponential manner. For nonnutrient liquids, the healthy stomach tends to empty liquids with a half-emptying time of 20 minutes or less. On the other hand, solids are initially retained selectively within the stomach until particles have been triturated to a size smaller than 2 mm, at which point they can be emptied in a linear fashion from the stomach. Thus, the gastric emptying of solids consists of an initial lag period, followed by a more linear postlag gastric-emptying phase. The small intestine transports solids and liq-

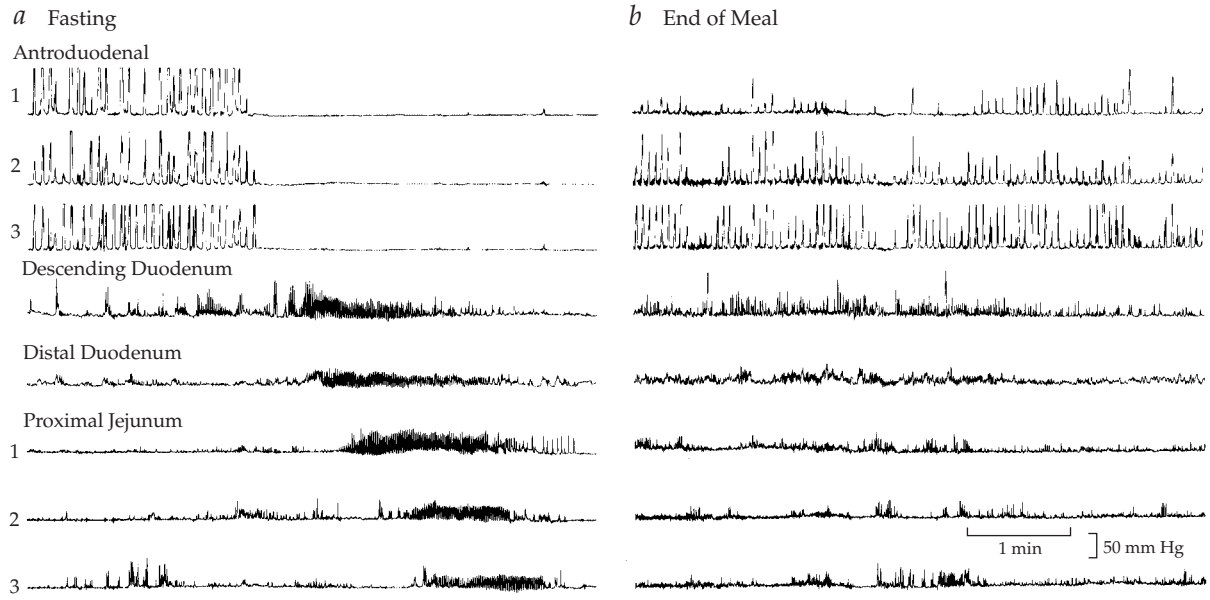

Figure 1 **Normal gastrointestinal motility. Note the normal interdigestive migrating motor complex during the fasting phase (*a*) and the irregular but persistent antral and intestinal phasic pressure activity in the fed phase (*b*).**[57]

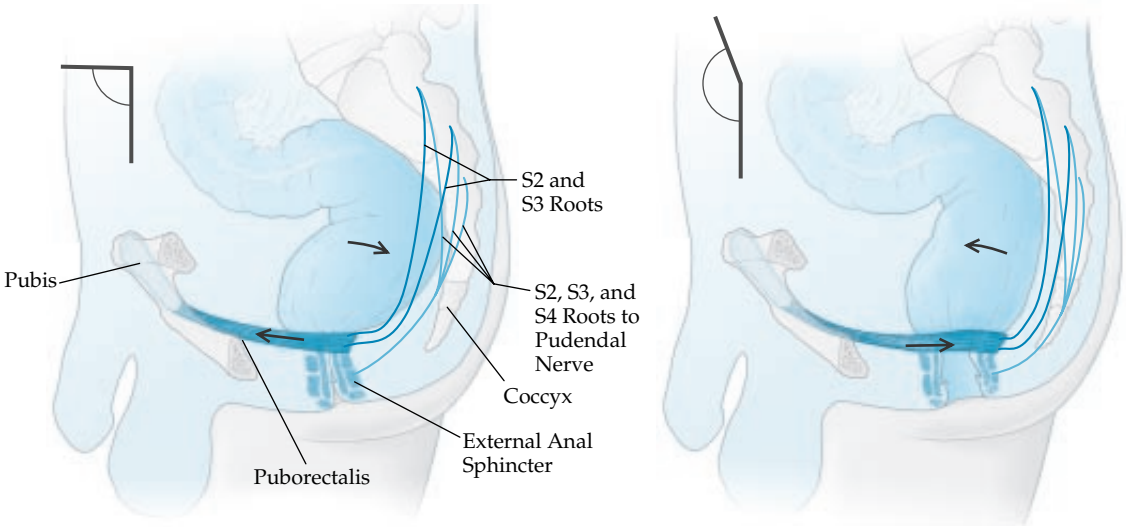

Figure 2 **Normal defecation requires relaxation of the puborectalis and external anal sphincter, straightening of the rectoanal angle, and an increase in intraluminal pressure, usually induced by the Valsalva maneuver. Defecation may be obstructed if any of these functions is impaired.[58]**

uids at approximately the same rate. Because there is a separation of the two phases in the stomach, it is clear that liquids may arrive in the colon before the head of the solid phase of the meal. Ileal emptying of chyme is characterized by bolus transfers.

Another important function of the stomach is the initial relaxation response that occurs after the ingestion of food. This response, also called accommodation, is mediated by the vagus nerves and involves the activation of intrinsic nitrergic inhibitory nerves in the wall of the stomach. Failure of gastric accommodation results in symptoms such as early fullness, satiety, and bloating and may contribute to nausea, indigestion (dyspepsia), or discomfort postprandially.[5,6]

The colon serves as a reservoir to facilitate absorption of fluids, electrolytes, and short-chain fatty acids produced by bacterial metabolism of unabsorbed carbohydrates. This reservoir function is centered predominantly in the ascending and transverse colonic regions. The descending colon functions as a conduit for the relatively rapid transit of feces to the sigmoid colon, which acts as a second reservoir. Emptying of the sigmoid colon is largely under volitional control. The defecatory process requires the Valsalva maneuver to raise intra-abdominal pressure, which is transmitted to the rectal contents, and relaxation of the puborectalis (or pelvic floor) and external anal sphincter,[4] which necessitates a coordinated series of functions [*see Figure 2*]. This facilitates the opening or straightening of the rectoanal angle and expulsion of stool. The control and function of contractions in the colon are not fully understood; some irregular contractions serve to mix its contents, whereas high-amplitude propagated contractions (HAPCs), which occur on average four to six times a day, are sometimes associated with mass movement of colonic residue and lead to defecation. After meals of at least 500 kcal, there is a greater propensity for HAPCs to develop and for the tone (background state of contractility) of the colon to increase and lead to bowel movements in the first 2 hours after meals.[7]

CONTROL OF GI MOTOR AND SENSORY FUNCTIONS

Motor function of the gut depends on the contraction of the smooth muscle cells and their integration and modulation by enteric and extrinsic nerves.[1] Smooth muscle contraction results from fluxes of ions that alter the electrical potential of the cell membrane. The enteric nervous system—approximately 100 million (10^8) neurons organized in ganglionated plexi (submucosal and myenteric being the predominant plexi)—is organized in intricate excitatory and inhibitory programmed circuits [*see Figure 3*]. These circuits play essential roles in controlling peristalsis and the migrating motor complex. Among the enteric plexi, there are also interstitial cells of Cajal, which are thought to serve as pacemakers. Enteric nerves are also important in mediating sensation from the gut. Visceral sensation, as with somatic sensation, is mediated by A-delta fibers (which respond to short, sharp stimuli) and polymodal C-unmyelinated fibers (which tend to respond to more prolonged stimuli). The latter nerves mediate pain as well as the autonomic and emotional responses that are commonly noted in patients with functional GI diseases.[8]

Extrinsic neural control is subdivided into the craniosacral parasympathetic outflow and the thoracolumbar sympathetic supply. The cranial outflow is predominantly through the vagus nerve, which supplies neural control from the stomach down to the right side of the colon, and the sacral parasympathetic supply, which provides neural control to the left colon and, through ascending intracolonic fibers, the more proximal regions of the colon. Parasympathetic supply is excitatory to nonsphincteric muscle. Sympathetic fibers to the GI tract arise from levels T5 to L1 of the intermediolateral column of the spinal cord. Sympathetic fibers are stimulatory to sphincteric muscle and relaxatory to nonsphincteric muscle. The prevertebral sympathetic ganglia integrate afferent impulses from the gut and sympathetic supply from the central nervous system. Derangement of any of these intrinsic or extrinsic control mechanisms may lead to altered gut motor function [*see* Gastroparesis and Chronic Intestinal Pseudo-obstruction, *below*].[1]

Structural Diseases and Their Effects on GI Motility

Disturbances of gastric and proximal small bowel motility are frequently observed in symptomatic patients after gastric surgery. Uncoordinated phasic pressure waves occur in the Roux limb after Roux-en-Y partial gastrectomy.[9] In these pa-

tients, the vagotomized gastric remnant may also contribute to the development of symptoms, because relaxation and contraction of the gastric remnant are deranged after vagotomy and partial gastric resection. In practice, pharmacologic agents are generally ineffective in this situation; further resection of the gastric remnant may relieve the symptoms resulting from upper gut stasis in about two thirds of these patients.[10]

Another frequently encountered postoperative disorder is the postfundoplication syndrome. An excessively tight repair of hiatal hernia may result in dysphagia; the increase in the use of laparoscopic fundoplication has led to a greater appreciation of the frequency with which this procedure results in postprandial upper abdominal pain, gas, bloating, and a dyspeptic condition that seems further aggravated by the patient's inability to belch as a result of the effective wrap.[11]

In subacute mechanical obstruction, proximal small bowel manometry shows simultaneous prolonged contractions separated by periods of quiescence. This pattern was shown to have a positive predictive value of 80%,[12] and patients showing this pattern should undergo further careful assessment with enteroclysis, laparoscopy, or laparotomy to exclude obstruction. The increased availability and experience of laparoscopic surgeons have led to less need for motility tests to diagnose mechanical obstruction.

Small bowel fistulas, diverticula, and postsurgical blind loops are all associated with bacterial overgrowth, but the pathogenic sequence is not always clear. Experimentally, bacterial toxins induce migrating action potential complexes in the rabbit ileum, as well as abnormal motility, rapid transit through the small bowel, diarrhea, and steatorrhea. It has also been suggested that multiple jejunal diverticula may result from abnormal neuromuscular function.[13]

Volvulus of the stomach, small bowel loops, cecum, and sigmoid colon may present as acute or subacute symptoms caused by mechanical obstruction. These need to be differentiated from conditions that primarily affect the motor apparatus, such as gastroparesis and pseudo-obstruction.

Functional Gastrointestinal Disorders

Functional GI disorders are characterized by disturbances of motor or sensory functions in the absence of mucosal or structural abnormality or of known biochemical or metabolic disorders. These syndromes affect one or more regions of the GI tract and include functional dysphagia, nonulcer dyspepsia,[2] IBS,[3] slow-transit constipation,[4] and outlet obstruction to defecation[4] (also termed evacuation disorders).

Functional GI disorders share common pathogenetic features, including abnormal motility, heightened visceral sensation, and psychosocial disturbance.[2,3] In some patients, these syndromes are preceded by an episode of gastroenteritis. The abnormal motility may be characterized by rapid or slow transit of food or residue through the bowel or abnormal gastric relaxation to accommodate the meal.[5,6] Abnormal contractile patterns have been described, but more important, patients perceive a sensation of excessive gut contractions.[8] In patients with these conditions, there is frequently evidence of psychological comorbidity, such as anxiety, depression, or obsessive-compulsive disorder.[3] These factors appear to influence the decision of patients to consult their physicians.

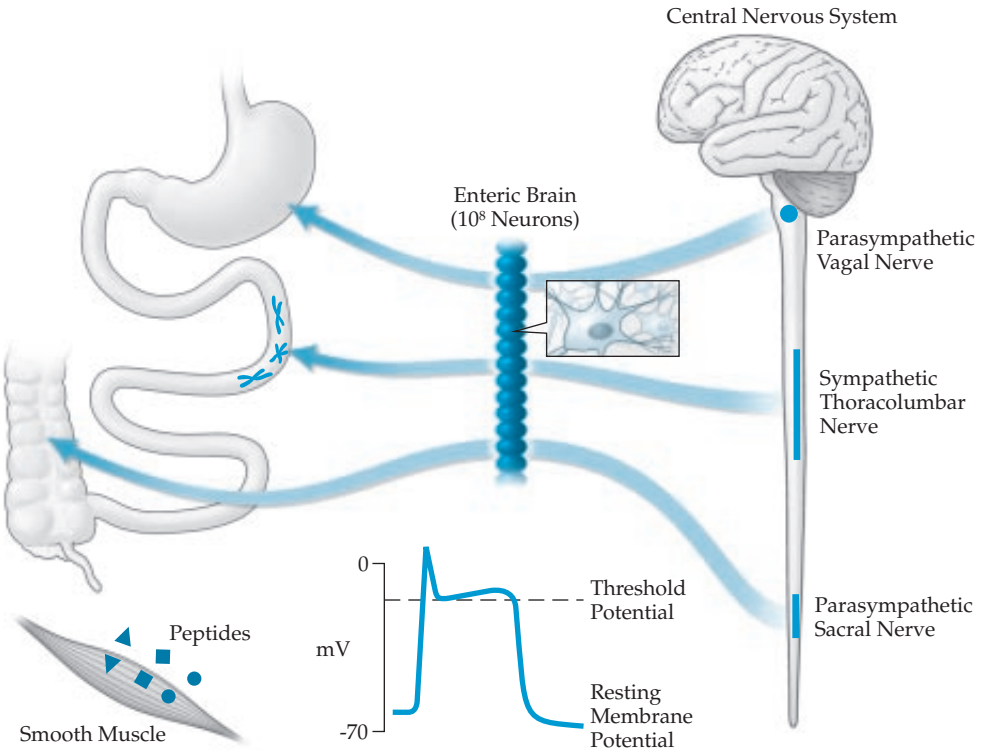

Figure 3 **Control of gut motility. Interactions between extrinsic neural pathways and the intrinsic nervous system (enteric brain) modulate contractions of gastrointestinal smooth muscle. Peptide-receptor interactions alter muscle membrane potentials by stimulating bidirectional ion fluxes. In turn, membrane characteristics dictate whether or not the muscle cell contracts.[59]**

Dyspepsia (from the Greek term for bad digestion) that is not caused by ulcers is characterized by upper abdominal symptoms in the postprandial period, such as nausea, vomiting, pain, bloating, anorexia, and early satiety. It affects about 20% of the population of the United States.

Pathogenesis

Factors other than altered gastric emptying, increased gastric sensitivity, and psychosocial distress may contribute to the development of nonulcer dyspepsia, but the pathogenesis remains unclear. A subgroup of patients may suffer nonerosive reflux esophagitis; others may have *Helicobacter pylori* gastritis. The role *H. pylori* infection plays in dyspepsia is uncertain, but current epidemiologic evidence and the results of eradication studies do not support a causal relationship.[14,15] Dyspepsia is also associated with impaired gastric relaxation or accommodation.[5,6]

Diagnosis

The history usually provides information on the specific symptoms or the spectrum of symptoms experienced by the patient. However, the symptoms have little discriminative value for predicting the physiologic alterations in an individual patient. Studies have suggested that the presence of postprandial fullness or satiation soon after starting the meal may be indicative of delayed gastric emptying and reduced gastric accommodation, respectively.[5,6,16] Moreover, weight loss of more than 5 kg is more frequent in patients with reduced gastric accommodation.[5] However, weight loss should not be dismissed on the basis of being a functional alteration; it mandates performance of endoscopy to exclude ulceration or cancer. The physical examination is usually normal. On rare occasions, there may be a succussion splash in the epigastrium from the retention of food in the stomach. An epigastric mass, hepatomegaly, or supraclavicular lymphadenopathy may suggest that the dyspepsia is the result of malignancy.

In the presence of alarm features such as dysphagia, bleeding, or weight loss in association with dyspepsia, it is essential to exclude mucosal diseases, such as ulcer or cancer.[2] Cancer may still be present, however, even when these alarm features are absent. Patients are reassured by a negative endoscopic examination.

In most cases, the underlying cause of dyspepsia will not be obvious from the history and physical examination. For new-onset dyspepsia, endoscopy and testing for *H. pylori* infection are generally recommended.

The presence of heartburn suggests a component of gastroesophageal reflux. Reflux needs to be differentiated from rumination,[17] which results in the effortless regurgitation of undigested food within 30 minutes after oral ingestion; rumination occurs with virtually every meal and is not associated with nausea. The symptoms that appear to be most closely related to impaired gastric relaxation or accommodation are early satiety and weight loss.[5] This impairment of accommodation may also contribute to hypersensitivity of the stomach of such patients to intraluminal stimuli. There is great interest in identifying ways to demonstrate this hypersensitivity before therapy is initiated, because such knowledge would have a bearing on choice of therapy. Tests in which the patient drinks water or a nutrient beverage have been devised to evaluate the maximal tolerated volume and the symptoms of fullness, satiety, bloating, nausea, and pain at a defined period after ingestion (typically 30 minutes).[5,18,19] These tests are noninvasive and inexpensive, and they have been introduced into clinical practice in some centers. However, they do not necessarily differentiate disturbances in the accommodation response from hypersensitivity per se. Until recently, measurement of accommodation required the placement of an intragastric balloon to measure fasting and postprandial volumes.[5] Recently, a novel imaging approach was developed to measure accommodation noninvasively by use of single-photon emission computed tomography.[6]

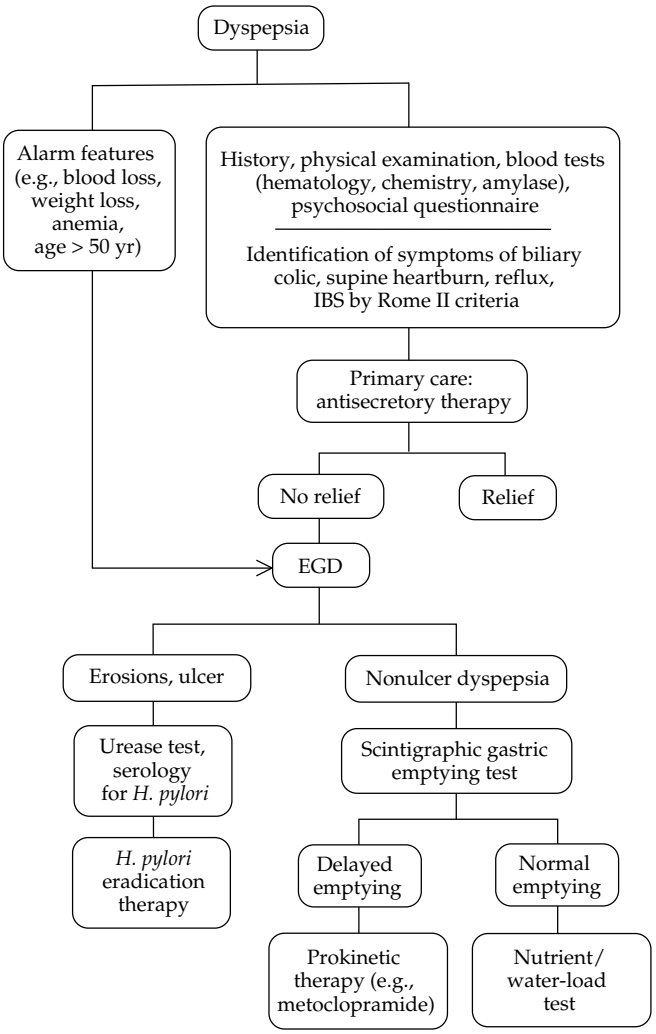

Figure 4 **Algorithm for the treatment of dyspepsia.[2] (IBS—irritable bowel syndrome; EGD—esophagogastroduodenoscopy)**

Simple, cost-effective tests for mucosal disease, gastric emptying,[20-22] and gastric accommodation[6] provide a rational alternative to the use of sequential empirical trials for identifying the mechanism causing dyspepsia[2] [*see Figure 4*].

Treatment

In clinical practice, dyspepsia is often treated with acid-suppressing regimens consisting of proton pump inhibitors or H_2 receptor antagonists, though the evidence in favor of this approach is limited, and of all patients treated, a cure is achieved in less than one in 10.[23] Temporary acid suppression with a proton pump inhibitor or an H_2 receptor agonist may delay diagnosis of cancer.[24]

In cases of dyspepsia associated with *H. pylori* infection, eradication of the *H. pylori* infection results in resolution of the syn-

drome in only a small minority of patients[25,26]; the current consensus is that in the absence of erosions or ulcers, eradication of *H. pylori* is not indicated for treatment of dyspepsia,[13] though it is usually treated anyway because of concern with development of atrophy or gastric cancer in the long term.[27]

IRRITABLE BOWEL SYNDROME

Diagnosis

Clinical features IBS is characterized by abdominal pain and alteration in bowel movements. The pain is often worse after eating (experienced by about 30% of patients), is usually located in the lower quadrants or hypogastrium, and is aggravated before and relieved after a bowel movement. Bowel function is disturbed with either diarrhea (increased frequency or stools of loose consistency) or constipation (decreased frequency, abnormally hard stools, need to strain to complete bowel evacuation). Most patients also experience abdominal bloating, and some have a sense of incomplete rectal evacuation or pass mucus with stools. These symptoms constitute the Manning criteria or the Rome criteria[3] and are helpful in diagnosing IBS.

The sense of incomplete evacuation may also suggest a component of outlet obstruction to defecation or increased rectal sensitivity.[4] In clinical practice, the diarrhea may present as either of two variants: (1) loose to watery stools often associated with borborygmi, abdominal cramps, and a borderline-high 24-hour stool weight (i.e., 200 to 300 g/day) or (2) small, pelletlike, repetitive stools that are misinterpreted as diarrhea. Constipation may be reflected in a reduction in the frequency of bowel movements (fewer than three a week), in incomplete rectal evacuation, or in the need for excessive straining.

The rectal examination is important in excluding anorectal or pelvic floor spasms that obstruct defecation.

IBS may be associated with lactose intolerance and colonic diverticulosis in some patients. It is unclear whether the associated conditions actually contribute to the clinical syndrome. Some patients who manifest clinical features of IBS have celiac disease; the proportion of IBS patients with celiac disease is unclear from the literature.[28] The effect of the exclusion of gluten on IBS symptoms in these patients has not been evaluated.

Laboratory tests The diagnosis of IBS is facilitated by recognition of the symptom complex described above. However, it is a diagnosis of exclusion, requiring selected tests to exclude organic disease, such as stool examination for ova, parasites, and occult blood; blood tests; serologic testing for celiac disease; flexible sigmoidoscopy; and, in patients older than 45 years, barium colon x-ray or colonoscopy [*see Figure 5*].

Treatment

Constipation in patients with IBS responds to treatment with fiber or simple laxatives, including osmotic agents[29,30]; psychotherapy may also be beneficial.[31] The serotonin (5-HT_3) antagonist alosetron was found to provide adequate relief of pain, improved stool frequency, decreased urgency, and consistency for many patients whose predominant bowel disturbance was diar-

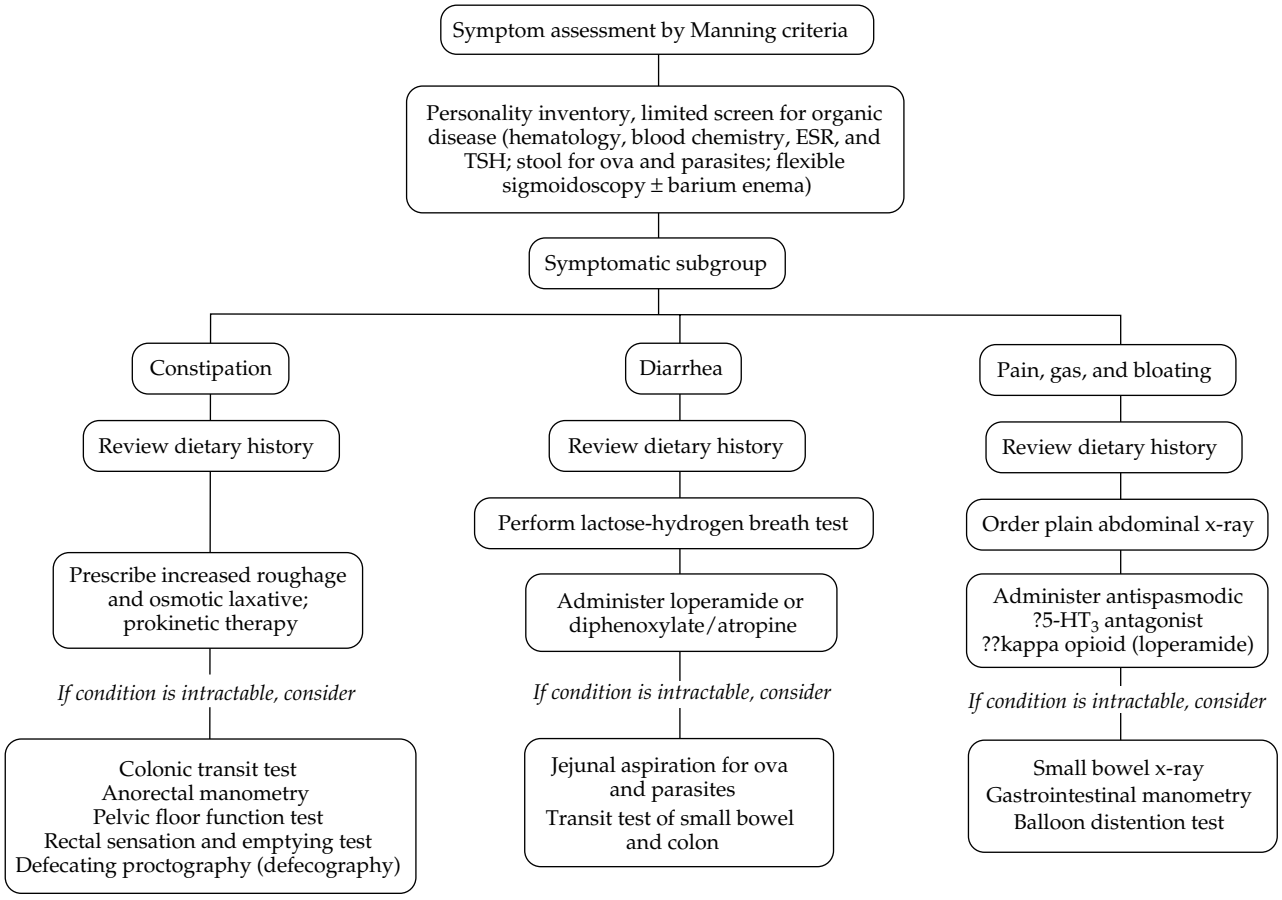

Figure 5 **Algorithm for irritable bowel syndrome.[60] (ESR—erythrocyte sedimentation rate; TSH—thyroid stimulating hormone)**

rhea.[32] The medication was withdrawn from the market, but it is possible that it will be reintroduced for specific indications. Other compounds in the same class (e.g., cilansetron) are undergoing trials. Other serotoninergic agents that activate the 5-HT_4 receptor may be approved for the treatment of constipation-predominant IBS.[33-35] IBS patients tend to use complementary and alternative medicine (CAM) more frequently than patients with organic bowel diseases. IBS patients who used CAM also were found to have significantly poorer quality-of-life scores for emotional and social factors than patients who did not use CAM.[36] Physicians need to be aware of this, both with regard to the potential for adverse interactions and as an indication of emotional unease in these patients.

SLOW-TRANSIT CONSTIPATION

Slow-transit constipation[4] is a motility disorder of the colon that results in prolonged transit.

Diagnosis

The diagnosis of slow-transit constipation should be made only after exclusion of mucosal diseases, such as tumors and strictures. It is most conveniently diagnosed by assessing mean colonic transit time through use of abdominal radiography and radiopaque markers. There are two commonly used variations of this method. The first type involves ingestion of 24 radiopaque markers in a soluble medication capsule on 4 successive days; plain abdominal radiography is performed on day 5. The number of markers in the colon approximates the mean colonic transit time in hours (normal: < 72 hours). The second variation requires that the patient ingest 20 markers on day 1; an abdominal x-ray is obtained on day 5. Normally, there should be fewer than five markers remaining in the colon. In all patients with delayed colonic transit, the possibility of outlet obstruction to defecation or a pangastrointestinal motility disorder must be ruled out.

Treatment

Treatment of slow-transit constipation consists of increasing dietary bulk or fiber and administering osmotic laxatives (e.g., magnesium salts when not contraindicated) and stimulant laxatives or colonic prokinetic agents.

A more severe variant of slow-transit constipation is colonic inertia. In this disorder, the colon fails to produce a motor response to physiologic stimuli, such as a meal, or to pharmacologic stimulation, as would occur, for example, after administration of neostigmine, 0.5 mg I.M., or intraluminal bisacodyl, 2 to 4 mg.

OUTLET OBSTRUCTION TO DEFECATION

Outlet obstruction to defecation (evacuation disorders) occurs when defecation dynamics [*see Figure 2*] function poorly and the patient is unable to expel stool.[4]

Diagnosis

The patient may present with constipation or the inability to have spontaneous and complete bowel movements; bloating; and left-sided abdominal pain. The syndrome may thus mimic IBS and is commonly associated with it. A careful clinical history is useful in identifying failure of evacuation; specifically, patients may experience the need for digital disimpaction of the rectum or digital pressure on the posterior wall of the vagina or the perineum to expel stool. Enemas may not be emptied. The rectal examination identifies an immobile perineum during the process of straining and a tight, unyielding puborectalis sling muscle abutting the rectum posteriorly. This tight pelvic floor persists during attempts to evacuate. In rare instances, the anal sphincter itself is spastic or the entire perineum balloons or herniates down as a result of years of straining or of multiple childbirths, which weaken the ligaments and muscles that normally support the pelvic floor and rectoanal angle.

Treatment

Occasionally, outlet obstruction is caused by an anatomic defect such as a rectocele or rectal internal mucosal prolapse; these are amenable to surgical correction. A spastic pelvic floor or spastic anal sphincter muscles usually respond to biofeedback and muscle relaxation exercises. Some patients with outlet obstruction to defecation have a profound psychological disorder or a history of abuse that requires identification and subsequent therapy.

Gastroparesis and Chronic Intestinal Pseudo-obstruction

PATHOGENESIS

Although several etiologic factors are involved in the development of gastric or small bowel motility disturbances [*see Table 1*], these can generally be grouped as disorders of the extrinsic nervous system, the enteric nervous system (including the interstitial cells of Cajal or intestinal pacemakers), or smooth muscle.[1]

Extrinsic Neuropathic Disorders

Extrinsic neuropathic processes include vagotomy, diabetes, amyloidosis, and a paraneoplastic syndrome usually associated with small cell carcinoma of the lung. Another common neuropathic problem in clinical practice is the effect of medications such as anticholinergics on neural control.

Enteric or Intrinsic Neuropathic Disorders

Disorders of the enteric nervous system are usually the result of a degenerative, immune, or inflammatory process.[37] The etiology can only rarely be ascertained in these disturbances; gastroparesis and pseudo-obstruction may be caused by viruses (including rotavirus, Norwalk virus, cytomegalovirus, and Epstein-Barr virus) or degenerative disorders associated with infiltration of the myenteric plexus with inflammatory cells [*see Figure 6*], including eosinophils. Idiopathic chronic intestinal pseudo-obstruction is a condition in which there is no disturbance of the extrinsic neural control and no underlying etiology for the enteric nervous system abnormality.

Full-thickness biopsies of the intestine may be required to evaluate the myenteric plexus[37] and interstitial cells of Cajal.[38] Regrettably, other than resection of the affected region (e.g., colectomy in slow-transit constipation), there are few therapeutic regimens that can be proposed on the basis of the information from the biopsy. The benefits of biopsy need to be weighed against the risk of complications associated with full-thickness intestinal biopsy, which include adhesion formation, with the potential for mechanical obstruction superimposed on episodes of pseudo-obstruction.

Smooth Muscle Disorders

Disturbances of smooth muscle may result in significant disorders of gastric emptying and small bowel transit as well as, occasionally, colonic transit. These disturbances include systemic sclerosis and amyloidosis. Dermatomyositis, dystrophia myotonica, and metabolic muscle disorders such as mitochondrial

Table 1 Classification of Gastroparesis and Chronic Intestinal Pseudo-obstruction

Type	*Myopathic*	*Neuropathic*	*Comments*
Familial	Familial visceral myopathies (autosomal dominant or recessive)	Familial visceral neuropathies, von Recklinghausen disease	Rare, often present in neonatal period or childhood; neurofibromata may also cause mechanical obstruction
Sporadic			
Infiltrative	Progressive systemic sclerosis	Early progressive systemic sclerosis	Manometry essential to differentiate pathophysiology (neuropathic vs myopathic)
	Amyloidosis	Amyloidosis	
General neurologic disease	Myotonic and other dystrophies	Diabetes, porphyria, spinal cord transection, dysautonomias, multiple sclerosis, brain stem tumor	For review, see reference 1
Infectious	—	Chagas disease, Norwalk virus, cytomegalovirus, Epstein-Barr virus	Nonspecific postviral causes appear to be common
Drug-induced	—	Tricyclic antidepressants, narcotics, anticholinergics, antihypertensives, vincristine	Adverse effects of medications to be excluded in all patients
Neoplastic	—	Paraneoplastic (small cell lung cancer, carcinoid lung tumors)	May require computed tomography to exclude tumor if chest x-ray is negative
Idiopathic	Sporadic hollow visceral myopathy	Chronic idiopathic intestinal pseudo-obstruction	Variable manifestations and severity

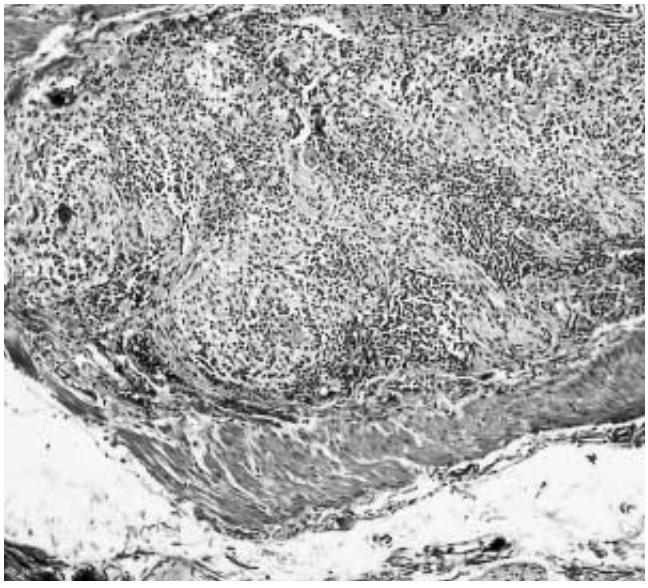
myopathy are seen infrequently and are suggested by the presence of ptosis, external ocular paralysis, acidosis, and peripheral neuromyopathy.[39] Hollow visceral myopathy may occur either sporadically or, rarely, in families. Motility disturbances may be the result of metabolic disorders such as hypothyroidism and hyperparathyroidism, but patients with these disorders more commonly present with constipation.

DIAGNOSIS

Clinical Features

The clinical features of gastroparesis and chronic intestinal pseudo-obstruction are similar and include nausea, vomiting, early satiety, abdominal discomfort, distention, bloating, and anorexia. In patients in whom stasis and vomiting are significant problems, there may be considerable weight loss, and disturbances of mineral and vitamin stores may result. The severity of the motility problem often manifests itself most clearly in the degree of nutritional and electrolyte depletion. Disturbances of bowel movements, such as diarrhea and constipation, indicate that the motility disorder is more extensive than gastroparesis. Significant vomiting may be complicated by aspiration pneumonia or Mallory-Weiss tears, which may result in acute GI hemorrhage. When patients have a more generalized motility disorder, there may also be symptoms referable to abnormal swallowing or delayed colonic transit.

a



b

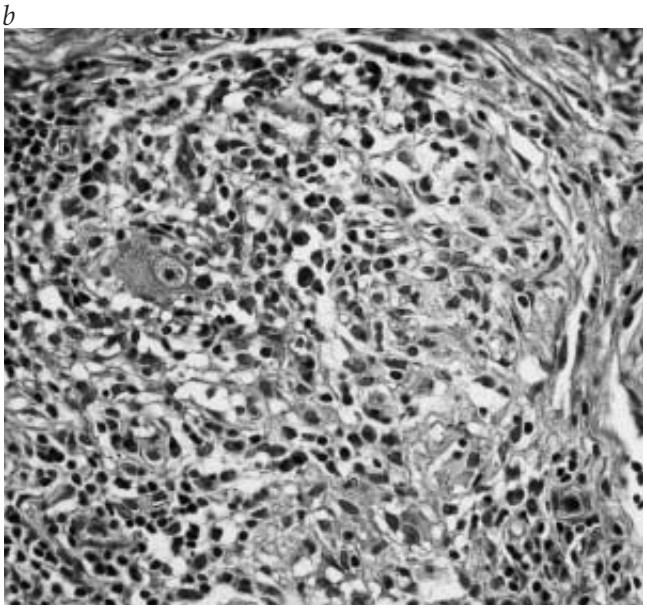


Figure 6 **Mononuclear infiltration in the gastric enteric plexus from a patient with small cell lung cancer and a paraneoplastic gastroparesis. The portion of the plexus rich in ganglion cells was expanded, but no necrosis was observed. Intact nerve fiber bundles can be seen (*a*) (original magnification: ×100). High-power view of the same field (*b*) shows mature small lymphocytes and abundant plasma cells. Although neurons are decreased in number, a normal-appearing ganglion cell can be seen just above the center of the image (original magnification: ×400).[61]**

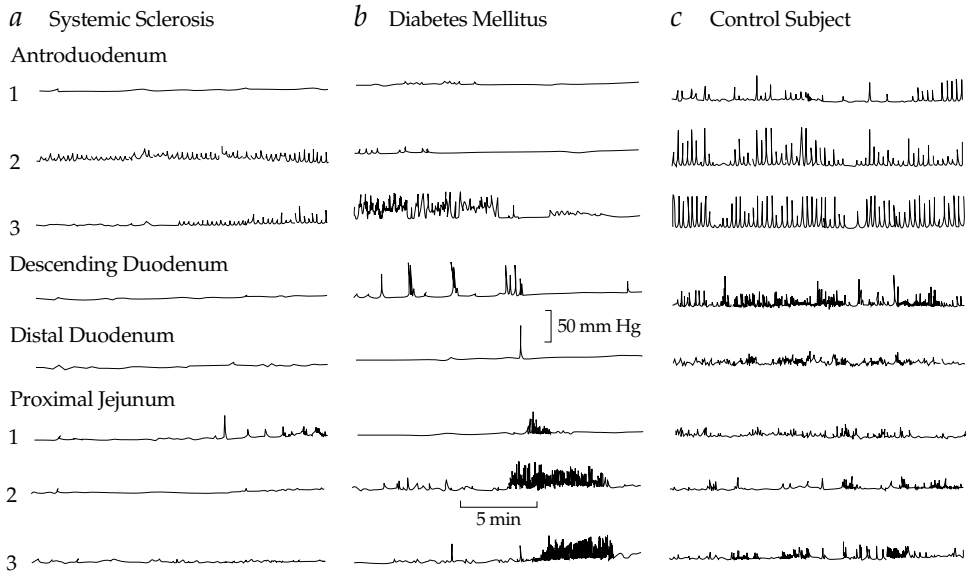

Figure 7 **Postprandial manometric profiles of patients with small bowel dysmotility caused by myopathy (*a*) and neuropathy (*b*), compared with a healthy control subject (*c*).**

Family history and medication history are essential to identify underlying etiologic factors such as diabetes mellitus that may result in gastric or small bowel motor disorders. A careful review of systems will help reveal an underlying collagen vascular disease (e.g., scleroderma) or disturbances of extrinsic neural control that also may be affecting the abdominal viscera. Such symptoms include orthostatic dizziness; difficulties with erection or ejaculation; recurrent urinary tract infections; dry mouth, eyes, or vagina; difficulties with visual accommodation in bright lights; and absence of sweating.

On physical examination, the presence of a succussion splash is usually indicative of a region of stasis within the GI tract, typically the stomach. The hands and mouth may show signs of Raynaud phenomenon or scleroderma. Testing of pupillary responses (to light and accommodation), blood pressure in the lying and standing positions, general features of a peripheral neuropathy, and external ocular movements can identify patients with an associated neurologic disturbance, such as those with a long history (usually longer than 10 years) of diabetes mellitus or oculogastrointestinal dystrophy.

The conditions to be differentiated are mechanical obstruction—which may occur because of peptic stricture or Crohn disease in the small intestine—functional GI disorders, and eating disorders such as anorexia nervosa and rumination syndrome. The degree of impairment of gastric emptying in eating disorders is relatively minor compared with diabetic and postvagotomy gastric stasis. Rumination syndrome is characterized by postprandial, effortless regurgitation of undigested food within 30 minutes after virtually every meal. This condition occurs in mentally challenged children (e.g., those with Down syndrome), and it is also being increasingly recognized in adolescents and adults of normal intelligence.[17] It is treatable by behavioral modification, including diaphragmatic breathing in the postprandial period.

Neonatal pseudo-obstruction rarely occurs alone; it is more often found in association with other anomalies requiring surgical correction, including gastroschisis, duodenal atresia, or megacystis. Prokinetic medications are usually ineffective, and many patients require parenteral nutrition and bowel decompression, including gastrostomies or enterostomies.[40]

Laboratory Tests

A motility disorder of the stomach or small bowel should be suspected whenever large volumes are aspirated from the stomach, particularly after an overnight fast, or when undigested solid food or large volumes of liquids are observed during an esophagogastroduodenoscopy. Barium studies rarely identify the etiology of the motor disorder except in small bowel systemic sclerosis, which is characterized by megaduodenum and packed valvulae conniventes in the small intestine. Barium x-ray, however, serves the important function of excluding mechanical obstruction. The diagnosis of a gastric or small bowel motility disorder, therefore, depends on a careful history and confirmation by transit tests.

The emptying of solids provides the best way to distinguish between healthy and disease states. If the patient's history includes an obvious etiologic factor, such as long-standing diabetes mellitus, it is usually unnecessary to pursue further investigations. When the cause of the gastric or small bowel transit disorder is unclear and the patient does not respond to treatment with a prokinetic agent, referral to a specialized center for autonomic tests and upper GI manometry may be needed [*see Figure 7*]. Transit tests, which can now be performed relatively simply and inexpensively,[20-22] enable good discrimination between healthy and disease states. The two most widely available approaches are the carbon-13 breath tests and scintigraphy with scans taken immediately after ingestion of the radiolabeled meal, as well as 1, 2, 4, and 6 hours later.[20] Manometry is generally available only in specialized centers; it may identify a myopathic or neuropathic disorder or an unsuspected mechanical obstruction resulting from simultaneous prolonged contractions at several levels of the intestine.[12]

In patients presenting with diarrhea, it is important to assess nutritional status (essential element and vitamin levels) and to exclude bacterial overgrowth by culture of small bowel aspirates. It is also important to exclude celiac sprue by small bowel biopsies. Bacterial overgrowth is relatively uncommon in neuropathic disorders but is more often found in myopathic conditions, such as scleroderma, that are more often associated with bowel dilatation.

TREATMENT

Four questions should be considered in the management of each patient. First, is the presentation acute or chronic? Second, is there evidence of a systemic disorder indicative of a neuropathy or myopathy? Third, what is the patient's state of hydration and nutrition? Fourth, which regions of the digestive tract are affected? The principal methods of management include correction of dehydration and nutritional deficiencies, the use of prokinetic and antiemetic medications [*see Table 2*], suppression of bacterial overgrowth, decompression of dilated segments, and surgery.[41]

Correction of Dehydration and Nutritional Deficiencies

Correction of dehydration and electrolyte and nutritional depletion is particularly important during acute exacerbations of gastroparesis or chronic intestinal pseudo-obstruction syndromes. Nutritional support should be tailored to the severity of the deficiencies of trace elements and dietary constituents in each patient. Dietary measures include the use of low-fiber and low-fat caloric supplements that contain iron, folate, calcium, and vitamins D, K, and B_{12}. Patients who have more severe symptoms, such as severe diabetic gastroparesis or severe myopathic pseudo-obstruction, may need parenteral or enteral nutrition supplementation.[31] For patients in whom supplementation of nutrition may be required for more than 3 months, it is usually best to place the enteral feeding tube via laparoscopy or minilaparotomy to secure the location of the tube in the intestine. Although severely affected patients may need parenteral nutrition, many patients continue to tolerate some oral feeding.

Prokinetic Therapy

Prokinetic medications (e.g., metoclopramide, 10 to 20 mg up to four times a day) are often used for the treatment of neuromuscular motility disorders.[41] Unfortunately, there is little evidence that they are effective in myopathic disturbances. Domperidone, a D_2 dopamine antagonist with antiemetic properties, relieves symptoms of diabetic gastroparesis,[42] but it is not approved for use in the United States.

Erythromycin, a macrolide antibiotic that stimulates motilin receptors partly through a cholinergic mechanism, results in the dumping of nondigestible and digestible solids from the stomach. Erythromycin lactobionate at a dosage of 3 to 6 mg/kg every 8 hours clears bezoars from the stomach in patients with diabetic gastroparesis.[43,44] The effect of oral erythromycin appears to be restricted by tachyphylaxis; there is little evidence that continued therapy is effective beyond 2 weeks, and GI upset may develop in some patients.[44]

Before its withdrawal in 2000, cisapride, a substituted benzamide that acts as a serotonin agonist, was used to treat altered motility, such as impaired gastric emptying, in patients with both gastroparesis and chronic intestinal pseudo-obstruction.[41]

Metoclopramide, with its antinausea and indirect cholinomimetic actions, is the current drug of choice for the treatment of motility disorders, though evidence for its efficacy is limited. Neuropsychiatric side effects such as dystonias are not infrequent, and rare cases of tardive dyskinesia have been reported. The usual dosage is 10 mg four times a day. Metoclopramide is also available for parenteral use; the usual dose is 10 mg I.M. or I.V. It should be used with caution, and a test dose (1 to 2 mg) is often used to exclude dystonic reactions resulting from an idiosyncratic reaction.

The peripheral dopaminergic antagonist domperidone has been shown to be efficacious in diabetic gastroparesis[45]; its efficacy is generally similar to that of metoclopramide. This agent suppresses emesis at the chemoreceptor trigger zone, which is outside the blood-brain barrier. Domperidone is not approved in the United States. The usual dosage is 30 to 80 mg/day in three or four divided doses. Novel prokinetics that are currently undergoing trial include the partial or full 5-HT_4 agonists such as tegaserod, levosulpiride, renzapride, and mosapride. Tegaserod accelerates gastric and small bowel transit in healthy persons[46] and small bowel transit in patients with constipation-predomi-

Table 2 Medications Used in the Treatment of Gastrointestinal Motility Disorders

Drug	*Dose*	*Efficacy Rating*	*Comments*
Gastroparesis			
Prokinetics			
Metoclopramide I.M. or p.o	10 mg t.i.d. + h.s.	Moderate	Central side effects; no evidence of efficacy below stomach level
Domperidone, p.o	10–30 mg t.i.d. + h.s.	Moderate	Not approved
Erythromycin I.V. or p.o.	40–200 mg t.i.d.	First choice if I.V. agent needed	Oral administration results in abdominal side effects after 2 wk
Cisapride p.o	10 mg t.i.d. + h.s.	Greater	Limited access because of drug interactions and potential for cardiac dysrhythmia
Octreotide s.c.	25–50 mg h.s.	Modest	For induction of MMCs to avoid bacterial overgrowth; if given with meals, retards transit
Antiemetics			
Prochlorperazine	5–12.5 mg p.r.n.	Significant for adult emesis	I.M., p.o., or rectal suppository
5-HT_3 antagonists (e.g., ondansetron)	0.15 mg/kg I.V. or p.o.	Modest	Less effective for dysmotility than for chemotherapy-induced emesis
Dumping, Diarrhea, or Short Bowel			
Octreotide	25 µg t.i.d., a.c.	Moderate	Adjunct to total parenteral nutrition and fluid replacement; prescribe multidraw vial; store in refrigerator
Irritable Bowel Syndrome Diarrhea			
Loperamide	2 mg up to 6 mg/day	First choice	No benefit for pain; very effective for diarrhea

5-HT_3 — serotonin MMCs — mucosal mast cells

nant irritable bowel syndrome.[47] It is chemically different from the benzamides and does not cause cardiac dysrhythmias.[35]

Octreotide, a cyclized octapeptide analogue of somatostatin, has been shown to induce activity fronts (phase III of the migrating motor complex) in the small intestine.[48] In an open trial, octreotide appeared to alleviate symptoms in patients with small bowel scleroderma who received the drug for up to 3 weeks.[49] However, it is unclear whether small bowel transit really improves with use of octreotide. In healthy persons, low doses of octreotide markedly retard small bowel transit.[50] Its therapeutic efficacy needs to be further assessed in clinical trials.

Symptomatic Relief

Standard antiemetics can be used for symptom relief. The more expensive 5-HT_3 antagonists (e.g., ondansetron) have not been proved to be of greater benefit than the less expensive antiemetic agents. Some patients have significant pain; if pain is associated with gut dilatation, decompression may be needed (see below). In the absence of dilatation, narcotics should be avoided, because these agents may aggravate the motility disorder. Parenteral ketorolac may be useful during acute exacerbations of pain.

Antibacterial Therapy

Bacterial overgrowth must be suppressed in infected patients with pseudo-obstruction. A common practice is to use a different antibiotic for 7 to 10 days each month to avoid development of bacterial resistance, although no trials have been performed to study this approach. Typical antibiotics used are doxycycline (100 mg b.i.d.), metronidazole (500 mg t.i.d.), ciprofloxacin (500 mg b.i.d.), or double-strength trimethoprim-sulfamethoxazole (two tablets b.i.d.). These measures usually result in significant symptomatic relief in those patients with diarrhea and steatorrhea.

Decompression

Decompression is rarely necessary in patients with chronic intestinal pseudo-obstruction and should be restricted to patients with severe motility disorders who are being cared for at tertiary care centers. Venting enterostomy creates a means to relieve abdominal distention and bloating and has been shown to significantly reduce the frequency of nasogastric intubations or hospitalizations for acute exacerbations in patients with severe intestinal pseudo-obstruction that require central parenteral nutrition.[40] Access to the small intestine may also provide a way to deliver nutrients by the enteral route. Enteral tubes are available that facilitate both aspiration and feeding with the same apparatus.

Electrical Stimulation and Gastric Pacing

Electrical stimulation and gastric pacing is an evolving treatment option for patients who do not respond to standard medical therapy[51]; however, the evidence for efficacy of electrical stimulation is controversial, and the mechanism for relieving symptoms is unknown.

Surgical Treatment

Surgical treatment should be considered whenever the motility disorder is localized to a portion of the gut that can be resected. In clinical practice, the two most common surgical therapies are (1) colectomy and ileoproctostomy for intractable symptoms associated with slow-transit constipation, colonic inertia, or pseudo-obstruction and (2) completion gastrectomy for patients with stasis syndrome after gastric surgery.[40] The role of small bowel transplantation in patients with pseudo-obstruction is unclear. Successful transplants have been performed in children with pseudo-obstruction,[52] but the experience in adults is limited.[52]

PROGNOSIS

The prognosis depends on the severity of the case. Patients with suspected postviral gastroparesis appear to have a good overall prognosis, with restoration of nutrition and reduction of symptoms within 2 years. On the other hand, patients with myopathic and dilated bowel have persistent symptoms, are more prone to develop bacterial overgrowth, and usually require long-term parenteral nutrition, which carries inherent morbidity. Between these extremes are patients with mild to moderately severe motility disorders who have recurrent or chronic symptoms. These patients can usually be managed as outpatients with dietary supplementation to maintain nutrition (including liquid formula supplements) and medications (e.g., prokinetics or antiemetics) and decompression to relieve symptoms.

Dumping Syndrome and Accelerated Gastric Emptying

Rapid gastric emptying results from impaired relaxation of the stomach upon ingestion of food. Postprandial intragastric pressure is relatively high and results in active propulsion of liquid foods from the stomach. A high caloric (usually carbohydrate) content of the liquid phase of the meal evokes a rapid insulin response with secondary hypoglycemia. These patients may also have impaired antral contractility and gastric stasis of solids, which may paradoxically result in a clinical picture of both gastroparesis (for solids) and dumping (for liquids). Typically, these conditions follow truncal vagotomy and gastric drainage procedures; with the use of more selective vagotomies in the treatment of peptic ulceration, it is likely that the prevalence of these problems may decrease. The most useful means of assessment is a dual-phase (solid and liquid) radioisotopic gastric emptying test.

Management of dumping[53] includes patient education (particularly regarding the avoidance of high-nutrient liquid drinks) and, possibly, the addition of guar gum or pectin to retard liquid emptying. If these measures are ineffective, pharmacologic approaches, such as use of subcutaneous octreotide (50 to 100 mg) 15 minutes before meals, decreases many of the vasomotor symptoms and also retards gastric emptying and small bowel transit, thereby relieving associated hypoglycemia and diarrhea.[54,55]

Rapid-Transit Dysmotilities of the Small Bowel

Rapid transit through the small bowel is a minor component of IBS in some patients.[4] However, it is a major component of other diseases and results in a significant loss of fluid and osmotically active solutes that overwhelm colonic capacitance and reabsorptive capacity and result in severe diarrhea. Examples include postvagotomy diarrhea, short bowel syndrome, diabetic diarrhea, and carcinoid diarrhea.[56] These disturbances of small bowel transit can best be identified by use of scintigraphy or, if scintigraphy is not available, by use of the lactulose-hydrogen breath test.

The objectives of treatment are restoration of hydration and nutrition and retardation of small bowel transit. Dietary interventions include avoidance of hyperosmolar drinks (e.g., virtually all soft drinks), use of iso-osmolar or hypo-osmolar rehydration solutions, and reduction of the fat content in the diet to

around 50 g a day to avoid delivery of unabsorbed fat to the colon (where their metabolites are cathartic). Correction of nutritional deficiencies (commonly, calcium, magnesium, potassium, and water- and fat-soluble vitamins) is often required.

Pharmacotherapy should be delivered in a stepwise fashion. First, an opioid agent in high dosage (e.g., loperamide, 4 mg) is given one-half hour before each meal and at bedtime to suppress the small bowel transit and colonic response to feeding. Next, verapamil (40 mg b.i.d.) or clonidine (0.1 to 0.2 mg orally or by patch) should be given, and if these are ineffective or produce unacceptable side effects (usually hypotension), subcutaneous octreotide, starting at 50 μg before meals, should be prescribed.[54] Patients with less than 1 m of residual small bowel may be unable to sustain fluid and electrolyte homeostasis without parenteral support. However, it is almost invariably possible to maintain patients with more than 1 m of residual small bowel with oral nutrition, pharmacotherapy, and supplements.

XV LIVER AND PANCREAS TRANSPLANTATION

Robert L. Carithers, Jr., m.d.
James D. Perkins, m.d.

Liver Transplantation

More than 4,500 liver transplants are performed annually in the United States.[1] Enhancements in surgical technique and the availability of powerful immunosuppressive agents have resulted in steady improvement in patient survival. As a result, liver transplantation has been accepted as the standard of care for patients with severe acute or chronic liver disease in whom conventional modalities of therapy have failed. The major obstacle to the procedure is the critical shortage of donor organs.

candidates for transplantation

Any patient with acute or chronic liver failure is a potential candidate for liver transplantation; there are a number of common indications [*see Table 1*].[2]

The methods of evaluating candidates for transplantation include careful history and physical examination, echocardiography, color flow Doppler imaging of the portal vein, computed tomographic angiography of the hepatic arterial supply, and a thorough evaluation of social factors and support. Echocardiography is useful in assessing left ventricular function and detecting pulmonary hypertension, which is seen in as many as 5% of cirrhotic patients.[3] Color flow Doppler studies of the portal vein are used to gauge the integrity of portal vein flow. If portal vein thrombosis is detected, the transplant surgeon can obtain extra donor vessels to bypass the blockade if necessary. CT angiography permits detection of small hepatocellular carcinomas, detection of aberrant arterial blood supply to the liver, and visualization of the splenic artery. Rigorous evaluation of the patient for any addictive behavior and assessment of the patient's social support system allow the transplant team to plan in advance for any needed services, which may include counseling, specialized addiction treatment, housing, transportation, and financial assistance for medications and other expenses.

Table 1 Common Indications for Liver Transplantation

- Chronic hepatitis
  - Hepatitis C
  - Hepatitis B
  - Autoimmune hepatitis
- Cholestatic liver disease
  - Biliary atresia (in children)
  - Primary biliary cirrhosis
  - Sclerosing cholangitis
- Metabolic diseases
  - Wilson disease
  - α_1-Antitrypsin deficiency
  - Hemochromatosis
- Malignancy
  - Primary hepatocellular carcinoma
  - Hemangioendothelioma
- Alcoholic liver disease
- Cryptogenic cirrhosis
- Miscellaneous conditions
  - Hepatic veno-occlusive disease
  - Nonalcoholic steatohepatitis
  - Tyrosinemia
  - Crigler-Najjar syndrome
- Fulminant hepatic failure
  - Hepatitis B
  - Hepatitis A
  - Acetaminophen overdose
  - Other drug-induced hepatitis
  - Toxin-induced hepatitis
  - Other viral hepatitides

contraindications to transplantation

Patients with severe neurologic or cardiopulmonary disease cannot withstand the stress of transplantation surgery. Patients with cirrhosis who have severe pulmonary hypertension rarely survive the operation and perioperative period.[4] Other contraindications to transplantation include severe or morbid obesity, extrahepatic malignancies, systemic infection, and cholangiocarcinoma.[5] The most common surgical contraindication to liver transplantation is thrombosis of the portal vein and other splanchnic veins to such an extent that no viable portal blood flow can be achieved.[6] Finally, the most frequent contraindications to liver transplantation are ongoing destructive behavior resulting from drug or alcohol addiction and the inability of the patient to comply with the complex medical regimen required after the operation.

timing of transplantation

Determining the optimal timing for liver transplantation can be as important as patient selection. A few simple clinical approaches have proved useful in determining the prognosis of patients with liver disease. These approaches include use of the Child-Turcotte-Pugh (CTP) classification [*see Table 2*], use of the Mayo model for predicting survival in patients with end-stage liver disease (MELD), the determination of degree of ascites, and the identification of other complications of cirrhosis.[7,8]

The MELD model, which employs a scoring system based on the serum bilirubin level, the serum creatinine level, and the international normalized ratio (INR) for prothrombin time, is now used for the allocation of donor organs in patients on liver transplant waiting lists in the United States.[9,10] MELD scores range from 6 to 40, with higher scores representing sicker patients; waiting time in the MELD system serves as a tiebreaker between patients with the same score.[11] The United Network for Organ Sharing provides on their Web site a resource for calculating MELD scores for individual patients.[12] The MELD score is able to accurately predict 3-month mortality of patients with chronic liver disease who are on the liver waiting list [*see Figure 1*].[11] Under the CTP system, sicker patients often did not survive the 1- to 2-year wait for a donor organ. By replacing the CTP scoring system with the MELD system and by eliminating patient waiting time as a major factor in the allocation of donor organs, the sickest patients are granted earlier access to donor organs. CTP classification and assessment of the complications of cirrhosis remain valuable tools for determining the optimal referral of patients to transplant centers.[8] For example, transplantation improves survival only in those patients with pretransplant CTP scores of 7 or greater. As a result, a CTP score of 7 or higher remains a reasonable threshold for referral of patients to centers for potential transplantation. New-onset ascites and development of other, more ominous complications of cirrhosis (e.g., spontaneous bacterial peritonitis and hepatorenal syndrome) indicate the need for immediate referral of patients to a transplant center.

OPERATIVE PROCEDURES

Most liver transplants are performed using a whole cadaveric liver placed in the orthotopic position. To increase the overall organ supply and especially to aid young children, for whom there is a chronic shortage of donor organs, a cadaveric liver can be divided into parts for more than one recipient [*see Figure 2*]. The same techniques can be used with living donors, with only part of the liver being removed for transplantation. Living related donor transplantation for children is a well-established procedure.[13] Living related donor transplantation for adults is also being performed at many transplantation centers, although donor safety remains a major concern.[14,15]

Liver transplantation is a complex, time-consuming operation that requires vascular reconstruction of the hepatic venous drainage to the inferior vena cava, to the hepatic artery, and to the portal vein. The hepatic vein of the donor organ is anastomosed to the inferior vena cava of the recipient; the donor hepatic artery is anastomosed to the recipient hepatic artery; and the portal vein is reconstructed by a vein graft or patch. Biliary reconstruction is usually accomplished by use of an end-to-end anastomosis of the proximal donor bile duct attached to the distal recipient duct; however, in recipients with diseased ducts, the donor duct is usually anastomosed to the jejunum by way of a Roux-en-Y loop.

A number of complications can be anticipated after liver transplantation, including perioperative and surgical complications, immunologic and infectious disorders, and a variety of medical complications.

COMPLICATIONS OF TRANSPLANTATION

Perioperative and Surgical Complications

The most serious immediate complication seen after liver transplantation is nonfunction of the transplanted liver, which occurs in 5% to 10% of cases. In these cases, patients fail to recover neurologic function; coagulopathy fails to improve spontaneously; and there is progressive jaundice and acidosis. Emergent retransplantation is the only recourse for these patients.

Other important surgical complications encountered after liver transplantation include hepatic artery thrombosis, portal vein thrombosis, and biliary tract complications (e.g., bile leaks and obstruction). Biliary tract complications are the most common; fortunately, most can be managed effectively with endoscopic techniques.[16] Hepatic artery thrombosis is a much more serious complication that can result in the need for retransplantation. A variety of surgical and nonsurgical factors are associated with increased risk of hepatic artery thrombosis. Included among the nonsurgical factors are immunologic status, hypercoagulable states, tobacco use, and cytomegalovius infection.[17]

Table 2 Child-Turcotte-Pugh (CTP) Classification*

	Score		
	1	*2*	*3*
Encephalopathy (grade)	None	1–2	3–4
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dl)	1–2	2–3	> 3
Albumin (g/dl)	> 3.5	2.8–3.5	< 2.8
Prothrombin time (seconds prolonged)	1–4	4–6	> 6

*Minimum CTP score, 5 points; maximum CTP score, 15 points. CTP class A: 5 to 6 points. CTP class B: 7 to 9 points. CTP class C: 10 to 15 points.

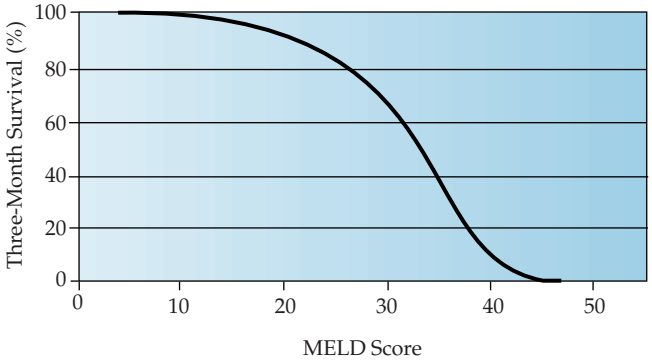

Figure 1 **Estimated 3-month survival as a function of the MELD score.[11]**

Immunologic Complications (Graft Rejection)

Two types of allograft rejection are seen after liver transplantation: cellular and ductopenic. Cellular rejection, which is usually manifested by elevated aminotransferase levels, is most commonly seen 6 to 10 weeks after transplantation. The diagnosis is confirmed by liver biopsy, which reveals cellular invasion of small bile ducts and vascular endothelium. Most patients respond rapidly to increased immunosuppression. Ductopenic rejection is a more indolent process that usually presents as progressive jaundice months to years after transplantation. Liver biopsies reveal gradual disappearance of intrahepatic bile ducts. Most patients with this condition ultimately require retransplantation.

Infectious Complications

Infections remain among the most serious complications encountered after liver transplantation. Many potential pathogens (e.g., *Pneumocystis carinii* and cytomegalovirus) can usually be prevented with aggressive prophylaxis. In the early postoperative period, the most common pathogens are fungal and nosocomial bacterial infections. Candidiasis and aspergillosis, which remain the most serious infections encountered after liver transplantation, often occur in malnourished, critically ill patients.[18] After the first few months following surgery, cytomegalovirus infection and recurrent hepatitis B and C virus infections become much more prominent. Infection with antimicrobial-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) or vancomycin-resistant *Enterococcus faecium* (VREF), is associated with increased postoperative mortality.[19]

Complications of Immunosuppressive Therapy

A number of immunosuppressive agents are now available for use after solid-organ transplantation. These agents include cyclosporine, tacrolimus, azathioprine, mycophenolate mofetil, sirolimus, and corticosteroids, as well as various polyclonal or monoclonal antilymphocyte preparations.[20] Most liver transplant recipients receive either cyclosporine or tacrolimus in combination with one or more other immunosuppressive agents.

Complications from cyclosporine and tacrolimus Cyclosporine and tacrolimus are both associated with a number of

complications, including renal dysfunction, neurologic toxicity, hypertension, pancreatic injury, and a variety of metabolic abnormalities. Renal failure occurs in 10% of patients who take cyclosporine or tacrolimus within 10 years after transplantation.[21] Patients with a glomerular filtration rate of less than 40 ml/min/kg body surface area 1 year after transplantation are at high risk for subsequent renal failure. Replacing calcineurin inhibitors with other immunosuppressive agents, such as mycophenolate mofetil, may improve renal function in some patients, although monotherapy with mycophenolate mofetil is associated with a slight increase in the risk of rejection.[22] Some patients receiving cyclosporine or tacrolimus experience severe neuropsychiatric complications, including psychosis, seizures, and apraxia.[23] Many patients who take these drugs complain of headaches, tremors, and severe musculoskeletal pains. Hypertension, which is quite common in patients who take either cyclosporine or tacrolimus, is thought to result from peripheral and renal vasoconstriction [24] Pancreatic damage with development of type 1 (insulin-dependent) diabetes mellitus is more common after the use of tacrolimus. Patients who take either drug can experience hyperkalemia, hyperuricemia, and elevated cholesterol and triglyceride levels.[25] Switching patients from cyclosporine to tacrolimus appears to reduce the severity of hyerlipidemias in some patients.[26,27] Treatment with low-dose cerivastatin or pravastatin also has been shown to significantly improve lipid profiles without adversely affecting liver function.[28] Cyclosporine, but not tacrolimus, is associated with gingival hyperplasia and excessive hair growth, particularly on the arms and face.

Complications from azathioprine and mycophenolate mofetil Azathioprine and mycophenolate mofetil can cause bone marrow depression with leukopenia, thrombocytopenia, and anemia. A number of patients who take mycophenolate mofetil also experience gastrointestinal side effects, including nausea, abdominal pain, and diarrhea. Long-term corticosteroid therapy is associated with obesity, hypertension, glucose intolerance, cataracts, osteoporosis, and hypercholesterolemia. Side effects of sirolimus include gastrointestinal symptoms and marked elevations of serum lipids, particularly when sirolimus is used in combination with cyclosporine.[29]

Complications from drug-drug interactions Both cyclosporine and tacrolimus are extensively metabolized in the liver, primarily via the cytochrome P-450 IIIA enzyme. As a result, both drugs are prone to numerous drug-drug interactions.[20] The most dramatic examples include interactions with ketoconazole and phenytoin. Ketoconazole inhibits the P-450 IIIA enzyme and can result in marked increases in circulating levels of cyclosporine and tacrolimus. In contrast, phenytoin induces the enzyme, resulting in enhanced metabolism of cyclosporine and tacrolimus and difficulty maintaining adequate circulating levels of both drugs. A number of other commonly used drugs have lesser but important effects on cyclosporine and tacrolimus metabolism. Awareness of these interactions is important in managing patients after transplantation.

Delayed complications from immunosuppressive drugs Most of the delayed complications seen after liver transplantation are secondary to the long-term use of immunosuppressive drugs. The most common of these complications include renal dysfunction, hypertension, diabetes, hyperkalemia and hyperuricemia, hyperlipidemia, obesity, and malignancies.[30] Hypertension can usually be effectively managed with a combination of calcium channel blockers and beta blockers.[31] Transient hyperkalemia can be managed effectively with sodium poly-

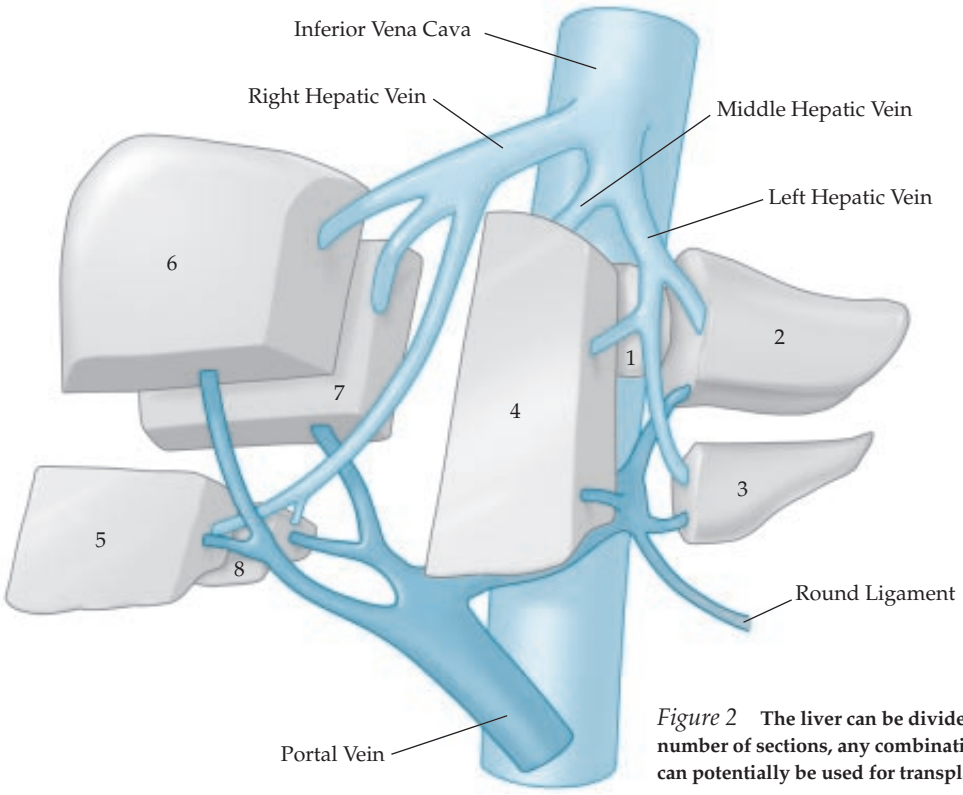

Figure 2 **The liver can be divided into a number of sections, any combination of which can potentially be used for transplantation.**

styrene sulfonate. If hyperkalemia is sustained, fludrocortisone can be used. Although many patients experience hyperuricemia after liver transplantation, very few experience gout. Treatment of gout is difficult because allopurinol can interfere with azathioprine metabolism, which can result in profound, life-threatening leukopenia, and because nonsteroidal anti-inflammatory drugs often worsen renal dysfunction. The necessity for treatment of hyperlipidemia after liver transplantation remains unclear. Obese patients who have undergone liver transplantation need a regular exercise program, limited caloric intake, and reduction or discontinuance of corticosteroids.[32] After age-related cardiovascular complications, malignancies are the leading cause of late death in liver transplant recipients. The most common tumors seen in these patients are lymphoproliferative disorders associated with chronic viral infections and skin cancers (e.g., squamous cell carcinoma and Kaposi sarcoma).[33] Many more recipients of liver transplantation are now receiving the bulk of their care from general internists, gastroenterologists, and primary care physicians. As a result, recognition of potential long-term complications and the need for appropriate immunizations and regular screening visits have become increasingly important.[34]

Disease-Specific Complications

Certain patients require specific management after liver transplantation because of potential disease-specific complications. For example, progressive liver disease can develop rapidly in patients with hepatitis B and can become fatal within a year after transplantation. However, if they are treated with aggressive antiviral therapy before and after transplantation, these patients have an excellent outcome, with minimal risk of severe recurrent disease.[35] Most potential transplant candidates now receive lamivudine therapy before the operation to reduce levels of circulating virus. Some patients with decompensated cirrhosis have such a dramatic response that transplantation can be postponed indefinitely.[36] After surgery, most patients now receive continuous treatment with hepatitis B immune globulin plus lamivudine to prevent recurrent disease.[37] There is concern about the emergence of YMDD (tyrosine-methionine-aspartate-aspartate) mutations after long-term therapy with lamivudine; however, patients resistant to lamivudine therapy have been successfully treated with adefovir dipivoxil, which has recently received approval by the Food and Drug Administration.[38]

Patients with chronic hepatitis C who undergo liver transplantation invariably have persistent infection after the operation. However, the long-term survival of these patients approximates that seen in other transplant recipients.[39] Nevertheless, some patients develop severe disease that can progress rapidly to cirrhosis and liver failure within the first few years after liver transplantation.[40] The optimal management of these patients, which may include pretransplantation and posttransplantation antiviral therapy and retransplantation, remains unclear. Because chronic liver disease secondary to hepatitis C is the leading indication for liver transplantation, management of such cases is an issue of increasing importance.

Patients with liver disease caused by sclerosing cholangitis often have associated inflammatory bowel disease. Although the transplant effectively addresses their liver disease, these patients remain at high risk for colon cancer. As a result, they require careful monitoring with colonoscopy and biopsies at least annually. If severe dysplasia is detected, these patients can be effectively treated with colectomy.

Liver transplantation has emerged as the optimal treatment for most patients with hepatocellular carcinoma (HCC). Excellent disease-free survival after transplantation is associated with patients who have (1) a single tumor no greater than 5 cm in diameter; (2) no more than three lesions, none of which is greater than 3 cm in diameter; (3) no radiographic evidence of vascular invasion; and (4) no evidence of metastases on head and chest CT scans and bone scans.[41] The major obstacles to effective utilization of transplantation have been the availability of donor organs and long delays before transplantation could be accomplished. The issue of long waiting periods before transplantation has been addressed in the new MELD system for allocation of donor organs, which gives patients with HCC who are optimal candidates for transplantation elevated scores to facilitate early transplantation.[10]

OUTCOMES AFTER TRANSPLANTATION

Survival after liver transplantation has improved steadily over the past 10 years. Most centers now report 1-year survival rates of 85% to 90% and 5-year survival rates of 75% to 80%.[1,2] During the same interval, the costs have progressively decreased as the result of reduced hospitalization for most patients.[42] The quality of life for most patients after successful transplantation is quite good. Most patients have been able to return to work, and physically active recipients have returned to vigorous endeavors, including marathon running and mountain climbing.

Pancreas Transplantation

Pancreas transplantation, which aims at providing physiologic insulin replacement, is a therapy that reliably achieves euglycemia in patients with type 1 diabetes mellitus. Islet transplantation (engrafting only the insulin-producing B cells of the pancreas) is an exciting alternative that is still in its clinical infancy.[43,44] One of the major difficulties preventing this technique from becoming widespread is that more than one pancreas is required to provide the recipient with enough islets to become euglycemic.

Since the first vascularized pancreas transplantation in 1966, more than 17,000 have been performed worldwide.[45,46] Approximately 83% of pancreas transplantations have been performed with simultaneous kidney transplantations from the same donors (i.e., simultaneous pancreas and kidney, or SPK, transplantation), with the recipients being those in whom renal failure is imminent or those who are already on dialysis.[46] Of the remaining transplantations, 12% have been performed as a pancreas after kidney (PAK) transplantation in diabetic patients who have had a previous kidney transplant, and 5% have been performed as a pancreas transplantation alone (PTA) in diabetic patients who have not yet experienced significant renal failure.[46]

The goals of pancreas transplantation are to improve the quality of life for patients with type 1 diabetes mellitus, reverse the metabolic abnormalities caused by the disease, and prevent the secondary complications of the disease. Despite these lofty goals, postoperative complications and the need for long-term immunosuppression have rendered pancreas transplantation controversial except in a select subpopulation of patients.

CANDIDATES FOR TRANSPLANTATION

During evaluation, it is essential to confirm the diagnosis of type 1 diabetes mellitus, to confirm that secondary complica-

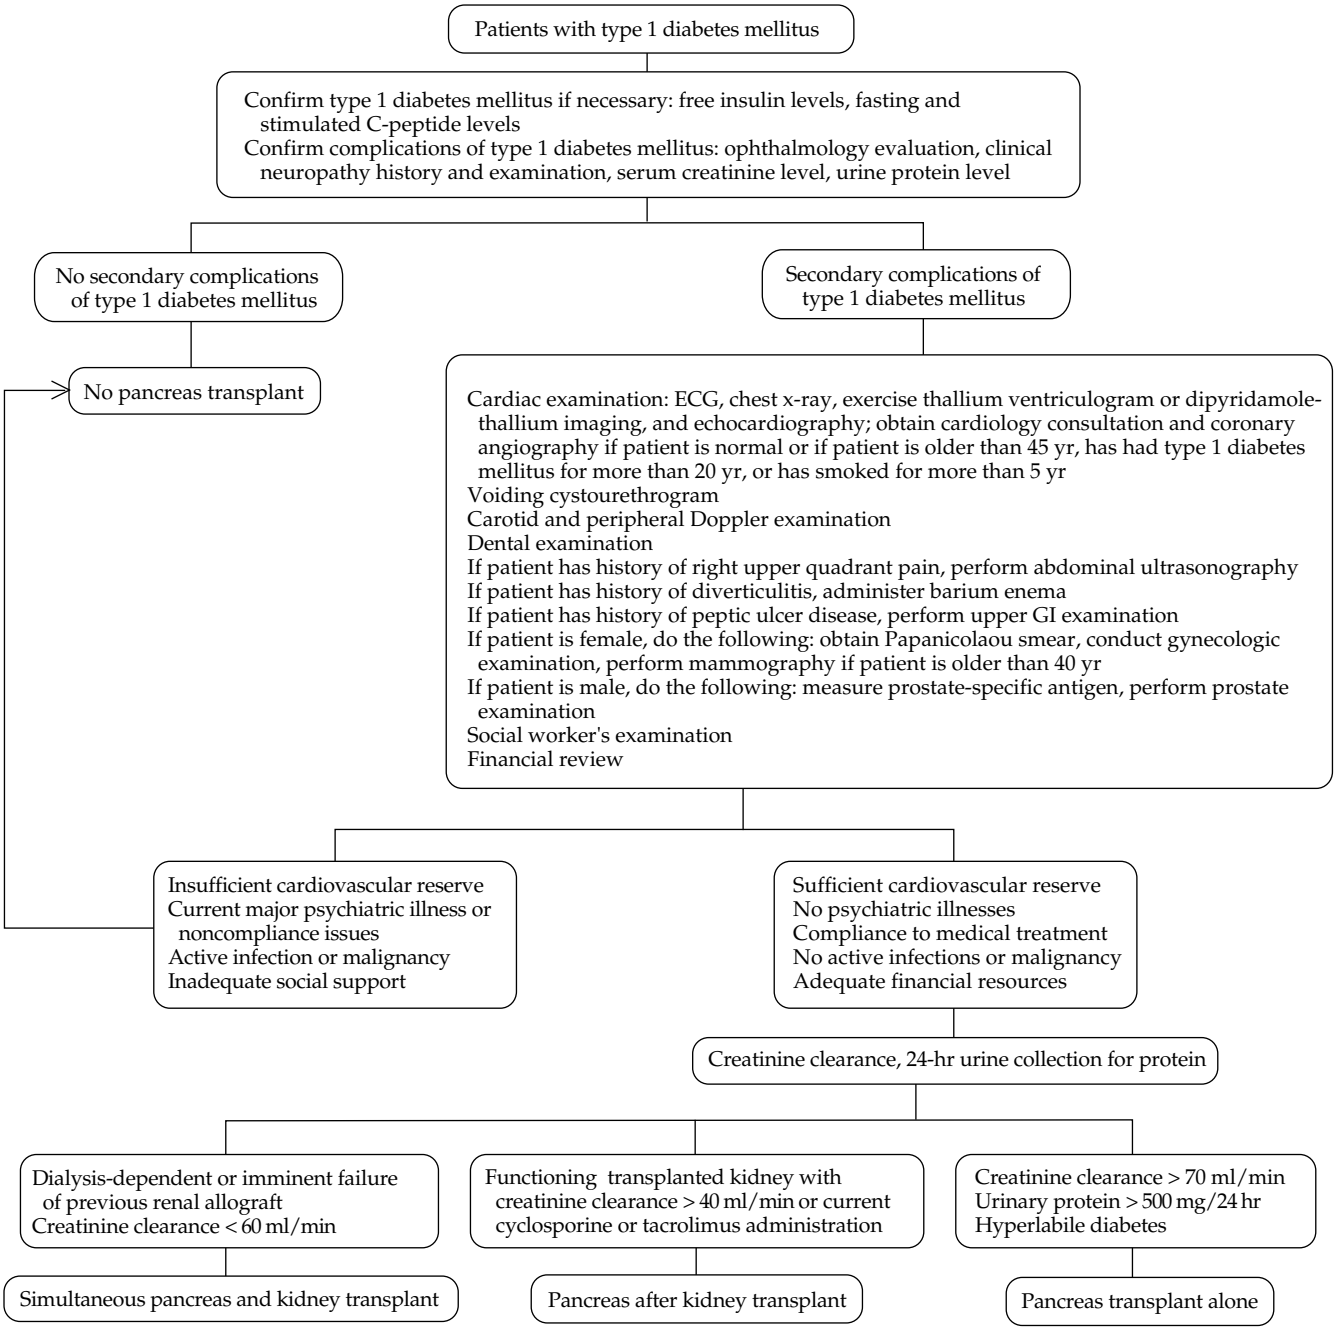

Figure 3 **Algorithm for evaluation of patients with type 1 (insulin-dependent) diabetes mellitus being considered for pancreas transplantation.**

tions of diabetes are present, to determine the candidate's ability to undergo a major operation, and to rule out any contraindications to the operation.[47] The type of procedure to be performed is determined by the renal function status of the potential recipient [*see Figure 3*].

CONTRAINDICATIONS TO TRANSPLANTATION

Patients with insufficient cardiovascular reserve (e.g., recent myocardial infarction), with a left ventricular ejection fraction below 50%, or with coronary angiographic evidence of significant uncorrectable coronary artery disease should not undergo pancreas transplantation[47] [*see Figure 3*]. Unnecessary loss of pancreas grafts is avoided by excluding patients with current major psychiatric illness or evidence of significant noncompliance. In addition, transplantation should not be considered in patients with an active infection or malignancy.

Other contraindications are controversial and depend on the individual transplantation center. Extremity amputations because of vascular disease usually indicate severe generalized vasculopathy and suggest a condition in which pancreas transplantation would not be beneficial. Patients whose weight is greater than 130% of their ideal body weight often have insulin resistance and, as a result, are not helped by transplantation.[47] Continued cigarette use often indicates poor compliance in patients who have already been strongly encouraged to stop smoking. Severe neurogenic bladder dysfunction usually pre-

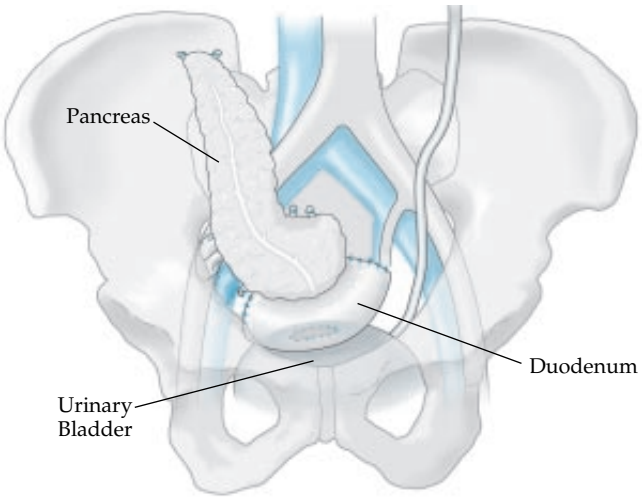

Figure 4 **During the pancreas transplantation procedure, the pancreaticoduodenal graft is anastomosed to the posterolateral aspect of the urinary tract. The arteries and veins of the graft are anastomosed to the common iliac vessels.**

dicts a complicated postoperative course and is considered a contraindication at some centers.

OPERATIVE PROCEDURES

The operation of pancreas transplantation includes placement of the pancreas graft, usually in the right lower quadrant, with the reconstructed arteries of the pancreas anastomosed to the common iliac artery [*see Figure 4*].[48] To provide drainage for pancreatic exocrine excretions, the increasingly favored procedure is to anastomose the duodenum of the graft to the recipient's small bowel as opposed to the mobilized urinary bladder.[46,48,49] The venous drainage of the graft is achieved by anastomosing the portal vein either to the mobilized common iliac vein or to the portal vein.[48,49] In SPK transplantation, the kidney is placed in the left lower quadrant.

PERIOPERATIVE CARE

In the immediate postoperative period, specific care should be directed toward monitoring cardiovascular function.[48] Insulin infusions are generally given for a few days to rest the transplanted islets. Because many patients have some form of diabetic gastropathy, a nasogastric tube is required for 4 to 7 days postoperatively. A urinary catheter is required for an extended period to reduce the risk of complications from neurogenic bladder dysfunction.

COMPLICATIONS OF TRANSPLANTATION

Surgical Complications

Vascular thrombosis, the leading cause of nonimmunologic pancreatic graft failure, occurs in 12% of transplants (5% arterial and 7% venous), usually within the first week after transplantation.[50] With rare exception, salvage of the graft is impossible, and delaying removal of the nonfunctional graft can risk the recipient's life.

Immunologic Complications (Graft Rejection)

Rejection is the leading cause of graft loss after a successful pancreas transplant procedure.[46] Urinary amylase determinations remain the most useful biochemical parameter for indicating rejection in bladder-drained allografts; however, the gold standard for diagnosis of rejection is histopathologic evaluation of the graft.[51] Rejection can be confirmed histologically because tissue samples of the graft can be obtained by percutaneous biopsies.[51]

Complications of Medical Therapy

Dehydration and metabolic acidosis are the next most common adverse effects that follow bladder-drained pancreas transplantations. There is obligatory loss of pancreatic secretions rich in sodium and bicarbonate into the urinary tract. All transplant recipients must increase their fluid and salt intake, and most require continuous oral bicarbonate supplementation. The dehydration and metabolic acidosis can be avoided by use of enteric-drained pancreas transplantation, which is a major reason for the popularity of this technique.[49]

Graft pancreatitis, which is also a common side effect, is manifested by hyperamylasemia, abdominal pain, and graft tenderness. Most bladder-drained grafts can be successfully treated with bladder drainage by catheter for a few days, although a few require conversion to enteric drainage.

Tacrolimus has become the mainstay of immunosuppressive therapy for pancreas transplantation, permitting steroid withdrawal in selected patients.[52] Complications associated with immunosuppressive therapy are similar to those associated with hepatic transplantation.

OUTCOMES AFTER TRANSPLANTATION

Metabolic Outcomes

Successful pancreas transplantation results in normalization of glucose and hemoglobin A_{1c} levels.[47] Glucose tolerance tests are normal or near normal; however, insulin levels are much higher than normal in recipients of pancreas transplantation. The systemic venous drainage of the graft causes elevated plasma levels of insulin, which is known to be a potent regulator of plasma lipoprotein metabolism. As a result, SPK transplantation recipients have a more favorable lipid profile than patients with type 1 diabetes mellitus who have kidney transplants.[53]

Effect on Disorders Associated with Type 1 Diabetes Mellitus

Diabetic nephropathy A transplanted pancreas can prevent or reduce the nephropathy that eventually develops in diabetic patients with a kidney graft. Pancreas transplantation also reduces the risk of recurrent diabetic nephropathy in the kidneys of SPK transplant recipients.[54] In contrast, diabetic glomerular lesions are improved by PTA, but reversal requires more than 5 years of normoglycemia.[55]

Retinopathy Pancreas transplantation appears to have a stabilizing effect on retinopathy. In one study, most diabetic patients who underwent SPK transplantations experienced no progression of diabetic retinopathy but did require maintenance laser therapy.[56]

Neuropathy Reestablishment of the euglycemic state by successful pancreas transplantation halts or reverses diabetic neuropathy. In patients who undergo kidney transplantations, the neuropathy initially improves with elimination of uremia but tends to worsen during longer follow-up. In patients who

also receive pancreas transplants, the severe and prevalent peripheral neuropathy shows a rapid initial improvement followed by stabilization.[57]

Vasculopathy Pancreas transplantation has at least a partial beneficial effect on the macroangiopathy of the carotid artery in patients with type 1 diabetes mellitus.[58] Also, compared with type 1 diabetes mellitus patients who receive kidney transplants, SPK recipients show improvement of diabetic microangiopathy.[56,59] The progression of coronary atherosclerosis in patients with functioning pancreas grafts is reduced.

Survival Outcomes

Patient survival exceeds 95% at 1 year and 90% at 3 years. Graft survival (complete insulin independence) exceeds 85% at 1 year and 75% at 3 years.[46] Patients who undergo SPK transplantation have a markedly improved 10-year survival, compared with diabetic patients who undergo kidney transplantation alone.[60,61]

Quality of Life

Quality of life in terms of general health perception, physical ability, and sexual activity is higher for SPK transplant recipients than for patients with type 1 diabetes mellitus who receive kidney transplants and is far higher for SPK transplant recipients than for patients who remain on hemodialysis.[62]

I APPROACH TO HEMATOLOGIC DISORDERS

David C. Dale, m.d.

Hematology deals with the normal functions and disorders of the formed elements in the blood (i.e., erythrocytes, leukocytes, and platelets) and the plasma factors governing hemostasis. The blood sustains life by transporting oxygen and essential nutrients, removing waste, and delivering the humoral and cellular factors necessary for host defenses. Platelets and coagulation factors, together with vascular endothelial cells, maintain the integrity of this system. Some hematologic disorders such as anemia, leukocytosis, and bleeding are quite common, occurring secondary to infectious, inflammatory, nutritional, and malignant diseases. Other disorders, including the hematologic malignancies, are far less common. This subsection presents the general principles for understanding the hematopoietic system [*see other subsections under Hematology for a more detailed description of the pathophysiology of specific hematologic diseases and their treatment*].

Hematopoiesis

Hematopoiesis begins in the fetal yolk sac and later occurs predominantly in the liver and the spleen.[1] Recent studies demonstrate that islands of hematopoiesis develop in these tissues from hemangioblasts, which are the common progenitors for both hematopoietic and endothelial cells.[2] These islands then involute as the marrow becomes the primary site for blood cell formation by the seventh month of fetal development.[3] Barring serious damage, such as that which occurs with myelofibrosis or radiation injury, the bone marrow remains the site of blood cell formation throughout the rest of life. In childhood, there is active hematopoiesis in the marrow spaces of the central axial skeleton (i.e., the ribs, vertebrae, and pelvis) and the extremities, extending to the wrists, ankles, and the calvaria. With normal growth and development, hematopoiesis gradually withdraws from the periphery. This change is reversible, however; distal marrow extension can result from intensive stimulation, as occurs with severe hemolytic anemias, long-term administration of hematopoietic growth factors, and hematologic malignancies. The term medullary hematopoiesis refers to the production of blood cells in the bone marrow; the term extramedullary hematopoiesis indicates blood cell production outside the marrow in the spleen, liver, and other locations.

Organization of Hematopoietic Tissues

In its normal state, the medullary space in which hematopoietic cells develop contains many adipocytes and has a rich vascular supply [*see Figure 1*].[4] Vascular endothelial cells, marrow fibroblasts, and stromal cells are important sources of the matrix proteins that provide structure to the marrow space; these cells also produce the hematopoietic growth factors and chemokines that regulate blood cell production.[5] The vascular endothelial cells also form an important barrier that keeps immature cells in the marrow and permits mature hematopoietic elements to enter the blood. The abundant adipocytes may influence hematopoiesis by serving as a localized energy source, by synthesizing growth factors, and by affecting the metabolism of androgens and estrogens.[6] Marrow macrophages remove effete or apoptotic cells and clear the blood of foreign materials when they enter the marrow. Osteoblasts and osteoclasts maintain and remodel the surrounding cancellous bone and the calcified lattice, which crisscrosses the marrow space.[4]

The thymus, lymph nodes, mucosa-associated lymphatic tissues, and the spleen have multiple hematopoietic functions. Early in development, they are major sites of hematopoiesis. In adulthood, they are principally sites of lymphocyte development, processing of antigens, development of effector T cells, and antibody production [*see 6 Immunology/Allergy*]. In leukemia and the myeloproliferative disorders, the size and cellular architecture of these tissues are deranged, leading to many of the clinical manifestations of these disorders [*see 12:XVI Acute Leukemia and 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*].

Hematopoietic Stem Cells

All cells of the hematopoietic system are derived from common precursor cells, the hematopoietic stem cells.[7] These cells are difficult to identify, in part because they normally represent only about 0.05% of marrow cells. Through self-renewal, this population is maintained at a constant level.[8] Through the use of monoclonal antibodies that recognize specific cell surface molecules expressed selectively on developing hematopoietic cells and other specialized techniques, the stem cells can now be separated from other marrow cells. With these methods, very primitive hematopoietic stem cells have been found to be positive for c-kit and thy-1 but negative for CD34, CD38, CD33, and HLA-DR.[8] For clinical purposes, $CD34^+$ progenitor cell populations, which contain stem cells and some more mature cells, are often used for hematopoietic stem cell transplantation[9] [*see 5:XI Hematopoietic Stem Cell Transplantation*].

Stem cells give rise to daughter cells, which undergo irreversible differentiation along various hematopoietic cell lineages [*see Figure 2*].[10] Many aspects of the earliest steps in this differentiation process are not well understood. With lineage commitment, however, differentiation, maturation, and release of cells to the blood come under the control of well-defined hematopoietic growth factors. In the early phases of differentiation, the regulatory roles played by these growth factors overlap.[11] Later in development, some growth factors are lineage specific, meaning that they govern the maturation and deployment of single lineages. Erythropoietin (EPO) (erythrocytes), thrombopoietin (TPO) (platelets), granulocyte colony-stimulating factor (G-CSF) (neutrophils), and macrophage colony-stimulating factor (M-CSF) (monocytes) are the best-characterized lineage-specific factors.

Hematopoietic Growth Factors

The hematopoietic growth factors, also referred to as hematopoietic cytokines, are a family of glycoproteins produced in the bone marrow by endothelial cells, stromal cells, fibroblasts, macrophages, and lymphocytes; they are also produced at distant sites, from which they are transported to the marrow through the blood [*see Table 1*]. The naming of these factors is somewhat confusing. Erythropoietin and throm-

bopoietin derive part of their names from the Greek word poiesis, meaning "to make." The colony-stimulating factors were first recognized because of their capacity to stimulate early hematopoietic cells to grow into clusters and large colonies in tissue culture systems. The term interleukin denotes factors that are produced by leukocytes and that affect other leukocytes. This is a large family of factors that predominantly govern lymphocytopoiesis, but many members also have broad effects on other lineages. The discovery of new growth factors and of the biologic consequences of deficiencies or excesses of these factors continues to evolve rapidly.

Hematopoietic cells have distinctive patterns of expression of growth factor receptors, and the patterns evolve as the cells differentiate [*see Figure 2*].[11] Each growth factor binds only to its specific receptor.[12] It is now known that some growth factors share components of the receptor (e.g., interleukin-3 [IL-3], IL-5, and granulocyte-macrophage colony-stimulating factor [GM-CSF] share a common β chain of their receptor); specificity comes from other unique or private components of the receptor. Binding of the ligand to the receptor leads to a conformational change, activation of intracellular kinases, and, ultimately, the triggering of cell proliferation.[13,14] For some growth factors, these pathways are well defined; for others, the pathways are still unclear [*see Figure 3*].

Hematopoietic growth factors not only stimulate cell proliferation but also prolong cell survival; that is, they have antiapoptotic effects.[15] For some lineages, such as neutrophils and monocytes, growth factor receptors occur on fully mature cells; exposure of these cells to the factors primes the cells for an enhanced responsiveness to bacteria or other stimulators of their metabolic activity. Thus, for cells of the neutrophil lineage, the growth factors G-CSF and GM-CSF can stimulate early hematopoietic cell proliferation, increase the number of cells produced by the marrow, prolong the life span of these cells, and augment cell functions.[16]

Erythropoietin

The peritubular interstitial cells located in the inner cortex and outer medulla of the kidney are the primary site for erythropoietin production.[17] In response to hypoxia, transcription of the erythropoietin gene in these cells increases, resulting in increased secretion of erythropoietin. The protein is then transported through the blood to the marrow to stimulate erythropoiesis. With renal failure, erythropoietin production is severely impaired. In infections and many chronic inflammatory conditions, the erythropoietin response is blunted, and erythropoietin levels are low.[18]

Erythropoietin is a glycosylated protein that modulates erythropoiesis by affecting several steps in red cell development. The most primitive identifiable erythroid cells, the burst-forming unit–erythroid cells (BFU-E), are relatively insensitive to erythropoietin. More mature cells, the colony-forming unit–erythroid cells (CFU-E), are very sensitive. Erythropoietin treatment prolongs survival of erythroid precursors, shortens the time between cell divisions, and increases the number of cells produced from individual precursors.[19]

Erythropoietin can be administered intravenously or subcutaneously for the treatment of anemia caused by inadequate endogenous production of erythropoietin.[20] Treatment is maximally effective when the marrow has a generous supply of iron and other nutrients, such as cobalamin and folic acid.[21] For patients with renal failure, who have very low erythropoietin levels, the starting dosage is 50 to 100 units S.C. three times a week. The most easily monitored immediate effect of increased endogenous or exogenous erythropoietin is an increase in the blood reticulocyte count. Normally, as red cell precursors mature, the cells extrude their nucleus at the normal blast stage. The resulting reticulocytes, identified by the supravital stain of their residual ribosomes, persist for about 3 days in the marrow and 1 day in the blood. Erythropoietin shortens the transit time through the marrow, leading to an increase in the number and proportion of blood reticulocytes within a few days.

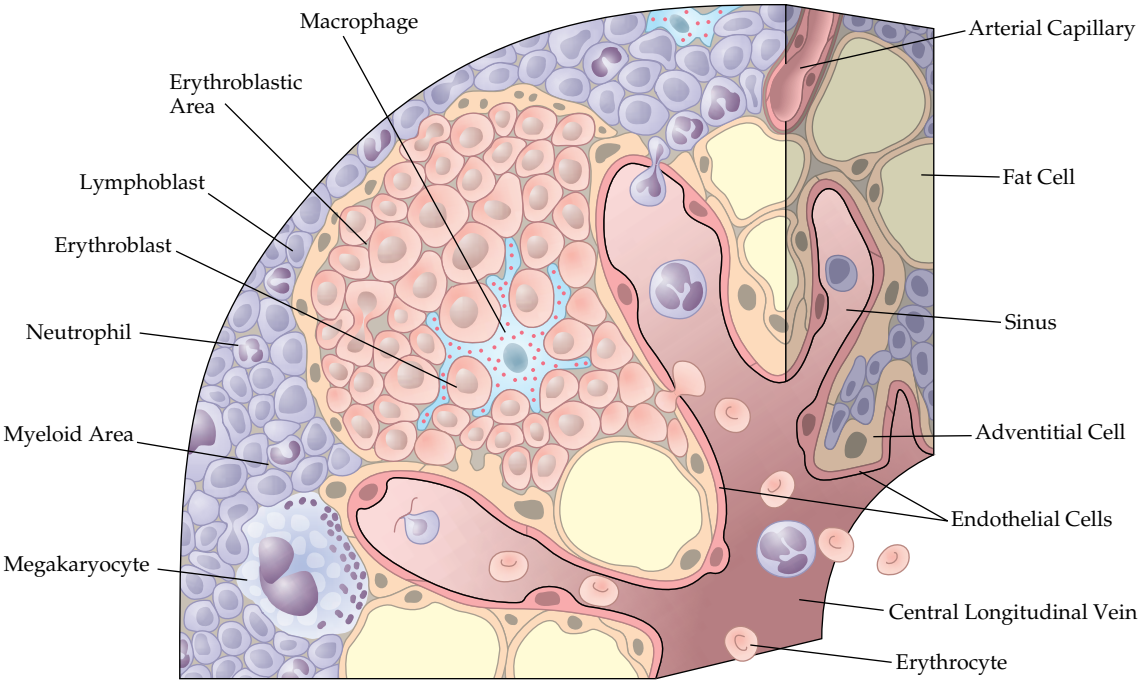

Figure 1 **The architecture of the bone marrow showing the various types of cells.**

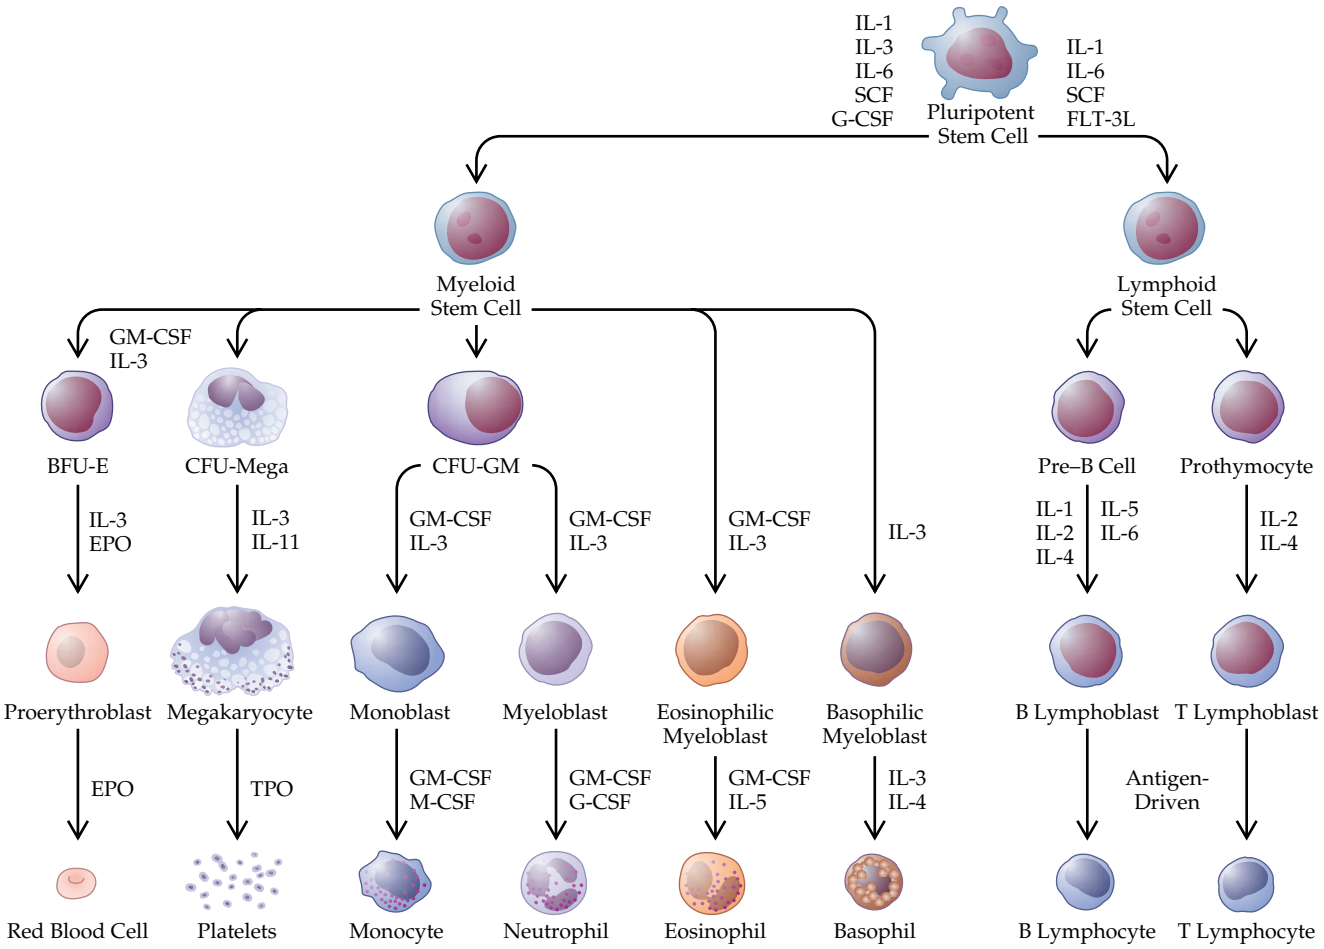

Figure 2 **The pattern for development of various types of blood cells in the bone marrow. (BFU-E—burst-forming unit–erythroid; CFU-GM—colony-forming unit–granulocyte-macrophage; CFU-mega—colony-forming unit–megakaryocyte; EPO—erythropoietin; EPOR—surface component of the erythropoietin receptor; FLT-3L—fms-like tyrosine kinase 3 ligand; G-CSF—granulocyte colony-stimulating factor; GM-CSF—granulocyte-macrophage colony-stimulating factor; IL—interleukin; M-CSF—macrophage colony-stimulating factor; TPO—thrombopoietin; SCF—stem cell factor)**

In some conditions, particularly chronic inflammatory diseases, the effectiveness of erythropoietin can be predicted from measurement of the serum erythropoietin level by immunoassay.[17,18] It may be cost-effective to measure the level before initiating treatment in patients with anemia attributable to suppressed erythropoietin production, such as patients with HIV infection, cancer, and chronic inflammatory diseases. Several studies have shown that erythropoietin treatment decreases the severity of anemia and improves the quality of life for these patients. In patients with anemia caused by cancer and cancer chemotherapy, current guidelines recommend erythropoietin treatment if the hemoglobin level is less than 10 g/dl.[22]

Thrombopoietin

The development of megakaryocytes from hematopoietic stem cells and the level of platelets in the blood are governed by thrombopoietin.[23] Thrombopoietin is produced primarily by the liver and is similar to erythropoietin in structure. However, thrombopoietin has broader biologic effects than erythropoietin, stimulating the proliferation and release of hematopoietic stem cells from the bone marrow and prolonging survival of these cells.[24] Thrombopoietin signals through its specific receptor, called cMpL, expressed on hematopoietic cells. Plasma thrombopoietin levels are inversely related to the blood platelet count. Deficiencies in thrombopoietin cause thrombocytopenia, and excesses in thrombopoietin cause thrombocytosis. Recombinant human thrombopoietin is being studied for use in the treatment of thrombocytopenia of diverse causes. Thrombopoietin is not yet approved for clinical use.[24]

Granulocyte Colony-Stimulating Factor

G-CSF is a glycosylated protein produced by monocytes, macrophages, fibroblasts, stromal cells, and endothelial cells throughout the body.[25] It stimulates the growth and differentiation of neutrophils both in vitro and in vivo. G-CSF levels are normally very low or undetectable but increase with bacterial infections or after administration of bacterial endotoxin.[16] G-CSF (the synthesized form is known as filgrastim or lenograstim) administration causes a dose-dependent increase in the blood neutrophil count in healthy persons. Studies in animals have shown that G-CSF deficiency causes neutropenia.[26] As with erythropoietin, administration of G-CSF leads to an acceleration in the development of neutrophils in the bone marrow, with the neutrophils shifting at an earlier stage than normal from the marrow to the blood.[27]

Table 1 Hematopoietic Growth Factors

Factor	*Other Names*	*Cell Source*	*Chromosome Location*	*Function*
EPO	Erythropoietin	Juxtaglomerular cells	7q	Stimulates erythrocyte formation and release from marrow
TPO	Thrombopoietin; megakaryocyte growth and development factor (MGDF)	Hepatocytes, renal and endothelial cells, fibroblasts	3q27	Stimulates megakaryocyte proliferation and platelet formation
G-CSF	Granulocyte colony-stimulating factor; filgrastim; lenograstim	Endothelial cells, monocytes, fibroblasts	17q11.2-q21	Stimulates formation and function of neutrophils
GM-CSF	Granulocyte-macrophage colony-stimulating factor	T cells, monocytes, fibroblasts	5q23-q31	Stimulates formation and function of neutrophils, monocytes, and eosinophils
M-CSF	Macrophage colony-stimulating factor; colony stimulating factor–1 (CSF-1)	Endothelial cells, macrophages, fibroblasts	5q33.1	Stimulates monocyte formation and function
IL-1α and IL-1β	Interleukin-1α and -1β, endogenous pyrogen hemopoietin-1	Monocytes, keratinocytes, endothelial cells	2q13	Proliferation of T cells, B cells, and other cells; induces fever and catabolism
IL-2	T cell growth factor	T cells ($CD4^+$, $CD8^+$), large granular lymphocytes (natural killer, or NK, cells)	4q	T cell proliferation, antitumor and antimicrobial effects
IL-3	Multi–colony stimulating factor; mast cell growth factor	Activated T cells; large granular lymphocytes (NK cells)	5q23-q31	Proliferation of early hematopoietic cells
IL-4	B cell growth factor; T cell growth factor II; mast cell growth factor II	T cells	5q23-q31	Proliferation of B cells and T cells; enhances cytotoxic activities
IL-5	Eosinophil differentiation factor; eosinophil colony-stimulating factor	T cells	5q23.3-q32	Stimulates eosinophil formation; stimulates T cell and B cell functions
IL-6	B cell stimulatory factor II; hepatocyte stimulatory factor	Monocytes, tumor cells, B cells and T cells, fibroblasts, endothelial cells	7p	Stimulates and inhibits cell growth; promotes B cell differentiation
IL-7	Lymphopoietin 1; pre–B cell growth factor	Lymphoid tissues and cell lines	8q12-q13	Growth factor for B cells and T cells
IL-11	Plasmacytoma stimulating factor	Fibroblasts, trophoblasts, cancer cell lines	19q13.3-q13.4	Stimulates proliferation of early hematopoietic cells; induces acute-phase protein synthesis
IL-12	Natural killer cell stimulating factor	Macrophages, B cells	5q31-q33; 3p12-q13.2	Stimulates T cell expansion and interferon-gamma; synergistically promotes early hematopoietic cell proliferation
LIF	Leukemia inhibitory factor	Monocytes and lymphocytes; stomal cells	22q	Stimulates hematopoietic cell differentiation
SCF	Stem cell factor; kit ligand; steel factor	Endothelial cells; hepatocytes	4q11-q20	Stimulates proliferation of early hematopoietic cells and mast cells
FLT-3 ligand	fms-like tyrosine kinase 3; STK-1	T cells, stromal cells, and fibroblasts	19q13.3	Stimulates early hematopoietic cell differentiation; increases blood dendrite cells

G-CSF is approved for the treatment of neutropenia after cancer chemotherapy, for acceleration of neutrophil recovery after bone marrow transplantation, for mobilization of hematopoietic progenitor cells from the marrow to the blood in hematopoietic transplantation, and for the treatment of severe chronic neutropenia. The usual dosage is 5 mg/kg S.C. daily; higher doses are used to mobilize progenitor cells, and lower doses are used for long-term treatment of neutropenia. A new formulation of G-CSF, in which G-CSF is conjugated to polyethylene glycol to reduce renal clearance, was recently approved for marketing. Its principal advantage is that one injection is sufficient to stimulate marrow recovery after standard doses of cancer chemotherapy. Side effects of either form of G-CSF are principally musculoskeletal pain and headaches during the period of rapid marrow expansion soon after therapy is initiated. Other side effects are uncommon.

Granulocyte-Macrophage Colony-Stimulating Factor

GM-CSF is a glycosylated protein produced by many types of cells, including T cells.[28] GM-CSF stimulates formation of neutrophils, monocytes, and eosinophils and may also enhance the growth of early cells of other lineages. In contrast to G-CSF, GM-CSF levels generally do not increase with infections or acute inflammatory conditions,[29] and neutropenia does not result from deficiencies of GM-CSF.[30] The marrow effects of G-CSF and GM-CSF are similar, but GM-CSF is less potent in elevating the blood neutrophil count.[31] GM-CSF (the synthesized form is known as sargramostim or molgramostim) is approved

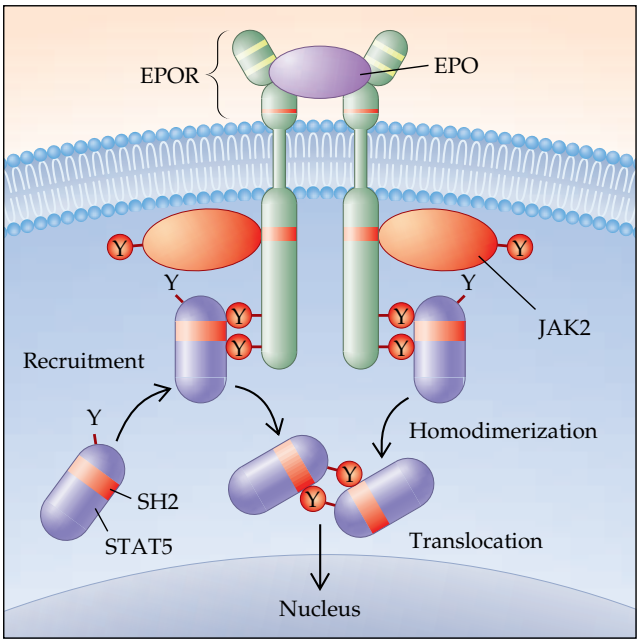

Figure 3 **A model of how hematopoietic growth factors interact with their receptors to initiate cell proliferation. (EPO—erythropoietin; JAK2—Janus kinase 2; SH2—Src homology 2; STAT5—signal transducer and activator of transcription 5)**

in the United States for acceleration of marrow recovery after bone marrow transplantation or chemotherapy and for mobilization of progenitor cells from the marrow. The usual dosage is 250 mg/m^2/day S.C. Its side effects include bone and musculoskeletal pain, myalgias, and injection-site reactions.

Interleukin-11

IL-11 (oprelvekin) is a pleiotropic cytokine that is expressed by, and active in, many tissues.[32] IL-11 acts synergistically with other growth factors, including thrombopoietin, to stimulate megakaryocyte development and platelet formation. It is approved for use in the prevention of severe thrombocytopenia and for patients who need platelet transfusions after chemotherapy. The usual dosage is 50 mg/kg/day S.C. Its side effects include edema, tachycardia, and dyspnea.

Other Growth Factors

Several other hematopoietic growth factors have potential clinical uses. IL-3 acts at an early phase in hematopoiesis to stimulate cell proliferation but has relatively little effect on peripheral counts. IL-3 has been molecularly coupled to other growth factors, including GM-CSF, G-CSF, and TPO, to produce hybrid molecules that are under investigation. Stem cell factor (SCF) and fms-like tyrosine kinase 3 (FLT-3) ligand are other early-acting factors under investigation. M-CSF is a selective factor for monocytes and macrophage formation. IL-5 is a similar selective factor for the generation of eosinophils.

It is presumed that normally, hematopoietic cell formation is governed by combinations of factors, released in a cascade, that closely coordinate the development of these cells. The details of how this process occurs, however, are not yet clear. Numerous laboratory and clinical studies have investigated combinations of factors, but the therapeutic benefit of using multiple growth factors is not yet proved.

DYNAMICS OF HEMATOPOIESIS

In the marrow, blood cells develop in two phases, the proliferative and the maturational phases. During cell proliferation, the precursors of blood cells normally undergo cell division at intervals of about 18 to 24 hours. In the maturational phase, cell division ceases, but final features are added before the cells enter the blood. During this phase, erythrocytes normally lose all their nuclear material, acquire their biconcave shape, and develop their final content of enzymes necessary for maintaining the biconcave shape and resisting destruction by oxidative stress. Normally, it takes 7 to 10 days for erythrocytes to develop from their early precursors, but this process can be accelerated by erythropoietin therapy.[33]

Neutrophils acquire most of their granules (known as the primary, secondary, and tertiary granules), which are necessary for their microbicidal activities, during the proliferative phase.[34] During maturation, their nuclear chromatin condenses, the glycogen content of the cytoplasm increases, and the surface properties governing the circulation, adherence, and migration to tissues are added.[35] Neutrophils reach a fully mature state in the marrow before they are released into the blood. These mature marrow cells are called the marrow neutrophil reserve. Quantitatively, this neutrophil pool is substantially larger—probably

Table 2 Causes of Lymphadenopathy[42]

Infections
- Bacterial: streptococci,* *Staphylococcus aureus*,* syphilis,*† cat-scratch disease,* *Mycobacterium tuberculosis* and other mycobacteria,† brucellosis,† leptospirosis,† meliodiosis,† chancroid, plague, tularemia, rat-bite fever
- Viral: adenovirus,* HIV,*† infectious mononucleosis,*† herpes simplex,* measles,† rubella,† cytomegalovirus,† hepatitis,† Kawasaki disease
- Mycotic: sporotrichosis, histoplasmosis,† coccidioidomycosis†
- Rickettsial: Rocky Mountain spotted fever,*† scrub typhus†
- Chlamydial: *Chlamydia trachomatis*, lymphogranuloma venereum
- Protozoan: toxoplasmosis,† trypanosomiasis,† kala-azar†
- Helminthic: filariasis,† onchocerciasis

Immunologic Causes
- Stings and bites*
- Drug reactions*†: phenytoin, hydralazine
- Serum sickness*†
- Collagen vascular diseases: rheumatoid arthritis,† dermatomyositis,† angioimmunoblastic lymphadenopathy†

Malignancies
- Hematologic: Hodgkin disease,* acute leukemia,† chronic lymphocytic leukemia,† chronic myelogenous leukemia,† lymphoma,† myelofibrosis†
- Other: metastatic carcinoma, sarcomas

Endocrine Diseases
- Hyperthyroidism†

Histiocytic Disorders
- Lipid storage disease,† malignant histiocytosis,† Langerhans (eosinophilic) histiocytosis

Miscellaneous
- Sarcoidosis, amyloidosis,† chronic granulomatous disease, lymphomatoid granulomatosis, necrotizing lymphadenitis

*Most common causes in general practice in the United States.

†Usually cause generalized lymphadenopathy.

five to 10 times larger—than the total circulating supply of neutrophils. Normally, it takes 10 to 14 days for blood neutrophils to develop from early precursors, but this process is accelerated in the presence of infections and by treatment with G-CSF or GM-CSF [*see 5:VII Nonmalignant Disorders of Leukocytes*].

Platelets form from the breaking apart of the cytoplasm of the fully mature megakaryocytes, which are also derived from hematopoietic stem cells.[23] Megakaryocytes undergo reduplication of their nuclear chromatin without cell division, which results in the production of extremely large cells. When marrow damage occurs from chemotherapeutic agents and after hematopoietic transplantation, the megakaryocytes are often the slowest cells to recover, and thrombocytopenia is often the last cytopenia to resolve.

There are important differences in the dynamics or kinetics of erythrocytes, platelets, and leukocytes in the blood. For instance, neutrophils have a blood half-life of only 6 to 8 hours; essentially, a new blood population of neutrophils is formed every 24 hours.[35] Erythrocytes last the longest by far: the normal life span is about 100 days.[33] These differences partially account for why neutrophils and their precursors are the predominant marrow cells, whereas in the blood, erythrocytes far outnumber neutrophils. Similarly, the short half-life and high turnover rate of neutrophils account for why neutropenia is the most frequent hematologic consequence when bone marrow is damaged by drugs or radiation. Finally, transfusion of erythrocytes and platelets is feasible because of their relatively long life span, whereas the short life span of neutrophils has greatly impeded efforts to develop neutrophil transfusion therapy.

Clinical Manifestations of Hematologic Disorders

The following signs and symptoms are frequently observed in patients with hematologic diseases.

WEAKNESS, FATIGUE, AND PALLOR

Weakness and fatigue are common complaints of patients with anemia, especially if it is of recent onset, such as anemia caused by recent blood loss or acute hemolysis.[36] Anemia that develops gradually, particularly in inactive persons, may cause only fatigue. Fatigue is a very common complaint of patients with infections, inflammatory diseases, and malignancies. Several recent studies document that raising hemoglobin levels with erythropoietin injection decreases fatigue in patients with cancer or HIV infection.[37,38] Other common causes of fatigue include chronic lung diseases, congestive heart failure, endocrine disorders, and depression.

Pallor is recognized by examining the conjunctiva, mucous membranes, nail beds, and palmar creases—tissues lacking melanin pigmentation. The World Health Organization has developed a simple clinical scale to measure pallor for diagnosing anemia when blood counts are not available. The sensitivity and specificity of this scale vary between 70% and 90%, depending on the population and severity of the anemia.[39,40] Other causes of pallor include edema (including myxedema) and vasoconstriction caused by cold temperatures, hemorrhage, hypoglycemia, or shock.

PAIN

Pain, particularly bone pain, is an important marker of hematologic disease. Pain is usually generalized in patients with acute leukemia and multiple myeloma,[41] but most frequently, it is felt in the back or pelvis. With metastatic breast, colon, or lung cancer, the pain is more often localized and asymmetrical. In sickle cell disease, severe bone pain and pain in many other tissues occur with vascular obstruction and infarction caused by obstruction of blood flow by the aggregation of abnormal cells [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*]. Bone pain mimicking these disorders occurs with marrow expansion in response to treatment with hematopoietic growth factors.

FATIGUE, PHARYNGITIS, AND FEVER

Fatigue, pharyngitis, and fever are a frequently observed sequence in patients with acutely developing neutropenia, occurring as an idiosyncratic or toxic reaction to many drugs. In cases of severe neutropenia, cough and respiratory symptoms, perianal pain and tenderness, or acute abdominal pain often occurs and necessitates immediate medical assessment [*see 5:VII Nonmalignant Disorders of Leukocytes*].

MOUTH ULCERS, GINGIVITIS, AND CERVICAL ADENOPATHY

Mouth ulcers, gingivitis, and cervical adenopathy are common problems of patients with chronic neutropenia [*see 5:VII Nonmalignant Disorders of Leukocytes*]. Gingivitis is a serious problem, often leading to periodontal disease and tooth loss.

LYMPHADENOPATHY AND SPLENOMEGALY

Lymphadenopathy is a common presentation of infectious, inflammatory, and hematologic diseases, particularly the lymphomas and leukemias [*see Table 2*]. Lymphadenopathy may occur without associated symptoms, but often, fatigue and intermittent fever (e.g., Pel-Ebstein fever) occur. In contrast to acute infectious diseases leading to tender lymphadenopathy, in most hematologic disorders the lymph nodes and spleen are nontender, with a soft to rubbery consistency. Splenomegaly is often more difficult to detect than lymphadenopathy; most of the diseases causing lymphadenopathy can also cause splenic enlargement.

BLEEDING

Bleeding occurs as a consequence of thrombocytopenia, deficiencies of coagulation factors, or both [*see 5:XIII Hemorrhagic Disorders*]. Thrombocytopenia usually presents as petechial bleeding that is first observed in the lower extremities. Coagulation factor deficiencies more often cause bleeding into the gastrointestinal tract or joints. Intracranial bleeding, however, can occur with a deficiency of platelets or coagulation factors and can be catastrophic.

THROMBOSIS

Thrombosis can be either venous or arterial [*see 5:XIV Thrombotic Disorders*]. With venous thrombosis, swelling, tenderness, and pain beyond the obstruction usually occur, and embolization to the lungs is a frequent concern. Venous thrombosis usually occurs after inactivity or obstruction of venous flow or with imbalances of coagulation factors. On the other hand, arterial thrombosis usually occurs because of abnormalities of the arterial wall from atherosclerosis or acute vascular injury, as in thrombotic thrombocytopenic purpura, or from thrombocytosis in the myeloproliferative disorders.

Laboratory Evaluation

The following basic tests are widely used to diagnose hematologic disorders.

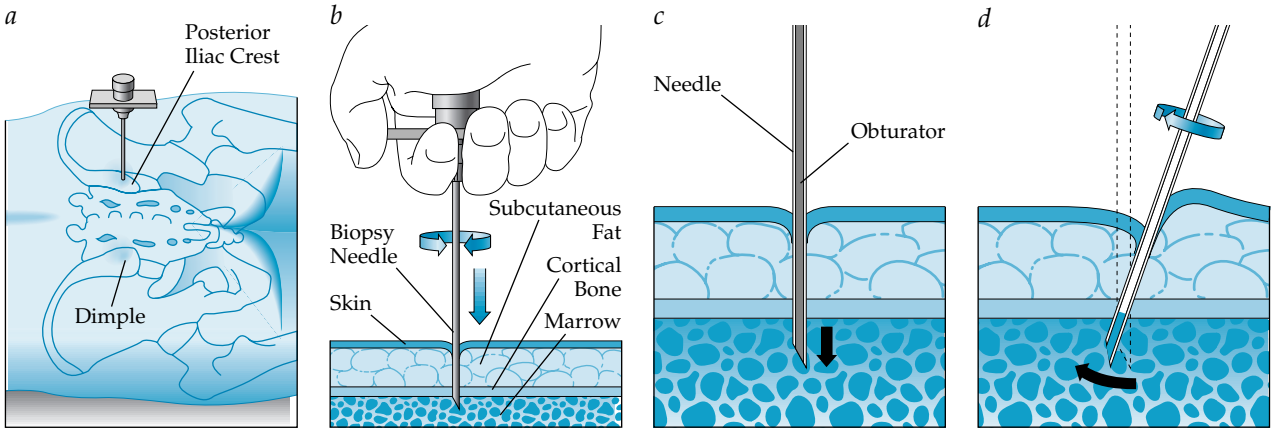

Figure 4 **Bone marrow aspirate and biopsy procedure. (*a*) The posterior iliac crest is the usual site for sampling; (*b*) the needle is placed through the skin to the marrow space; (*c*) the marrow sample is aspirated; and (*d*) the biopsy sample is carefully removed.**

COMPLETE BLOOD CELL COUNTS

CBCs are routinely performed in most laboratories through the use of an electronic particle counter, which determines the total white blood cell and platelet counts and calculates the hematocrit and hemoglobin levels from the erythrocyte count and the dimensions of the red cells. Abnormalities in the CBC are described in other Hematology subsections [*see also the* Normal Laboratory Values *section*].

PERIPHERAL BLOOD SMEARS

Peripheral blood smears usually stain with Wright stain. When examined by light microscopy, they reveal the size and shape of blood cells, which allows an estimate to be made of the amount of hemoglobin in erythrocytes. Differential leukocyte counts, enumerating the number of neutrophils, monocytes, lymphocytes, eosinophils, and basophils, are made by manually counting cells on the blood smears or by using an automated cell counter [*see the* Normal Laboratory Values *section*]. The morphology of the leukocytes often provides a clue for the diagnosis of leukemia and for recognizing some disorders of leukocytes that lead to susceptibility to infections [*see 5:VII Nonmalignant Disorders of Leukocytes*].

RETICULOCYTE COUNTS

Reticulocyte counts are useful for evaluating the marrow response to anemia [*see the* Normal Laboratory Values *section*]. Normally, during their first 24 to 36 hours in the circulation, young red cells contain residual ribosomal RNA, which precipitates with certain dyes such as methylene blue. An increase in the proportion or absolute number of reticulocytes occurs a few days after significant blood loss or in response to red blood cell destruction in hemolytic anemias. Low reticulocyte counts in chronic anemia suggest either an endogenous erythropoietin deficiency or a marrow abnormality.

BONE MARROW EXAMINATION

Hematopoietic cells of the bone marrow can be removed by aspiration or by needle biopsy. In adults, the best site is the posterior iliac crest, with the patient in a prone position [*see Figure 4*]. Under special circumstances and in children, other sites can be used, such as the anterior iliac crest, the sternum, or the long bones. With local anesthesia and sterile technique, the patient experiences only transient pain. Bleeding or infection at the injection site is quite uncommon. The aspirate yields cells for morphologic examination, and differential counts reveal the ratio of myeloid cells to erythroid cells (M:E ratio) [*see the* Normal Laboratory Values *section*]. A biopsy reveals the cellularity of the marrow at the site sampled. Biopsies are particularly useful for examination of the marrow for infiltrative cells (e.g., in lymphomas or carcinomas involving the marrow) and for diagnosing leukemia, characterized by the marrow's being so densely packed with cells that none of the bone marrow can be aspirated. Biopsies take longer for interpretation because they must be decalcified and stained before examination.

Imaging Studies

Radionuclide scanning (e.g., using technetium-99m) reveals the extent of the hematopoietic tissue in the marrow because the phagocytic cells of the marrow take up the radiolabeled particles. Marrow scanning is sometimes used to determine the extensiveness of the hematopoietic tissue; more often, it is useful in determining whether there are localized areas of increased uptake resulting from infection or a malignancy that has metastasized to the marrow. Computed tomography and ultrasonography are useful in determining the size of lymph nodes and the spleen, but they are not particularly useful for marrow examination. The marrow is seen well with magnetic resonance imaging. This technique is principally used to look for infiltrative processes in the marrow space, such as those that occur in malignancies and infections.

II RED BLOOD CELL FUNCTION AND DISORDERS OF IRON METABOLISM

Gary M. Brittenham, m.d.

Red Blood Cell Function

The red blood cell, or erythrocyte, carries oxygen from the lungs to peripheral tissues for utilization and brings carbon dioxide from tissues to the lungs for excretion.[1] The mature erythrocyte dedicates more than 95% of its intracellular protein, as hemoglobin, to these tasks. Hemoglobin, the oxygen transport molecule, binds oxygen molecules at the high oxygen tensions of the pulmonary alveoli and releases oxygen molecules at low oxygen tensions to peripheral tissues.[2,3] Hemoglobin also acts as a carrier of nitric oxide (NO), a third respiratory gas that seems to regulate oxygen delivery.[4] The exact role of NO in the cardiorespiratory cycle is debated,[5] but NO is a potent vasorelaxant that reportedly is released during arteriovenous transit, increasing blood flow and therefore oxygen transport in hypoxic tissue.[4]

The cell membrane of the erythrocyte is a flexible structure composed of a lipid bilayer with integral proteins. These proteins anchor the membrane to an underlying protein skeleton that maintains the biconcave discoid form of the cell.[6] This shape optimizes passage of the cell through the circulatory system and permits apposition of erythrocytes and parenchymal cells across the thin endothelium of capillaries, facilitating exchange of oxygen and carbon dioxide.

In the erythrocyte, a variety of metabolic pathways maintain the iron of hemoglobin in the ferrous state, protect against oxidant damage, generate 2,3-diphosphoglycerate (2,3-DPG) to help regulate oxygen affinity, and maintain osmotic stability through a series of membrane pumps.[7] Without erythrocytes, blood plasma can carry only about 5 ml O_2/L; with erythrocytes containing normal hemoglobin, whole blood can transport about 200 ml O_2/L or more.[1]

Structure of Hemoglobin

Hemoglobin is a spherical molecule composed of two pairs of dissimilar globin chains, with a heme group, ferroprotoporphyrin IX, bound covalently at a specific site in each chain.[3] The major adult hemoglobin, hemoglobin A, is formed from a pair of α chains (each containing 141 amino acids) and a pair of β chains (each containing 146 amino acids) and is written as $\alpha_2\beta_2$ [*see Figure 1*].

The configuration of hemoglobin shifts with oxygenation and deoxygenation.[2,8] The deoxy configuration of hemoglobin is stabilized through the binding of protons and 2,3-DPG, a highly charged anion. With oxygenation of one subunit, these bonds are sequentially broken, and the resulting change in tertiary structure increases oxygen affinity of the remaining unliganded subunits.[2] This phenomenon is termed cooperativity or heme-heme interaction. As oxygen is released in the tissues, a reversal of this process decreases oxygen affinity, facilitating the release of oxygen. Conformational changes also contribute to the decrease in oxygen affinity with decreasing pH.[2] This effect, called the Bohr effect, is physiologically beneficial both in the lungs, where elimination of carbon dioxide raises the pH, enhancing

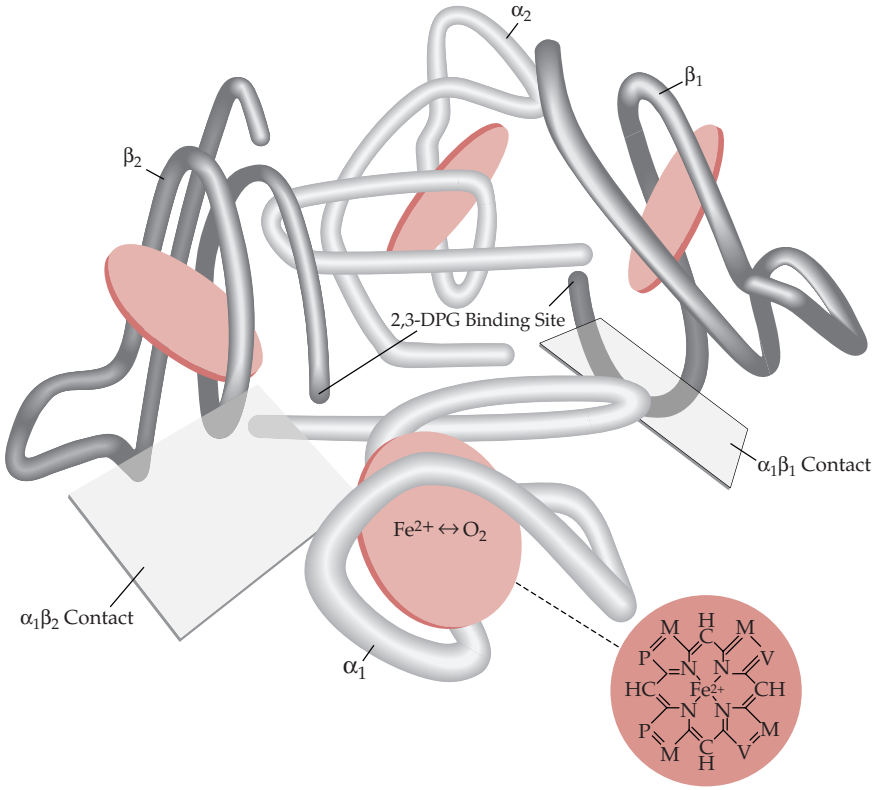

Figure 1 **A model of the hemoglobin molecule shows the relative alignment of the α chains (light gray) and β chains (dark gray). 2,3-Diphosphoglycerate (2,3-DPG), a glycolytic intermediate, binds in the central cavity of the hemoglobin and stabilizes the deoxygenated form by cross-linking the β chains, thus reducing the oxygen affinity of hemoglobin. Note that the α and β chains are in contact at two points. On oxygenation, movement of the iron atom into the plane of the heme group (colored disks) apparently triggers other structural changes in the α and β subunits as the molecule assumes the oxygenated conformation. Sliding occurs at the $\alpha_1\beta_2$ interface, and the spacing between the two β chains is reduced in oxyhemoglobin. In the detail showing the structure of heme, M is methyl, V is vinyl, and P is propionic acid.**

oxygen affinity and uptake, and in tissues, where carbon dioxide uptake decreases the pH, lowering oxygen affinity and facilitating oxygen release.

FACTORS AFFECTING THE OXYGEN-CARRYING CAPACITY OF HEMOGLOBIN

Oxygen-Hemoglobin Dissociation Curve

The oxygen-hemoglobin dissociation curve [*see Figure 2*] is a plot of the equilibrium between oxygen and hemoglobin at various oxygen tensions (P_{O_2}).[3] At sea level and at a partial pressure of oxygen of about 90 mm Hg, hemoglobin is 97% saturated in the lungs. After unloading oxygen to tissues, at a P_{O_2} of about 40 mm Hg in mixed venous blood, the hemoglobin saturation is about 75%. The P_{50} (i.e., the partial pressure of oxygen at which hemoglobin is 50% saturated) is a useful measure of the oxygen affinity of hemoglobin: the higher the affinity, the lower the P_{50}. Under normal physiologic conditions (i.e., a temperature of 37° C [98.6° F]; pH of 7.4; 2,3-DPG level of 5 mmol/L; and carbon dioxide tension [P_{CO_2}] of 40 mm Hg), the P_{50} of normal adult blood is 26 ± 1 mm Hg. The P_{50} is decreased (shifted to the left on the oxygen-hemoglobin dissociation curve) by increasing pH, decreasing 2,3-DPG, or decreasing temperature.

Effects of 2,3-Diphosphoglycerate

The glycolytic intermediate 2,3-DPG, which is present in mature erythrocytes at approximately the same intracellular concentration as hemoglobin, is the most important allosteric regulator of oxygen affinity.[3] With acute hypoxia, 2,3-DPG concentrations increase within hours, which shifts the oxygen-hemoglobin dissociation curve to the right. The increase in the 2,3-DPG concentration promotes delivery of oxygen to tissues but also impedes the acquisition of oxygen in the lungs. Short-term adaptation to hypoxic stress may be helped if the supply of oxygen is plentiful and the cardiopulmonary reserve is robust. At high altitude, with the cardiovascular system unable to effectively meet increased circulatory demands, or in other pathologic circumstances, increased amounts of 2,3-DPG may be counterproductive.[3]

OXYGEN TRANSPORT

Several other physiologic factors function in an integrated manner to provide an adequate supply of oxygen, including blood volume, blood viscosity, pulmonary and cardiac function, and regional blood flow.[9] The concentration of circulating red blood cells depends on the production of erythropoietin by the kidney and the erythropoietic response of the erythroid marrow.[10] Hemoglobin transport of NO, which binds to both heme iron and globin, may help match regional blood flow and oxygen requirements. In peripheral tissues, the erythrocyte may release NO, which would relax the microvasculature, improve blood flow, and enhance oxygen delivery.[4,5] An intriguing development has been the identification of a new class of so-called hexacoordinate hemoglobins (expressed in nerve cells[11] or a wide array of tissues[12]), whose functions are not yet established but which may facilitate oxygen transport, help protect against hypoxia, or scavenge reactive oxygen species.

CARBON DIOXIDE TRANSPORT

After delivering oxygen, hemoglobin binds with carbon dioxide.[13] Deoxyhemoglobin has a higher binding affinity for carbon dioxide than does oxyhemoglobin, facilitating unloading of carbon dioxide from tissues and pulmonary excretion.[13] Most of the carbon dioxide from tissue capillaries is transported to the lungs as bicarbonate, with about 10% carried as a carbamino complex reversibly bound to the globin chains.

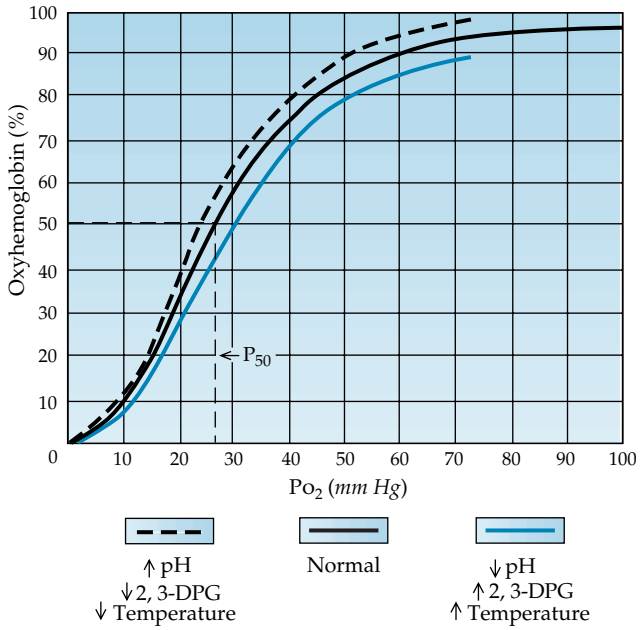

Figure 2 **The normal oxygen-hemoglobin dissociation curve (solid black line) is shifted by changes in temperature, pH, and the intracellular concentration of 2,3-DPG. P_{50} stands for 50% oxygen saturation; PO_2 stands for oxygen tension.**

Iron Metabolism

Remarkable progress continues to be made in understanding disorders of iron metabolism and in improving the diagnosis and management of both iron deficiency and iron overload.[14,15] In the body, iron transports and stores oxygen, carries electrons, catalyzes reactions in oxidative metabolism, and sustains cellular growth and proliferation. With iron deficiency, the body is unable to produce sufficient amounts of heme, other iron-porphyrin complexes, metalloenzymes, and other iron-containing compounds to sustain normal functions. With iron overload, excess iron can catalyze free radical reactions that can damage cellular membranes, proteins, and nucleic acids, resulting in progressive cellular and organ damage and eventual death.

PATTERNS OF IRON BALANCE AND METABOLISM

The concentration of iron in the human body is carefully regulated and is normally maintained at about 40 mg Fe/kg in women and about 50 mg Fe/kg in men. Iron balance is the result of the difference between the amount of iron taken up by the body and the amount lost [*see Figure 3*]. Because humans are unable to excrete excess iron, iron balance is physiologically regulated by the control of iron absorption. The two major factors that influence iron absorption are the level of body iron stores and the extent of erythropoiesis.[16] If iron stores increase, absorption decreases; if stores decrease, absorption increases. Absorption also increases with increased erythropoietic activity, especially with ineffective erythropoiesis. Most of the iron in the body is located in the erythron, which consists of the totality of circulating erythrocytes and their precursors in the bone mar-

row. The predominant pathway of internal iron flux is a one-way flow from the plasma iron transport protein, transferrin, to the erythron, and then through the monocyte-macrophage system back to transferrin [*see Figure 3*]. The erythron uses about 80% of the iron passing through the transferrin compartment each day. Normally, the majority of this iron is used for hemoglobin synthesis and returned to the circulation within red blood cells. Small quantities of iron are stored in ferritin, enter the iron-containing enzymes of immature erythroid cells, or are lost in the products of ineffective erythropoiesis. At the end of their life span, senescent red cells are phagocytized by specialized macrophages in the spleen, bone marrow, and liver, which then return most of the iron to the transferrin compartment, where the cycle begins again. The phagocytosis of flawed and aged erythrocytes accounts for almost all of the storage iron normally found in the macrophages of the liver, bone marrow, and spleen. By contrast, the parenchymal cells of the liver may either take iron from, or give iron to, plasma transferrin. Under normal physiologic conditions, iron recycling is very efficient; less than 0.05% of the total body iron is acquired or lost each day.

MOLECULAR BASIS OF IRON METABOLISM

A number of proteins are now known to be involved in the absorption, transport, utilization, and storage of iron. Some of these proteins have more than one function.

Systemic Iron Transport

Transferrin is the physiologic carrier of iron through the plasma and extracellular fluid.[15] Apotransferrin, transferrin without attached iron, is a single-chain glycoprotein with two structurally similar lobes. Binding of a ferric ion to one of these lobes yields monoferric transferrin; binding of ions to both yields diferric transferrin. The transferrin saturation is the proportion of the available iron-binding sites on transferrin that are occupied by iron atoms, expressed as a percentage. In humans, almost all the circulating plasma apotransferrin is synthesized by the hepatocyte.[17] After delivering iron to cells, apotransferrin is promptly returned to the plasma to again function as an iron transporter, completing 100 to 200 cycles of iron delivery during its lifetime in the circulation.[15]

Cellular Iron Uptake

Specific receptors for transferrin, which are found on the surface membrane of all nucleated cells, provide the route of entry for transferrin-bound iron. The affinity of transferrin receptors is greatest for diferric transferrin, intermediate for monoferric transferrin, and almost negligible for apotransferrin. These differences in affinity contribute to the efficiency of iron delivery. Two forms of the transferrin receptor have now been identified and are designated as transferrin receptor 1 and transferrin receptor 2.[15] Both consist of paired subunits, each of which can

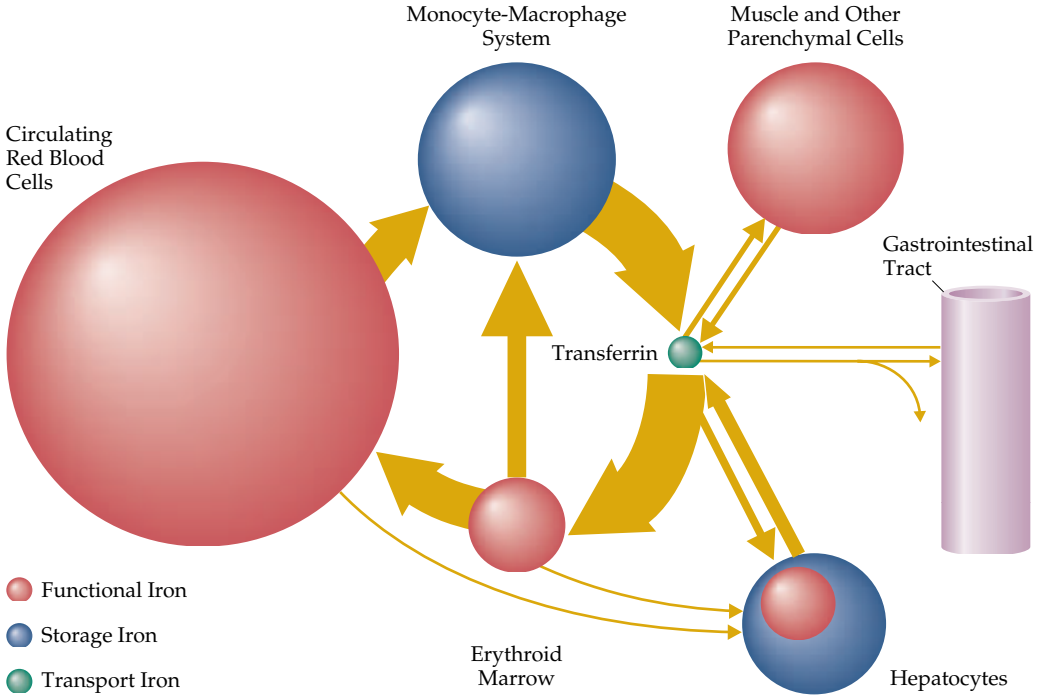

Figure 3 **Body iron supply and storage. The figure shows a schematic representation of the routes of iron movement in the adult.[95] The area of each circle is proportional to the amount of iron contained in the compartment, and the width of each arrow is proportional to the daily flow of iron from one compartment to another. The major portion of iron is found in the erythron as hemoglobin iron (28 mg/kg in women; 32 mg/kg in men) dedicated to oxygen transport and delivery. Small amounts of erythron iron (< 1 mg/kg) are also present in heme and nonheme enzymes in developing red cells. The remainder of functional iron is found as myoglobin iron (4 mg/kg in women; 5 mg/kg in men) in muscle and as iron-containing and iron-dependent enzymes (1 to 2 mg/kg) throughout the cells of the body. Small amounts of iron are deposited within ferritin in erythroid cells, but most storage iron (5 to 6 mg/kg in women; 10 to 12 mg/kg in men) is held in reserve by hepatocytes and macrophages in the liver, bone marrow, spleen, and muscle. The small fraction of transport iron (about 0.2 mg/kg) in the plasma and extracellular fluid is bound to the protein transferrin, which carries iron to meet tissue needs throughout the body.**

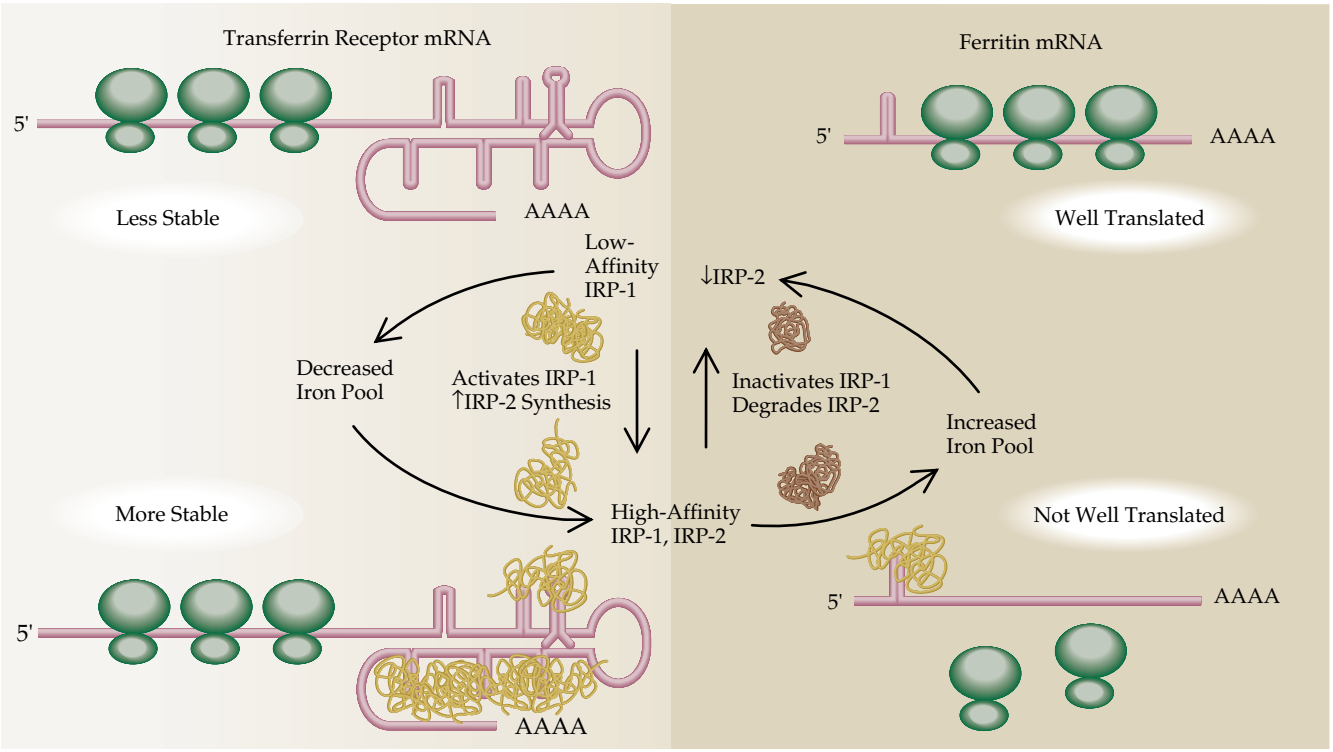

Figure 4 **Regulation of transferrin receptor and ferritin expression by the iron regulatory proteins IRP-1 and IRP-2.**

bind a molecule of transferrin. Although their extracellular structures are quite similar,[18] the two forms of the receptor have important functional differences. The binding affinity of transferrin receptor 1 for diferric transferrin is about 25-fold to 30-fold greater than that of transferrin receptor 2. Expression of transferrin receptor 1 is regulated by intracellular iron levels (see below), but that of transferrin receptor 2 is not. Transferrin receptor 1 is expressed by all iron-requiring cells, whereas transferrin receptor 2 is most highly expressed on hepatocytes and developing erythroid cells. Transferrin receptor 1 is required for life in mammals[19]; transferrin receptor 2 cannot compensate for the absence of transferrin receptor 1. Transferrin receptor 2 seems to have other functions in maintaining iron homeostasis (see below).

The delivery of transferrin-bound iron begins with the binding of two molecules of monoferric or diferric transferrin to a transferrin receptor on the cell surface.[15] The iron-transferrin–transferrin receptor complex then moves to the interior of the cell within an endosome, where it releases its iron. The dissociated iron is then taken up by the divalent metal transporter–1 (DMT1) and transported across the endosomal membrane for utilization or for storage in the cell.[19] Freed of its iron, the transferrin—now apotransferrin—binds avidly to the transferrin receptor and is carried back to the cell membrane and released into the plasma. [15]

Cellular Iron Storage

Cellular iron storage utilizes ferritin, a protein found in the cytoplasm of virtually all cells. Ferritin is a spherical shell that can store as many as 4,500 atoms of iron in its interior. Ferritin functions both as a safe storage site for iron and as a readily accessible reserve for iron that has been acquired by the cell in excess of its immediate needs.[20] Accordingly, the greatest amounts of ferritin are found in cells dedicated to iron storage (e.g., macrophages and hepatocytes) and in cells with the highest iron requirements for the synthesis of iron-containing compounds (e.g., developing erythroid cells). Apoferritin, or ferritin without attached iron, is composed of 24 oblong subunits that are designated as H (heavy) and L (light). Ferritin molecules with a greater proportion of H subunits seem to be more active in iron metabolism; ferritin molecules with a greater abundance of L subunits apparently are used for the longer-term storage of iron. A ferritin H–like protein assembled into ferritin shells has been identified within iron-loaded mitochondria of patients with impairment of heme synthesis.[21] In patients with sideroblastic anemia, most of the iron in ringed sideroblasts is sequestered in mitochondrial ferritin.[22]

Regulation of Cellular Iron Uptake and Storage

Cellular iron uptake and storage are regulated through the synthesis of transferrin receptors and ferritin. This synthesis is coordinated by the iron-regulatory proteins IRP-1 and IRP-2 [*see Figure 4*]. When intracellular iron levels are low, IRP-1 and IRP-2 bind to messenger RNA (mRNA) stem-loop elements known as iron-responsive elements (IREs) in transcripts.[23] Transferrin receptor synthesis is regulated by controlling the stability of cytoplasmic transferrin receptor mRNA, whereas ferritin synthesis is regulated by controlling translation of ferritin mRNA without changing the amount of ferritin mRNA in the cytoplasm. As a result, changes in the amounts of the IRPs have opposite effects on the production of transferrin receptor and ferritin, allowing iron to self-regulate its intracellular availability. IRPs also regulate mRNAs for other proteins involved in iron uptake,[24] availability, release,[25] and utilization.[26]

Macrophage Hemoglobin Catabolism and Iron Release

Specialized macrophages in the bone marrow, liver, and spleen selectively recognize and phagocytize erythrocytes that are senescent or damaged.[27] On average, each of these macrophages can

phagocytize one erythrocyte a day.[28] After ingesting the erythrocyte, the macrophage lyses the erythrocyte membrane. The hemoglobin within then undergoes oxidative precipitation and rapid catabolism into heme.

Any hemoglobin released into plasma by intravascular hemolysis is rapidly bound by haptoglobin. Macrophages remove the haptoglobin-hemoglobin complex from plasma by binding[29] and endocytosis; the complex is then digested in lysosomes, liberating heme.

The heme from both sources is degraded by the microsomal enzyme heme oxygenase, yielding biliverdin IXa, carbon monoxide, and iron[30,31]; the iron is either stored in ferritin or returned to plasma, apparently via ferroportin.[27,32] The outpouring of iron from macrophages in the bone marrow, liver, and spleen to plasma apotransferrin normally constitutes the largest single flux of iron from cells in the body.[30] Unsaturated transferrin is not required for the release of iron from the macrophages; apotransferrin does not enter the macrophage and accepts iron only after the release of iron from the cell. Rather, a major determinant of the rate of iron exit from the macrophage is ceruloplasmin, which establishes a rate of oxidation of ferrous iron.[33] After oxidation, the ferric iron can be bound and transported by transferrin back to the erythron and other iron-requiring tissues.

Other Pathways of Iron Exchange

Heme that is released into the plasma as a result of intramedullary or intravascular hemolysis is bound by hemopexin. The heme-hemopexin complex is delivered to the hepatocyte via specific receptors and internalized, and the heme is catabolized to liberate the iron.[34] The hepatocyte may either donate iron to plasma transferrin or receive iron from it.[35] At high transferrin saturations, iron moves from the plasma to the liver; at low saturations, iron is mobilized from hepatocyte stores and supplied to plasma transferrin. Normally, the overall magnitude of iron exchange by hepatocytes is only about one fifth that by macrophages. Other pathways of iron movement involve approximately equal exchanges: about 1 mg Fe/day is absorbed and lost, about 3 mg Fe/day is transferred between the plasma and extravascular transferrin compartments, and about 2 mg Fe/day moves between extravascular transferrin and parenchymal tissues.

Intestinal Iron Absorption

The amount of iron in the body is regulated by control of iron absorption in the proximal small intestine. Both heme iron and nonheme iron enter through the brush border of intestinal enterocytes.[36] The exact means by which heme iron is absorbed are still uncertain, but nonheme iron seems to be taken up via the apical iron transporter DMT1 (the same iron transporter that provides an exit for iron from the endosome; see above) and perhaps via other routes.[37] DMT1 is a proton-coupled symporter with a broad substrate range that includes other metallic cations, but its physiologic function appears to be the uptake of Fe^{2+}.[19] DMT1 is a ferrous iron transporter, but most dietary iron is in the ferric form. Duodenal cytochrome b, a heme protein highly expressed in duodenal brush border membrane, reduces luminal iron to the ferrous state for transport into enterocytes via DMT1.[38] Once within the enterocyte, the absorbed iron may be transported across the basolateral membrane into the plasma or stored within ferritin and then lost when the enterocyte is exfoliated. The details of the handling of iron in the enterocyte remain obscure, but as in the macrophage, ferroportin seems to serve as the transmembrane channel for the transfer of ferrous iron into the plasma,[32] and hephaestin is a ceruloplasmin homologue that is required for the efficient exit of iron from the basolateral membrane of the enterocyte into the systemic circulation.[39]

Regulation of Body Iron Absorption and Storage

The molecular mechanisms responsible for the regulation of body iron stores through control of iron absorption are still not understood, but some of the proteins involved have been identified. The gene *HFE*, which is mutated in most patients with hereditary hemochromatosis (see below), has been identified,[40] but the means by which the normal gene product, HFE, regulates iron balance remains uncertain. HFE is found in crypt cells in the duodenum, in tissue macrophages, and in Kupffer cells in the liver. Two mutually exclusive functions have been suggested for HFE: decreasing iron uptake by binding to transferrin receptor (thereby competing with transferrin) and inhibiting iron release from macrophages.[41,42] The relative effects of these offsetting activities may be determined by the balance between serum transferrin saturation and serum transferrin–receptor concentrations.[43] Other models give the liver a central role in the regulation of iron homeostasis.[44] The observations that tissue iron overload can result from mutations in two other proteins, transferrin receptor 2[45] (see above) and hepcidin,[46] indicate that these proteins are also involved in the pathway for regulation of iron balance. Hepcidin, an antimicrobial peptide produced by hepatocytes, seems to act as an iron-regulatory hormone whose expression is inversely related to both iron absorption and macrophage iron release. In HFE-associated hereditary hemochromatosis, expression of hepcidin is not increased despite hepatic iron overload, suggesting that HFE may be involved in the regulation of hepcidin expression in response to changes in body iron stores.[47] Despite these intriguing observations, elucidation of the molecular mechanisms underlying the regulation of body iron absorption and storage will likely await the identification of other key proteins involved.

Iron Deficiency

DEFINITIONS

Iron deficiency designates conditions in which the body's iron requirements exceed iron supply. Iron is needed to restore physiologic loss, which is just under 1 mg/day in men and is about 1.5 mg/day in menstruating women[35]; iron is also needed for growth and pregnancy and to replace pathologic losses. Sequential stages of decreases in body iron can be identified [*see Table 1*]. A decrease in iron stores without a change in the amounts of functional iron compounds is designated as reduced iron stores. When iron stores are exhausted, patients may be described as having iron depletion. Further decrements in the level of body iron result in limited production of hemoglobin and other iron-containing functional compounds; this stage is termed iron-deficient erythropoiesis. Still further decreases in body iron produce iron deficiency anemia.

EPIDEMIOLOGY

Iron deficiency is the most common nutritional deficiency worldwide. Its prevalences are highest in developing countries, where 30% to 70% of the population may be affected[48]; in comparison, the overall prevalence of iron deficiency is less than 20% in the industrialized countries of Europe and North America.[48] In

Table 1 Changes in Iron Stores and Distribution with Increased or Decreased Body Iron Content

Condition	*Marrow Iron (0–6+)*	*Liver Iron (μmol/g, dry weight)*	*Plasma Ferritin (μg/L)*	*Plasma Transferrin Receptor (mg/L)*	*Plasma Iron (μg/dl)*	*Transferrin Saturation (%)*	*Protoporphyrin (μg/dl Red Blood Cells)*	*Red Blood Cells*
Iron deficiency anemia	0	< 3.0	< 12	10	< 40	< 10	150	Microcytic, hypochromic
Iron stores depletion	0 to trace amounts	3.0	< 20	5.5	< 115	< 30	30	Normal
Reduced iron stores	1+	< 10.0	< 25	5.5	< 115	30	30	Normal
Normal	2–3+	15.0 ± 5.0	100 ± 60	5.5 ± 1.5	115 ± 50	35 ± 15	30	Normal
Increased iron stores, hereditary hemochromatosis	2–3+	100	1,000	5.5	> 150	> 60	30	Normal
Increased iron stores; transfusional iron overload	4+	200	1,000	5.5	> 150	> 50	30	Normal
Massive iron overload, hereditary hemochromatosis	3–4+	400	4,000	5.5	200	> 60	30	Normal
Massive iron overload; transfusional iron overload	6+	800	4,000	5.5	200	> 90	30	Normal

the United States, the Centers for Disease Control and Prevention estimate that the prevalence of iron deficiency is greatest in toddlers 1 to 2 years of age (7%) and in adolescent girls and adult women 12 to 49 years of age (9% to 16%).[49]

ETIOLOGY

Iron deficiency can result from increased iron requirements, inadequate iron supply, or both [*see Table 2*]. Blood loss is the most common cause of increased iron requirements that lead to iron deficiency. In men and postmenopausal women, iron deficiency is almost always the result of gastrointestinal blood loss.[50] In menstruating women, genitourinary blood loss often accounts for increased iron requirements. Oral contraceptives tend to decrease menstrual blood loss, whereas intrauterine devices tend to increase menstrual bleeding. Other causes of genitourinary bleeding and respiratory tract bleeding can also increase iron requirements [*see Table 2*]. For blood donors, each donation results in the loss of 200 to 250 mg of iron. During periods of growth in infancy, childhood, and adolescence, iron requirements may outstrip the supply of iron available from diet and stores.[51] Iron loss from tissue growth during pregnancy and from bleeding during delivery and post partum averages 740 mg.[35,51] Breast-feeding increases iron requirements by about 0.5 to 1 mg /day.

An insufficient supply of iron may contribute to the development of iron deficiency. In infants and in women with high iron requirements, diets containing inadequate amounts of bioavailable iron increase the risk of iron deficiency.[51] In older children, men, and postmenopausal women, a poor supply of dietary iron is almost never the only factor responsible for iron deficiency; therefore, other etiologic factors must be sought, especially blood loss.[50,52,53] Impaired absorption of iron is an uncommon cause of iron deficiency. In some patients, intestinal malabsorption of iron is only one aspect of more generalized malabsorption[54] [*see Table 2*]. Gastric surgery, especially partial or total gastric resection or gastroenterostomy for bypass of the duodenum, may result in iron deficiency. Although absorption of dietary iron may be poor in such patients, therapeutic iron salts are usually well absorbed, and the iron deficiency can be readily corrected.

The risk of iron deficiency is especially high when iron requirements are increased and the supply of iron is inadequate. For example, infants who are fed cow's milk often become iron deficient because of the combination of increased iron losses from cow's milk–induced gastrointestinal bleeding and the small amounts of bioavailable iron in cow's milk.[51,55] Women with high iron requirements because of menstruation often have diets that contain little bioavailable iron and contain inhibitors of iron absorption, such as calcium. A common mutation of the transferrin gene (designated as G277S) has been associated with a reduction in the circulating transferrin concentration and may predispose menstruating women to iron deficiency.[56] The mechanism underlying this effect is unknown.

DIAGNOSIS

Clinical Manifestations

Patients with iron deficiency may be asymptomatic and their disorder recognized only because of abnormal results of laboratory tests.[51] Other patients may come to medical attention because of the manifestations of the underlying disorder that produced iron deficiency, but they may have no findings resulting from the iron deficiency. Still other patients may present with the signs and symptoms common to all anemias, such as weakness, dizziness, easy fatigability, pallor, irritability, and other indefinite and nonspecific complaints. Iron deficiency may also be associated with signs and symptoms that are unrelated to anemia, such as angular stomatitis, glossitis, postcricoid esophageal stricture or web, and gastric atrophy. In addition, a high prevalence of iron deficiency has been found in patients with the restless legs syndrome, a neurologic disorder characterized by a distressing, irresistible urge to move the legs (akathisia).[57] Finally, some patients present with one or more of the limited number of signs and symptoms thought to be highly specific for iron deficiency, which include blue sclerae[58] and koilonychia. Pagophagia, or pica with ice, is thought to be another highly specific symptom of iron deficiency and disappears shortly after iron therapy is begun.[59] Other types of pica may accompany iron deficiency, but

Table 2 Causes of Iron Deficiency

INCREASED IRON REQUIREMENTS
- Blood loss
  - Gastrointestinal tract
    - Hemorrhagic lesions (e.g., hiatal hernia, esophageal varices, gastritis, duodenitis, peptic ulcer, cholelithiasis, intrahepatic bleeding, inflammatory bowel disease, diverticulosis, hemorrhoids, or adenomatous polyp)
    - Occult gastrointestinal malignancy
    - Chronic ingestion of drugs (e.g., alcohol, salicylates, steroids, and nonsteroidal anti-inflammatory drugs)
    - Helminthic infections (e.g., hookworm, *Schistosoma mansoni, S. japonicum*, or severe *Trichuris trichiura*)
    - Other (e.g., vascular purpura with scurvy, aberrant pancreas, Meckel diverticulum, hereditary hemorrhagic telangiectasia, other vascular ectasia of the bowel, or colonic polyposis)
  - Genitourinary tract
    - Menstrual blood loss
    - Other (e.g., uterine malignancies or fibroids, stones, infarction, infection with *S. haematobium*, inflammatory disease, malignancy of the urinary tract, or chronic hemoglobinuria or hemosiderinuria resulting from paroxysmal nocturnal hemoglobinuria or chronic intravascular hemolysis)
  - Respiratory tract
    - Chronic recurrent hemoptysis
    - Idiopathic pulmonary siderosis
    - Goodpasture syndrome
  - Blood donation
- Growth
  - Infants, premature infants
  - Children
  - Adolescents
- Pregnancy and lactation

INADEQUATE IRON SUPPLY
- Diets with insufficient amounts of bioavailable iron
- Impaired absorption of iron
  - Intestinal malabsorption (e.g., steatorrhea, sprue, celiac disease, diffuse enteritis, atrophic gastritis with achlorhydria, or pica)
- Gastric surgery

none is as specific a symptom as pagophagia. The nonhematologic consequences of iron deficiency are diminished exercise tolerance and work performance and impaired immunity and resistance to infection.[60,61] In children, iron deficiency seems to adversely affect growth, motor development, behavior, and cognitive function[51,62]; these abnormalities may not be reversible with later treatment.

Laboratory Tests

Iron deficiency anemia is the only microcytic hypochromic anemia associated with lack of iron stores. In other microcytic hypochromic disorders, marrow iron stores are normal or increased. Indirect measures of body iron can be used to identify a characteristic sequence of changes that occur as body iron decreases from the iron-replete normal levels to levels found in iron deficiency anemia [*see Table 2*]. Measurement of the serum ferritin concentration is the most useful test for the detection of iron deficiency, because serum ferritin concentrations decrease as body iron stores decline.[50] A serum ferritin concentration below 12 µg/L is virtually diagnostic of absent iron stores. In contrast, a normal serum ferritin concentration does not confirm the presence of storage iron, because serum ferritin concentration may be increased independently of body iron by infection, inflammation, liver disease, malignancy, and other conditions.[63] Because the serum transferrin receptor concentration seems to be unaffected by these conditions, determination of this value (or the ratio of the serum transferrin receptor concentration to the serum ferritin concentration) provides a means of distinguishing between the anemia of iron deficiency and the anemia associated with chronic inflammatory disorders.[64-66] The concentration ratio of the serum transferrin receptor to serum ferritin can also provide a quantitative estimate of body iron stores that may be useful in monitoring iron status in patients who are highly susceptible to iron deficiency, such as infants, preschool children, and pregnant women.[67] The serum iron level and serum transferrin saturation are decreased in both iron deficiency and infectious or inflammatory states and therefore are of little practical assistance in distinguishing between these conditions. An alternative approach to the detection of an impaired iron supply for erythropoiesis is the use of hematologic indices derived from automated analyzers, such as the proportion of hypochromic cells and reticulocyte cellular indices.[68,69] These measurements of erythrocyte and reticulocyte indices may be particularly useful in the evaluation of iron-restricted erythropoiesis in patients with chronic renal failure or chronic disease who are treated with erythropoietin.[70] An empirical trial of iron therapy may also be an effective means of establishing the diagnosis of iron deficiency.

Although bone marrow examination is now seldom performed solely for the assessment of iron status, the diagnosis of iron deficiency can almost always be verified by direct assessment of marrow iron stores. If no iron stores are present, the diagnosis of iron deficiency is established; if hemosiderin (an intracellular granule that stores iron-containing molecules) is found, iron deficiency is excluded. In addition, with iron deficiency, marrow sideroblasts will be absent or present in low numbers (less than 10% of the number of normoblasts).

TREATMENT

Therapy for iron deficiency anemia should both correct the hemoglobin deficit and replace storage iron [*see Sidebar*, Iron Replacement Therapy]. Oral and parenteral replacement therapies yield similar results,[50,51] but for almost all patients, oral iron is the treatment of choice.[50] Oral iron therapy is effective, safe, and inexpensive.[71] Because of the risk of local and systemic adverse reactions, parenteral iron should be used only in the small number of patients who cannot absorb or tolerate oral iron or whose iron requirements cannot be met by oral therapy because of chronic, uncontrollable bleeding or other blood loss. In severe iron deficiency anemia, red cell transfusions are needed in rare instances to prevent cardiac or cerebral ischemia. Red cell transfusions may also sometimes be necessary for patients whose chronic rate of iron loss exceeds the rate of replacement possible with parenteral therapy. Although the majority of patients take oral iron without difficulty, 10% to 20% experience side effects related to iron—most commonly, gastrointestinal complaints. Despite manufacturers' claims, there are no clinically significant differences between different iron salts.

Iron deficiency can almost always be treated effectively. Alleviation of symptoms often occurs within the first few days of treatment. With uncomplicated iron deficiency, the initial hematologic response—a mild reticulocytosis—usually begins within 3 to 5 days after the start of therapy, reaches a maxi-

Iron Replacement Therapy

ORAL IRON THERAPY

- Indication
  - Treatment of choice for iron deficiency anemia
- Initial therapy to correct iron deficiency anemia
  - Ferrous iron salt (e.g., ferrous sulfate) given separately from meals in two or three divided doses; for example, ferrous sulfate tablets, 325 mg three times a day, or ferrous gluconate tablets, 300 mg two or three times a day
- Continued therapy to replace iron stores
  - Ferrous iron salt given as a single daily dose of approximately 60 mg of elemental iron until the plasma ferritin concentration is > 50 µg/L (often requires 6 mo or more of treatment)
- Management of side effects
  - Gastrointestinal side effects are the most common (10%–20% of patients) and usually can be managed symptomatically by (1) giving iron with or immediately after meals, (2) reducing the amount of iron in each dose, or (3) reducing the dose frequency to once daily

PARENTERAL IRON THERAPY

- Indications
  - Chronic, uncontrollable blood loss producing iron needs that cannot be met by oral iron therapy
  - Malabsorption of iron
  - Intolerance of oral iron despite repeated modifications in dosage regimen
- Risks
  - Immediate, life-threatening anaphylactic reactions
  - Delayed but severe serum sickness–like reactions with fever, urticaria, adenopathy, myalgias, and arthralgias
  - Exacerbation of rheumatoid arthritis and related conditions
  - Local reactions with intramuscular iron (skin staining, muscle necrosis, phlebitis, and persistent pain at injection site)
- Precautions
  - Iron dextran is the only currently available parenteral preparation; a 0.5 ml test dose is to be given at least 1 hr before every intramuscular or intravenous injection of iron dextran, but the value of this precaution is limited because anaphylaxis is not dose dependent and can occur with the test dose
- Administration and dosage
  - Parenteral iron may be administered either intramuscularly (limited to 2 ml or 100 mg of iron per injection) or intravenously (as an undiluted injection, as a total-dose infusion, or as an additive to total parenteral nutrition); because of the risks of therapy, recommendations of the manufacturers and recent-study recommendations for treatment should be reviewed carefully before parenteral iron is given

mum within 8 to 10 days, and declines thereafter. After the first week, the hemoglobin concentration begins to increase and is usually normal within 6 weeks. Microcytosis may not resolve completely for as long as 4 months. If the iron deficiency is treated with oral iron at a dosage of 200 mg/day or less, the serum ferritin concentration remains below 12 µg/L until the anemia is corrected and then gradually rises as storage iron is replenished. If the response to iron therapy is not complete and characteristic, review and reevaluation of the patient is mandatory.[50] One of the most common problems is mistaking the anemia of chronic disease for the anemia of iron deficiency. Recovery may be retarded by coexistent disorders, including other nutritional deficiencies; liver or kidney disease; infectious, inflammatory, or malignant disorders; or continued occult blood loss. In the event of incomplete recovery in a patient who is being treated with oral iron, the form and dosage of iron used should be reviewed, compliance evaluated, and the possibility of malabsorption considered.

Iron Overload

DEFINITIONS

Iron overload arises from a sustained excess of iron supply over iron requirements and causes characteristic patterns of changes in functional, transport, and storage iron. The amount of body iron is normally controlled by regulation of dietary iron absorption. Iron overload develops with conditions that modify or circumvent the regulation of intestinal iron absorption. Because humans have no physiologic means of eliminating excess iron, any persistent increase in intake may eventually result in iron overload. When the extent of iron accumulation exceeds the body's ability to safely sequester the surplus iron, characteristic patterns of tissue damage develop. The precise manifestations of iron overload depend on the underlying abnormality responsible but generally are governed by the magnitude of the body iron burden; the rate at which the increase in body iron has occurred; the distribution of the excess iron between storage sites in macrophages and potentially more harmful deposits in parenchymal cells; and the coexistence of conditions that may ameliorate (e.g., ascorbate deficiency) or worsen (e.g., alcohol use or hepatitis) the outcome. The most common consequences of iron overload are liver disease, pancreatic disease (associated with diabetes mellitus), cardiac dysfunction, endocrine disorders (associated with gonadal insufficiency), arthropathy, and, with some forms of iron overload, specific neurologic abnormalities.

Increased iron absorption may develop because of primary disorders leading to abnormal control of iron absorption, such as hereditary hemochromatosis, or as a secondary consequence of acquired or inherited conditions, such as chronic liver disease or the iron-loading anemias. Iron overload may also result from chronic red blood cell transfusion, which bypasses intestinal control of iron uptake [*see Table 3*].

PRIMARY IRON OVERLOAD

By far the most common forms of primary iron overload are those related to mutations in the *HFE* gene. Some of the genes responsible for less common forms of primary iron overload have now been identified, providing valuable insights into the control of iron metabolism. Testing for mutations in the *HFE* gene has become an essential step in the evaluation of primary iron overload, and continued progress is anticipated in genetic characterization of these disorders.

HFE-Associated Hereditary Hemochromatosis

Epidemiology Hereditary HFE-associated hemochromatosis (hemochromatosis type 1), an autosomal recessive disease, is the most common genetic disorder in persons of northern European descent.[72] Data from the Third National Health and Nutrition Examination Survey (NHANES III) suggest that in the United States, 9.54% of the non-Hispanic white population is heterozygous and 0.30% is homozygous for the most common mutation in *HFE,* C282Y (see below).[73]

Etiology and genetics The discovery of *HFE*, the gene on chromosome 6p21.3 that is mutated in most cases of hereditary hemochromatosis,[40] has revolutionized both the understanding and the diagnosis of this disorder. Although the underlying mechanism is still not understood, a defect in the HFE protein results in an inappropriate increase in iron absorption that leads to a progressive buildup of body iron. Initially, the overload has a predominantly parenchymal pattern of deposition, with iron first

accumulating in hepatocytes; subsequently, the iron builds up in the pancreas, heart, and other organs.[74,75] Characteristically, macrophage iron levels in the bone marrow may be normal or even decreased despite severe parenchymal iron deposition [*see Table 1*].

Two missense mutations in the *HFE* gene, usually designated as C282Y and H63D, are responsible for up to 85% of the cases of hereditary hemochromatosis in the United States[73]; in other areas of the world, the percentage ranges from about 60% to almost 100%.[75] In the United States, 15% or more of patients with primary iron overload have neither of these mutations but are clinically indistinguishable from patients who do have one of these mutations.[40] Some of these patients are found to have other mutations in the *HFE* gene. Patients without evidence of mutations on chromosome 6p are classified as having non–HFE-associated hereditary hemochromatosis. The proportion of patients with non–HFE-associated hemochromatosis is higher in populations from southern Europe.[76]

Clinical manifestations Homozygotes for hereditary hemochromatosis may have no distinctive clinical manifestations, especially at younger ages. In homozygotes who present with hereditary hemochromatosis in middle age or later, the classic tetrad of clinical signs is liver disease, diabetes mellitus, skin pigmentation, and gonadal failure.[74,75] Arthropathy may be an early manifestation of the disease and is frequently present in patients with advanced disease. Cardiac failure may develop and may even be the presenting symptom in untreated homozygotes. Body iron stores have usually increased from the normal amount of 1 g or less to 15 to 20 g or more by the time symptoms of parenchymal damage occur, usually in middle or late life. Additional increases in body iron may be fatal, although some patients are able to tolerate a total iron accumulation of as much as 40 to 50 g or more.[77] Men are affected at younger ages than women, presumably because of iron losses during menstruation and childbearing. Environmental factors (e.g., dietary iron content, blood donation or loss, and alcohol use) and coexisting disorders (e.g., viral hepatitis) may greatly influence the rate and severity of organ damage.[74] The penetrance of HFE-associated hereditary hemochromatosis is a subject of controversy. In a study of 41,038 patients attending a health-appraisal clinic in the United States, the results were interpreted as showing that less than 1% of homozygotes develop frank clinical hemochromatosis,[78,79] although this interpretation has been questioned.[80] The Hemochromatosis and Iron Overload Screening (HEIRS) study of more than 100,000 adults should help clarify both the penetrance and the prevalence of HFE-associated hemochromatosis and other forms of iron overload in the United States.[81]

Table 3 Causes of Iron Overload

Primary	Hereditary hemochromatosis HFE associated (type 1) Non–HFE associated Transferrin receptor 2 associated (type 3) Juvenile hemochromatosis (type 2) Chromosome 1q21 associated (type 2A) Hepcidin associated (type 2B) Autosomal dominant hemochromatosis Ferroportin 1 associated (type 4) Ferritin H–subunit mRNA A49U mutation associated Atransferrinemia Aceruloplasminemia
Secondary	Iron-loading anemias (refractory anemias with hypercellular erythroid marrow) Chronic liver disease Porphyria cutanea tarda Insulin resistance–associated hepatic iron overload African dietary iron overload* Medicinal iron ingestion* Parenteral iron overload Transfusional iron overload Inadvertent iron overload from therapeutic injections
Perinatal	Neonatal hemochromatosis Hereditary tyrosinemia (hypermethionemia) Cerebrohepatorenal syndrome GRACILE (Fellman) syndrome
Focal sequestration of iron	Idiopathic pulmonary hemosiderosis Renal hemosiderosis Associated with neurologic abnormalities Pantothenate kinase–associated neurodegeneration (formerly Hallervorden-Spatz syndrome) Neuroferritinopathy Friedreich ataxia

*May have a genetic component.
GRACILE—growth retardation, aminoaciduria, cholestasis, iron overload, lactacidosis, and early death

Screening and diagnostic tests Screening for hereditary hemochromatosis can use both phenotypic and genotypic methods and is indicated for patients with chronic liver disease or symptoms and signs associated with iron overload.[75,82] Phenotypic screening can provide biochemical evidence of iron overload, but no single test or combination of tests will identify all patients who are genetically susceptible to iron loading.[78] Genotypic screening for the most common *HFE* mutations, C282Y and H63D, in populations of northern European ancestry can identify a majority of those patients at risk for the development of primary iron overload. In pedigree studies, genotyping should replace HLA typing in the assessment of siblings of a C282Y homozygote.[75] In addition, genotyping the spouse of a C282Y homozygote is a cost-efficient strategy that leads to a more selective investigation of children for the hemochromatosis gene. Nonetheless, such limited genetic screening will not detect other mutations associated with iron loading; is less useful in other population groups, such as those originating from southern Europe,[76] Africa,[83] or Asia; and provides no indication of the extent of iron excess. Population screening has been advocated[82,84] but has not been undertaken generally because of uncertainties about disease penetrance[78]; the disease burden and natural history of iron overload; and a variety of ethical, legal, and social concerns.[75,78]

Measurement of the serum transferrin saturation is usually recommended as the initial phenotypic screening determination.[75,82,84,85] Although individual laboratories may have their own reference ranges, a persistent value of 45% or higher is often recommended as a threshold value for further investigation. The serum ferritin concentration is then used as a biochemical indicator of iron overload, and in the absence of complicating factors, increased concentrations suggest increased iron stores.[74] Genetic testing should then be considered in patients with abnormal elevations in transferrin saturation, serum ferritin, or both. The exact role of genetic testing in screening and diagnosis depends in part on the population being examined because of variations in the proportion of patients with hereditary hemochromatosis who have *HFE* mutations.

Once genetic testing has identified a patient as homozygous for the C282Y mutation (i.e., C282Y/C282Y), an elevated transferrin saturation establishes the diagnosis of hereditary hemochromatosis.[85] Liver biopsy, formerly a standard part of the diagnostic process, is no longer needed in most cases. Liver biopsy is indicated to detect cirrhosis if the serum ferritin level is above 1,000 μg/L[86]; biopsy may also be considered in patients with hepatomegaly, patients with abnormal findings on liver function tests, and patients who are older than 40 years.[74,85,87]

Patients who are heterozygous for the C282Y mutation and wild type (i.e., C282Y/wild type) have serum transferrin saturations and serum ferritin concentrations that are similar to those of wild-type homozygotes (i.e., wild type/wild type),[88,89] and these patients do not develop clinically important iron overload.[88] Consequently, finding a persistently elevated level of transferrin saturation, serum ferritin concentration, or both in a C282Y/wild type heterozygote should lead the clinician to search for other causes of iron overload.[85]

In patients who are heterozygous for the C282Y mutation and H63D, the other major *HFE* mutation (i.e., C282Y/H63D), mild to moderate iron overload may develop, but the penetrance of this genotype is even less than that of C282Y/C282Y homozygotes.[74,75,85,87] Heterozygotes for H63D (i.e., H63D/wild type) may have elevated transferrin saturation levels[90] but do not develop iron overload. Homozygotes for H63D (i.e., H63D/H63D) also may have elevated transferrin saturation levels, but the risk of clinically important iron overload is slight.[90] Less common mutations of the *HFE* gene have been identified[91]; S65C heterozygotes with either C282Y (i.e., S65C/C282Y) or H63D (i.e., S65C/H63D) may develop mild iron overload.

Several diagnostic approaches can be pursued in patients with phenotypic evidence of iron overload who are neither homozygous for C282Y (C282Y/C282Y) nor heterozygous for C282Y and H63D (C282Y/H63D). These approaches include further genetic testing for less common *HFE* mutations and for non-*HFE* mutations associated with iron loading; noninvasive assessment of the liver iron concentration[92]; and liver biopsy, which permits a definitive diagnosis of hereditary hemochromatosis regardless of genotype.[74,85,87] Evaluation of the biopsy specimen should include quantitative determination of the nonheme iron concentration, histochemical evaluation of the pattern of iron deposition, and pathologic assessment of tissue injury. Calculation of the hepatic iron index—the hepatic iron concentration (expressed as μmol Fe/g of liver, dry weight) divided by the age of the patient in years—may be helpful in distinguishing homozygotes for hereditary hemochromatosis from heterozygotes or from patients with increased body iron associated with chronic (usually alcoholic) liver disease.[74,87] In the absence of other causes of iron overload, a hepatic iron index greater than 1.9 is evidence for hereditary hemochromatosis. In patients with evidence of increased body iron levels, further evaluation should be directed toward detecting complications of iron overload and may include liver function tests, assessment of glucose tolerance and hormonal function, cardiac examination, joint and bone x-rays, and, especially if cirrhosis is present, screening for hepatocellular carcinoma.[74,85,87]

Treatment The treatment of choice for hereditary hemochromatosis is phlebotomy to reduce the body iron levels to normal or near-normal and maintain them in that range.[74,85,87] In patients with hereditary hemochromatosis who develop cardiac failure, the use of both phlebotomy and chelation therapy has been suggested. Phlebotomy therapy should be started as soon as the diagnosis of the homozygous state for hereditary hemochromatosis has been established; postponement only increases the risk of organ damage from iron overload. The phlebotomy program should remove 500 ml of blood (containing 200 to 250 mg of iron) once weekly or, for heavily loaded patients, twice weekly until the patient is iron deficient.[85] Before each phlebotomy, the hematocrit or hemoglobin concentration should be measured. Initially, the hematocrit and hemoglobin levels will decline by about 10% of their initial values but may then rise as the rate of erythropoiesis increases to match the demands of phlebotomy. Measurements of serum ferritin, iron, and transferrin saturation should be done regularly to follow the progress of iron removal. As iron is removed, the serum ferritin concentration will decrease progressively but the serum transferrin saturation will remain raised until iron stores are almost exhausted. Finally, when all the storage iron has been removed, the ferritin concentration will fall to less than 12 μg/L, the serum iron concentration and transferrin saturation will drop, and the hemoglobin concentration will decrease to less than 10 g/dl for 2 weeks without further phlebotomy. In patients with hereditary hemochromatosis, prolonged treatment is often needed. For example, if the initial body iron burden is 25 g, complete removal of the iron burden with weekly phlebotomy may require 2 years or more. After the iron load has been completely removed, a lifelong program of maintenance phlebotomy is required to prevent reaccumulation of the iron burden.[85] Typically, phlebotomy of 500 ml of blood every 3 to 4 months is needed. The goal of maintenance phlebotomy should be to maintain a serum ferritin concentration of less than about 50 μg/L.

If phlebotomy therapy removes the iron load before diabetes mellitus or cirrhosis develops, the patient's life expectancy is normal.[93] If cirrhosis develops, however, the risk of hepatocellular carcinoma is increased by more than 200-fold.[74] In hereditary hemochromatosis, hepatomas develop almost exclusively in patients with hepatic cirrhosis and are the ultimate cause of death in 20% to 30% of these patients, even after successful removal of the iron burden. Phlebotomy therapy is almost always indicated for patients with hereditary hemochromatosis, even when cirrhosis or organ damage is already present, because further progression of the disease can be stopped and alleviation of some organ dysfunction is possible.

Non–HFE-Associated Hereditary Hemochromatosis

Clinically, non–HFE-associated hereditary hemochromatosis is indistinguishable from hereditary hemochromatosis associated with *HFE* mutations. Genetically, the non-HFE disorder is heterogeneous. One subset of this autosomal recessive disorder, designated as hemochromatosis type 3, is caused by mutations of the gene encoding transferrin receptor 2 on chromosome 7q22.[45]

Juvenile Hemochromatosis

Juvenile hemochromatosis, designated as hemochromatosis type 2, is a rare autosomal recessive disorder in which severe iron overload develops before age 30. The two sexes are affected equally, and patients may present with cardiomyopathy, hypogonadism, impaired glucose tolerance, or some combination of these manifestations.[94] Genetically, two subtypes have so far been distinguished. Type 2A shows linkage to chromosome 1q21, but the responsible gene has not yet been identified.[95] Type 2B is caused by mutations in the gene for hepcidin on chromosome 19q13.[46]

Autosomal Dominant Hemochromatosis

Hemochromatosis with an autosomal dominant pattern of inheritance is also genetically heterogeneous, and at least one variety has been designated as hemochromatosis type 4. Several families have been identified with iron overload associated with mutations in the ferroportin gene (*SLC11A3*) on chromosome 2q32. Characteristically, initial iron accumulation is predominantly reticuloendothelial and the serum ferritin concentration is increased, with relatively low transferrin saturation; mild anemia early in life has been reported in a number of those affected. Some, but not all, of those with ferroportin mutations have also developed parenchymal iron overload.[96] A single Japanese family has been described with autosomal dominant iron overload ascribed to a point mutation (A49U) in the iron-responsive element (IRE) of H-ferritin mRNA.[97] Autosomal dominant hemochromatosis has also been reported in a Melanesian kindred, but the genetic basis has not been determined.[98]

Atransferrinemia and Aceruloplasminemia

Iron overload may also result from two rare autosomal recessive disorders in which the synthesis of plasma proteins vital for iron transport is absent or almost absent. In atransferrinemia, dietary iron is readily absorbed and circulates as nontransferrin plasma iron but cannot be used for erythropoiesis because of the lack of a physiologic means of transport into developing erythroid cells; affected persons die unless they receive transferrin infusion or blood transfusion.[99] In aceruloplasminemia, the deficiency of ceruloplasmin ferroxidase activity results in iron accumulation in the liver, pancreas, and brain, with smaller amounts of excess iron found in the spleen, heart, kidney, thyroid, and retina. Patients present with progressive neurodegeneration of the retina and basal ganglia and with diabetes mellitus in middle age.[100]

SECONDARY IRON OVERLOAD

Secondary iron overload may result from increased gastrointestinal absorption of iron, from transfusion of red blood cells, from inadvertent iatrogenic parenteral administration of iron, or from some combination thereof. Despite the progress made in understanding genetically determined increases in intestinal iron uptake, the pathophysiologic mechanisms responsible for the increased absorption of iron in secondary iron overload are still obscure.

Iron-Loading Anemias

The iron-loading anemias include congenital dyserythropoietic anemia, pyruvate kinase deficiency, thalassemia major (Cooley anemia) and thalassemia intermedia, hemoglobin E–β-thalassemia, a variety of forms of sideroblastic anemia, some myelodysplastic anemias, and other anemic disorders in which the incorporation of iron into hemoglobin is impaired. In patients with iron-loading anemias, severe iron overload may develop as a result of increased gastrointestinal iron absorption. Any red cell transfusions these patients receive will contribute to the iron loading. Because the extent of ineffective erythropoiesis, not the severity of the anemia, seems to determine the rate of iron loading, severe iron overload may develop in patients with only slight or mild anemia.[101] The clinical manifestations and pathology that may develop in patients with iron-loading anemias are similar to those seen in hereditary hemochromatosis, including liver disease, diabetes mellitus, endocrine disorders, and cardiac dysfunction.[102] Suppression of hepcidin synthesis by anemia, hypoxia, or both has been suggested as a potential mechanism for the increased iron absorption,[103] but the distinctive influence of ineffective erythropoiesis remains to be explained.

Other Causes and Forms of Absorption-Related Iron Overload

Chronic liver disease Some patients with chronic liver disease, including those with alcoholic cirrhosis and those with portacaval shunting, may experience minor or modest degrees of iron loading as a result of increased dietary iron absorption.[74] The mechanisms responsible for the increased gastrointestinal iron uptake have not been identified, although ineffective erythropoiesis and hyperferremia associated with alcohol-induced folate and sideroblastic abnormalities have been proposed as etiologic factors.[104] Body iron stores are increased only to a minor degree, typically to 2 to 4 g, but in alcoholic cirrhosis, the higher the liver iron, the shorter the survival.

Porphyria cutanea tarda Symptomatic patients with porphyria cutanea tarda, a hepatic porphyria, usually have a modest increase in body iron levels that almost always is the result of increased gastrointestinal absorption.[102] In patients who are of European ancestry, *HFE* mutations are common and may contribute to the pathogenesis of both the familial and the sporadic forms of the disorder.[105]

Insulin resistance–associated hepatic iron overload An iron-overload syndrome characterized by an increased serum ferritin level with a normal transferrin saturation level in association with glucose or lipid metabolic abnormalities, or both, was first described in 1997[106] and has come to be known as insulin resistance–associated hepatic iron overload.[107] The iron overload is typically mild or moderate, and the histologic appearance is distinct from that of HFE-associated hemochromatosis.

African dietary iron overload In sub-Saharan Africa, iron overload in association with greatly increased dietary iron intake from a fermented maize beverage home-brewed in steel drums has been described. Iron burdens may be as great as those found in hereditary hemochromatosis, and patients may develop liver disease (with cirrhosis and hepatoma), pancreatic disease (with diabetes mellitus), endocrine disorders, and cardiac dysfunction. Although increased dietary iron intake was long considered the sole cause of the increased iron absorption in this disorder, a series of pedigree studies has suggested that a genetic component may be involved and may be common in populations of African ancestry.[83]

Medicinal iron ingestion Ingestion of iron supplements can undoubtedly contribute to the body iron burden of patients with iron-loading disorders, but the extent to which orally administered iron can increase the body iron stores of normal individuals remains uncertain. Although some case reports have described iron accumulation in patients who have taken medicinal iron for long periods, the potential involvement of an unrecognized iron-loading mutation in these individuals cannot be excluded.

Transfusional and Other Parenteral Iron Overload

Etiology and diagnosis An adequate transfusion program can sustain life in patients with severe chronic refractory anemia, but transfusion therapy alone produces a progressive accumulation of the iron contained in transfused red cells.[108,109]

Iron accumulation from transfusion initially occurs predominantly in macrophage sites, followed by redistribution to parenchymal tissues. In patients with severe congenital anemias, such as thalassemia major and the Blackfan-Diamond syndrome, regular transfusions can prevent death from anemia in infancy and permit normal growth and development during childhood. Treatment of acquired transfusion-dependent anemias, such as aplastic anemia, pure red cell aplasia, and hypoplastic or myelodysplastic disorders, among others, may result in the development of marked iron overload. If the transfusion-dependent anemia includes erythroid hyperplasia with ineffective erythropoiesis, increased gastrointestinal iron absorption may add to the iron loading. In such cases, dietary iron uptake may be minimized by suppression of erythropoiesis with an adequate transfusion program. Although sickling disorders (e.g., sickle cell anemia and sickle cell–β-thalassemia) are not transfusion-dependent, these patients may acquire a considerable iron load from repeated transfusions for the prevention of stroke, painful crises, and other recurrent complications.[110] Because humans lack a physiologic means of eliminating excess iron, iron contained in transfused red cells progressively accumulates and eventually damages the liver, heart, pancreas, and other organs; death usually occurs from cardiac failure. In younger patients, the iron burden results in growth failure and, in adolescence, delayed or absent sexual maturation. Parenteral medicinal iron may needlessly add to the iron burden in patients with refractory microcytic anemias who are misdiagnosed as iron deficient.

Treatment About 200 to 250 mg of iron is added to the body iron load with each unit of transfused red cells. Most transfusion-dependent patients require 200 to 300 ml/kg of blood a year; for example, a 70 kg adult requires about two to three units of blood every 3 to 4 weeks, adding about 6 to 10 g of iron a year. The severity of iron toxicity seems to be related to the magnitude of the body iron burden. Almost all patients who have been treated with transfusion alone and have received 100 or more units of blood (about 20 to 25 g of iron) have developed cardiac iron deposits, often in association with signs of hepatic, pancreatic, and endocrine damage.[108,109] For patients who are transfusion dependent or severely anemic, the only way to prevent iron overload is treatment with a chelating agent capable of complexing with iron and permitting its excretion. The only iron-chelating agent now available for clinical use in North America is deferoxamine B, a siderophore produced by *Streptomyces pilosus*. Clinical trials with deferoxamine have documented the effectiveness of iron chelation as therapy for iron overload, demonstrating that regular iron chelation can decrease the body iron burden, alleviate organ dysfunction, and improve survival.[108] Although toxic side effects can occur, especially with intensive therapy, deferoxamine has been a remarkably safe drug, even with near-lifelong use in some patients.[109]

Iron chelation therapy should be started early to prevent the accumulation of toxic amounts of iron in vulnerable tissues and to maintain body iron stores at concentrations associated with a low risk of early death and clinical complications. The longer chelation therapy is delayed, the greater the risk of iron toxicity. Because deferoxamine is poorly absorbed after oral administration and rapidly eliminated from the circulation, deferoxamine must be given by slow subcutaneous or intravenous infusion over 9 to 12 hours each day at least 5 days a week to be optimally useful in the treatment of patients with transfusional iron overload.[108,109] In patients with thalassemia major and other congenital refractory anemias who have been transfusion dependent from early infancy, chelation therapy is best started after about 10 to 20 transfusions, usually when the patient is 3 or 4 years of age.[108,109] Deferoxamine is administered by slow subcutaneous infusion at a dosage not exceeding 25 mg/kg/day to minimize the risk of growth retardation. In older patients and adults with acquired refractory anemias who require regular transfusion and in patients with sickle cell disease who are chronically transfused for prevention of complications, early therapy also seems prudent, beginning after transfusion of 10 to 20 units of blood. The usual dosage of deferoxamine in these older patients is not more than 50 mg/kg/day, given over 9 to 12 hours by slow subcutaneous infusion at least 5 days a week. In some patients who are unable to tolerate the local pain and discomfort of subcutaneous infusion or who need rapid reduction of high body iron burdens, deferoxamine may be administered intravenously through implantable venous access ports. Compliance with these near-daily regimens of prolonged parenteral infusions may be difficult, and lack of compliance is the chief obstacle to effective iron chelation therapy. Administration of ascorbic acid can enhance deferoxamine-induced iron excretion but carries the risk of an internal redistribution of iron from relatively benign storage sites in macrophages to a potentially toxic pool in parenchymal cells. Although the evidence is anecdotal, large doses of ascorbic acid should be regarded as hazardous in patients with iron overload. Although deferoxamine is a generally safe and nontoxic drug in the iron-loaded patient, systemic complications have been reported, including allergic anaphylactoid reactions, infections, visual abnormalities and auditory dysfunction, and growth retardation.[108,109] As a result, regular evaluation for drug toxicity should be included in the management of any patient receiving deferoxamine, including annual audiograms, retinal examination, and assessment of growth in children and adolescents. The risk of many of these complications may be minimized by adjusting the deferoxamine dose to the magnitude of the body iron load. New and promising chelating agents are in development[111] or in clinical trials,[112] but none is yet available for clinical use.

Additional Rare or Uncommon Forms of Iron Overload

Perinatal iron overload occurs in several forms. Neonatal hemochromatosis is a heterogeneous group of disorders associated with severe congenital hepatic disease and deposits of iron in the liver, pancreas, heart, and other extrahepatic sites, with evidence of autosomal recessive inheritance in some cases.[113] Several rare metabolic abnormalities of the neonate may be associated with abnormal iron deposition, including hereditary tyrosinemia (hypermethioninemia); Zellweger cerebrohepatorenal syndrome[114]; the tricho-hepato-enteric syndrome; and the GRACILE (or Fellman) syndrome.[113]

Focal sequestration of iron is found in other rare disorders, including idiopathic pulmonary hemosiderosis and renal hemosiderosis. Such abnormal iron deposition is associated with neurologic abnormalities in Friedreich ataxia, in pantothenate kinase–associated neurodegeneration (formerly Hallervorden-Spatz syndrome), and in neuroferritinopathy.[115] Finally, hyperferritinemia with autosomal dominant congenital cataract[116] is a disorder of iron metabolism in which affected family members present with early-onset, bilateral nuclear cataracts and moderately elevated serum ferritin concentrations.[116] The body iron level is

normal in these patients, but overload is often suspected because of the elevated serum ferritin concentrations.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III ANEMIA: PRODUCTION DEFECTS

STANLEY L. SCHRIER, M.D., F.A.C.P.

Classification of Production Defects

Red blood cell production defects cause anemia that is marked by a low absolute reticulocyte count. Examination of the peripheral blood count and the bone marrow aids in classifying these disorders. The marrow characteristically shows one of the following:

1. A normal ratio of myeloid cells to erythroid cells (M:E ratio), normal overall cellularity, and a normal pattern of erythroid maturation.
2. Virtual absence of normal bone marrow elements caused by aplasia (absence of marrow cells) or by replacement of normal marrow elements by fibrosis, solid tumors, granulomas, or leukemia.
3. Erythroid hyperplasia with increased cellularity. Because of defects of erythroid maturation, there is ineffective erythropoiesis or intramedullary hemolysis. Erythroid precursors die in the marrow, and few cells reach the periphery.

Production Defects Associated with Apparently Normal Bone Marrow

ANEMIA OF CHRONIC DISEASE

Definition

The anemia of chronic disease occurs secondary to neoplastic, infectious, and inflammatory diseases and other chronic illnesses, including liver disorders, congestive heart failure, and diabetes mellitus.[1,2] Hematocrit values usually range from 27% to 35%, although 20% of patients have hematocrit values below 25%.[2]

Pathophysiology

The anemia of chronic disease usually results from a combination of slightly shortened red blood cell survival, the sequestration of iron in the reticuloendothelial system, and erythropoietin levels that are less than expected for the degree of anemia.[1,2] Red blood cells usually have a normal morphologic appearance, although they may occasionally be mildly hypochromic and microcytic. The serum iron and transferrin levels are low, and iron saturation is frequently as low as 15%.[1,2] The serum ferritin level is usually normal or elevated.[2,3] All these changes can be induced by the inflammatory cytokines (e.g., interleukin-1 [IL-1]; tumor necrosis factor–α; interferons alfa, beta, and gamma; and perhaps transforming growth factor–β).[4] Under experimental conditions, these cytokines reduce erythropoietin production, cause hypoferremia, increase serum ferritin levels, impair erythropoiesis, and block release of iron from reticuloendothelial cells.[5] Hepcidin, a newly described mediator of iron metabolism, may be the major mediator of the anemia of chronic disease[6]; hepcidin production is increased up to 100-fold with inflammation. Hepcidin seems to be the long-sought mediator that transmits iron stores to the gut. Hepcidin is secreted when iron stores, primarily in the liver, are increased, and it blocks iron absorption from the gut and causes iron to be trapped in macrophages.[6]

Diagnosis

Mild anemia, with normal or elevated levels of leukocytes and platelets, in a patient with a chronic illness suggests the diagnosis of anemia of chronic disease. This normocytic or hypochromic and microcytic anemia is easily misdiagnosed as iron deficiency anemia, thalassemia trait, or a sideroblastic anemia. If the diagnosis is uncertain after careful examination of the blood smear, the most useful tests for making the diagnosis are measurement of the serum ferritin level and, in rare cases, bone marrow examination that includes an iron stain [*see Table 1 and Figure 1*]. In some cases, there is more than one cause of the anemia, and thorough examination of the patient may be required to establish the primary cause. For example, a patient who has anemia of chronic disease resulting from carcinoma of the colon may also be iron deficient because of intestinal bleeding. HIV infection produces complex hematologic effects, including Coombs-positive autoimmune hemolytic anemia, but it also

Table 1 Differential Diagnosis of Hypochromic Anemias

	Anemia of Chronic Disorders	*Iron Deficiency Anemia*	*Thalassemia Trait*	*Sideroblastic Anemias*
Smear	Usually normochromic, normocytic but can be mildly hypochromic, microcytic	Varies with the degree of the anemia [*see 5:II Red Blood Cell Function and Disorders of Iron Metabolism*]	Hypochromia, target cells, microcytes, basophilic stippling	May be similar to that of the thalassemia trait
Serum iron level	Low	Low	Normal	High
Iron-binding capacity	Low	High	Normal	Normal
Percent saturation	5–16	0–16	Normal (20–40)	60–90
Serum ferritin level	Normal or high	Low	Normal	High
Marrow iron in reticuloendothelial cells	+ + to + + +	0	+ + to + + +	+ + + +
Marrow iron in sideroblasts	0	0	+ + to + + +	+ + + + with ringed sideroblasts
Marrow erythroid precursors	Normal	Generally normal; cytoplasm may be scanty	Usually mild erythroid hyperplasia	Intense erythroid hyperplasia with dyserythropoiesis

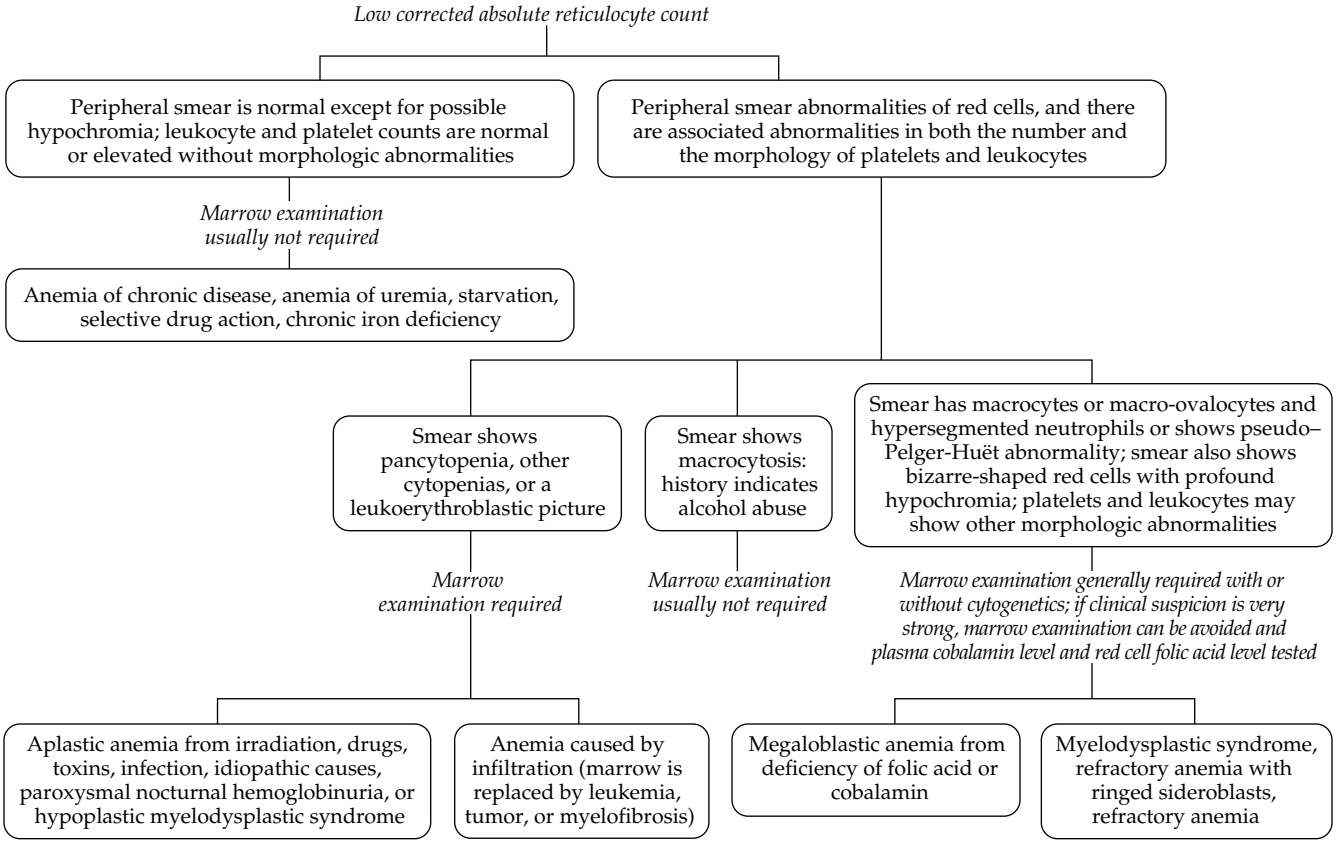

Figure 1 **Flowchart shows steps in the diagnosis of anemia caused by production defects. This type of anemia is suggested by a low corrected reticulocyte count or the finding of associated leukocyte or platelet abnormalities on the peripheral blood smear.**

causes anemia of chronic disease in the majority of patients with AIDS.[7]

Treatment

Identifying and treating the primary disease is the most important part of managing the anemia of chronic disease. Oral or parenteral iron administration is usually not helpful. Erythropoietin is the standard treatment for patients with anemia of chronic disease. For many patients, administration of pharmacologic doses of erythropoietin corrects the anemia of chronic disease by overriding the defect in erythropoietin production. It is useful to obtain a baseline measurement of the plasma erythropoietin level, because a response to erythropoietin is unlikely in patients whose endogenous levels are above 500 mU/ml. Erythropoietin responses have been reported in patients with rheumatoid arthritis,[8] AIDS,[9] inflammatory bowel disease,[10,11] and cancer.[12] To respond optimally, the patient must have adequate available iron stores (i.e., normal or elevated ferritin level or marrow iron stain) [*see 5:I Approach to Hematologic Disorders*]. Previously, the recommendation was to start the patient on 100 to 150 U/kg subcutaneously three times weekly; however, most physicians give a single subcutaneous dose of 40,000 units of erythropoietin weekly.[13]

If the hemoglobin level does not rise after 12 weeks, erythropoietin should be discontinued. A longer-acting form of erythropoietin, darbepoietin alfa, can be given subcutaneously at doses of 100 μg weekly or 200 μg every other week.

ANEMIA IN SEVERE RENAL DISEASE

Pathophysiology and Etiology

The predominant cause of anemia in renal disease is a deficiency of erythropoietin production by the diseased kidneys. If underlying inflammatory renal disease is present, there may be a component of anemia of chronic disease.[14] Anorexia and poor iron intake, frequent blood sampling, and loss of erythrocytes during hemodialysis may produce iron deficiency. Folic acid deficiency, hypersplenism, and secondary hyperparathyroidism with marrow fibrosis[4] may also promote anemia.

Anemia in hemodialysis patients can be caused by aluminum toxicity, as well. This anemia was initially identified in patients who had so-called dialysis dementia. Very high plasma aluminum levels probably result from aluminum contamination of the dialysis fluid or gastrointestinal absorption of the aluminum gels taken to bind dietary phosphates. In vitro experiments have shown that aluminum inhibits the growth of the erythroid precursors colony-forming unit–erythroid (CFU-E) and burst-forming unit–erythroid (BFU-E).[15]

Diagnosis

The blood smear should be examined for erythrocyte fragmentation or echinocytosis to exclude other causes of the anemia. The presence of Heinz bodies suggests that oxidative hemolysis has occurred, perhaps caused by oxidants in the hemodialysis fluid.

Treatment

Erythropoietin is the standard treatment for anemic patients with renal disease. Erythropoietin therapy can eliminate the transfusion requirement for patients on hemodialysis and in patients with progressive renal disease who do not yet require hemodialysis. Such treatment significantly improves their quality of life.[16] Side effects, such as hyperkalemia and hypertension, occur infrequently. It is customary to start therapy with 50 U/kg of erythropoietin three times weekly, either intravenously or subcutaneously, and to increase the dosage as necessary to bring the hemoglobin level to the desired value. Parenteral iron supplementation improves the response. ImFed (a form of iron dextran) can be given intramuscularly or intravenously at doses ranging from 100 to 500 mg, with an anticipated frequency of reaction of 4.7%. Ferrlecit (a form of sodium ferric gluconate) can be infused intravenously (125 mg over 1 hour), with the occasional occurrence of hypotension and rash.[12] In a study of patients with anemia caused by aluminum toxicity, treatment with I.V. deferoxamine (30 mg/kg I.V. at the end of each dialysis session) produced substantial improvement.[17]

ANEMIA SECONDARY TO OTHER CONDITIONS

Alcohol Abuse

Excessive alcohol ingestion—either acute or chronic—has profound hematologic effects.[18] Ingestion of about 80 g of alcohol (one bottle of wine, six pints of beer, or one-third bottle of whiskey) daily may produce macrocytosis,[19] stomatocytosis,[20] thrombocytopenia,[21] vacuolization of proerythroblasts, ringed sideroblasts,[20] a sharp drop in serum folic acid levels, and a rise in serum iron levels; it may also impair the reticulocyte response to administered folic acid in a patient known to be folic acid deficient. Acute alcohol ingestion itself does not produce a megaloblastic anemia.[18] It has been postulated that alcohol-induced hematologic toxicity is mediated through acetaldehyde, the major metabolite of ethanol, which is far more toxic and reactive than ethanol. The mechanism for these alcohol-induced abnormalities may be the formation of antibodies against acetaldehyde–hemoglobin adducts.[20] Megaloblasts, macro-ovalocytes, and hypersegmented polymorphonuclear neutrophils (PMNs) usually appear when concomitant folic acid deficiency is present. Chronic alcohol abuse often results in concomitant folic acid or iron deficiency, severe liver disease, GI bleeding, hypersplenism, and the anemia of chronic disease.

Starvation

Starvation resulting from anorexia nervosa or protein deficiency can cause anemia and even pancytopenia. Hemolysis may also be present [*see Figure 2*]. The bone marrow biopsy is hypocellular, with a characteristic gelatinous background material consisting of acid mucopolysaccharides. The anemia can occur despite normal folic acid and cobalamin (vitamin B_{12}) levels and can be corrected with proper nutrition.

Hypothyroidism

Hypothyroidism impairs erythrocyte production. The presence of macrocytosis in a hypothyroid patient suggests concomitant dietary folic acid deficiency or pernicious anemia.

Panhypopituitarism

The mild anemia that is associated with severe panhypopituitarism can be corrected by replacement of adrenal, thyroid, and gonadal hormones; the enhancing effect of androgens on the action of erythropoietin is well known.

Aging

The hemoglobin levels, red blood cell indices, and leukocyte and platelet counts of healthy older people are similar to those of younger adults; this finding was confirmed in a study of patients who were 84 years of age or older.[22] Thus, a workup is required when anemia occurs in such older patients. The evaluation and treatment of anemia in the aged has become increasingly important because the presence of anemia (hemoglobin concentration [Hgb] < 12 g/dl in women and < 13 g/dl in men) is an independent risk factor for decline in quality of life.[23]

Production Defects Associated with Marrow Aplasia or Replacement

The combination of anemia and neutropenia or thrombocy-

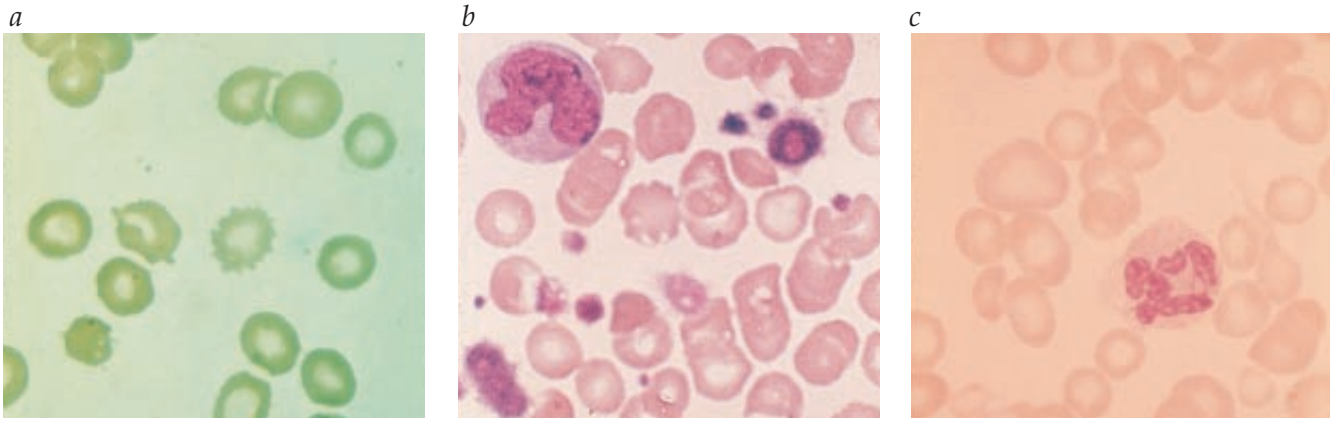

Figure 2 **The peripheral smear changes seen in severe liver disease or starvation (*a*) include distinct variation in size and shape of red blood cells; both sharply spiculed cells (spur cells) and scalloped erythrocytes are prominent. The leukoerythroblastic blood smear (*b*) indicates marrow replacement with extramedullary hematopoiesis. It is characterized by variation in the size and shape of red blood cells, by the presence of nucleated red blood cells in the peripheral blood, by giant platelets, and by immaturity in the myeloid series. In folic acid or cobalamin deficiency (*c*), the smear is characterized by variation in erythrocyte size and by distinct macrocytosis. Occasionally, fish-tailed erythrocytes are present, along with hypersegmented neutrophils.**

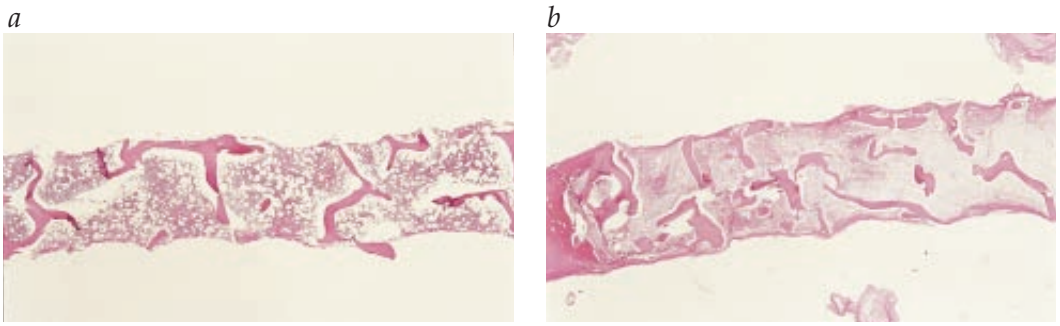

Figure 3 **Shown are (*a*) biopsy of normal bone marrow and (*b*) biopsy of bone marrow from a patient with aplastic anemia showing almost complete aplasia.**

topenia or the combination of all three of these abnormalities (i.e., pancytopenia) usually indicates that the hematopoietic marrow is damaged. If the marrow cavity is infiltrated but pluripotent stem cells are intact, extramedullary hematopoiesis will often develop in the organs of fetal hematopoiesis (i.e., spleen, liver, and distal bones).

Pancytopenia can be congenital or acquired. The finding of combined cytopenias or of immature cells in the blood (myelocytes, metamyelocytes, and erythroblasts)—that is, a leukoerythroblastic blood smear—suggests extramedullary hematopoiesis [*see Figure 2*]. These findings are an indication for bone marrow aspiration and biopsy.

APLASTIC ANEMIA

Definition

Pancytopenia (i.e., anemia, neutropenia, and thrombocytopenia) and aplastic marrow on biopsy examination [*see Figure 3*] establish a working diagnosis of aplastic anemia. The biopsy specimen must not be taken from a marrow site that has been irradiated. It is essential to determine the severity of aplastic anemia. Severe aplastic anemia (SAA) is defined by (1) marrow of less than 25% normal cellularity or marrow of less than 50% normal cellularity in which fewer than 30% of the cells are hematopoietic, and (2) two out of three abnormal peripheral blood values (absolute reticulocyte count < 40,000/μl, absolute neutrophil count [ANC] < 500 μl, or platelet level < 20,000/μl). These criteria have been criticized as being relatively insensitive. Some investigators prefer to identify a cohort of patients with very severe aplastic anemia (VSAA) as those who had an ANC less than 200/μl.[24]

Etiology

Aplastic anemia has a number of causes [*see Table 2*], although in many cases the exact cause cannot be determined.

Ionizing irradiation and chemotherapeutic drugs used in the management of malignant and immunologic disorders have the capacity to destroy hematopoietic stem cells. With careful dosing and scheduling, recovery is expected. Certain drugs, such as chloramphenicol, produce marrow aplasia that is not dose dependent. Gold therapy and the inhalation of organic solvent vapors (e.g., benzene or glue) can also cause fatal marrow failure.

In 2% to 10% of hepatitis patients, severe aplasia occurs 2 to 3 months after a seemingly typical case of acute disease, usually in young men. Often, the hepatitis has no obvious cause, and tests for hepatitis A, B, and C are negative.[25] There is a high incidence of aplastic anemia after liver transplantation in patients with severe non-A, non-B hepatitis.[26]

Several lines of evidence support the possibility that immune disorders can lead to aplasia. Marrow aplasia occurs in graft versus host disease (GVHD).[27] Immunosuppressive preconditioning improves the chances of successful transplantation of syngeneic marrow into patients with aplastic anemia,[28] and immunosuppressive therapy has been used successfully to treat idiopathic aplastic anemia.[27,28] The blood of some patients with aplastic anemia appears to contain suppressor T cells that suppress the growth of the committed progenitor cells known as colony-forming unit–granulocyte-macrophage (CFU-GM). The suppressor T cells may act by producing interferon gamma.[28] The result of these complex immune mechanisms involving suppressor T cells is a profound decrease in primitive hematopoietic cells as measured by both the long-term culture–initiating cell (LTC-IC) assay and the ability to form secondary colonies from the colonies surviving 5 weeks of marrow culture.[29]

Aplasia can also be part of a prodrome to hairy-cell leukemia [*see 12:XV Chronic Lymphoid Leukemias and Plasma Cell Disorders*],

Table 2 Causes of Aplastic Anemia

IRRADIATION	
DRUGS	
	Agents whose use regularly causes myelosuppression
	Alkylating agents: melphalan, cyclophosphamide, chlorambucil, busulfan
	Antimetabolites: azathioprine, 6-mercaptopurine, hydroxyurea, methotrexate
	Other antitumor agents: daunorubicin, doxorubicin, carmustine, lomustine, amsacrine
	Agents whose use occasionally causes myelosuppression
	Chloramphenicol, gold compounds, arsenic, sulfonamides, mephenytoin, trimethadione, phenylbutazone, quinacrine, indomethacin, diclofenac, felbamate
TOXINS	Benzene, glue vapors
INFECTIONS	Non-A, non-B, non-C hepatitis, infectious mononucleosis, parvovirus infection (attacks erythroid precursors), HIV
MALIGNANT DISEASES	Hairy-cell leukemia, acute lymphocytic leukemia, acute myeloid leukemia (rarely), myelodysplastic syndromes
CLONAL DISORDERS	Paroxysmal nocturnal hemoglobinuria
IMMUNE-MEDIATED APLASIA	Eosinophilic fasciitis
INHERITED DISORDERS	Fanconi anemia
PREGNANCY	

acute lymphoblastic leukemia [*see 12:XVI Acute Leukemia*], or, in rare cases, acute myeloid leukemia; or it can develop in the course of myelodysplasia [*see 12:XVI Acute Leukemia*].

Diagnosis

The patient with aplastic anemia may seek medical attention because of fatigue and shortness of breath. Accompanying thrombocytopenia may cause petechiae, oral blood blisters, gingival bleeding, and hematuria depending on the level of the platelet count. By far the major problem associated with aplastic anemia is the recurrent bacterial infections caused by the profound neutropenia. Sepsis, pneumonia, and urinary tract infections are common among patients with aplastic anemia. Invasive fungal infections may cause death, especially in patients with severe neutropenia.

The diagnosis of aplastic anemia requires a marrow aspirate and biopsy [*see Figure 3*], as well as a thorough history of drug exposures, infections, and especially symptoms suggesting viral illnesses and serologic test results for hepatitis, infectious mononucleosis, HIV, and parvovirus [*see Figure 4*]. Measurement of red cell CD59 is helpful in the diagnosis of paroxysmal nocturnal hemoglobinuria.

It is also important to determine the severity of aplastic anemia [*see* Aplastic Anemia, Definition, *above*]. Severe cases are associated with a very low rate of spontaneous remission and a mortality of 70% within 1 year. In contrast, 80% of patients who have milder forms of aplastic anemia survive for 1 year.[24]

Differential Diagnosis

The differential diagnosis of pancytopenia includes chronic lymphocytic leukemia, systemic lupus erythematosus, and congestive splenomegaly. In these diseases, however, the marrow is not aplastic but rather shows hyperplasia of the involved cell lines. Other conditions that cause pancytopenia include hypoplastic myelodysplastic syndrome, acute leukemia, megaloblastosis, and large granular lymphocytic leukemia.[30]

Treatment of Mild Aplastic Anemia

Treatment of milder forms of aplastic anemia involves removing the offending agent and providing supportive therapy, primarily transfusion therapy, anticipating that the remaining pluripotent stem cells will repopulate the marrow.

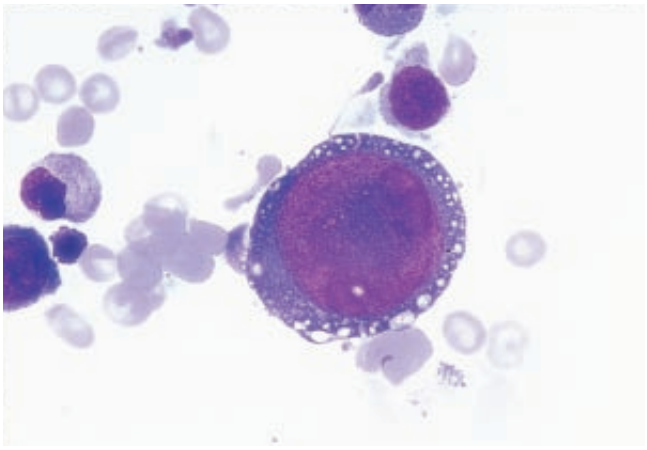

Figure 4 **Giant pronormoblast, evident on this marrow smear, strongly suggests a diagnosis of parvovirus infection.**

Supportive therapy Thrombocytopenia is often a major problem associated with aplastic anemia. It should be managed by platelet transfusion as needed to control or prevent bleeding. Usually, a threshold of 10,000 platelets/μl is used for transfusion, but conservative treatment is best, and as few transfusions as possible are given. Extensive platelet replacement may result in allosensitization to platelets and may complicate future allogeneic bone marrow transplantation. Red blood cell transfusions are given as required to control the symptoms and signs of anemia.

Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have been given to patients to raise the absolute neutrophil count and help combat infection. They are usually ineffective when used alone, because of the severe deficiency in precursor cells, which are the target for the actions of G-CSF and GM-CSF.[31] It is generally preferable to proceed to definitive treatment: immunosuppressive therapy or preferably allogeneic bone marrow transplantation if a matched sibling donor is available [*see 5:XI Hematopoietic Cell Transplantation*].[32]

Definitive therapy Transplantation from a matched sibling after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin, together with the use of methotrexate and cyclosporine for GVHD prophylaxis, is a very effective regimen for patients with aplastic anemia. Current results suggest a cure rate greater than 90%.[33] Results with mismatched or unrelated matched donors are somewhat worse; therefore, patients with aplastic anemia who are without sibling donors are often given a trial of immunosuppressive therapy before transplantation.

Three forms of immunosuppression have been shown to produce partial remission in aplastic anemia.[31,32,34] Antithymocyte globulin (ATG) produced sustained remission in about half of the patients in a randomized trial.[32] High-dose corticosteroids improved blood counts in about 40% of treated patients, and cyclosporine was also shown to be beneficial.[32] (Androgens such as oxymetholone may have a role in the treatment of severe aplastic anemia but are not given alone.[31,34])

Although each of these agents can be used individually or consecutively in the treatment of aplastic anemia, a controlled study suggests that results are better when all three are used simultaneously.[31,32] The combination of ATG, a corticosteroid, and cyclosporine resulted in an actuarial survival of 62% at 36 months. The first signs of response occurred at about 4 weeks; the median time to remission was 60 to 82 days.[32] In this study, patient outcome was related to the quality of hematologic response. An 11-year follow-up report confirmed the effectiveness of the combination of ATG, corticosteroids, and cyclosporine. The relapse rate was 38%, and clonal or malignant diseases developed in 25% of patients.[35]

One recommendation, based on the usual availability of horse ATG in the United States,[31,32] is to administer horse ATG at a dosage of 40 mg/kg/day in 500 ml of saline for 4 days over a period of 4 to 5 hours through an I.V. line equipped with a microaggregate in-line filter. The toxic side effect of ATG is serum sickness, which can usually be controlled with corticosteroids. Prednisone (60 to 100 mg/day) is given orally in divided doses, or methylprednisolone (40 mg) is added to the infusion bottle, and the dose can be increased to 1 mg/kg/day. Corticosteroid therapy is adjusted to control serum sickness, but it can usually be tapered after 2 weeks and stopped after 30 days. Because ATG can lower platelet counts, platelet transfusions are given as

needed to maintain the platelet count at more than 20,000 μl.

Cyclosporine (10 to 12 mg/kg/day) is given orally in two divided doses, with the aim of achieving whole blood trough levels of 500 to 800 ng/ml or a serum level of 100 to 200 ng/ml. After 29 days, the cyclosporine dosage can be tapered for a trough whole blood level of 200 to 500 ng/ml.[31,32] The cyclosporine is continued for at least 6 months. Cyclosporine can cause hypertension, renal toxicity, hypomagnesemia, vitiligo, tremors, hypertrichosis, susceptibility to *Pneumocystis carinii* pneumonia (PCP), and gingival hyperplasia.[31,32] In one study, 300 mg of aerosolized pentamidine was given every 4 weeks as PCP prophylaxis.[32]

In another study, G-CSF (5 μg/kg/day) was given subcutaneously for the first 90 days, along with I.V. methylprednisolone (2 mg/kg/day on days 1 through 5, followed by 1 mg/kg/day on days 6 through 10, and tapered off in 30 days), with good results.[36]

In contrast to patients who undergo allogeneic bone marrow transplantation, patients who respond to immunosuppressive therapy are not actually cured. Many of these patients continue to have moderate cytopenia[37]; 20% to 36% experience relapses of aplastic anemia,[31,32,37] and as many as 20% to 36% eventually develop clonal disorders, such as paroxysmal nocturnal hemoglobinuria, myelodysplastic syndrome, and acute leukemia.[31,32] Patients also are at increased risk for the development of solid tumors after treatment of aplastic anemia, but the risk is the same for patients who underwent immunosuppressive therapy as it is for those who underwent allogeneic bone marrow transplantation.[38] More than 50% of patients who have relapses of aplastic anemia after initially responding to immunosuppressive therapy may respond to a second course of therapy. [31,32] For unresponsive patients, a trial of rabbit ATG may work. The rabbit ATG (3.5 mg/kg/day diluted in saline and infused over 6 to 8 hours for 5 consecutive days)[39] is given along with cyclosporine (5 mg/kg/day p.o. on days 1 through 180, then tapered) and G-CSF (5 μg/kg/day on days 1 through 90).

An intriguing report concerns 10 patients with severe aplastic anemia who were treated with high-dose I.V. cyclophosphamide (45 mg/kg/day) for 4 consecutive days.[40] Some patients also received cyclosporine. Only one course of I.V. cyclophosphamide was given. Seven of 10 patients had a complete hematologic response, and six were still alive after a median follow-up of 10.8 years (range, 7.3 to 17.8 years). However, a trial comparing high-dose cyclophosphamide with ATG was ended early because of excessive cyclophosphamide-induced morbidity and mortality.[41] Therefore, the role of high-dose cyclophosphamide in the treatment of aplastic anemia needs extensive clarification.

Treatment of Severe Aplastic Anemia

The choice of appropriate therapy for patients with SAA is influenced by age and disease severity. The European Group for Blood and Marrow Transplantation reported on the results of immunosuppressive therapy in 810 patients subdivided into three age groups: younger than 49, 50 through 59, and older than 60. The 5-year survival rates for those with SAA were 86%, 72%, and 54%, respectively; for those with VSAA, the comparable rates were 49%, 40%, and 21%.[42] Older patients had more bleeding and infections.

Patients younger than 20 years Allogeneic bone marrow transplantation should be performed in patients younger than 20 years if a matched sibling donor is available. Although there are risks, including chronic GVHD and organ dysfunction caused by the conditioning program,[31] 50% to 80% of patients may be cured; the incidence of later clonal disorders is very low.[34] Allogeneic bone marrow transplantation, along with conditioning programs consisting of cyclophosphamide and ATG, produced an actuarial survival rate of 69% after 15 years.[34] Patients younger than 20 years who do not have a matched sibling donor should consider transplantation from a matched unrelated donor. Allogeneic transplantation from a matched unrelated donor initially produced a 2-year survival rate of only 29% because of severe GVHD.[31] In a study of 15 patients who received unrelated-donor transplantations, all were reported alive at 2 to 86 months (mean follow-up, 51 months); only one patient developed extensive GVHD, and five (33%) developed moderate to acute GVHD. These results suggest that conditioning regimens that contain ATG and cyclophosphamide are improving the treatment outcomes for unrelated donor transplantation in this patient group.[43]

Patients between 20 and 45 years of age Patients between 20 and 45 years of age who are in excellent health and have a fully matched sibling donor may be able to tolerate GVHD and thus benefit from the curative potential of an allogeneic bone marrow transplant. Some experts propose that allogeneic bone marrow transplantation should be considered for patients in this age group,[34] particularly because newer conditioning programs seem to be capable of reducing the severity of GVHD.[31,44] In a study of 154 patients younger than 46 years who received allogeneic transplantation, the median survival was 29 months, and the probability of overall survival at 5 years was 56%.[45]

Patients older than 45 years Previously it was thought that the impact of GVHD was too severe for patients older than 45 years, and it was suggested that these patients receive immunosuppressive therapy.[31,34] However, conditioning programs containing ATG and cyclophosphamide seem to be more tolerable, and even heavily pretreated patients as old as 59 years have done well after allogeneic marrow transplantation.[46]

ACQUIRED PURE RED CELL APLASIA

Definition

In adults, pure red cell aplasia (PRCA) is an acquired disorder. The anemia is severe (hematocrit usually less than 20%), reticulocytopenia is profound (often 0%), the absolute reticulocyte count is usually less than 10,000/μl, and marrow erythroid precursors are virtually absent. Marrow myeloid and megakaryocytic elements are preserved, however, and the peripheral platelet and white blood cell counts are also normal.

Pathophysiology

In PRCA, erythropoiesis is thought to be inhibited primarily by immune mechanisms, including autoantibody-mediated and T cell–mediated suppression of erythroid progenitors, usually at a stage after the CFU-E stage of erythroid differentiation and before formation of proerythroblasts. T cells, particularly of the large granular lymphocyte (T-LGL) class, may be involved in the suppression of erythropoiesis, and in some cases, there is evidence that the suppression is caused by clonal T cells.[47] Autoantibody inhibition of erythropoietin has also been described, but it is quite uncommon.[48] Two other mechanisms probably cause

Table 3 Causes of Acquired Pure Red Cell Aplasia

Primary

- Associated with thymoma in 10%–15% of cases[51]
- Idiopathic causes

Secondary

- Neoplasia: chronic lymphocytic leukemia, chronic myeloid leukemia, Hodgkin and non-Hodgkin lymphomas; large granular lymphocytic proliferative disorders; prodrome to myelodysplastic syndromes[51]
- Systemic lupus erythematosus or rheumatoid arthritis
- Associated with pregnancy
- Associated with autoimmune hemolytic anemia
- Drugs: those most commonly associated are phenytoin, chlorpropamide, zidovudine,[57] trimethoprim-sulfamethoxazole, isoniazid[51]
- Multiple endocrine gland insufficiency
- Primary amyloidosis
- Infections: infectious mononucleosis, viral hepatitis, parvovirus infection, HIV[51]
- ABO-incompatible bone marrow transplantation

PRCA: (1) a specific attack on erythroid precursors by the parvovirus B19 (one report indicated that 14% of cases were caused by this virus[49]) and (2) an underlying hematopoietic clonal abnormality that may be a prodrome to myelodysplastic syndrome.[48]

Etiology

PRCA may be caused by a variety of processes, including neoplasia, autoimmune disorders, drugs, and infections [*see Table 3*].

The association of PRCA with LGL proliferation and leukemia is increasingly being recognized.[30] The routine use of T cell receptor gene rearrangement studies in one series showed that nine of 14 patients had a clonal LGL disorder.[50] Presumably, these LGL cells directly mediate inhibition of erythropoiesis.[49,50] In perhaps as many as 20% of cases, PRCA may be a prodrome to the myelodysplastic syndromes or acute myeloid leukemia.[49,51]

Erythroblastopenia also occurs in a small percentage of patients with autoimmune hemolytic anemia [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*] and may be caused by autoantibody attack on maturing normoblasts.

The treatment of HIV infection with zidovudine (AZT) produces, in virtually all patients, an anemia that is usually marked by significant macrocytosis.[52] Moderate erythroid hypoplasia is the usual cause of this anemia, which can progress to PRCA.

Parvovirus infection is the cause of the transient aplastic crises that occur in patients who have severe hemolytic disorders. The marrow in patients with such disorders must compensate for the peripheral hemolysis by increasing its production up to sevenfold and thus typically shows an intense erythroid hyperplasia. Although parvovirus can affect all precursor cells, the red cell precursors are the most profoundly affected.[49]

PRCA can complicate ABO-incompatible allogeneic bone marrow transplantation; the recipient's serum continues to express anti-A or anti-B isohemagglutinins against donor A or B antigen expressed on the surface of erythroid progenitors.[51] With PRCA of pregnancy, antibodies against BFU-E usually disappear after delivery, coinciding with clinical remission.[53]

Diagnosis

The patient with PRCA presents with symptoms characteristic of anemia—namely, weakness, fatigue, and shortness of breath. White blood cell and platelet counts are normal morphologically and functionally. A very low reticulocyte count—either a relative reticulocyte value of less than 0.2% or a very low absolute reticulocyte count of less than 10,000 μl—should prompt the physician to order a bone marrow aspirate. In a patient with PRCA, a bone marrow aspirate and biopsy typically show normal myelopoiesis, lymphopoiesis, and megakaryocytopoiesis; erythropoiesis is virtually absent. In the absence of any apparent cause of PRCA, four conditions must be considered: idiopathic PRCA, thymoma, hypoplastic myelodysplastic syndromes (MDS), and LGL leukemia. The workup to diagnose PRCA usually includes computed tomography of the chest to evaluate the possibility of thymoma, immunophenotypic analysis of circulating blood or marrow lymphocytes to identify LGL proliferation, marrow cytogenetics to evaluate the possibility of MDS, and antibody tests for parvovirus.[49] A diagnostic hallmark of parvovirus infection is the appearance of giant pronormoblasts in the marrow [*see Figure 4*]. The distinction between PRCA associated with the myelodysplastic syndromes and acute myeloid leukemia may be difficult to determine at the time of diagnosis unless a typical myelodysplastic cytogenetic abnormality is detected during a bone marrow examination.

Treatment

Two general principles of management in PRCA are transfusions for symptomatic anemia and cessation of possible offending drugs. No specific therapy is indicated in those forms of PRCA that are self-limited, such as pregnancy, ABO-incompatible bone marrow transplantation, and some cases of parvovirus infection.[51,53] Treatment of PRCA depends on the identified cause. If a thymoma is present, it should be removed surgically[52]; this procedure leads to patient improvement in about one third of such cases.[51] When surgery is impossible, one should consider a course of prednisone combined with octreotide, a somatostatin analogue that binds to thymomas and may inhibit the function of thymic immune cells.[54]

Treatment of other causes of PRCA is based on the supposition that the attack is immune mediated and therefore will respond to immunosuppressive therapy. Treatment can begin with the administration of 60 mg of oral prednisone daily in divided doses; this regimen should be continued for 1 to 3 months.[49] If a patient fails to respond, as indicated by a rise in the reticulocyte count, cyclophosphamide or azathioprine should be added at a dosage of 2 to 3 mg/kg/day orally. Patients with marrow cytogenetic abnormalities suggestive of myelodysplastic syndrome respond poorly.[49,50] Some patients who are refractory to other forms of therapy have responded well to I.V. IgG (0.4 g/kg/day for 5 days).[55]

Patients with LGL proliferation as the underlying cause respond well to cyclophosphamide.[50,56] Usually, low doses of cyclophosphamide (50 to 100 mg/day p.o.) for 3 to 6 months suffice to produce remission, which is sometimes associated with disappearance of LGL proliferation.[50,57] Patients who respond poorly usually respond to oral cyclosporine.[50,57] Cyclosporine (12 mg/kg/ day) has been shown to produce responses of approximately 65%, even in patients who did not respond to corticosteroids, plasmapheresis, cyclophosphamide, or azathioprine therapy.[51,58]

For patients in whom parvovirus infection is the cause of PRCA, I.V. IgG works well; the standard dosage is 0.4 g/kg/day for 5 days.[49] For AIDS patients with parvovirus infection and PRCA, I.V. IgG may have to be continued.[57] Recovery

from the transient crises of parvovirus infection occurs spontaneously in 1 to 2 weeks after onset of the infection.

ATG therapy for patients with refractory PRCA is similar to that for patients with aplastic anemia (40 mg/kg/day I.V. for 4 days).[51] Other drugs that have been used in refactory cases are azathioprine (2 to 3 mg/kg/day), antilymphocyte globulin, and anti-CD20 monoclonal antibody.[31] In very refractory cases, allogeneic bone marrow transplantation can be effective.[59]

Production Defects with Marrow Erythroid Hyperplasia and Ineffective Erythropoiesis

DEFINITION

Anemia with a low reticulocyte count may occur despite intense marrow erythroid hyperplasia. This paradoxic situation is the hallmark of ineffective erythropoiesis or intramedullary hemolysis. Generalized erythroid impairment may be present, or specific subpopulations of erythroid precursors may be involved. Some of these subpopulations escape death in the marrow, but their progeny are so severely damaged that they are rapidly removed from the circulation, thus giving the picture of peripheral hemolysis. Other signs of ineffective erythropoiesis include jaundice, a very high serum lactic dehydrogenase level, and 75% to 90% saturation of serum iron-binding capacity. The classic ferrokinetic picture shows rapid plasma iron clearance, which indicates intense erythroid precursor activity. The delivery of labeled red blood cells to the peripheral circulation, however, is dramatically reduced, which suggests that the precursors are being destroyed by intramedullary hemolysis.

The differential diagnosis includes megaloblastic anemias, sideroblastic anemias, thalassemia [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*], myelodysplastic syndromes [*see 12:XVI Acute Leukemia*], and agnogenic myeloid metaplasia [*see 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*].

MEGALOBLASTIC ANEMIAS

Etiology

Megaloblastic anemias are caused by cobalamin or folic acid deficiency, by drugs that interfere with the synthesis of DNA or with the absorption or metabolism of cobalamin, and by genetic disorders that interfere with DNA metabolism or with the absorption or distribution of cobalamin.

Pathophysiology

Megaloblastic erythropoiesis is characterized by defective DNA synthesis and arrest at the G_2 phase, with impaired maturation and a buildup of cells that do not synthesize DNA and that contain anomalous DNA. This condition leads to asynchronous maturation between the nucleus and cytoplasm.[60] RNA production and protein synthesis continue; thus, larger cells, or megaloblasts, are produced. Ineffective erythropoiesis results, and there is disagreement about the presence of increased apoptosis.[61,62] It is presumed that similar defects in DNA synthesis characterize the mucosal abnormalities of the stomach and tongue. In the granulocytic line, the presence of giant metamyelocytes represents ineffective granulopoiesis.[60]

The role of folic acid and cobalamin The interactions between folic acid and cobalamin are critical in the metabolism of single carbon units, mainly methylene and formyl analogues, which have a key role in the synthesis of DNA and purines [*see Figure 5a*].[63] There are two major coenzymes of cobalamin, adenosylcobalamin and methylcobalamin. Adenosylcobalamin is the coenzyme for methylmalonyl–coenzyme A mutase, which catalyzes a step in the catabolism of propionic acid [*see Figure 5b*].[63] Methylcobalamin is the coenzyme for methionine synthase, which functions as a methyltransferase in the reaction that converts 5-methyltetrahydrofolate (CH_3-THF_1) to tetrahydrofolate (THF_1) [*see Figure 5a*].[63] Cobalamin and folic acid [*see Figure 6*] combine in the methionine synthase reaction [*see Figure 5a*], in which the methyl group of CH_3-THF_1 is transferred to cobalamin to form methylcobalamin. Methylcobalamin then transfers its methyl group to homocysteine to form methionine. The monoglutamated THF_1, which is formed by this reaction, is polyglutamated by the enzyme folylpolyglutamate synthase, and a methylene group is added to it by the serine-glycine methyltransferase to form 5,10-methylene THF_n. 5,10-Methylene THF_n provides its methylene to convert deoxyuridylate to thymidylate, a key step in DNA synthesis. 5,10-Methylene THF_n can also be directly converted to CH_3-THF_1 by the enzyme 5,10-methylene tetrahydrofolate reductase, thereby making its methyl group available.

Formyl THF_n (also called leucovorin, folinic acid, or citrovorum factor) has an important role in purine synthesis and DNA metabolism. It can be generated by oxidation of 5,10-methylene THF_n or directly from THF_n by the enzyme formyl THF synthase, with methionine providing the formate group [*see Figure 5a*].[63] When cobalamin is deficient, CH_3-THF_1 cannot transfer its methyl group to cobalamin; therefore, THF_1 is not free to be polyglutamated by folylpolyglutamate synthase [*see Figure 5a*]. The polyglutamated form is required for synthesis of either 5,10-methylene THF_n or formyl THF_n; thus, DNA synthesis and purine synthesis are blocked. This hypothesis, the methylfolate trap hypothesis, is supported by the finding of increased levels of CH_3-THF_1 in the plasma of cobalamin-deficient patients. An alternative explanation is the formate starvation hypothesis, wherein cobalamin deficiency impairs methionine generation, which therefore cannot provide the methyl groups needed by the enzyme formyl THF_n synthase to produce formyl THF_n.

Other aspects of folic acid and cobalamin metabolism Neither folic acid nor cobalamin is produced by humans in adequate amounts; both must be absorbed from food. Cobalamin, in particular, is derived from microbial sources and is ingested in the form of meat or eggs.

Most of the dietary folic acid is in the polyglutamate form and is absorbed at the intestinal mucosa. Absorption of radioactively labeled folic acid approaches 80% of a 200 μg dose.[60,63] The serum folic acid level appears to be maintained by folic acid absorbed from food. Enterohepatic circulation of folic acid has been observed in which folic acid passing into the bile and small intestine is quantitatively reabsorbed. In an animal model, ethanol administration blocks the entry of folic acid into the bile. This effect could account, in part, for the sharp fall in the serum folic acid level seen 8 hours after alcohol consumption. A similar fall in serum folic acid level follows phenytoin ingestion. The daily requirement of cobalamin is about 1 μg, and the amount usually provided by the Western diet, which is rich in animal products, is about 5 to 15 μg.[64]

R proteins are a class of cobalamin-binding glycoproteins found in saliva and gastric juice; they are produced by granulocytes and other tissues. Intrinsic factor (IF) is a 45 kd glycopro-

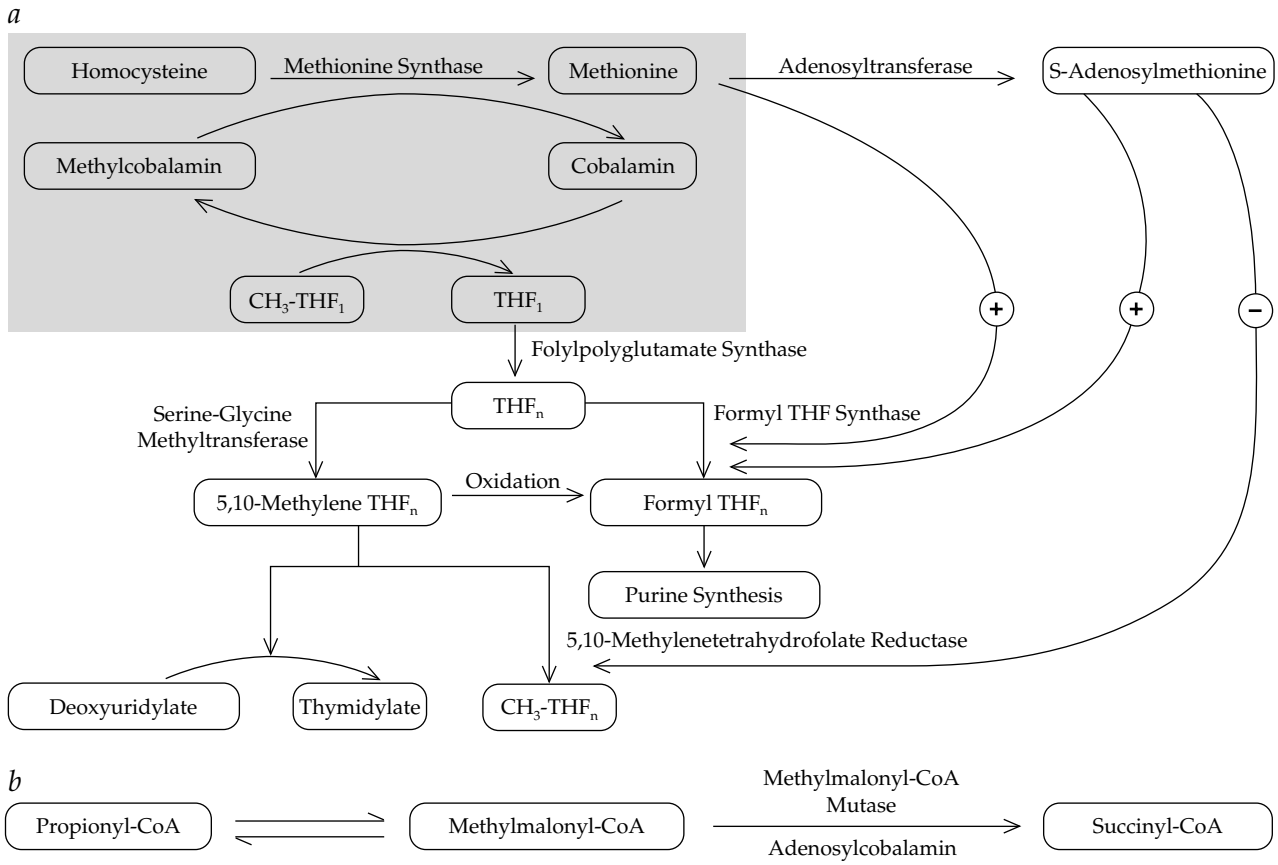

Figure 5 **(*a*) Intracellular interdependent cofactor activity of cobalamin and folic acid is essential in DNA synthesis and metabolism.[63] (*b*) Adeno-sylcobalamin is a cofactor in the synthesis of succinyl–coenzyme A from methylmalonyl–coenzyme A.[63] (CoA—coenzyme A)**

tein, secreted by gastric parietal cells, that is highly specific for unaltered cobalamin. The R protein–cobalamin complex does not bind to ileal receptors and thus is not absorbed. In the stomach, cobalamin binds preferentially to R proteins rather than to IF[60,63,64]; thus, it is the physiologically inactive R protein–cobalamin complex that is discharged into the duodenum. In the duodenum and small intestine, however, the pancreatic proteases along with pepsin degrade the R proteins, freeing cobalamin and allowing it to bind to IF. Thus, gastric atrophy and pancreatic insufficiency contribute to cobalamin malabsorption.[63,64] The IF-cobalamin complex, in the presence of Ca^{2+} and at a pH level greater than 5.4, binds specifically to a limited number of sites on the microvilli of mucosal cells in the terminal portion of the ileum, where absorption takes place [*see Figure 7*].[63,64]

In the plasma, most of the cobalamin is bound to the physiologically unimportant R proteins, transcobalamins I and III (TC-I and TC-III), which are about 70% saturated with cobalamin.[65] The physiologically important transport protein is transcobalamin II (TC-II), which has considerable specificity for cobalamin and is only 5% to 10% saturated with cobalamin. Receptors for the TC-II–cobalamin complex are present on many cell membranes. TC-II binds about 90% of a newly injected dose of cobalamin; and the complex is rapidly cleared, with a half-life of 6 to 9 minutes.[66,67] In persons with congenital TC-II deficiency, which results in severe megaloblastic anemia, both plasma cobalamin transport and cobalamin absorption are impaired. Impaired cobalamin absorption implies that TC-II has a role within the ileal enterocyte, where cobalamin is transferred from IF to TC-II.

The elevation of cobalamin levels seen in patients with chronic granulocytic leukemia or significant granulocytosis is caused by increases in TC-I and, to a lesser extent, TC-III, which are produced in granulocytes.

MEGALOBLASTIC ANEMIA CAUSED BY COBALAMIN DEFICIENCY (PERNICIOUS ANEMIA)

Pathophysiology

Cobalamin deficiency in pernicious anemia is thought to result from an autoimmune gastritis and an autoimmune attack on gastric intrinsic factor. There are two types of anti-IF antibodies: one of these antibodies blocks attachment of cobalamin to IF, and the other blocks attachment of the IF-cobalamin complex to ileal receptors.[66] Clinically, highly specific anti-IF antibodies are found in about 70% of patients with pernicious anemia. A second component of pernicious anemia is chronic atrophic gastritis that leads to a decline in IF production. The chronic atrophic gastritis in pernicious anemia is also associated with an increased risk of intestinal-type gastric cancer and of gastric carcinoid tumors.[67] Pernicious anemia occurs in association with other autoimmune disorders. In one study, autoimmune thyroid disorders were observed in 24% of 162 patients with pernicious anemia.[68]

Diagnosis

Clinical manifestations In addition to macrocytic and megaloblastic anemia, the patient with cobalamin deficiency

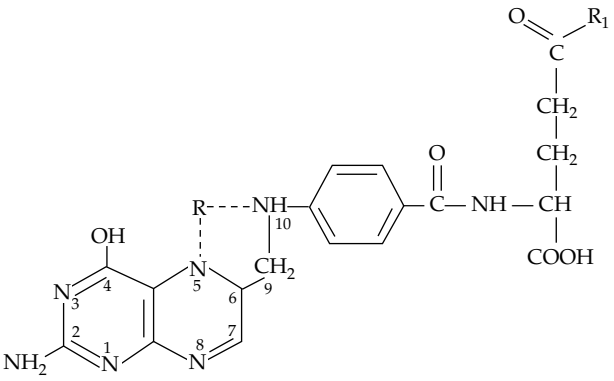

Figure 6 **Folic acid functions as a coenzyme in single-carbon transfer reactions. It is not physiologically active until it is reduced at positions 5, 6, 7, and 8 to tetrahydrofolate (THF). Single-carbon groups (R) such as methyl analogues and formate are added at either position 5 or position 10, or they may bridge from 5 to 10, as shown. There may be several glutamates attached in sequence (R_1), which convert the monoglutamate to the polyglutamate form. Enzymes of the intestinal mucosa split polyglutamates back to monoglutamate, whereas liver enzymes add glutamate to tetrahydrofolate or to other reduced folic acids.**

may present with weakness, lethargy, jaundice, and dementia, as well as atrophy of the lingual papillae and glossitis. Neuropathy is the presenting feature in about 12% of patients with cobalamin (vitamin B_{12}) deficiency without concomitant anemia.[69] Patients with severe cobalamin deficiency initially complain of paresthesia. The sense of touch and temperature sensitivity may be minimally impaired. Memory impairment and depression may be prominent.[69] The disease may progress, involving the dorsal columns, causing ataxia and weakness. The physical examination reveals a broad-base gait, Romberg sign, slowed reflexes, and loss of sense of position and feeling of vibration (especially when tested with a 256 Hz tuning fork). If the disorder is not detected and treated, the lateral columns become involved, resulting in weakness, spasticity, inability to walk, sustained clonus, hyperreflexia, and Babinski sign. Because the peripheral nerves, as well as the dorsal and lateral columns, are involved, these neurologic manifestations are sometimes termed subacute combined degeneration or subacute combined system disease.

Cobalamin deficiency appears to be the cause of various neuropsychiatric disorders, with such symptoms as paresthesia, ataxia, limb weakness, gait disturbance, memory defects, hallucinations, and personality and mood changes.[65] These symptoms, however, cannot be easily accounted for by the type of spinal cord lesions that occur in patients with cobalamin deficiency. Investigators have tried to determine whether a defect in methionine synthesis or an abnormality in propionic acid metabolism accounts for the neuropathy associated with cobalamin deficiency [*see Figure 5b*], but the exact mechanism remains obscure. Accruing evidence supports the impairment of methionine synthase as the cause of the neuropathy.[60,69] A recent study measured various metabolites of cobalamin and discovered that only high levels of plasma cysteine were predictive of neurologic dysfunction.[70]

Diagnostic workup The evaluation of suspected cobalamin deficiency generally proceeds in two stages: documenting the presence of the vitamin deficiency and determining its cause (e.g., pernicious anemia, malabsorption, dietary lack). The diagnosis can often be established by (1) measurement of the serum cobalamin concentration, (2) evaluation of specific metabolites, and (3) use of the Schilling test to establish malabsorption of cobalamin.

Macrocytosis (mean corpuscular volume [MCV] greater than 100 fl) is a hallmark of cobalamin deficiency, but it may be masked by concurrent disorders, such as iron deficiency. If macrocytocis is not apparent on examination of the peripheral smear, it is easily detected when red blood cell counts are made with an electronic particle counter. The peripheral smear shows macro-ovalocytes, fish-tailed red blood cells, hypersegmented neutrophils, and, occasionally, nucleated red blood cells [*see Figure 2*]. The finding that a single polymorphonuclear neutrophil has six lobes or that 5% of PMNs have five lobes constitutes strong evidence of megaloblastic anemia. In severe cases, granulocytopenia and thrombocytopenia are present. Examination of the bone marrow is usually not necessary, but if performed, it reveals megaloblastic erythroid hyperplasia and giant metamyelocytes.[60] If severe iron deficiency is concurrent with macrocytosis, the full morphologic expression of megaloblastosis is blocked, although the giant metamyelocytes in the marrow and hypersegmented PMNs in the peripheral blood will still be present.

Plasma cobalamin levels and red blood cell folic acid levels should be measured if the MCV is greater than 100 fl. If performed, a bone marrow aspirate and biopsy typically reveal

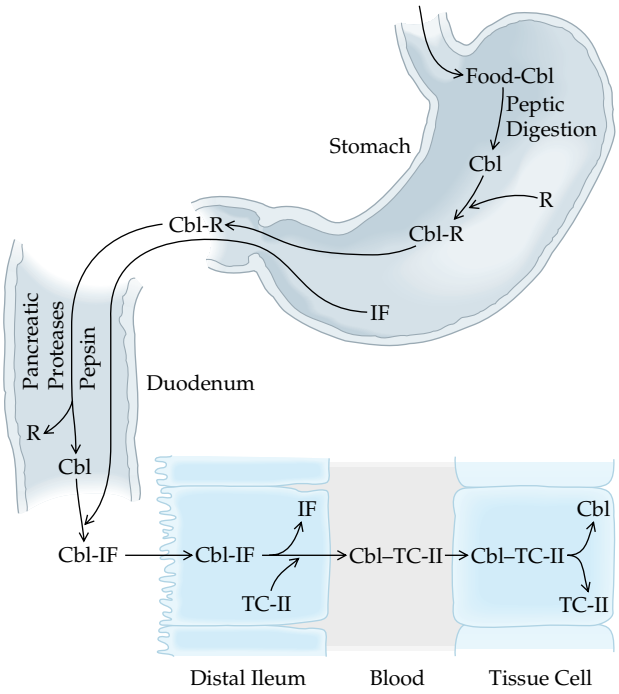

Figure 7 **Cobalamin assimilation. Dietary cobalamin (Cbl) enters the stomach and binds to R protein. This physiologically inactive complex enters the duodenum. In the small intestine, pancreatic enzymes and pepsin digest the R protein, and Cbl binds to intrinsic factor (IF). The Cbl-IF complex passes through the intestine until it reaches receptors on the microvilli of mucosal cells in the distal ileum. The Cbl is then transferred to transcobalamin II (TC-II), which circulates in the blood until it binds to receptors on cells in the body and is internalized.**

enormous megaloblastic erythroid hyperplasia with giant metamyelocytes.[60] The hypercellularity detected on bone marrow examination can be so dramatic and megaloblasts so immature that clinicians still sometimes make the erroneous diagnosis of leukemia.[60,71]

The standard approach to determining the cause of proven cobalamin deficiency has traditionally relied on the Schilling test, which is becoming difficult to order. The Schilling test measures the absorption of cobalamin labeled with cobalt-57 (^{57}Co). After 1 μg of radioactively labeled cobalamin is given orally, 1,000 μg of unlabeled cobalamin is given parenterally. The parenteral dose saturates transcobalamins I, II, and III, so that a significant portion of the absorbed material is flushed and excreted in the urine. If the amount of ^{57}Co-labeled cobalamin measured in an accurately collected 24-hour urine sample is less than 10% of the dose that was administered orally, cobalamin absorption is poor.

There are increasing numbers of reports of patients with proven pernicious anemia who have low or borderline serum cobalamin levels but normal Schilling test results. As the gastric atrophic lesion of pernicious anemia progresses, the ability to produce acid-pepsin is lost before all IF activity disappears. Thus, the ability to cleave the R protein–cobalamin complex, freeing cobalamin to bind to IF, is impaired. Coexisting infection with *Helicobacter pylori* may further impair production of acid-pepsin.[72] However, there may be sufficient IF to bind the free oral cobalamin administered in the Schilling test and therefore yield a normal value.

Malabsorption of cobalamin can be demonstrated by means of a food Schilling test, which is not available clinically. This test is performed with eggs from chickens that have been injected with radioactive cobalamin[73] and indicates whether there is insufficient acid-pepsin to split the cobalamin-enzyme complex and release free cobalamin to be bound by IF. If pernicious anemia is strongly suspected in a patient whose Schilling test result is apparently normal and whose plasma cobalamin is not diagnostically low, other steps should be taken to confirm the diagnosis, including examination of the blood cell morphology, measurement of the anti-IF antibody, or performance of a therapeutic trial with parenterally administered cobalamin. Measurement of the serum levels of homocysteine and methylmalonic acid is increasingly being used, because both are elevated as a consequence of cobalamin deficiency [*see Figures 5a and b*].[74]

If the initial Schilling test demonstrates reduced excretion of cobalamin, a second phase of the test may be conducted, aimed at correcting cobalamin absorption caused by pernicious anemia. In this phase of the test, supplementary oral IF is administered and will normalize the cobalamin absorption unless the supplementary IF is not fully active, the patient secretes antibodies to IF, or the patient is taking drugs that interfere with cobalamin absorption. In no case, however, will supplementary cobalamin be effective in patients with intestinal malabsorption. It is important to recognize that prolonged cobalamin deficiency impairs intestinal epithelial cells and thus impairs absorption. Therefore, the second stage of the test should only be performed after several weeks of cobalamin replacement therapy. If the result of the second stage of the Schilling test is abnormally low, this suggests the presence of generalized malabsorption, such as may occur in sprue, pancreatic insufficiency, or blind loop syndromes.

Factors affecting test results Concurrent α-thalassemia may minimize the macrocytosis of pernicious anemia.[75] This possibility should be considered particularly in patients of African descent, among whom there is a high incidence of α-thalassemia (about 30%). Anemia of chronic disease or anemia resulting from blood loss and iron deficiency can also reduce the degree of macrocytosis but will not affect the hypersegmentation of neutrophils. In one study, iron deficiency was discovered in 20% of 121 patients with pernicious anemia[76]; in another study, 19% of patients with pernicious anemia were not anemic, and 33% did not have macrocytosis.[77]

Falsely low serum cobalamin levels occur during pregnancy and in folic acid deficiency states.[74] In the past, a decline in the serum cobalamin level was usually not considered important unless the value was very low (i.e., < 150 pg/ml). It has become clear, however, that patients with serum cobalamin levels as high as 250 pg/ml and perhaps higher may have cobalamin deficiency.[73,77,78] Fortunately, the finding of macro-ovalocytes or hypersegmented PMNs on the peripheral smear remains a sensitive indicator for the presence of cobalamin deficiency.

Determining the underlying cause After the presence of macrocytosis and a reduced cobalamin level have been identified, the cause of these conditions must be determined. It is important to remember that macrocytosis can be caused by conditions other than pernicious anemia, including folic acid deficiency, liver disease, alcohol abuse, reticulocytosis, and ingestion of drugs such as antimetabolites, alkylating agents, and zidovudine.[52,75] Cobalamin deficiency can be caused by inadequate absorption resulting from gastric abnormalities (e.g., pernicious anemia, gastritis) and small bowel disease (e.g., tropical sprue, Crohn disease), and pancreatic insufficiency [*see Table 4*].

Gastric surgery in which the IF, pepsin, and acid-secreting components are removed often results in cobalamin deficiency (it occurred in 31% of patients in one study[79]). Patients who have undergone gastric surgery should be regularly screened by measurements of plasma cobalamin or homocysteine levels and supplemented with lifelong cobalamin therapy if the levels are low.[79]

Pancreatic insufficiency can result in malabsorption of cobalamin if the damaged pancreas does not produce enough trypsin and chymotrypsin for digesting the R protein–cobalamin complex and freeing the vitamin to form the complex with IF [*see Figure 7*] [*see 4:V Diseases of the Pancreas*].

There are other causes of cobalamin deficiency. In vegetarians, especially vegans, profound nutritional megaloblastic anemia can develop as a result of very low cobalamin intake. Deficiencies of folic acid and iron have also been observed in vegans.[80] A careful patient history should indicate the possibility of inadequate dietary intake of cobalamin. Infants of vegan mothers can become severely cobalamin deficient, particularly when they are breast-fed.[65] Cobalamin deficiency is surprisingly common in less well developed countries where people are not strict vegans.[65] The incidence is particularly high in pregnant women and in preschool-age children.[65]

Treatment

Specific replacement should be started promptly after the diagnosis has been made and serum samples have been taken to determine cobalamin levels. Patients who have a low serum cobalamin level and macrocytic anemia should undergo a trial of parenteral cobalamin therapy. The diagnosis of cobalamin deficiency is confirmed if cobalamin therapy produces a reticulocytosis in 3 to 4 days that is associated with a rise in the hemoglobin level and a fall in the MCV.

Table 4 Causes of Cobalamin Deficiency

Inadequate Diet
Strict vegetarianism
Inadequate Absorption
Gastric abnormalities that produce deficient or defective intrinsic factor
Pernicious anemia
Total gastrectomy
Gastritis
Small bowel disease
Ileal resection or bypass
Blind loop syndrome with abnormal gut flora
Malabsorption
Tropical sprue
Crohn disease
Pancreatic insufficiency
Interference with Cobalamin Absorption
Drugs
Neomycin
Biguanides
Colchicine
Ethanol
Aminosalicylic acid
Omeprazole
Fish tapeworm competing for cobalamin
Degradation of Cobalamin Coenzymes
N_2O anesthesia
Rare Congenital Disorders
Transcobalamin II deficiency
Defective intrinsic factor production

If the patient has symptoms of severe anemia, packed red blood cells can be transfused; the transfusion should be administered very slowly to avoid precipitating or aggravating congestive heart failure. This circumstance is one of the few in which a single-unit transfusion may be justified, because it may produce a 25% increase in oxygen-carrying capacity. A large dose of cobalamin should be given because the retention of parenterally administered cobalamin is poor but variable; the vitamin is inexpensive and has no harmful side effects. The reticulocyte response begins in 4 to 6 days, and the granulocyte count, if low, begins to increase at the same time. The hypersegmentation of PMNs disappears after 10 to 14 days, which suggests that in the megaloblastic anemias, granulopoiesis is affected by cobalamin deficiency at two different steps: (1) the lobe number of the PMNs is determined, and (2) granulocytes mature and leave the marrow.[55] Weekly dosages of 1,000 μg of parenteral cobalamin for 6 weeks should be followed by parenteral dosages of 1,000 μg monthly for life. The standard parenteral preparation is cyanocobalamin. For pancreatic insufficiency, cobalamin can be given parenterally or pancreatic enzymes can be administered orally. Specific therapy must be designed for patients with intestinal forms of malabsorption.

Because a small amount of cobalamin is absorbed even in the absence of IF and because only 1 μg/day is required, oral cobalamin has proved adequate for replacement in patients with pernicious anemia, freeing the patient from monthly injections (2,000 μg/day p.o. is recommended).[81]

Diagnosis

Clinical manifestations The patient with folic acid deficiency has a clinical presentation that is distinct from that of the patient with cobalamin deficiency.[82] The patient may abuse alcohol or other drugs and have poor dietary intake of folic acid. Patients with folic acid deficiency are more often malnourished than those with cobalamin deficiency. The gastrointestinal symptoms in folic acid deficiency are similar to those in cobalamin deficiency but may be more severe than those in pernicious anemia. Diarrhea is often present. The hematologic manifestations of folic acid deficiency are the same as those of cobalamin deficiency: severe macrocytic anemia, a low absolute reticulocyte count, and a characteristic blood smear showing macro-ovalocytes, occasional megaloblasts, and hypersegmented neutrophils. Patients with megaloblastic anemia who do not have glossitis, a family history of pernicious anemia, or the neurologic features described for cobalamin deficiency may have folic acid deficiency.

Diagnostic workup A meticulous dietary history is important because food faddism, poor dietary intake, and alcoholism are the usual causes of severe folic acid deficiency [*see Table 5*]. Cobalamin and folic acid deficiencies frequently coexist and are not easily distinguished. In evaluating patients for folic acid deficiency, values for the levels of serum folic acid, serum cobalamin, and red blood cell folic acid must be obtained. The red blood cell folic acid level reflects tissue stores[83] but may be reduced in patients with severe cobalamin deficiency. In isolated cases, the serum folic acid level of cobalamin-deficient patients is usually normal or elevated. Severe, long-standing cobalamin deficiency leads to anorexia and GI disturbances, which may cause dietary folic acid deficiency. As a result, both serum cobalamin and folic acid levels are low, producing a double-deficiency state.

A serum folic acid level less than 2 ng/ml is consistent with folic acid deficiency, as is a red blood cell folic acid level less than 150 ng/ml. If the test results are inconclusive or if it is necessary to distinguish the megaloblastosis of folic acid deficiency from that of cobalamin deficiency, measurements of the serum methylmalonate and homocysteine levels are helpful. If both metabolite tests are normal (i.e., methylmalonate level of 70 to 270 nmol/L and total homocysteine level of 5 to 14 μmol/L), deficiency of both vitamins is ruled out. If the methylmalonate level is normal but the total homocysteine level is increased, folic acid deficiency is likely and investigation into the underlying cause is appropriate.[83]

Determining the underlying cause Folic acid deficiency is most frequently caused by poor dietary intake, but it may also result from inadequate absorption secondary to disease or drug administration [*see Table 5*]. Ingestion of ethanol by well-nourished individuals does not produce megaloblastosis, but in patients with borderline folic acid stores, ethanol can lower serum folic acid levels and block the reticulocyte response to folic acid administration. Alcohol may block release of folic acid from tissues to the serum.

Megaloblastic anemia occurring as a consequence of drug administration or pregnancy is likely to be caused by folic acid deficiency. Many of the antineoplastic and immunosuppressive agents produce megaloblastosis; these include fluorouracil, hy-

Table 5 Causes of Folic Acid Deficiency

Mechanism	*Cause*
Absolutely inadequate intake	Alcoholism Nutritional deficiencies
Relatively inadequate intake (resulting from increased folic acid requirements)	Pregnancy Severe hemolysis Chronic hemodialysis or peritoneal dialysis
Inadequate absorption	Tropical sprue Gluten-sensitive enteropathy (nontropical sprue) Crohn disease Lymphoma or amyloidosis of small bowel Diabetic enteropathy Intestinal resections or diversions
Drug-induced interference with folic acid metabolism	Action of dihydrofolate reductase blocked by methotrexate, trimethoprim, pyrimethamine Reduced folate absorption and tissue folate depletion caused by sulfasalazine Interference of unknown mechanism caused by phenytoin, ethanol, antituberculosis drugs, ?oral contraceptives

droxyurea, mercaptopurine, thioguanine, cytarabine, and azathioprine. In pregnant women, the presence of megaloblastosis may not be initially apparent. Because the combination of folic acid and iron deficiency is common, full expression of megaloblastosis is often blocked, and the patient will have a dimorphic anemia rather than the easily identifiable macro-ovalocytosis. Hypersegmentation of PMNs persists.[60,83]

An abnormality in folate metabolism can be caused by a chromosomal mutation, and women who are homozygous for this defect are thought to be at higher risk for pregnancies affected by neural tube defects. One of the enzymes that regulates homocysteine levels, 5,10-methylenetetrahydrofolate reductase has a genetic variant, C677T. Individuals homozygous for this variant have increased plasma homocysteine levels that are lowered by folate supplementation. About 5% to 10% of the general population are homozygous for this variant. Both pregnant and nonpregnant women who are homozygous for the C677T mutation have significantly lower red blood cell folic acid levels.[84] These women may be susceptible to cardiovascular disease and stroke and may bear children with neural tube defects.[84,85] It would be advisable to know before pregnancy that a woman is homozygous for this variant, and genetic testing would be helpful if a woman has a family history of this defect.

A number of intestinal disorders cause folic acid deficiency. These include severe pancreatic disease and small bowel disease, including malabsorption, ileal disease, Crohn disease, resection, and bypass [*see Table 5*]. When there is no apparent cause of cobalamin deficiency, it may be practical to suspect an undiagnosed disease of malabsorption. In one prospective study of patients who had laboratory-defined folate deficiency, 10.9% were positive for celiac disease antibodies and 4.7% had histologically confirmed celiac disease.[86]

Treatment

Standard therapy for folic acid deficiency is 1 mg/day orally. The response, manifested by reticulocytosis in 4 to 6 days, loss of megaloblastosis, and the return of normal blood counts, confirms the diagnosis of folic acid deficiency. Neutrophil hypersegmentation disappears only after 10 to 14 days, however.[60] Patients with megaloblastosis and severe bone marrow depression secondary to administration of drugs that block dihydrofolate reductase, such as pyrimethamine and methotrexate, may be treated with folinic acid. In the case of toxicity after single large doses of methotrexate, a single equivalent dose of I.M. folinic acid (i.e., milligram for milligram) will suffice. For toxicity after chronic pyrimethamine therapy, 1 to 5 mg of folinic acid daily can be given without blocking the antimalarial effects of pyrimethamine. Megaloblastosis caused by anticonvulsant therapy can be treated with 1 mg of folic acid daily. Supplementation during pregnancy is advised and may also be useful for patients who have severe chronic hemolysis.

In most patients (i.e., those who do not require a large amount of folic acid because of conditions such as hemolysis or pregnancy), a hematologic response occurs after administration of 200 μg of folic acid daily. The increased demand of folic acid during pregnancy requires administration of about 200 to 300 μg/day.[87] Furthermore, folic acid supplementation seems to prevent fetal neural tube defects.[88] Such neural tube defects may occur in the embryo or very early in gestation—even before the pregnancy is confirmed.[89,90] Therefore, it is recommended that women of childbearing age or those who plan to become pregnant receive about 400 μg of folic acid a day. Women who are homozygous for the C677T mutation should also take folic acid supplements. Staple foods such as flour and cereal grains can be fortified with folic acid. Concern has been expressed, however, that folic acid supplementation may mask the megaloblastosis of pernicious anemia, causing the development of severe neuropathy rather than anemia.[89]

SIDEROBLASTIC ANEMIAS

Definition

The sideroblastic anemias are a heterogeneous group of disorders characterized by anemia, ringed sideroblasts in the marrow, and ineffective erythropoiesis.[91] There are hereditary and acquired forms; the latter are subdivided into benign and malignant variants. A fairly common form is the myelodysplastic syndrome called refractory anemia with ringed sideroblasts. Other than alcohol and drugs (e.g., isoniazid), the secondary causes of these diseases remain largely unknown.

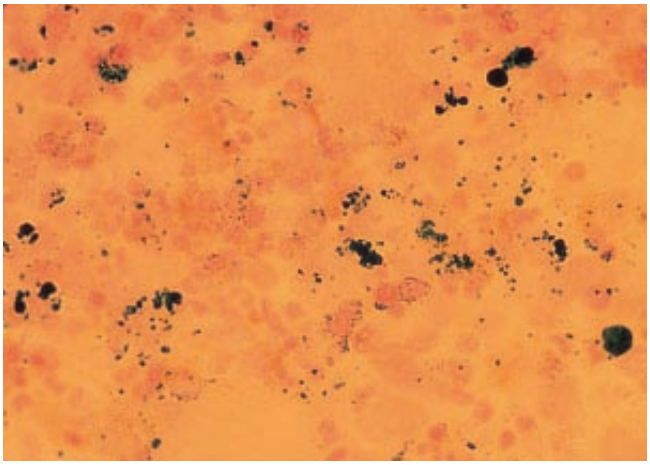

Figure 8 **Prussian blue stain shows ringed sideroblasts in the bone marrow of a patient who has idiopathic sideroblastic anemia.**

Table 6 Sideroblastic Anemias

Type	*Disorders*
Hereditary variant, probably benign	Sex-linked disorders, autosomal disorders
Acquired variant, probably benign	Mitochondrial DNA deletions (Pearson syndrome)
Probably benign variant	Induced by drugs (e.g., isoniazid or other antituberculosis drugs) or by lead intoxication; alcoholic sideroblastosis; pyridoxine-responsive anemia
Clonal disorder (myelodysplastic syndrome)	Refractory anemia with ringed sideroblasts, acquired idiopathic sideroblastic anemia

Pathophysiology

Abnormalities of heme synthesis are probably the most frequent cause of the hereditary sideroblastic anemias. Molecular defects of the enzyme 5-aminolevulinate synthase have been described as the cause of this abnormality.[90,92] This enzyme initiates the heme synthetic pathway, and its impairment profoundly affects heme synthesis. In other cases, there are major deletions in mitochondrial DNA. Iron enters erythroid precursors, but because heme synthesis is impaired, the iron cannot be incorporated into heme and accumulates on the cristae of mitochondria.[90]

Diagnosis

The principal feature common to all sideroblastic anemias is a refractory or progressive anemia. However, mild, lifelong anemia may go unnoticed. The diagnosis of sideroblastic anemia is established by reticulocytopenia; the red blood cells on smear are frequently profoundly hypochromic and microcytic, and distorted red blood cells and basophilic stippling may be noted.[93,94] Occasionally, Pappenheimer bodies (deposits of iron that stain with the Prussian blue reagent) are present in the red blood cells. There are ringed sideroblasts seen on the marrow aspirate (bone marrow normoblasts with heavy incrustations of nonferritin iron on the mitochondria) [*see Figure 8*]. Because of ineffective erythropoiesis, there is saturation of serum iron-binding capacity (usually approaching 80%) and elevation of the serum lactate dehydrogenase level. Cytogenetic study of the bone marrow may reveal one of the typical patterns seen in the myelodysplastic syndromes. The sideroblastic anemias can be classified into four groupings: hereditary (probably benign), acquired (probably benign), probably benign, and clonal disorder [*see Table 6*].

Treatment

For prognostic purposes, it is important to decide whether the patient has a benign or malignant form of sideroblastic anemia. It is also important to recognize reversible forms of sideroblastic anemia (e.g., those caused by alcoholism, folic acid deficiency, and drugs such as isoniazid and chloramphenicol) and to discontinue any potentially offending agents.

Indicators of myelodysplasia include granulocytopenia, thrombocytopenia, dysplastic marrow granulopoiesis, bilobed megakaryocytes, and typical cytogenetic abnormalities. In rare cases, patients have a reticulocyte and hemoglobin response to pyridoxine (200 to 600 mg/day), with or without folic acid.[95]

IV HEMOGLOBINOPATHIES AND HEMOLYTIC ANEMIAS

Stanley L. Schrier, m.d.

Alteration of the erythrocyte membrane usually signals the reticuloendothelial macrophages to remove the damaged red blood cell (RBC) from the circulation. In extraordinary circumstances, however, the damage to the membrane is so great that the erythrocyte undergoes hemolysis, and its intracellular contents, including hemoglobin, are liberated into the plasma. This chapter describes structural and functional features of normal erythrocytes and diseases involving membrane architecture, RBC proteins, and extracorpuscular factors that can lead to shortened RBC survival.

Development, Structure, and Physiology of the Erythrocyte

Erythroid precursor cells undergo four or five cell divisions in the bone marrow and then extrude their nuclei and become reticulocytes. As these enucleate cells mature, hemoglobin synthesis decreases. The cells lose most of their transferrin receptors and enter the peripheral blood; they survive in the circulation for about 4 months.

As they move through the circulation, erythrocytes must withstand severe mechanical and metabolic stresses, deform to traverse capillaries with diameters half their own, resist high shearing forces while moving across the cardiac valves, survive repeated episodes of stasis-induced acidemia and substrate depletion, and avoid removal by the macrophages of the reticuloendothelial system. They must also maintain an internal environment that protects hemoglobin from oxidative attack and sustain the optimum concentration of 2,3-bisphosphoglycerate (2,3-BPG) needed for hemoglobin function.

HEMOGLOBIN

The normal adult RBC contains three forms of hemoglobin (Hb): HbA (96%), HbA_2 (2% to 3%), and HbF (< 2%). Normal HbA ($\alpha_2\beta_2$) is composed of two α chains, coded by four genes on chromosome 16, and two β chains, coded on chromosome 11. HbA_2 is composed of two α chains and two δ chains ($\alpha_2\delta_2$), and fetal hemoglobin (HbF) is composed of two α chains and two γ chains ($\alpha_2\gamma_2$). The genes for the β, δ, and γ chains are closely linked to one another on chromosome 11. The extraordinarily high concentration of hemoglobin in the RBC—33 to 35 g/dl (the mean corpuscular hemoglobin concentration, or MCHC)—produces a viscous solution intracellularly.

NONHEMOGLOBIN CYTOSOL

Erythrocytes principally utilize glucose to maintain the reducing power that protects the cell against oxidative attack, to generate the 2,3-BPG required to modulate the function of hemoglobin, and to control the salt and thus the water content of the RBC by the actions of adenosine triphosphate (ATP) and the transport adenosine triphosphatases (ATPases) [*see Table 1*]. The water and the hemoglobin content of the RBC determine the mean corpuscular volume (MCV) and the MCHC.

PLASMA MEMBRANE

The RBC normally has a discoid shape with a diameter of 7 to 8 μm, an MCV of 85 to 90 femtoliters (fl) (1 fl = 10^{-15} L), and a surface area of 140 μm^2 [*see Figure 1*]. Its unique shape enables it to squeeze through capillaries as narrow as 3 μm in diameter.

Lipids (phospholipids and cholesterol) account for 50% of the weight of the surface membrane. The phospholipids are distributed asymmetrically in the membrane bilayer, with positively charged ones in the outer half and relatively negatively charged ones predominantly in the inner half. This asymmetry permits the selective intercalation of small charged molecules into either the outer or inner half of the bilayer, producing echinocytes or stomatocytes [*see Figure 1*].

The RBC membrane proteins include integral and peripheral proteins. Integral proteins interact with and span the hydrophobic phospholipid bilayer [*see Figure 2*]. The major integral proteins of the erythrocyte membrane are the glycophorins (which contain most of the membrane sialic acid and carry the MNSs blood group antigens) and band 3, which is the anion and bicarbonate transporter.

Table 1 Erythrocyte Metabolism

Pathway	*Product*	*Functions of Metabolic Products*
Glycolysis by Embden-Meyerhof pathway	ATP	Serves as a substrate for all kinase reactions, for the ATPase-linked sodium-potassium pump, for the ATPase-linked calcium efflux pump, and for other ATPases of the RBC membrane, including aminophospholipid translocase Maintains deformable state of RBC membrane
	2,3-DPG	Interacts with deoxyhemoglobin, shifting equilibrium to favor unloading of O_2 from oxyhemoglobin Acts as an intracellular anion that cannot cross the RBC membrane
	NADH	Acts as a substrate for a methemoglobin reductase, enabling it to reduce methemoglobin (Fe^{3+}) to hemoglobin (Fe^{2+})
Pentose phosphate pathway (hexose monophosphate shunt)	NADPH	Serves as a substrate for another methemoglobin reductase in methemoglobin reduction (a fail-safe mechanism) Serves as a coenzyme for glutathione reductase in reduction of oxidized glutathione; reduced glutathione (GSH) protects RBC against oxidative denaturation

ATP—adenosine triphosphate 2,3-DPG—2,3-diphosphoglycerate NADH—reduced nicotinamide-adenine dinucleotide NADPH—reduced nicotinamide-adenine dinucleotide phosphate

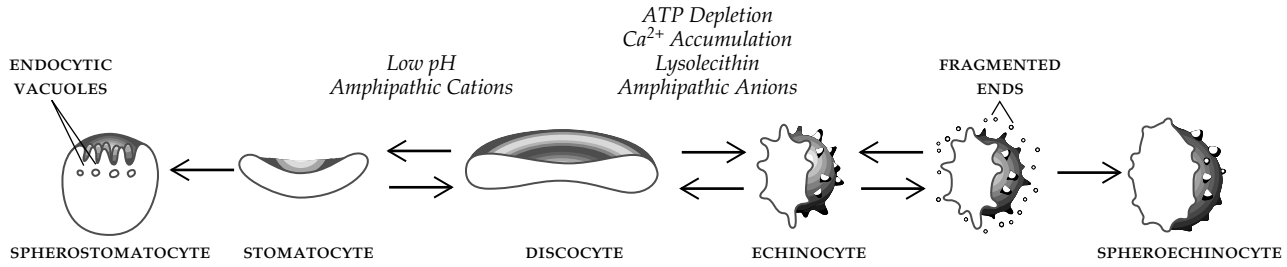

Figure 1 **The normal erythrocyte, or discocyte, undergoes shape changes in response to conditions created by treatment with certain agents. Most changes are reversible if inducing agents are removed before the permanent loss of membrane material.**

The peripheral proteins are all found at the cytosol face of the membrane. The interaction of these peripheral proteins, which include spectrin and actin, results in the tough but resilient cytoskeleton of the erythrocyte. The peripheral cytoskeleton, in turn, is connected to the integral proteins [*see Figure 2*].[1,2]

The membrane carbohydrates contribute to the external negative charge of the membrane and function partly as blood group antigens. Some of these glycolipids associate with phosphatidylinositol to form a glycolipid anchor, called the glycosylphosphatidylinositol (GPI) anchor. These GPI anchors provide the membrane-anchoring site for several classes of proteins that have important biologic functions at membrane surfaces, including several that serve to control complement action [*see* Paroxysmal Nocturnal Hemoglobinuria, *below*].[3]

CONTROL OF HYDRATION AND VOLUME

Control of RBC volume has considerable pathophysiologic importance because the water and cation contents of RBCs determine intracellular viscosity and the ratio of surface area to volume. The Na^+ and K^+ content is determined by passive diffusion and by active transport, primarily through Na^+,K^+-ATPase. The major intracellular anion is Cl^-, which enters the RBC with high permeability through band 3. The K^+-Cl^- cotransporter drives the K^+-Cl^- gradient and is activated by RBC swelling and low intracellular pH, causing a net loss of K^+ and Cl^-. The Ca^{2+}-ATPase actively pumps Ca^{2+} out of the RBC, making the free cytosolic Ca^{2+} content less than 0.1 μM—four orders of magnitude lower than the plasma concentration of 1 mM. The Gardos channel, which is a Ca^{2+}-activated K^+ efflux channel, plays an important role in volume regulation. Water enters and exits through a water channel called CHIP 28 (28 kd channel-forming integral membrane protein) or aquaporin. Other important intracellular anions are 2,3-BPG and hemoglobin, neither of which penetrates the cell membrane. When the concentration of free cytosolic Ca^{2+} rises to levels even as low as 0.3 μM, the channel is activated and results in a net loss of K^+. If such a loss is not corrected, the affected RBC becomes dehydrated.[4]

SHAPE CHANGES

ATP depletion, calcium ion accumulation, or treatment with lysolecithin or with anionic amphipathic compounds transforms the normal erythrocyte, or discocyte, into an echinocyte—a crenated spiculated cell sometimes called a burr cell [*see Figure 1*]. Calcium, acting either alone or in concert with the calcium-binding protein calmodulin, can effect the echinocytic shape change. If the echinocytic process persists, fragmentation or budding of the tips of the echinocyte leads to loss of membrane components, particularly of band 3 and phospholipids. This results in loss of surface area, a reduction in the ratio of surface area to volume, and the formation of poorly deformable spheroechinocytes.

PRINCIPLES OF BLOOD FLOW

The major determinants of blood flow are the hematocrit; the plasma concentration of proteins such as fibrinogen and immunoglobulins, which influence the degree of rouleau formation or aggregation; RBC deformability; the caliber of blood vessels; and the shear rate (the ratio of flow rate to tube radius). At the low shear rates that exist in postcapillary venules, the RBCs tend to clump in asymmetrical masses, with a consequent increase in blood viscosity and resistance to flow.

CELL AGING AND DEATH

In the bone marrow, the developing reticulocyte progressively loses its residual RNA over a 4-day period after nuclear extrusion. At the conclusion of this stage, the reticulocyte can no longer engage in protein synthesis. The active K^+-Cl^- cotransporter functions to reduce cell volume. With the membrane protein assembly complete, the resulting mature cell enters the circulation and survives for a period of 100 to 120 days.[5] Erythrocyte death is an age-dependent phenomenon and may be related to mechanical and chemical stresses the cell encounters in the circulation. As the erythrocyte ages, it loses water and its surface area diminishes. The ratio of surface area to volume decreases and the mean corpuscular hemoglobin concentration increases, impairing cell deformability. In addition, decreased enzymatic activity lowers the cell's ability to withstand metabolic stress. Aging may be manifested by changes at the erythrocyte's surface, such as a decrease in the density or type of surface charge or the appearance of a senescence neoantigen, perhaps oxidatively clustered band 3 [*see Figure 2*], that binds specific immunoglobulins and complement components.[6] By such changes, the age-worn erythrocyte signals its incapacity to the reticuloendothelial system, triggering removal by macrophages.

Under physiologic conditions, slightly less than 1% of the RBCs are destroyed each day and are replaced by a virtually identical number of new cells. For a 70 kg (154 lb) man with a blood volume of about 5 L, about 50 ml of whole blood, containing approximately 22 ml of packed erythrocytes, is destroyed and replaced each day. Inasmuch as one third of each erythrocyte is hemoglobin, the replacement of these cells requires the synthesis of about 7 g of hemoglobin each day. Normal adult bone marrow can readily increase its erythroid output fivefold. After extensive and prolonged anemic stress, erythroid production can be raised by as much as seven or eight times. The supply of iron, however, places an important limit on RBC replacement: three fourths of the iron used in the synthesis of cells in a day comes from cells that were destroyed on the previous day.

General Features of Hemolytic Anemias

The severity of anemia is determined both by the rate of RBC destruction and by the marrow's capacity to increase erythroid production. When a person has a healthy marrow, erythrocyte survival time can be reduced from 120 days to 20 days without inducing anemia or jaundice; however, a substantial reticulocytosis will be present in such cases.

Most forms of hemolysis are extravascular; the damaged cell signals its changed status to the reticuloendothelial system via its membrane and is removed. In unusual circumstances in which damage to the erythrocyte is devastating—as in some forms of complement-mediated lysis—or in circumstances in which the reticuloendothelial system cannot cope with the burden of damaged cells, intravascular lysis develops and leads to hemoglobinemia.

Hemoglobin released to the plasma is degraded to αβ dimers, which bind to haptoglobin. The hemoglobin-haptoglobin complexes are removed by the reticuloendothelial system. When the haptoglobin-binding capacity is exceeded, αβ dimers pass into the glomerular filtrate. Some of the αβ dimers are excreted into the urine directly, producing hemoglobinuria, whereas others are taken up by renal tubule cells. Iron-containing renal tubule cells may be excreted for several days after an episode of intravascular hemolysis. Hemosiderinuria can be identified with Prussian blue stain. Free plasma hemoglobin can dissociate into globin and hemin. Hemin may bind to hemopexin and may reach the renal tubule cells in that form, or it may bind to plasma albumin, producing methemalbuminemia.

Intravascular hemolysis may produce severe anemia acutely. In addition, erythrocytic membrane particles released into the plasma may act as potent stimuli for disseminated intravascular coagulation. Acute severe hemolysis is also a cause of acute renal failure [*see 10:VI Acute Renal Failure*]. When a patient compensating for a marked increase in hemolysis has an infection that sharply impairs marrow erythroid activity,[7] the hemoglobin level may fall dramatically—a condition called aplastic crisis. With chronic hemolysis, pigment stones often develop in the gallbladder.

Causes of hemolysis may be classified as either extracorpuscular or intracorpuscular. The intracorpuscular causes, which are essentially erythrocyte defects, comprise membrane abnormalities, metabolic disturbances, and disorders of hemoglobin structure or biosynthesis. Extracorpuscular causes represent abnormal elements within the vascular bed that attack and destroy normal erythrocytes. Because erythrocytes with intracorpuscular defects that cause hemolysis are intrinsically abnormal, when they are transfused into normal recipients, their survival time is characteristically short. Of the intracorpuscular defects, only one disorder, paroxysmal nocturnal hemoglobinuria, is not hereditary.

Erythrocyte Membrane Defects

DISORDERS OF SALT AND WATER METABOLISM

Hydrocytosis (Hereditary Stomatocytosis)

Hydrocytosis is a hereditary disorder that usually presents early in life as partly compensated hemolytic anemia; occasionally, the spleen is palpable. The MCV is usually elevated. The peripheral smear shows stomatocytes [*see Figure 3*]. Passive flux of both Na^+ and K^+ increases greatly. The Na^+,K^+-ATPase is overwhelmed; the cation concentration and thus the water content of the RBC increase, accounting for the increase in MCV and the decrease in the ratio of surface area to volume. Stomatocytes appear to adhere more avidly than normal RBCs, a finding that may account for the reported increase in thromboembolic events.[8] Perhaps more importantly, the number of RBCs with phosphatidylserine exposed on the outer membrane surface is increased. Phosphatidylserine—a relatively negatively charged

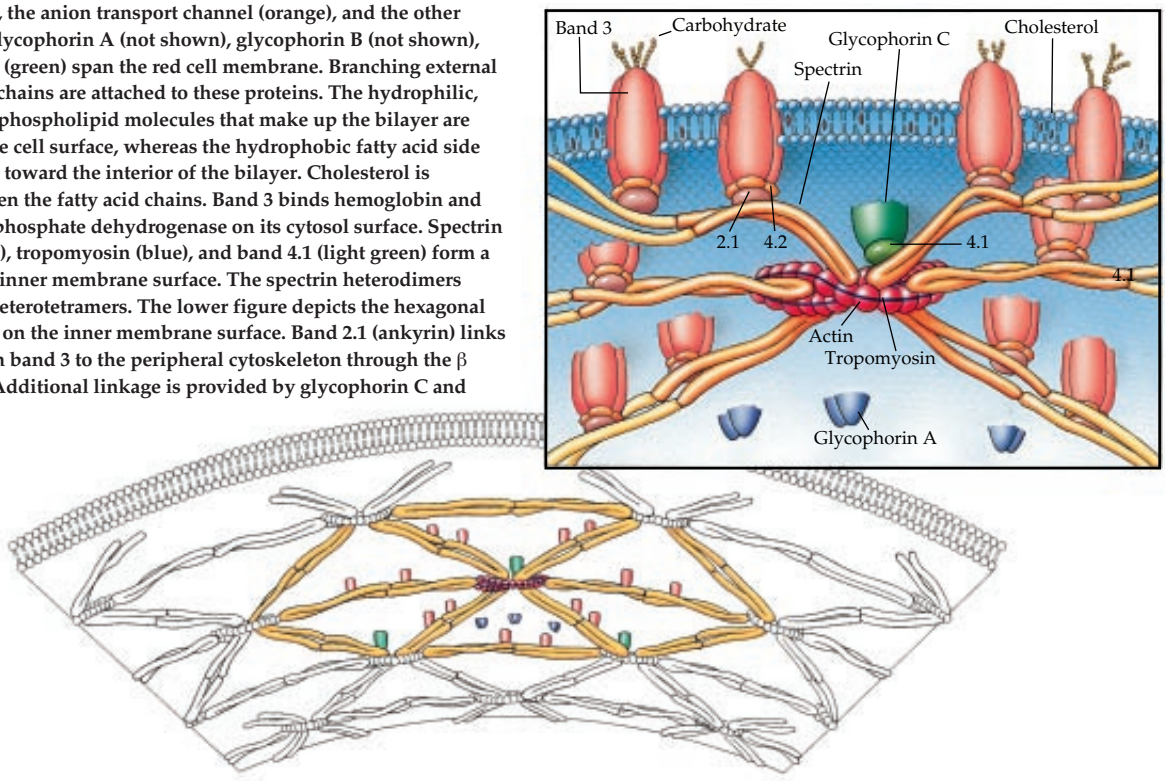

Figure 2 **Band 3, the anion transport channel (orange), and the other integral proteins glycophorin A (not shown), glycophorin B (not shown), and glycophorin C (green) span the red cell membrane. Branching external carbohydrate side chains are attached to these proteins. The hydrophilic, polar heads of the phospholipid molecules that make up the bilayer are oriented toward the cell surface, whereas the hydrophobic fatty acid side chains are directed toward the interior of the bilayer. Cholesterol is intercalated between the fatty acid chains. Band 3 binds hemoglobin and glyceraldehyde-3-phosphate dehydrogenase on its cytosol surface. Spectrin (yellow), actin (red), tropomyosin (blue), and band 4.1 (light green) form a latticework on the inner membrane surface. The spectrin heterodimers associate to form heterotetramers. The lower figure depicts the hexagonal cytoskeletal lattice on the inner membrane surface. Band 2.1 (ankyrin) links the integral protein band 3 to the peripheral cytoskeleton through the β chain of spectrin. Additional linkage is provided by glycophorin C and band 4.1.**

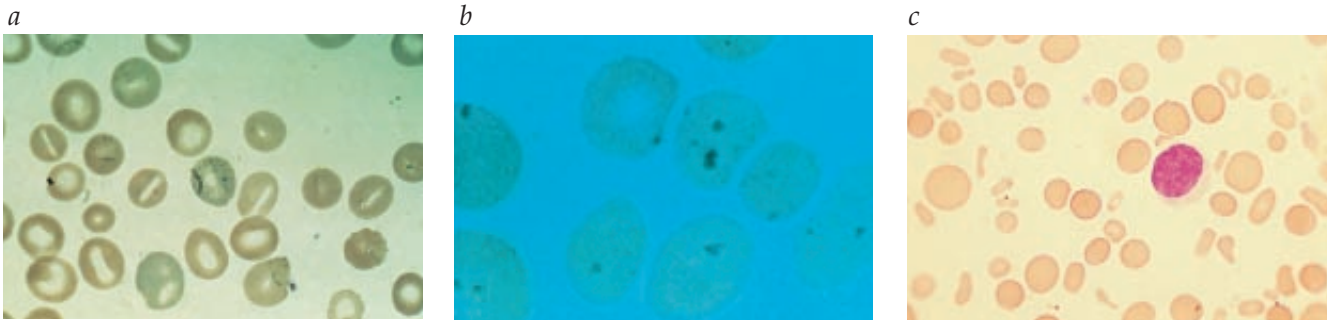

Figure 3 **Stomatocytes are identified by slitlike areas of central pallor (*a*); the smear also shows microspherocytes, which are a more advanced stage of stomatocytosis. On scanning electron microscopy or examination of wet preparations, the microspherocytes are shown to be stomatocytes. Microspherocytes are seen in hereditary spherocytosis and in autoimmune hemolytic anemia, as well as in other conditions characterized by relatively selective loss of membrane material or increase in cell volume. Supravital stain of erythrocytes (*b*) shows single and multiple blue-staining Heinz bodies within counterstained erythrocytes. Phase microscopy can also be used to demonstrate Heinz bodies. Elliptocytes are visualized in a smear from a patient with hereditary elliptocytosis (*c*).**

phospholipid that is normally found predominantly in the inner membrane layer—provides a nidus for thrombin formation and thus may also contribute to the tendency to thrombosis.[9] Splenectomy may lead to improvement in the anemia. Other therapies may eventually prove useful; vaso-occlusive events were controlled in one patient by long-term RBC transfusion and in another by therapy with pentoxifylline.[8]

Xerocytosis

Xerocytosis, another hereditary hemolytic disorder, is characterized by a membrane defect that leads to loss of cations, particularly K^+. Dehydration of erythrocytes occurs because the K^+ leak exceeds the Na^+ influx, possibly as a result of an overactive K^+-Cl^- cotransporter. Patients present with variably compensated hemolysis. Splenomegaly is not a prominent feature. The peripheral smear is variable, showing target cells, stomatocytes, echinocytes, or so-called hemoglobin puddling (i.e., hemoglobin collected around the circumference of the cell). MCHC is increased. Because these rigid cells are removed in many parts of the reticuloendothelial system, splenectomy is of little benefit.[10] In rare instances, xerocytosis can cause nonimmune hydrops fetalis.[11]

PROTEIN ABNORMALITIES

Hereditary Elliptocytosis

There are perhaps 250 to 500 cases of hereditary elliptocytosis per million population.[10] Three morphologic variants are seen: (1) common hereditary elliptocytosis, (2) spherocytic hereditary elliptocytosis, and (3) stomatocytic hereditary elliptocytosis.[12] Most patients with common hereditary elliptocytosis are heterozygous for this autosomal dominant disorder and have only elliptical RBCs or, at worst, compensated hemolysis. Homozygotes for the disorder may have severe uncompensated hemolytic anemia.

Under applied shear stress, erythrocytes assume an elliptical shape; when the stress is removed, the cell normally recoils to its discoid shape. It has been hypothesized that membrane defects in hereditary elliptocytosis interfere with normal recoil. The membrane defect appears to be a lesion in the membrane cytoskeleton; RBC membranes from patients with hereditary elliptocytosis are almost invariably mechanically fragile.

The diagnosis is made in patients with extravascular intracorpuscular hemolysis who have elliptocytes on the peripheral smear. Elliptocytosis can also be seen in severe iron deficiency, myeloproliferative and myelodysplastic disorders, and, occasionally, cobalamin and folate deficiencies.[12] Results of the osmotic fragility test are usually normal. Splenectomy has been useful in patients with severe common hereditary elliptocytosis.

Hereditary Propoikilocytosis

The syndrome of hereditary (autosomal recessive) pyropoikilocytosis, a variant of hereditary elliptocytosis, causes severe hemolysis in young children. It is caused by an abnormal α or β spectrin mutation. The blood smear shows extreme microcytosis and extraordinary variation in the size and shape of erythrocytes [*see Figure 3*]. Splenectomy may reduce the rate of hemolysis.

Hereditary Spherocytosis

Hereditary spherocytosis is usually inherited as an autosomal dominant trait and affects about 220 per million people worldwide. A rare autosomal recessive variant of hereditary spherocytosis has been described.

Because of a loss of surface membrane, RBCs assume a microspherocytic shape and thus cannot deform sufficiently to pass through the splenic vasculature; splenic trapping of RBCs, hemolysis, and a compensatory increase in RBC production result. The underlying membrane defects lead to budding of membrane vesicles under conditions of metabolic depletion. These membrane vesicles are enriched in phospholipids from the bilayer, as well as in associated transmembrane proteins [*see Figure 2*]. The underlying molecular lesions appear to consist of deficiencies of spectrin, spectrin-ankyrin, band 3, and band 4.2 (palladin).[12,13]

About 25% of patients with hereditary spherocytosis have completely compensated hemolysis without anemia; their disorder is diagnosed only when a concomitant condition, such as infection or pregnancy, increases the rate of hemolysis or reduces the marrow's compensatory capacity. In other patients, mild anemia, pigmented gallstones, leg ulcers, and splenic rupture may develop. Aplastic crises may be precipitated by ordinary respiratory tract infections, especially by parvovirus infection.[7] It is important to remember that this disease can become apparent during the first year of life, when increased splenic maturation resulting in RBC removal combined with a sluggish erythropoietic response can result in anemia severe enough to require RBC transfusion.[14]

This diagnosis is suggested by a predominance of microspherocytes on the peripheral smear [*see Figure 3b*], an MCHC of 35 g/dl or greater, reticulocytosis, mild jaundice, splenomegaly,

and a positive family history, although at least half of newly diagnosed patients have no family history. Confirmation of the diagnosis is made by a 24-hour incubated osmotic fragility test. A negative Coombs test and a family history positive for hereditary spherocytosis rule against a diagnosis of acquired autoimmune hemolytic anemia. Splenectomy eradicates clinical manifestations of the disorder, including aplastic crises.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria (PNH) is a somatic clonal disorder of hematopoietic stem cells. PNH involves the *PIG-A* gene, which maps to the short arm of the X chromosome.[15] The mutation results in a deficiency of the membrane-anchoring protein phosphatidylinositol glycan class A; the resulting mature hematopoietic cells are usually chimeric. Normal human erythrocytes, and probably platelets and neutrophils, modulate complement attack by at least three GPI membrane-bound proteins: DAF (CD55), C8-binding protein (C8BP), and MIRL (CD59). In the absence of the GPI anchor, all of the proteins that use this membrane anchor will be variably deficient in the blood cells of persons with PNH.[16] Because the defective synthesis of GPI affects all hematopoietic cells, patients with PNH may have variable degrees of anemia, neutropenia, or thrombocytopenia, or they may have complete bone marrow failure.[17]

Diagnosis

Classically, acute episodes of intravascular hemolysis are superimposed on a background of chronic hemolysis. The patient typically notes hemoglobinuria on voiding after sleep.[18,19] Recurrent venous occlusions lead to pulmonary embolism and hepatic and mesenteric vein thrombosis, possibly resulting from release of procoagulant microparticles derived from platelets.[20] A literature review found that thrombotic events accounted for 22% of deaths in patients with PNH.[21] Occasionally, PNH patients with thrombosis are mistakenly thought to have psychosomatic disorders because they complain of recurrent severe pain in the abdomen and back that has no obvious cause. In these cases, the associated anemia and hemolysis may be very mild, and episodes of hemolysis do not necessarily correlate with bouts of pain.

A diagnosis of PNH should be considered in any patient with chronic or episodic hemolysis. The diagnosis should also be considered for patients with recurrent venous thromboembolism, particularly if the thrombus occurs in a site such as the inferior vena cava or the portal mesenteric system or if it produces Budd-Chiari syndrome. Evidence of intravascular hemolysis, such as hemoglobinemia; reduced serum haptoglobin; increased serum methemalbumin; hemoglobinuria; or hemosiderinuria, suggests the diagnosis. The combination of marrow hypoplasia and hemolysis is an important clue. PNH may occur in association with aplastic anemia. Erythrocyte morphology is usually normal. Diagnosis is made by specific tests based on fluorescence-activated cell sorter analysis using antibodies that quantitatively assess DAF (CD55) and particularly MIRL (CD59) on the erythrocyte or on the leukocyte surface.[22]

Treatment

In PNH, the anemia is occasionally so severe (hemoglobin level < 8 g/dl) that the patient needs transfusions regularly[19]; therefore, the choice of transfusion component is critical. It is believed that infusion of blood products containing complement may enhance hemolysis. Infusion of donor white blood cells (WBCs), which are ordinarily present in a unit of packed RBCs, into an HLA-immunized recipient may provide the antigen-antibody reaction that activates complement by the classical pathway. In such a case, the use of special leukocyte-poor units may be helpful [*see 5:X Transfusion Therapy*].

A trial of prednisone (e.g., 60 mg a day with rapid tapering, or 20 to 60 mg every other day) may reduce transfusion requirements and may be helpful in alleviating the anemia. Splenectomy is of very questionable benefit. Surgery is risky in patients with PNH because stasis and trauma accentuate hemolysis and venous occlusion. If surgery is to be performed, prophylactic anticoagulation with warfarin in the perioperative period should be considered.

Patients with PNH are frequently iron deficient. The simple administration of iron to correct this defect, however, often aggravates hemolysis because iron therapy produces a cohort of new cells, many of which are susceptible to complement-mediated lysis. Transfusion before iron therapy may help circumvent this problem because it will decrease the erythropoietic stimulus to the marrow.

Thrombocytopenia resulting from poor platelet production may necessitate platelet transfusions [*see 5:X Transfusion Therapy*].[18] Budd-Chiari syndrome and inferior vena cava thrombosis must be diagnosed and treated quickly with heparin, followed by long-term administration of warfarin. If heparinization is ineffective, thrombolytic therapy (e.g., streptokinase) may be used.[23] Children and adolescents with PNH that is complicated by aplastic anemia should be considered for allogeneic bone marrow transplantation.[19,24] In case reports, the anemia associated with PNH responded to erythropoietin,[25] and four patients with severe neutropenia and thrombocytopenia responded to combinations of granulocyte–colony-stimulating factor (G-CSF) and cyclosporine.[26]

Prognosis

A study of 80 patients with PNH indicated that median survival was 10 years.[18] The causes of PNH-related death were thrombocytopenia, PNH hemolysis, thromboses, or PNH-associated aplastic anemia [*see 5:III Anemia: Production Defects*]. Of interest is that 15% of patients experienced spontaneous remission.[18] In rare instances, prolonged and severe iron loss may occur as a result of chronic hemosiderinuria, producing iron deficiency; some patients develop transfusion-associated hemochromatosis.[19]

Acute myeloid leukemia may develop during the course of PNH. In one series, this occurred in three of 80 patients; in another series, of 220 patients, the incidence of myelodysplastic syndromes was 5% and the incidence of acute leukemia was 1%.[19]

Abnormalities of Erythrocyte Metabolism

DEFECTIVE REDUCING POWER

The reducing power of the erythrocyte is provided by reduced glutathione (GSH) and the reduced coenzymes nicotinamide adenine dinucleotide (NADH) and nicotinamide-adenine dinucleotide phosphate (NADPH) [*see Table 1*]. When erythrocytic stores of these materials are inadequate, hemoglobin and membrane-associated proteins can be oxidized, leading to the production of Heinz bodies, which consist predominantly of oxidative degradation products of hemoglobin [*see Figure 3b*]. Erythrocytes containing Heinz bodies are rigid and are therefore selectively removed by the reticuloendothelial system.

Defective Glutathione Synthesis

Deficiencies of certain enzymes involved in GSH synthesis lead to oxidative attacks on erythrocytes and to hemolysis. Several reports have described families whose members show almost negligible GSH synthesis and have hemolysis associated with the production of Heinz bodies. Glutathione peroxidase deficiency apparently contributes to hemolysis in newborn infants.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Glucose-6-phosphate dehydrogenase (G6PD) is the first enzyme in the pentose phosphate pathway, or hexose monophosphate shunt. It catalyzes the conversion of $NADP^+$ to NADPH, a powerful reducing agent. NADPH is a cofactor for glutathione reductase and thus plays a role in protecting the cell against oxidative attack. RBCs deficient in G6PD are therefore susceptible to oxidation and hemolysis.[27,28]

G6PD deficiency is one of the most common disorders in the world; approximately 10% of male blacks in the United States are affected, as are large numbers of black Africans and some inhabitants of the Mediterranean littoral. This disorder confers some selective advantage against endemic malaria. For example, in a study in Ghana on pregnant women (who are highly susceptible to falciparum malaria and its consequences), the prevalence of infection was 66% in normal women, 58% in G6PD heterozygotes, and 50% in homozygotes.[29]

The gene for G6PD is on the X chromosome at band q28; males carry only one gene for this enzyme, so those males that are affected by the disorder are hemizygous. Females are affected much less frequently because they would have to carry two defective G6PD genes to show clinical disease of the same severity as that in males. However, expression of a defective G6PD gene is not completely masked in heterozygous women; in fact, such women exhibit highly variable G6PD enzyme activity. According to the X-inactivation, or Lyon-Beutler, hypothesis,[28] females heterozygous for G6PD have two cell lines: one that contains an active X chromosome with a gene for normal G6PD and another that contains an active X chromosome with a gene for deficient G6PD. Chance partly determines the relative proportions of the two cell lines, which in turn control the clinical severity of the defect.

Classification

There are three clinical classes of G6PD deficiency: class I, which is the uncommon chronic congenital nonspherocytic hemolytic anemia; class II, in which the enzyme deficiency is severe but hemolysis tends to be episodic; and class III, the most common variant, in which the enzyme deficiency is moderate and hemolysis is caused by oxidant attack. The severity of the hemolysis and the anemia is directly related to the magnitude of the enzyme deficiency, which is determined by the half-life of the enzyme. The normal G6PD half-life is 62 days; in class III G6PD deficiency, the enzyme has a half-life of 13 days; and in class II deficiency, G6PD has a half-life of several hours. The cloning and sequencing of the G6PD gene have clarified the classification of G6PD deficiency; before the sequencing of the G6PD gene, more than 300 variants of G6PD deficiency had been described.[28]

Etiology

Hemolysis occurs in persons with class III G6PD deficiency after exposure to a drug or substance that produces an oxidant stress. Ingestion of, or exposure to, fava beans may cause a devastating intravascular hemolysis (known as favism) in G6PD-deficient patients, but it usually occurs only in those with the Mediterranean variant of class II deficiency. Fava beans contain isouramil and divicine, two strong reducing agents whose actions eventuate in the oxidation of membrane proteins. This produces a rigid cell in which hemoglobin is confined to one part of the cytosol; the other part of the cytosol appears as a clear ghost (i.e., the classic bite, hemiblister, or cross-bonded cell) [*see Figure 4*]. These membrane defects cause extravascular and intravascular hemolysis.[27] Severe infections, diabetic ketoacidosis, and renal failure also reportedly trigger hemolysis.

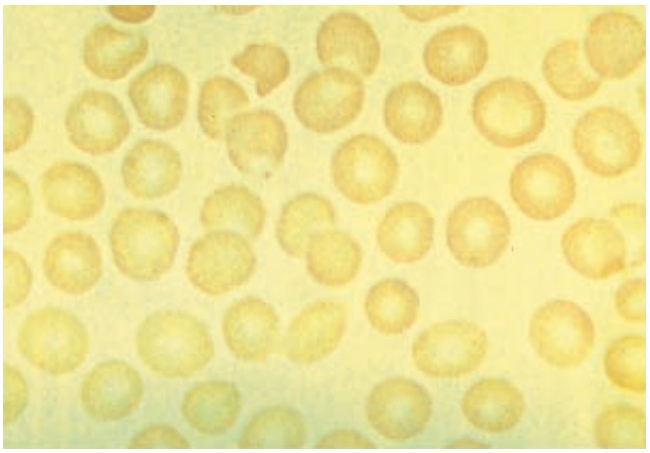

Figure 4 **Bite, hemiblister, or cross-bonded cells are indicative of oxidative attack leading to oxidative hemolysis.**

Diagnosis

Hemolytic anemia characterized by the appearance of bite cells and Heinz bodies after administration of certain drugs suggests the possibility of G6PD deficiency [*see Table 2*]. Dapsone, which is capable of inducing oxidant-type hemolysis, has increasingly come into use as prophylaxis for *Pneumocystis carinii* pneumonia in patients infected with HIV [*see 7:XXXIII HIV and AIDS*]. Therefore, it is important to screen potential users of dapsone for G6PD deficiency with the standard enzymatic tests. Other agents with oxidative potential, such as amyl nitrite ("poppers"), can cause hemolysis.[30]

Other disorders to be considered in the differential diagnosis of oxidative hemolysis include unstable hemoglobinopathy, he-

Table 2 Drugs That Produce Hemolysis in G6PD-Deficient Patients

Class	*Example*
Antimalarials	Primaquine Chloroquine
Sulfonamides	Sulfamethoxazole Sulfapyridine
Sulfones	Dapsone
Analgesics	Acetanilid Phenacetin Acetylsalicylic acid (10 g/day)
Nitrofurans	Nitrofurantoin Furazolidone
Water-soluble vitamin K derivatives	Menadiol

moglobin M disease, and deficiencies of other enzymes essential to glutathione metabolism. A G6PD screening test or direct enzyme assay usually resolves the question. Patients with A-type G6PD (class III) deficiency and brisk reticulocytosis, however, may have a near-normal G6PD level because young RBCs have relatively high G6PD levels. In such cases, it is best to repeat the tests when the reticulocyte count returns to normal. Information on genetic testing for G6PD deficiency can be found on the Internet at http://www.geneclinics.org.

Treatment

Avoidance of drugs that may produce hemolysis is critical in management. Acute favism requires circulatory support, maintenance of good renal blood flow, and transfusions with erythrocytes that are not G6PD deficient. The physician must also be alert to the possible onset of disseminated intravascular coagulation.

DEFECTS IN GLYCOLYSIS

The series of reactions constituting the glycolytic pathway generates several products, such as ATP, that have various essential functions in erythrocyte metabolism [*see Table 1*]. Defects involve the major glycolytic pathway (Embden-Meyerhof pathway) and generally interfere with ATP production.

Pyruvate kinase (PK) catalyzes the formation of pyruvate, a reaction associated with ATP synthesis. After G6PD deficiency, PK deficiency (autosomal recessive) is the second most common hereditary enzymopathy. Hemolysis, mild jaundice, and, occasionally, palpable splenomegaly are the presenting problems. The peripheral smear usually reveals normal RBCs, but in a few cases, the RBCs show extreme spiculation. Aplastic crises may occur.[7]

Congenital nonspherocytic hemolysis raises the possibility of PK deficiency. An enzyme assay establishes the diagnosis. Splenectomy should be considered for patients who require transfusions.

Glucose-6-phosphate isomerase deficiency is the third most common enzymopathy that leads to hemolysis. Other enzymopathies are quite rare. Screening tests and specific assays are available for deficiencies of such enzymes as hexokinase, phosphofructokinase, triose phosphate isomerase, phosphoglycerate kinase, and aldolase.

DEFECTS IN NUCLEOTIDE METABOLISM

In hemolytic anemia associated with pyrimidine 5′-nucleotidase deficiency, coarse basophilic stippling persists in mature erythrocytes, presumably because the enzyme deficiency prevents degradation of reticulocyte RNA. This accumulation results in expansion of the total RBC nucleotide pool to a level five times normal. Pyrimidine nucleotides accumulate, and adenine nucleotides are decreased. Glycolysis is impaired by an undetermined mechanism.

Disorders Involving Hemoglobin

CLASSIFICATION OF THE HEMOGLOBINOPATHIES

The clinically important hemoglobinopathies are classified into five categories on the basis of the underlying defect. The defects are as follows:

1. Hemoglobin tends to gel or crystallize (e.g., sickle cell anemia or hemoglobin C disease).
2. Hemoglobin is unstable (e.g., the congenital Heinz body anemias).
3. Hemoglobin has abnormal oxygen-binding properties (e.g., the disorder caused by hemoglobin Chesapeake).
4. Hemoglobin is readily oxidized to methemoglobin (e.g., methemoglobinemia).
5. Hemoglobin chains are synthesized at unequal rates (e.g., the thalassemias).

SICKLE CELL DISEASE

Sickle Cell Anemia

Definition Sickle cell anemia is an autosomal recessive disease caused by the substitution of the amino acid valine for glutamine at the sixth position of the β-hemoglobin chain, which results in the production of HbS.

Epidemiology From 8% to 10% of African Americans and a lesser percentage of persons with eastern Mediterranean, Indian, or Saudi Arabian ancestry have the sickle (HbS) gene. Disease develops in persons who are homozygous for the sickle gene (*HbSS*), in whom 70% to 98% of hemoglobin is of the S type. About 0.2% of African Americans have sickle cell anemia. The fact that the sickle gene occurs in populations living in regions endemic for falciparum malaria suggests that sickle heterozygosity confers a protective advantage against malaria.[31]

Restriction endonuclease analyses indicate that the sickle gene mutation probably arose spontaneously in at least five geographic locations. These variations are called Senegal, Benin, Central African Republic (or Bantu), Saudi-Asian, Cameroon, and Indian (which may be the same as the Saudi-Asian variant). These variants are important clinically because some variants are associated with higher output of γ-globin chains (and thus higher HbF levels); others are associated more often with the gene for α-thalassemia-2 [*see* The Thalassemias, *below*]. Either of these associations may alleviate some aspects of the sickling process.[31]

Pathophysiology Two major clinical features characterize sickle cell anemia: (1) chronic hemolysis and (2) acute, episodic vaso-occlusive crises that cause organ failure and account for most of the morbidity and mortality associated with the disease.

HbS liganded to oxygen or carbon monoxide shows near-normal solubility. When the molecule gives up its oxygen and changes to the deoxy S form, however, its solubility decreases. In an environment with reduced oxygen, HbS polymerizes into long tubelike fibers that induce erythrocytic sickling.[32]

The deoxyhemoglobin S polymer is in equilibrium with surrounding soluble molecules of deoxyhemoglobin S. An increase in the concentration of HbS, a decrease in pH, or an increase in the concentration of 2,3-BPG tends to stabilize the deoxy S form and enhances gelation.[32] In addition, sickled erythrocytes retain the K^+-Cl^- cotransport function and have sufficient intracellular calcium to activate the Gardos efflux channel[33] [*see* Control of Hydration and Volume, *above*]. These two mechanisms act together to produce a population of very dense sickled erythrocytes with MCHCs ranging up to 50 g/dl.[33] HbF inhibits polymerization,[33] so patients with high HbF values, such as those with the Saudi-Asian variant of sickle cell anemia, have milder disease.[31] When hypoxemia and the MCHC reach a critical level, polymerization occurs after a variable delay[33]; this delay represents the pe-

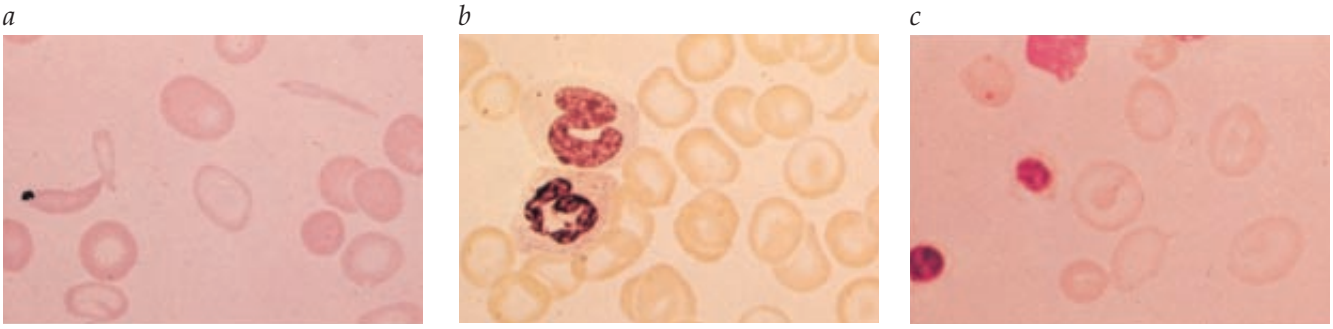

Figure 5 **Sickle cell anemia is characterized by markedly distorted sickle cells, including elongated forms (*a*). Target cells (*b*) are seen in a variety of conditions, including hypochromia caused by iron deficiency, hemoglobinopathies such as HbC variants and the thalassemias, and liver disease. Cooley anemia (*c*), or β-thalassemia major, is indicated by profound hypochromia, targeting, variation in size and shape of erythrocytes, and the presence of nucleated red cells.**

riod during which the deoxyhemoglobin S tetramers are slowly associating to form a nucleus. When the nucleus reaches a critical size, rapid, almost explosive gelation occurs. Free deoxyhemoglobin S tetramers rapidly attach to the nucleus to produce the long tubelike fibers that align to form parallel tubelike structures that distort the cell and produce the sickle shape [*see Figure 5*].

Most cells in the venous circulation are not sickled. However, sickling will occur if the time to polymerization is shortened to less than 1 second or if RBCs become trapped in the microcirculation. Some RBCs contain polymerized sickle hemoglobin even in the arterial circulation. Another manifestation of membrane damage in sickle cells is the irreversibly sickled cell, which retains its sickle shape even when reoxygenated.[34] Some of these poorly deformable RBCs are directly derived from a subpopulation of reticulocytes that are low in HbF[30] and are removed predominantly in the reticuloendothelial system. The rapid removal of these young cells, as well as older, dense, rigid cells that cannot traverse the monocyte-macrophage system, results in chronic extravascular hemolysis.

Because of the extreme sensitivity of sickling to the local environment, attention has been focused on cellular factors. The extreme hyperosmolality of the renal medulla (1,200 mOsm) dehydrates RBCs and raises the MCHC. Consequently, sickling sufficient to abolish the renal medullary concentrating ability may occur even in patients who have only the sickle trait.

Sickle Crisis and Ischemic Infarction

Sickle crisis is a potentially life-threatening vaso-occlusive complication of sickle disease. The initiating event in the sickle crisis is not known, nor is it clear why some patients have severe crises and others do not.

Clusters of increasingly rigid sickle cells will occlude the microvasculature in the followng circumstances: (1) the pH falls, deoxygenation increases, or the MCHC rises; (2) nitric oxide production decreases or nitric oxide is trapped and removed by free hemoglobin in plasma[35]; (3) microvascular disease is present; or (4) capillary transit time is prolonged. Thrombosis may also play a role in sickle occlusion. There is some disorganization of the membrane phospholipid bilayer, with phosphatidylserine moving to the outer leaflet, possibly enhancing the thromboembolic manifestations of sickle disease.[36] In sickle cell anemia, there also appears to be an increase in circulating endothelial cells, which abnormally express tissue factor and may provide an additional basis for thromboembolism.[37]

Blockage leads to ischemic infarction, the release of inflammatory cytokines, and an amplifying sequence of stasis-induced occlusion, which may progress to sickle crisis. Portal circulations in which oxygen tension is low, such as those in the liver or the kidney, are at particular risk for occlusion.

Risk factors predisposing to painful crises include a hemoglobin level greater than 8.5 g/dl, pregnancy, cold weather, and a high reticulocyte count. Nocturnal hypoxemia is an important risk factor in children.[38] Conversely, the low hematocrit in sickle cell anemia reduces blood viscosity and is protective. Sickle cell patients also characteristically have a high plasma fibrinogen level, which enhances the aggregation of already rigid erythrocytes and increases viscosity, particularly at the low shear rates encountered in the microcirculation.[39] Sickled RBCs also have a greater tendency to adhere to endothelial cells than do normal RBCs.[40] The role of leukocytes in this adhesion process is becoming clearer. Adminstration of G-CSF has led to sickle crises and even death.[41,42] Granulocyte-macrophage CSF (GM-CSF) has caused similar crises. The severity of sickle disease appears to parallel the level of the WBC count, and WBC cell-adhesion molecules seem to be critical to sickle vaso-occlusion.[43,44]

Diagnosis of Sickle Cell Disease

In the past, the diagnosis of sickle cell anemia was usually made on the basis of clinical manifestations occurring in childhood; the affected child was seen to have limitation in exercise tolerance, shortness of breath, tachycardia, frequent severe infections, and episodes of very painful dactylitis. Currently, many cases are identified on screening tests, which may be prompted by the diagnosis in a family member or performed as a routine neonatal procedure; in California and many other states, every fetal cord blood sample is examined by high-performance liquid chromatography (HPLC). Rarely, the disorder is diagnosed in adult life, occasionally during a first pregnancy, when prenatal screening reveals anemia. The general symptoms are limited exercise tolerance, exertional dyspnea, painful crises, bouts of jaundice, and even biliary colic.

The clinical appearance of the patient and a blood smear showing sickled cells, holly leaf cells, and erythrocytes with Howell-Jolly bodies are fairly suggestive of sickle cell anemia. Howell-Jolly bodies represent cytoplasmic remnants of nuclear chromatin that are normally removed by the spleen. Platelet and WBC counts are usually high. Unless an aplastic crisis is in

progress, causing a virtual absence of normoblasts, the marrow shows erythroid hyperplasia. Diagnosis is confirmed by performing a sickle preparation: a drop of blood is incubated with fresh 2% sodium metabisulfite, and the proportion of sickle cells is measured immediately and then 1 hour later. Commercial testing sets such as Sickledex rely on the relative insolubility of HbS in 1.0 M phosphate buffers to make the diagnosis. The most definitive tests for sickle cell anemia, however, are hemoglobin electrophoresis or HPLC, which indicate the relative percentages of HbS and HbF. All of these tests are also useful in screening family members for sickle cell trait. Patients who are heterozygous for both the HbS gene and the β-thalassemia gene may appear to be homozygous for HbS. Other varieties of sickling hemoglobin are observed very infrequently. DNA-based methods can also be used to pinpoint the specific genetic abnormality and to identify the subpopulations from which the patient descended[31]; further description and information on diagnostic testing is available online at http://www.geneclinics.org. Persons with sickle cell anemia and α-thalassemia have higher hemoglobin levels, lower reticulocyte counts, a lower MCHC, a lower MCV, and less-dense RBCs than persons who have sickle cell anemia alone. Such patients may have increased life expectancy and perhaps a different pattern of manifestations of veno-occlusive complications.[45] The combination of G6PD deficiency and sickle cell anemia has neither beneficial nor harmful effects.[46,47]

Management of Sickle Cell Disease

Sickle crisis Standard conservative management of sickle crisis centers on rest, hydration, and analgesia. In demonstrably acidotic patients, mild alkalinization should be induced by administration of a bicarbonate solution, which is prepared by addition of an ampule of sodium bicarbonate to 1 L of either 5% dextrose in water or half-normal saline. The bicarbonate solution should be infused at a rate of 5 to 7 ml/kg/hr for the first 4 hours and at 4 ml/kg/hr for the next 20 hours. The role of supplemental oxygen in patients with normal arterial oxygen tension (P_aO_2) and no cardiopulmonary problems is untested.

Pain management Pain [*see 11:XIV Pain*] is the major concern for 10% to 20% of patients with sickle cell anemia. Avascular necrosis of bone marrow produces excruciating pain that can last as long as 8 to 10 days. The need for pain relief sometimes results in habituation or addiction. Because there are few objective ways to monitor the sickle crisis, the physician may not know whether a demand for narcotics is a manifestation of drug-seeking behavior.

The patient who has sickle cell anemia should be provided with oral analgesics for use at home in an attempt to abort the pain crisis at its onset. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as naproxen (500 mg) and ketorolac (10 mg), can be used initially. If NSAIDs alone are not sufficient, they can be followed by a narcotic-analgesic combination, such as hydrocodone and acetaminophen or oxycodone and aspirin. Adjuvants such as oral diphenhydramine (50 mg) or lorazepam (1 to 2 mg) may calm the patient and perhaps antagonize the actions of released histamine.[48] If these measures, perhaps repeated every 6 hours, do not control the pain, the patient usually requires parenteral treatment. Care from the patient's regular physicians is far preferable to reliance on unfamiliar providers in emergency departments.[48] The patient needs rapid evaluation for possible infection, acute chest syndrome, bone infarction, and other complications, and the pain should be treated either with 10 mg of intravenous morphine along with 50 mg of intramuscular diphenhydramine every 2 hours or with 4 mg of intramuscular hydromorphone along with 50 mg of intramuscular diphenhydramine every 2 hours. If there is no pain relief or inadequate pain relief 30 minutes after the first dose, 50% of the initial dose of opiates can be administered; the respiratory rate should be monitored closely, particularly if it approaches 10 respirations a minute. Some units have used patient-controlled analgesia with good results. It is important to continue to administer parenteral analgesia at regular intervals and to provide increased doses for breakthrough pain. The patient will probably need a laxative and may need an antiemetic, such as prochlorperazine (10 mg p.o. or I.M.). If the patient responds, home therapy with oral controlled-release morphine, such as MS Contin, is usually effective. If pain continues for more than 8 to 12 hours, the patient will probably need to be hospitalized to receive extended therapy with increased doses of analgesia and parenteral fluids, along with observation.[48]

Alteration of sickle cell pathophysiology A clearer understanding of the kinetics of sickling suggests some future prospects for the therapy of sickle cell anemia. Decreasing the MCHC should diminish gelation. An approach that attempts to block the Ca^{2+}-dependent K^+ efflux (Gardos channel) [*see* Control of Hydration and Volume, *above*] has been tested in a sickle mouse model and shows promise in preventing RBC dehydration.[49,50]

Therapies to interfere with sickling are being actively pursued. The presence of 20% to 30% HbF in sickle RBCs markedly delays gelation, so a mechanism that would switch on the genes that control fetal hemoglobin synthesis and thus lessen the severity of sickle disease appears feasible.[51,52] Hydroxyurea produces an increase in F reticulocyte and HbF levels. In a phase III trial, patients treated with hydroxyurea (starting dosage, 15 mg/kg/day) had fewer painful crises, admissions for crisis, and episodes of acute chest syndrome, as well as required fewer transfusions, than patients given a placebo.[53] There was no effect on stroke; however, after 8 years of follow-up, mortality was reduced by 40%.[54] The beneficial effect of hydroxyurea accrued after about 8 weeks of therapy and was accompanied by an increase in MCV and an increase in the proportion of F cells; in addition, there was a decrease in neutrophils and a decrease in sickle RBC adhesion to endothelial cells.[55] Trials are also being conducted with butyrate, which can increase γ-chain production, thereby increasing HbF levels and interfering with gelation.[56,57] Demethylating agents such as 5-azacytidine and decitabine can also increase HbF to therapeutically useful levels. Because sickle cells adhere abnormally to the endothelium, attempts have been made to block adhesion; thus far, these efforts have not proved useful.

Inflammatory cytokines appear to play an important role in the sickle crisis, as evidenced by the fact that a predictor of success in hydroxyurea therapy is a decrease in the WBC count.[54,55] Other investigators are studying the possible vasodilatory role of nitric oxide.

Sibling-donor allogeneic bone marrow transplantation can result in cure or can lead to a substitution of sickle trait for sickle cell anemia. Bone marrow transplantation resulted in apparent cure in 15 of 22 carefully selected patients; there were two deaths (9%), and the remaining five patients had complications such as graft failure. Of the 22 patients, 12 had a history of stroke, five had a history of recurrent episodes of acute chest syndrome, and five had recurrent painful crises.[58]

Long-term transfusion therapy Long-term transfusion therapy has been found to prevent stroke.[59] Some investigators have shown that preventive transfusions reduce or eliminate pain crisis, episodes of acute chest syndrome, bacterial infection, and hospitalization.[60,61] Other authors, however, warn against the dangers of iron overload,[62,63] transfusion hepatitis, problems with venous access, and RBC alloimmunization.[64] Further studies may clarify the role of long-term transfusion therapy.

Complications and Their Management

Skeletal problems Aseptic necrosis (osteonecrosis) of the femoral head occurs in about 10% of patients, particularly those who also have α-thalassemia. Arthroplasty has been relatively ineffective, partly because of the presence of adjacent hard bone, which interferes with the placement of the prosthesis, and because of the increased risk of infection.[65]

Cardiopulmonary problems Cardiac complications associated with anemia are the result of a large increase in cardiac output. Such complications include chamber enlargement, cardiomegaly, left ventricular hypertrophy, and flow murmurs.[66] Acute myocardial infarction has occurred in relatively young adults who do not have coronary disease.[67] The incidence of pulmonary hypertension is unknown, but its presence markedly shortens survival.[68]

Acute pulmonary complications are a major cause of morbidity and mortality; such complications include local infection, vascular occlusions in the pulmonary vessels (both in situ thrombosis and embolism), and pulmonary fat embolism from ischemic marrow fat necrosis.[69] A large study of acute chest syndrome found that adult patients were afebrile but had shortness of breath, chills, and pain in the chest and in at least one extremity.[70] Infarctions of the thoracic vertebrae contribute substantially to the pain.[64] Physical examination frequently shows no abnormal chest findings. In one study, the P_aO_2 was found to be low, averaging 71 mm Hg but falling below 60 mm Hg in 25% of patients. In this study, the death rate in adults was 4.3%; death was preceded by a lower hemoglobin value, a higher WBC count, and multilobe involvement. Autopsy of 16 cases showed that nine patients had pulmonary embolism and fat emboli and possibly 20% had bacterial infections. In patients with acute chest syndrome and pulmonary infection, the most common infecting organism was *Chlamydia pneumoniae* (30%), followed by *Mycoplasma pneumoniae* (21%), respiratory syncytial virus (10%), *Staphylococcus aureus* (4%), and *Streptococcus pneumoniae* (3%).[71]

Usually, therapy for acute chest syndrome should include incentive spirometry,[64] antimicrobial therapy for patients with evidence of infection, the cautious use of analgesia, aggressive fluid replacement, and consideration of bronchoalveolar lavage to identify microbial infection or the fat-laden macrophages of fat emboli. Meticulous monitoring is required; repeat measurements of oxygenation should be made, and transfusions should be performed when clinically necessary. One of the most important benefits of hydroxyurea therapy is its ability to reduce the frequency of acute chest syndrome.[53,72] Children may also need supplementary penicillin prophylaxis.[73]

Hepatobiliary disease Cholelithiasis occurs in 30% to 70% of patients, some of whom exhibit signs and symptoms of cholecystitis.[74] There are conflicting data regarding frequency of cholecystitis or obstruction of the common bile duct.[74,75] If cholecystectomy is to be done, one should wait until the painful crisis is over. Transfusions should be given to raise the hemoglobin to 10 g/dl before surgery, if necessary, and the procedure should be done laparoscopically.[74]

Hepatic complications include congestive hepatopathy secondary to heart failure and viral hepatitis from frequent transfusions. Sickling in the liver can also produce hepatopathy. Often, serum bilirubin levels exceed 30 mg/dl in patients with intrahepatic cholestasis, and coagulation abnormalities may lead to hemorrhagic complications and death.

Renal and urologic complications Water loss as a result of an inability to concentrate urine may enhance the sickling process. The extremely hypertonic milieu of the renal medulla induces severe sickling and destruction of the vasa recta. Hematuria and papillary necrosis ensue. These complications are also observed in patients with sickle trait and in those who have sickle cell–hemoglobin C disease. The defect in renal concentrating ability appears to depend on the amount of HbS polymer contained in cells and is thus less severe in patients who also have α-thalassemia variants.[76]

Complications include renal tubular acidosis, hyperkalemia, and proteinuria. Treatment with enalapril reduces proteinuria, suggesting the presence of a component of glomerular capillary hypertension.[77] Renal failure, in association with worsening anemia, contributes to the death of about one fifth of patients older than 40 years who have homozygous sickle disease.

Priapism is an extraordinarily painful complication of sickle cell anemia and may result in impotence.[78] A United Kingdom study reported a good response in 13 of 18 patients treated for priapism with the alpha-adrenergic agonist etilefrine; however, this agent is not available in the United States.[79]

Neurologic disorders Neurologic complications of sickle cell disease include stroke, subarachnoid hemorrhage, and isolated functional losses that suggest a focal occlusion. The pathogenesis of occlusion of the large cerebral arteries is probably different from that of the microvascular occlusive events that occur in hypoxic capillary beds. The most likely underlying causes are damage to the vascular endothelium, followed by extensive intimal proliferation and then thrombosis of the damaged vascular bed.[45] In a multi-institutional study of 4,082 patients, the prevalence of cerebrovascular accidents (CVAs) was 4% to 5%; the incidence was 0.61 per 100 patient-years.[80] Of the CVAs, 54% were infarcts, 34% were hemorrhagic in nature, 11% were transient ischemic attacks (TIAs), and 1% had both infarctive and hemorrhagic features. Of the patients who survived, the recurrence rate of CVA was 14%. Mortality was 11%. Virtually all patients who died had hemorrhagic CVAs.

In a prospective study in which transcranial Doppler ultrasonography was used to pinpoint children at risk for stroke, treatment with standard care or transfusion therapy (to reduce the HbS concentration to < 30%) resulted in only one CVA, compared with 10 CVAs and one intracerebral hematoma in the 65 control subjects ($P < 0.002$). The trial was terminated early.[59] The success of this trial raises many serious questions about the necessity of ultrasonographic devices for successful management; the optimum duration of transfusion therapy; the inevitable consequences of transfusional hemochromatosis [*see* β-Thalassemia major (Cooley anemia), *below*] and the necessity for ethnically matched blood to minimize allotransfusion reaction; the willingness of patients and families to accept transfusion therapy; and the role of allogeneic bone marrow transplantation as a potential

alternative.[59,81] The risk of recurrent cerebrovascular events is increased in patients receiving long-term transfusion therapy who have multiple cerebral collateral vessels as a result of moyamoya disease (hazard ratio, 2.40).[82]

Ocular complications The major ocular problems associated with sickle cell anemia are retinopathy, vitreous hemorrhage, and neovascularization. Annual ophthalmologic evaluations are recommended. The efficacy of laser photocoagulation in treating sickle-induced ocular changes is currently being investigated.

Dermatologic complications Poorly healing leg ulcers can be an important cause of morbidity in patients with sickle cell anemia. The degree of anemia does not seem to correlate with the presence or severity of these ulcers, but incompetence of venous valves and the resulting venous insufficiency have been associated with ulceration.[83] Standard management includes debridement, control of local infection, use of wet-dry dressings, and possibly RBC transfusion. Local treatment with GM-CSF enhances healing, perhaps by stimulating the local growth of macrophages.[84] GM-CSF can be either injected perilesionally or added topically to the wound, but the more successful application method involves the subcutaneous injection of 100 μg of GM-CSF in each of four sites circumferentially around the ulcer at a distance of 5 mm from its edge (resulting in a total dose of 400 μg in the wound). In some circumstances, one treatment sufficed, whereas in others, weekly treatments for 4 to 12 weeks were necessary. This therapy has not been approved by the Food and Drug Administration.

Aplastic crisis Aplastic crisis rapidly lowers hemoglobin and hematocrit levels and produces reticulocytopenia, as it does in any chronic hemolytic state. Parvovirus infection has been found to cause aplastic crisis,[7] as has bone marrow necrosis.[85]

Susceptibility to infections Patients with sickle cell anemia are hyposplenic and exhibit complement system abnormalities. Deficient serum opsonizing activity for *Salmonella* organisms may confer an increased susceptibility to those infections, including osteomyelitis.

Anesthesia complications The hypoxemia and vascular stasis that may occur during general anesthesia enhance sickling and may lead to a sickle crisis in the postoperative period. In an analysis of almost 4,000 patients, 12 deaths were associated with 1,079 procedures, and there were more complications after regional anesthesia than after general anesthesia.[86] A simple transfusion program to raise the hemoglobin level to 10 g/dl was as effective as more aggressive preoperative programs in reducing the rate of complications.[87]

Pregnancy and contraception The dangers of pregnancy for women with sickle disease include pulmonary problems and an increased incidence of urinary tract infection, hematuria, preeclampsia, and maternal death. Presumably, pelvic hypoxemia and the vascular overload associated with pregnancy lead to enhanced sickling, with its attendant complications. Vaso-occlusion in the placenta may account for fetal death and low birth weight.

Experienced clinicians differ in their approach to the pregnant patient with sickle disease. Some advocate only meticulous conservative care, whereas others recommend prophylactic transfusions. A controlled study has indicated that there is no advantage to the use of prophylactic transfusions.[88]

Chorionic villus sampling (which can provide DNA for analysis in the first trimester of pregnancy), DNA amplification techniques, and probes that identify the specific nucleotide change of sickle cell anemia can give a relatively safe and very reliable prenatal diagnosis.[89]

Oral contraceptives may pose a special hazard to women with sickle cell anemia, because they have been associated with a slight increase in the incidence of stroke, venous thromboembolism, and myocardial infarction. However, the emerging evidence that daily use of oral contraceptives containing less than 50 mg of synthetic estrogens is relatively safe suggests that patients with sickle disease can take such medication with reasonable confidence. The use of the Norplant implantable contraceptive device is another alternative for some patients. In any event, pregnancy or abortion in sickle disease carries significant risk.[88]

Genetic Counseling

A key element to be considered in the provision of genetic counseling to patients with sickle trait or sickle disease is the significant morbidity in affected children and adults. Couples with sickle disease or sickle trait may want to have children despite the associated fetal and maternal risks. There are about 4,000 to 5,000 such pregnancies in the United States each year.[89] In one study, 286 of 445 pregnancies (64%) in mothers with sickle cell anemia proceeded to delivery; 21% of the infants were small and thus would be expected to require additional care, which the mother might have difficulty providing. In this study, there was one maternal death caused by sickle cell disease[90] [*see* Genetic Counseling and Prenatal Diagnosis, *below*].

Prognosis in Sickle Cell Disease

Whereas it was once assumed that most patients with sickle cell anemia would die by 20 years of age, the median age of death is now 42 years for men and 48 years for women.[51] This life expectancy is 25 to 30 years less than that of the general African-American population. Of the identified causes of death, only 18% involved organ failure—predominantly renal disease, heart failure, or the consequences of chronic strokes. Thirty-three percent of patients died during acute pain crises; these crises were frequently associated with the acute chest syndrome and were less often associated with stroke. The presence of α-thalassemia had no measurable effect. Predictors of poor outcome were a white cell count greater than 15,000/μl; a low HbF level; and organ involvement manifested by renal disease, acute chest syndrome, and neurologic events. Taking hydroxyurea had a significant impact on prognosis, with a 40% decrease in mortality and a reduction in painful crises.[91]

SICKLE VARIANTS

Sickle Trait

Heterozygosity for the sickle cell gene results in sickle trait (HbAS). The RBCs of persons with sickle trait have an HbS concentration of less than 50%; frequently, the level is as low as 30%.

Generally, persons with sickle trait lead normal, healthy lives. A few complications occur: hyposthenuria; renal hematuria; and, during pregnancy, bacteriuria and pyelonephritis. Splenic infarction occurs under conditions of hypoxia; it also occurs at high altitudes, predominantly in nonblack persons who have sickle cell anemia.

Sickle trait has been identified as a major risk factor for sudden death during basic training in the military[92]; death has resulted from unexplained cardiac arrest, heatstroke, heat stress, or rhabdomyolysis. Increasing age has been correlated with an increased risk of sudden death. However, these events have occurred under extreme conditions: very strenuous physical activity, usually in untrained persons, occasionally at high altitudes or in extreme heat. Usually, persons with sickle trait who are accustomed to physical activity do not have an increased risk of sudden death. For example, the incidence of sudden death in African-American football players with sickle trait is not higher than in other players.[93]

Therapeutic options for renal hematuria include the administration of diuretics, parenteral bicarbonate, transfusions, or ε-aminocaproic acid.

Sickle Cell–β-Thalassemia

When combined with sickle trait, a defect in the β-thalassemia gene produces a disease very similar to sickle cell anemia. The β-thalassemia gene reduces the rate of synthesis of the β^A chain, resulting in a predominance of β^S in patients with sickle trait. Depending on whether the patient has a β^0 or a β^+ thalassemia, the RBCs contain varying amounts of HbS, HbA, HbA_2, and HbF. Patients with β^0 thalassemia have no HbA, but only HbS, HbF, and HbA_2; thus, disease is severe in these patients. Diagnosis is based on an elevation in the level of HbA_2, HbF, or both on hemoglobin electrophoresis, as well as a positive family history of thalassemia and the sickle gene. In a study of 55 Greek patients, treatment with hydroxyurea resulted in distinct clinical improvement.[94,95] Further description and information on diagnostic testing is available online at http://www.geneclinics.org.

Sickle Cell–Hemoglobin C Disease

In sickle cell–hemoglobin C (HbSC) disease, almost equal amounts of HbS and HbC are formed. Between 1% and 2% of hemoglobin is HbF, and small amounts of HbA_2 are also present; however, HbA is absent. The increased sickling seen in these patients results from the pathologic effect of HbC [*see* Hemoglobin C Disease, *below*].[96] As many as 30% to 50% of patients with this disorder are not anemic and have only modest reticulocytosis. Patients may not be identified until the disorder manifests itself in the form of a vaso-occlusive crisis during surgery, pregnancy, or a medical emergency.[97] Splenomegaly, proliferative retinopathy, aseptic necrosis of long bones, and the acute chest syndrome[96] also occur. The peripheral smear [*see Figure 5*] shows irreversibly sickled cells in addition to target cells, stomatocytes, and erythrocytes with eccentric hemoglobin depositions, probably representing HbC aggregates or crystals. Diagnosis is confirmed by hemoglobin electrophoresis or HPLC.[97] Further information on diagnostic testing is available online at http://www.geneclinics.org.

Management is the same as that for sickle cell anemia. In a study of six patients with HbSC disease, treatment with hydroxyurea at a dosage of 1,000 mg/day resulted in an increase in MCV, a decrease in so-called stress reticulocytes, an increase in hemoglobin, and probably a reduction in cell density. Although not definitive, this small study suggests that hydroxyurea benefits patients with HbSC disease.[98] Life expectancy for patients with HbSC disease is almost 20 years greater than that for patients with HbSS disease.[51]

OTHER HEMOGLOBINOPATHIES

Hemoglobin C Disease

The HbC molecule is $\alpha_2\beta_2^{6glu\rightarrow lys}$; the gene mutation probably originated at a single site in Burkina Faso, in West Africa.[97] The presence of this hemoglobin produces almost no illness in the heterozygous state but causes mild compensated hemolysis and palpable splenomegaly in the homozygous state.

The relative insolubility of HbC is responsible for the pathologic changes associated with its presence. HbC probably interacts with the K^+-Cl^- cotransporter, which keeps it active, whereas the K^+-Cl^- cotransporter normally shuts off in RBCs after the reticulocyte stage. The result is a loss of K^+, cellular dehydration with elevated MCHC, and then aggregation and crystallization of the poorly soluble HbC.[97] The relative insolubility of HbC causes erythrocytes to become rigid and thereby subject to fragmentation and to loss of membrane material, resulting in the microspherocytes seen on a peripheral blood smear [*see Figure 3*].

Target cells, an important morphologic finding, constitute about 80% of the erythrocytes. HbC crystals are in the oxyhemoglobin state and dissolve when the RBCs are deoxygenated, probably accounting for the absence of vaso-occlusive episodes.

Diagnosis of hemoglobin C disease is based on blood-smear findings and the absence of evidence of either iron deficiency or thalassemia; the diagnosis is confirmed by hemoglobin electrophoresis. No therapy is required.

Hemoglobin E Disease

In hemoglobin E disease, lysine is substituted for glutamic acid at position 26 of the β-globin chain, resulting in an oxidatively unstable molecule. Hemoglobin E trait is found predominantly in Southeast Asia. It came to clinical attention in the United States as a result of the influx of Southeast Asians, in whom the incidence of this trait is about 10%.

Patients heterozygous for HbE have normal hemoglobin values, microcytosis, and no splenomegaly. Electrophoresis reveals that 70% of the hemoglobin is HbA, 25% is HbE, and the remainder is HbA_2 or HbF. Inexperienced laboratories may mistake HbE for HbA_2; the clue to this error is that HbA_2 never accounts for more than 8% of the total hemoglobin. A laboratory report of an HbA_2 level of 25% should prompt a review of the data.

Patients homozygous for HbE have mild anemia, with a hemoglobin level of about 12 to 13 g/dl, a low mean corpuscular volume, and an elevated RBC count but no reticulocytosis; they exhibit microcytes and target cells. Electrophoresis shows only HbE. Chronic hemolysis does not occur. Oxidant drugs such as dapsone should be avoided in both heterozygotes and homozygotes.

A serious clinical problem occurs when a patient is doubly heterozygous for HbE and β-thalassemia trait. Such patients present with β-thalassemia intermedia, characterized by severe anemia and splenomegaly (see below). These patients occasionally require transfusions of blood and even allogeneic bone marrow transplantation.[99] Further information on diagnostic testing is available online at http://www.geneclinics.org.

Unstable Hemoglobinopathies

Many individual variants make up the unstable hemoglobinopathies. The hemoglobin instabilities stem from amino acid substitutions that deprive the molecule of its heme group, alter the heme pocket, loosen the link between its α and β chains, or weaken the subunit structure [*see 5:I Approach to Hematologic Dis-*

orders]. The result is disruption and precipitation of hemoglobin, particularly when it is subjected to oxidant attack. Precipitated hemoglobin forms Heinz bodies, which are observed even in persons heterozygous for the unstable hemoglobin variant. Because of the deleterious effects of Heinz bodies on the erythrocyte and its membrane, significant hemolysis can occur even in the heterozygous state.

Diagnosis of an unstable hemoglobinopathy is suggested by the presence of a partly compensated chronic nonspherocytic hemolysis. Heinz bodies are observed in the erythrocytes of patients who have undergone splenectomy. Erythrocytes from patients who have not undergone splenectomy demonstrate Heinz bodies on incubation with brilliant cresyl blue dye. The differential diagnosis of a hemoglobinopathy includes G6PD deficiency; this disorder can usually be ruled out by direct assay for the enzyme.

Management includes avoidance of oxidant drugs. Splenectomy may be considered when hemolysis is severe and inadequately compensated.

Hemoglobin with Abnormal Oxygen Affinity

The presence of hemoglobin with increased oxygen affinity should be considered in the differential diagnosis of unexplained erythrocytosis, particularly if there is a familial association [*see 5:V The Polycythemias*]. Hemoglobin electrophoresis may reveal the disorder, but in suspected cases, measurement of the oxyhemoglobin dissociation curve [*see 5:I Approach to Hematologic Disorders*] is preferable as a basis for diagnosis. Hemoglobin Chesapeake and hemoglobin Rainier are examples of forms with particularly increased oxygen affinity.

The rare instances of hemoglobin with low oxygen affinity, such as hemoglobin Kansas, represent mutations. Patients with low-oxygen-affinity hemoglobinopathy are sometimes cyanotic because of enhanced oxygen unloading.

Methemoglobinemia

Methemoglobin is an oxidation product of hemoglobin in which iron is in the ferric form; thus, the molecule cannot bind oxygen reversibly. Ordinarily, 1% of hemoglobin is in the ferric state. Between 0.5% and 3% of deoxyhemoglobin is normally spontaneously oxidized to methemoglobin every day. The normal reducing power of erythrocytes [*see Table 1*] maintains the balance between oxidation and reduction. The enzyme system that reduces 95% of methemoglobin to hemoglobin involves two proteins, NADH-cytochrome b_5 reductase and cytochrome b_5, and also requires NADH. As the name suggests, NADH-cytochrome b_5 reductase uses NADH to reduce cytochrome b_5. Reduced cytochrome b_5 then reduces methemoglobin.[100,101] Novel mutations in the affected gene have been described.[102]

Most often, methemoglobinemia is acquired by ingestion of or exposure to oxidants that oxidize Fe^{2+} so fast that the reducing systems are overwhelmed [*see* Mechanism of Oxidative Attack, *below*].

There are two congenital forms of methemoglobinemia. In the hereditary enzymopenic form of methemoglobinemia, patients are homozygous or doubly heterozygous for a deficiency of NADH-cytochrome b_5 reductase.[103] These patients appear blue even when only about 10% of their hemoglobin is in the form of methemoglobin, but they are not sick and easily tolerate methemoglobin levels of 25% or more. In contrast, the presence of about 5 g/dl of reduced, deoxygenated hemoglobin produces cyanosis. Patients with this form of methemoglobinemia do not exhibit hemolysis and generally do not require treatment. Assay of NADH-cytochrome b_5 reductase, done by a special laboratory, can establish the diagnosis. If desired, methylene blue at a dosage of 100 to 300 mg/day orally can be used, but it may produce urinary discomfort.[100] Methylene blue transfers electrons from NADPH to methemoglobin.

The other hereditary form of methemoglobinemia is caused by HbM, of which there are five rare variants. Each of these variants contains an amino acid substitution in the heme pocket, which allows stable bonds to be formed between the heme iron and the amino acid side chains. These bonds keep hemoglobin in the Fe^{3+} form—a form that is unable to bind oxygen and is inaccessible to the reducing enzymes. The disorder is seen only in heterozygotes; about 30% of hemoglobin is abnormal, as detected by electrophoresis. Cyanosis is noted at birth. Hemolysis is minimal, and therapy is not needed.

THE THALASSEMIAS

The thalassemias have a worldwide distribution; in many regions, they are responsible for major medical, social, and economic perturbations. Throughout the world, the regions in which the thalassemias occur are contiguous with regions endemic for malaria, indicating that the heterozygous forms of thalassemia provide protection against malaria.[104] The techniques of molecular biology have helped elucidate the pathophysiology of these syndromes,[104] which in turn has enabled investigators to make unambiguous antenatal diagnoses. Using these data, expectant parents can make thoughtful, informed choices regarding the outcome of pregnancies in which the fetus is severely affected.

Molecular Genetics

Thalassemias result from gene deletion, abnormalities in transcription and translation [*see 9:VII Basic Genetics for the Clinician*], and instability of the mRNA directing globin synthesis or of the globin itself. The genes controlling the synthesis of the α and non-α chains of hemoglobin are located on chromosomes 11 and 16 [*see Figure 6*].

Pathophysiology

In a healthy person, the synthesis of α and β chains is meticulously coordinated to produce adult HbA ($\alpha_2\beta_2$). In contrast, patients with thalassemia usually demonstrate imbalanced synthesis of normal globin chains. Occasionally, however, thalassemia-like syndromes can result from diminished production of a structurally abnormal chain.[105] Because one of the globin chains is present in reduced amounts, the unpaired chain accumulates in the developing erythroid precursor cell, and toxicity results [*see Figure 6*]. Consequently, erythroid cells die in the marrow, giving rise to a classic form of ineffective erythropoiesis [*see 5:III Anemia: Production Defects*]; affected erythrocytes undergo hemolysis in the peripheral blood.

The β-thalassemias are characterized by diminished production of β-globin chains, causing unmatched α-globin chains to accumulate and aggregate. These aggregates of α chains precipitate, causing decreased ATP synthesis, potassium leak, and reduced amounts of surface sialic acid; the affected erythrocytes are misshapen and relatively rigid. The membrane Ca^{2+} barrier is breached, allowing Ca^{2+} to enter. These α-globin aggregates also appear to keep the K^+-Cl^- cotransporter functioning; as a result, in severe forms of β-thalassemia, dehydration of varying degree is seen.[106] The RBC membranes are unstable and fragment easily; there is evidence of oxidation of RBC membrane proteins 4.1 and

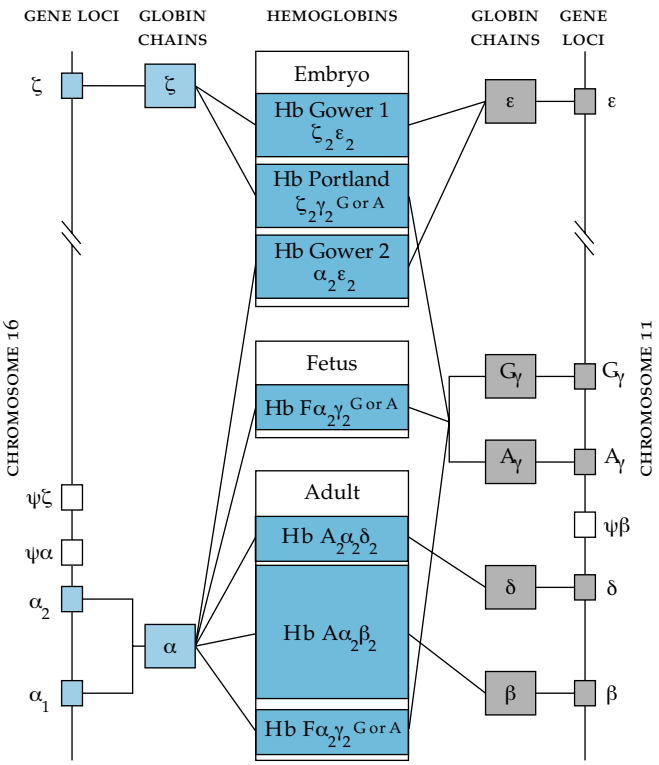

Figure 6 **The genes encoding the α and non-α chains that come together to form the hemoglobin tetramer lie on chromosomes 16 and 11, respectively. The α genes are present at duplicated loci. Six distinct species of normal hemoglobin have been described. Three of these hemoglobins are synthesized only during embryonic stages of development (Hb Gower 1, Hb Portland, and Hb Gower 2). HbF predominates during fetal development, and a small amount continues to be synthesized in adult life. HbA and HbA_2 constitute the major forms of adult hemoglobin. Different hemoglobin genes are activated at various stages of development. In the embryo, ξ chains combine with ε chains to yield Hb Gower 1 and with γ chains to form Hb Portland; α and ε chains are linked to form Hb Gower 2. There are two varieties of γ chains that are derived from separate loci and that differ in a single amino acid; $^{G}\gamma$ contains glycine at position 136, whereas $^{A}\gamma$ contains alanine at this position. The genes coding for the two other non-α chains, β and δ, which are required for the synthesis of adult hemoglobins, are switched on late in fetal development. The factors regulating this precisely coordinated sequence of changes in hemoglobin production are poorly understood; some evidence suggests that DNA segments intervening between the various hemoglobin genes may control the relative rates of synthesis of the adjacent gene products.**

spectrin [*see Figure 2*]; and phosphatidylserine migrates to the outer membrane layer, perhaps forming a nidus for thromboembolic events.[107,108] These destructive alterations of the membrane, which can be detected by macrophages, may in part be caused by local oxidation.[109,110] Abnormal accumulations of α chains probably account for the accelerated apoptosis and ineffective erythropoiesis seen in marrow erythroid precursors.[110] The overall decrease in hemoglobin synthesis per cell accounts for the observed hypochromia and target cell formation.

Patients with α-thalassemia demonstrate accumulations of excess β chains that, if present in sufficient amounts, form β_4 tetramers (HbH) [*see Figure 6*]. Such tetramers have high oxygen affinity and are unstable, aggregating in the presence of oxidative stresses such as infection. β-Globin aggregates also become attached to the erythrocyte's membrane skeleton, but they produce lesions different from those produced by α-globin aggregates. In the severe α-thalassemias, ineffective erythropoiesis is less prominent[85]; rather, destruction of peripheral RBCs is the critical characteristic. RBCs in severe α-thalassemia are rigid, but in contrast to those in severe β-thalassemia, the membranes in severe α-thalassemia are more stable than normal.[107,108] Also in contrast to β-thalassemia, the RBCs in severe α-thalassemia are uniformly overhydrated.[106]

Both α-thalassemia and β-thalassemia are characterized by variable degrees of anemia. This variation is attributable to varying degrees of ineffective erythropoiesis and hemolysis.[110] When the anemia is severe, the associated hypoxia induces a vigorous compensatory erythropoiesis, leading to expansion of the marrow cavity, osteopenia, and enlargement of reticuloendothelial organs; tumors may arise at sites of extramedullary erythropoietic activity. Destruction of erythroblasts and erythrocytes may predispose to cholelithiasis and obstructive jaundice. Patients with the more severe forms of thalassemia require regular transfusions, which may eventually generate clinically significant iron overload [*see 5:II Red Blood Cell Function and Disorders of Iron Metabolism*].

Diagnosis and Treatment of Thalassemia

The HbF and HbA_2 measurements that aid in the diagnosis of the β-thalassemias are readily available from clinical laboratories using hemoglobin electrophoresis and, more recently, HPLC. In contrast, the tests required to diagnose the α-thalassemias are quite sophisticated and in the past were performed only in institutions specifically engaged in thalassemia research. Currently, specialized laboratories can detect the number and position of deleted α-globin genes. Further description and information on diagnostic testing is available online at http://www.geneclinics.org.

The clinical diagnostic tools used to assess patients suspected of having α-thalassemia include clinical history, smear evaluation, calculation of indices, brilliant cresyl blue staining, and family studies. In practice, α-thalassemia trait is diagnosed on the basis of a finding of microcytosis in an iron-replete patient who has normal HbA_2 and HbF levels.

The diagnosis of either α- or β-thalassemia should be suspected when the MCV is less than 75 fl and the RBC count is greater than 5 million cells/μl. A patient with these two findings has an 85% chance of having a thalassemia syndrome.[111] In one study, diagnosis of thalassemia was not considered in about half of the patients with the disease.

β-*Thalassemia*

The deficient synthesis of β-globin characteristic of β-thalassemia leads to accumulation of unmatched α chains. A diagnostically significant development in β-thalassemia is the partial compensatory increase of the δ and γ chains that yields elevated levels of HbA_2 ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), respectively [*see Figure 5*]. The β-thalassemia variants produce three clinical syndromes: β-thalassemia major, β-thalassemia minor, and thalassemia intermedia.

β-Thalassemia major (Cooley anemia) β-Thalassemia major is usually a homozygous or doubly heterozygous condition; both parents of an affected individual carry a β-thalassemia trait. In β^0-thalassemia, the most severe variant, no β chains are synthesized; only HbF and HbA_2 are found. β^+-Thalassemia is somewhat less

severe. It is characterized by small amounts of β chains and small quantities of HbA in addition to HbF and HbA_2. δβ-Thalassemia is yet milder; it is caused by deletion of the δ-globin and β-globin genes. This mutation prohibits production of HbA_2 and HbA, permitting synthesis of fetal hemoglobin alone.

β-Thalassemia major is characterized by severe anemia that appears in the first year of life. Patients also have jaundice, hepatosplenomegaly, expansion of the erythroid marrow with secondary body changes (including retarded growth), and an increased susceptibility to infection.

Diagnosis is not difficult; no other condition closely resembles Cooley anemia. The peripheral smear shows nucleated RBCs, distorted hypochromic erythrocytes, and basophilic stippling, which represents aggregates of ribosomal RNA [*see Figure 5*]. Supravital staining reveals accumulations of excess unmatched α chains.

Management consists of aggressive transfusion therapy. The strategy involves transfusing to a hemoglobin level of about 12 g/dl, then allowing the hemoglobin level to fall to about 9 g/dl just before the next transfusion; this prevents such complications as heart failure, fluid overload, and skeletal deformity. Splenectomy is usually necessary to enhance survival of the patient's own RBCs as well as transfused RBCs.[112] Vaccination with pneumococcal vaccine is indicated because of the risk of pneumococcal sepsis after splenectomy.

Long-term transfusions eventually generate iron overload, which if untreated leads to death from cardiac hemochromatosis during adolescence. Iron overload should be managed prophylactically by infusion of subcutaneous deferoxamine, an iron chelator, before iron buildup occurs. Subcutaneous deferoxamine at a dosage of 50 mg/kg/day can effect iron losses of 50 to 200 mg/day but only if infused continuously over 8 to 12 hours for 5 days each week.[113] Such therapy not only prevents left ventricular dysfunction but also reverses already established abnormalities.[114] The beneficial effects of iron chelation have improved the prognosis for persons with Cooley anemia[114]: it is no longer inevitable that patients die in their 20s of arrhythmia and left ventricular failure. With current deferoxamine therapy, 61% of patients born before 1976 have had no cardiovascular disease. Compliant patients whose ferritin levels are mostly below 2,500 ng/ml have a survival rate of 91% after 15 years.[115] However, compliance with deferoxamine is a problem, and the cost of the drug, together with the cost of the pump and tubing that are required for administration, takes it out of reach of most patients in developing countries. Use of the oral iron chelator deferiprone remains a very contentious issue with regard to its safety and efficacy.[116] A new orally active tridentate iron chelator (ICL670) looked very promising in early trials, but it is currently available only on fixed protocols.[117] Bone marrow transplantation has been performed with HLA-matched sibling donors. More than 1,000 patients have now undergone allogeneic bone marrow transplantation from sibling donors who either were normal or had β-thalassemia trait.[118] Some patients with hemoglobin E β-thalassemia have a phenotype fully as severe as β-thalassemia major and require the same therapy, including allogeneic bone marrow transplantation.[99] Experience with cord blood transplantation is more limited.[119] Depending on the condition of the patient at the time of transplantation, the rate of transplantation-related mortality was 5% to 19%; the cure rate was 54% to 90%.[120,121] Other approaches to the treatment of severe β-thalassemia are still experimental.[56] However, two small clinical trials have shown hydroxyurea to be of benefit. This treatment probably works by increasing the production of γ chains, which combine with and remove the excess α chains, and by causing an increase in the production of HbF, a useful hemoglobin.[122,123]

β-Thalassemia minor (β-thalassemia trait) Patients with β-thalassemia minor are usually heterozygous for a β-globin mutation and have either mild or no anemia. The peripheral smear shows distinct hypochromia and microcytosis with basophilic stippling. Splenomegaly is occasionally found.

The HbA_2 level is elevated above 5% in 90% of patients, and the HbF level is raised above 2% in 50% of patients. This increase in fetal hemoglobin occurs in varying proportions per RBC (a phenomenon known as heterocellular distribution), as shown by the Kleihauer-Betke stain. Patients with higher HbF levels have less severe anemia. Heterozygotes for δβ-thalassemia produce increased amounts of HbF but only normal amounts of HbA_2.

Iron deficiency anemia should be excluded from the differential diagnosis of β-thalassemia trait [*see 5:II Red Blood Cell Function and Disorders of Iron Metabolism*]. Generally, it is easy to distinguish the two disorders. Both are associated with hypochromia and microcytosis, but iron deficiency produces hypoproliferation of RBCs, whereas β-thalassemia minor causes only a minimal reduction in their number. At a hemoglobin level of 9 g/dl, an iron-deficient patient has an RBC count of about 3 million cells/μl, whereas a patient with β-thalassemia trait has an RBC count of about 5 million cells/μl. If the diagnosis remains in doubt, measurement of the serum iron and iron-binding capacity or of the serum ferritin level can be used to distinguish these disorders. It is important to remember, however, that a patient with thalassemia trait may also be iron deficient as a consequence of vaginal bleeding, gastrointestinal bleeding, or both.

Thalassemia intermedia As the term implies, thalassemia intermedia is characterized by clinical manifestations of moderate severity. Patients with this syndrome have distinct anemia, with hemoglobin levels as low as 6 to 7 g/dl; they exhibit variable degrees of hepatosplenomegaly, but they usually do not require regular transfusions. During infections or other erythropoietic insults, however, transfusions may be needed transiently. In two small clinical trials, isobutyramide was found to be of benefit.[124,125]

β-Thalassemia–like variants The hemoglobinopathy associated with hemoglobin Lepore represents another β-thalassemia variant. Patients who are homozygous for this disorder present with Cooley anemia or thalassemia intermedia, and their RBCs contain only hemoglobin Lepore and HbF.[105]

Hereditary persistence of fetal hemoglobin The RBCs of patients heterozygous for hereditary persistence of fetal hemoglobin (HPFH) contain about 50% of HbF, whereas homozygotes have 100% of HbF. It was once believed that patients with HPFH were well and had minimal or no anemia, but some clinical variants of HPFH associated with distinct anemia have been described.

α-Thalassemia

The α-globin gene and the β-globin gene differ in two major respects. First, there are no fetal, neonatal, or adult substitutes for the α-globin genes; second, there are only two β-globin genes but four α-globin genes—two α-globin genes on each chromosome 16 [*see Figure 6*]. The normal α-globin genotype is designated

αα/αα. Patients who carry the α-thalassemia–1 variant exhibit a deletion of two α-chain genes from the same chromosome and thus have the --/ or α^0 haplotype; this deletion is common among Asian patients. Patients who have the α-thalassemia–2 variant have lost one α gene on one chromosome and show the -α/ or α^+ haplotype. Although this mutation is particularly frequent among blacks, it is also observed in Asian and Mediterranean populations. Five clinically distinct syndromes have been recognized among patients who carry different genotypes for the α-globin genes: hemoglobin Barts or hydrops fetalis (--/--); hemoglobin H disease (--/-α); heterozygous α-thalassemia–1 (--/αα); homozygous α-thalassemia–2 (-α/-α); and the silent carrier syndrome (-α/αα).

Hemoglobin Barts (hydrops fetalis) Children with hemoglobin Barts syndrome are homozygous for α-thalassemia–1 (--/--) and therefore produce no α chains. The unmatched γ chains form γ_4 tetramers (hemoglobin Barts). All infants with this condition are born hydropic, and most die unless rescued by intrauterine stem cell transplantation. The parents are usually heterozygous for α-thalassemia–1 (--/αα).

Hemoglobin H disease The clinical picture of hemoglobin H disease is that of variable hemolytic anemia occurring in patients of Asian, Middle Eastern, or Mediterranean origin. HbH, which precipitates on staining with brilliant cresyl blue, can usually be detected in the patient's freshly drawn RBCs. The molecular mechanisms may involve deletion of three α genes, as would be the case if the patient were doubly heterozygous for α-thalassemia–1 (--/) and α-thalassemia–2 (-α/), yielding a --/-α genotype. Splenomegaly is common. Patients usually do not require regular transfusions, but transient RBC support may be necessary when the patient has infection or experiences other oxidative stresses that lead to the precipitation of the unstable HbH and enhanced hemolysis. During pregnancy, anemia may become clinically severe and require RBC transfusion. Partners of pregnant patients with HbH disease should be screened because if the partner carries an α-thalassemia trait, the fetus may have homozygous α-thalassemia hydrops fetalis. Occasionally there is associated growth retardation and even iron accumulation in the absence of RBC transfusions.[126]

Heterozygous α-thalassemia Heterozygous α-thalassemia–1 (--/αα), a common genotype among Asians, causes mild or no anemia; rather, it engenders distinctly hypochromic, microcytic RBCs. Patients homozygous for α-thalassemia–2 (-α/-α), a common genotype among blacks, lack two α genes; the clinical manifestations of patients with this genotype resemble those of patients heterozygous for α-thalassemia–1. The heterozygous state for α-thalassemia–2 (-α/αα) is clinically undetectable and thus represents the silent carrier syndrome.

α-Thalassemia–like syndrome Hemoglobin constant spring (hemoglobin CS) is a structurally abnormal hemoglobin common in some Asian populations. The α-globin gene contains a mutation in the termination codon, resulting in the synthesis of an α-globin that contains an additional 31 amino acids. Patients heterozygous for this defect have a clinical picture similar to that of a patient homozygous for α-thalassemia–2. Patients homozygous for hemoglobin CS tend to have slightly more severe clinical manifestations than patients heterozygous for α-thalassemia–1. In patients who are doubly heterozygous for α-thalassemia–1 and alpha CS (--/αCS α) and who have HbH/HbCS, disease is slightly more severe than in those with hemoglobin H disease.[110]

Genetic Counseling and Prenatal Diagnosis

Parents who have had a stillborn hydropic infant or a child with Cooley anemia are justifiably reluctant to repeat the experience. Adults from thalassemia families who know themselves to be heterozygous for thalassemia are often eager to receive genetic counseling when starting their own families. Genetic counseling entails screening prospective parents on the basis of routine diagnostic tests and family studies. In addition, advances in molecular genetics can now provide accurate, unambiguous prenatal diagnoses of the thalassemias. In the first trimester, chorionic villus sampling combined with the use of polymorphic DNA markers and synthetic oligonucleotide probes can provide the definitive diagnosis in about 80% of cases of β-thalassemia [*see 9:VII Basic Genetics for the Clinician*].[127,128] Indeed, the incidence of births of infants with thalassemia major has fallen in several parts of the world. Different ethnic groups respond differently to genetic counseling.

Extracorpuscular Defects

Erythrocytes can be damaged through trauma or by antibodies, drugs, abnormally functioning organs, and toxins. These causes of an extracorpuscular defect should be considered whenever hemolysis develops in a patient who has no personal or family history of anemia.

MECHANICAL INJURY: MICROANGIOPATHIC HEMOLYSIS

Microangiopathic hemolysis is characterized by the appearance of bizarre, fragmented erythrocytes (e.g., schistocytes, or helmet cells) on a peripheral smear and by signs of intravascular and extravascular hemolysis.

Pathophysiology

The normal erythrocyte can withstand considerable elongation and twisting, but it disintegrates when subjected to strong stretching or shearing forces. Stresses of this magnitude have been observed to occur in jets produced by deformed aortic valves, by arteriovenous shunts, by ventricular septal defects, or by the older valvular prostheses.

Localized intravascular coagulation, in which fibrin strands bridge the arteriolar lumen, is thought to occur in arterioles supplying inflamed or neoplastic tissues. Fibrin strands lop off fragments of RBCs, whose membranes promptly reseal. Some of the erythrocyte contents leak out, however, producing varying degrees of intravascular hemolysis. The distorted RBCs are then removed by the reticuloendothelial system.

Diagnosis

Hemolysis in conjunction with typical blood smear findings is diagnostic of microangiopathic hemolysis [*see Figure 5*]. If the angiopathy is extensive, thrombocytopenia and disseminated intravascular coagulation develop. Causes include hemodynamic jets, vasculitis,[129] giant hemangiomas, thrombotic thrombocytopenic purpura, metastatic cancer,[130] certain infections (especially meningococcemia, rickettsial diseases, and hantavirus infection), hemolytic-uremic syndrome, disseminated intravascular coagulation, drugs (cocaine, cyclosporine, mitomycin, and tacrolimus), and even subclavian catheters.[130,131] Quinine has been identified

as a fairly common cause of drug-induced thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome.[132] A single case of microangiopathic hemolysis has been described in an infant with cutaneous anthrax.[133]

Treatment

In treating microangiopathic hemolysis, clinicians must focus primary attention on the underlying disease. Patients may become iron deficient and require iron therapy. Supplementation of depleted folate stores may stimulate erythropoiesis. In rare cases, anemia caused by an old prosthetic aortic valve may be severe enough to warrant valve replacement. Plasmapheresis provides effective therapy for TTP [*see 5:X Transfusion Therapy and 5:XIII Hemorrhagic Disorders*].

March hemoglobinuria March hemoglobinuria, a disorder that somewhat resembles microangiopathic hemolysis, usually occurs in young persons after prolonged marching or running or playing on bongo drums. The severe and repetitive trauma to the feet or hands is thought to destroy RBCs circulating in the vessels of the soles and palms. The patient notices red urine that clears in 1 day or less after the activity. Transient hemoglobinemia and hemoglobinuria without anemia, smear abnormalities, or reticulocytosis confirm the diagnosis. The use of padded shoes and the avoidance of paved surfaces may prevent recurrences in persons who continue running.

IMMUNE HEMOLYSIS

General Mechanisms

A classic, well-delineated example of immune (not autoimmune) hemolysis involves fetomaternal incompatibility at Rh locus D, in which the D-negative mother, after contact with D-positive erythrocytes, may produce an IgG anti-D antibody; the antibody crosses the placenta and attacks and destroys fetal erythrocytes. The fetus becomes jaundiced and has spherocytic erythrocytes.

The fetal RBCs, now coated with maternal IgG anti-D antibody, attach to fetal macrophages and monocytes that contain receptors for the Fc portion of these IgG molecules. Macrophagic digestion of portions of the erythrocytic membrane leads to the loss of considerable surface area. The resulting rigid spherocyte returns to the circulation and becomes trapped in the fetal reticuloendothelial system, particularly in the spleen. Hemolysis results. The IgG antibody is maximally active at 37° C; it generally cannot extensively activate the complement pathway, and it cannot agglutinate attacked RBCs suspended in saline.

The direct Coombs antiglobulin test [*see Figure 7*] is used clinically to detect IgG coating of RBCs. This test is negative in the mother, because her erythrocytes lack D antigen and thus are not coated with anti-D antibody. The indirect Coombs test [*see Figure 7*], which detects the presence of free serum antibody that reacts with RBCs, is positive for the mother's serum because she has circulating anti-D antibody. In the fetus, in contrast, the direct Coombs test is strongly positive because the fetus's RBCs, which express D antigen, are coated with maternal anti-D antibody. The results of the fetus's indirect Coombs test may be positive or negative, depending on the amount of anti-D antibody that has been transferred by the mother, the avidity of the anti-D antibody for fetal D-positive RBCs, and the availability of D antigen sites on fetal RBCs.

These antibodies are described as warm (maximum activity at 37° C [usually IgG1 or IgG3]) or cold (maximum activity at 5° C [usually IgM]). Antibodies have also been classified as complete (i.e., capable of agglutinating saline-suspended RBCs) and incomplete (i.e., incapable of agglutinating saline-suspended RBCs); their detection requires the use of techniques such as the direct Coombs antiglobulin test [*see Figure 7*] or enzyme treatment of RBCs.[134] Warm autoantibodies are usually incomplete, whereas cold agglutinins, which are for the most part IgM, are usually complete.[135]

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia is generally an acute disorder characterized by extravascular hemolysis. Intravascular hemolysis in this condition is rare and indicates that an extremely rapid rate of erythrocyte destruction is occurring or that the extravascular removal mechanisms have been overwhelmed.

Pathophysiology In autoimmune hemolytic anemia, for reasons that are unclear, autoantibodies form and are directed against central components of the erythrocyte (e.g., Rh antigen, Kell antigen,[134] glycophorin A).[136] Alternatively, the patient's RBCs are sensitized with both an IgG antibody and a complement component, usually C3d. In other circumstances, however, it appears that complement is fixed to the RBC surface by an IgM antibody that is subsequently washed away. Occasionally, the RBCs exhibit only complement components, and no IgG can be detected by the Coombs test. Complement fixation in such cases may be explained by the continued presence of IgG at a level below that detectable in the usual direct antiglobulin test; alternatively, a complement-fixing IgG or IgM antibody had been attached to the cell but was eluted in the testing procedure.[135]

The severity of hemolysis correlates with the number and class of IgG and, in rare cases, IgA molecules attached to the RBC surface. Antibody-coated RBCs attach to the macrophages' receptors (FcRI, FcRII, or FcRIII) by the antibody's Fc portion. The firm binding of RBCs to these macrophage receptors is then followed either by removal of a portion of the RBC membrane, which results in the production of a spherocyte, or by phagocytosis of the entire RBC.[134] Relatively low levels of IgG1 attachment to RBCs produce a positive result on direct Coombs antiglobulin testing without evidence of hemolysis (approximately 1,000 molecules per RBC), whereas much higher levels of IgG1 autoantibody per RBC are associated with frank hemolysis.[134] The combined presence of IgG and complement components may enhance the severity of hemolysis.

Erythrocytes sensitized to IgG alone are usually removed in the spleen, whereas RBCs sensitized to IgG and complement or to complement alone are generally destroyed in the liver, because hepatic Kupffer cells carry receptors specific for complement component C3b.

Differential diagnosis Both an idiopathic variety of autoimmune hemolytic anemia and a variety that occurs secondary to other disorders have been described. Such primary disorders include systemic lupus erythematosus, non-Hodgkin lymphoma (especially chronic lymphocytic leukemia), Hodgkin disease, cancer, myeloma, dermoid cyst, HIV infection, angioimmunoblastic lymphadenopathy with dysproteinemia, hepatitis C,[137] and chronic ulcerative colitis.

Diagnosis Patient presentations vary markedly, from asymptomatic to severe. A person may be found to have a positive Coombs test result when undergoing blood bank or blood

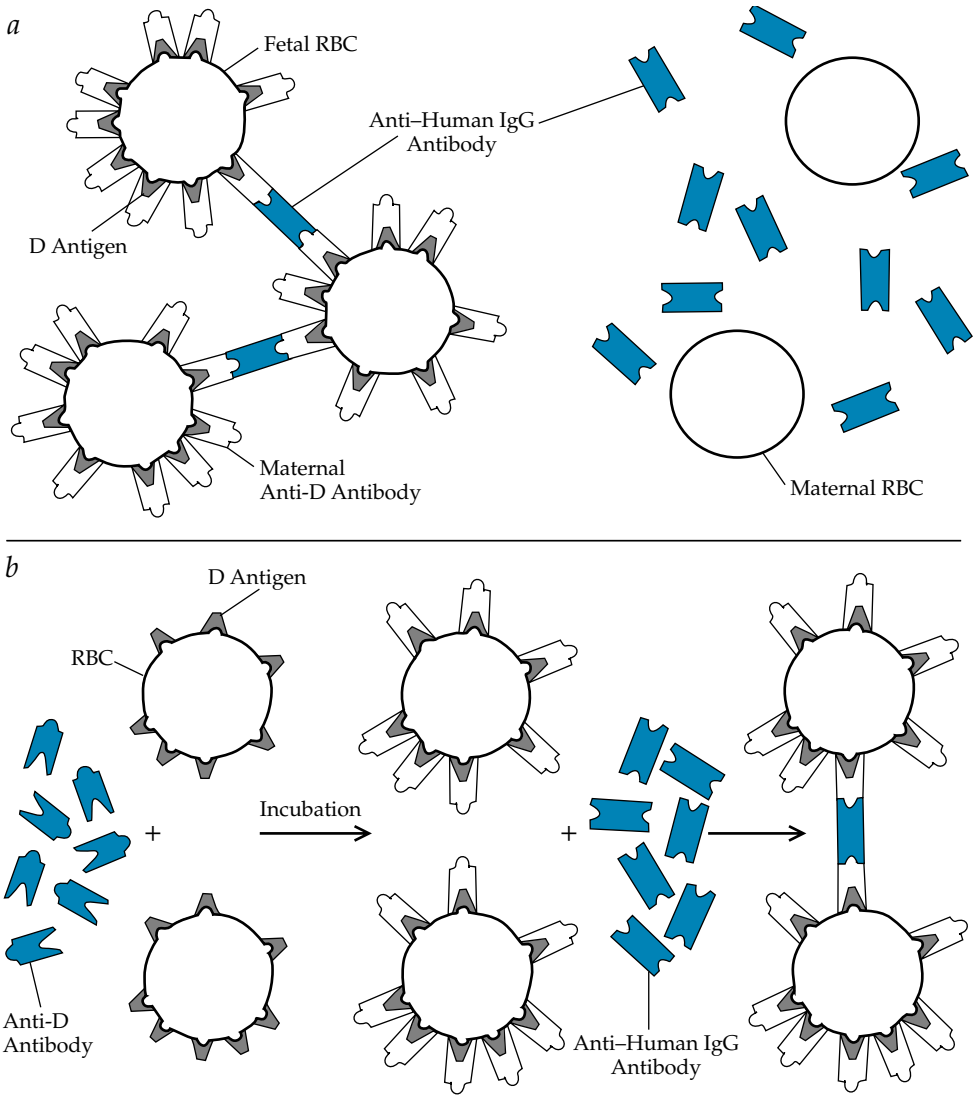

Figure 7 **The Coombs test detects the presence of human antibodies or complement components on erythrocytes or the presence of antibodies in serum. The test is useful in diagnosing Rh hemolytic disease of the newborn, autoimmune hemolysis, or potential hemolytic transfusion reactions. The figure illustrates Rh hemolytic disease of the newborn.**

In the direct Coombs test (*a*), fetal erythrocytes (RBCs) are shown with D antigen attached to their surfaces. Maternal anti-D antibody binds to the fetal erythrocytes at the D antigen sites in utero. Coombs antiserum, which contains antibody to human IgG, binds to the anti-D antibody on a sample of washed fetal erythrocytes, causing them to clump (a positive reaction). Washed maternal erythrocytes, having no D antigen, will have no attached anti-D antibody and are therefore not clumped by Coombs serum (a negative reaction).

In the indirect Coombs test (*b*), maternal or fetal serum is added to the red cells of another person or to panels of erythrocytes of known antigenic specificity; Coombs antiserum is then added. Clumping in this case occurs only if the test serum, such as the maternal serum, contains anti-D antibody and if the red cells chosen have the D antigen.

The direct Coombs test is used to detect immunoglobulin molecules already attached to erythrocytes, such as those found on the fetal erythrocytes in Rh hemolytic disease of the newborn or in autoimmune hemolytic anemia. Therefore, the test is done on the patient's thoroughly washed erythrocytes. The indirect Coombs test is used for determining whether specific antibodies are present in a serum sample, and it is performed on the patient's serum.

donation screening. Such persons can usually be shown to have complement or the combination of complement and IgG (usually IgG1 or IgG4) on their RBCs, but they are generally not undergoing hemolysis. By contrast, an acute hemolytic episode can lower the hematocrit from 45% to 15% in 2 days. With this extreme presentation, severe fatigue and cardiorespiratory symptoms will develop, together with jaundice, lymphadenopathy, and hepatosplenomegaly.

In severe cases, the blood smear shows macrocytosis, polychromatophilia, variable spherocytosis, and autoagglutination of RBCs. The platelet count is also occasionally depressed (Evans syndrome), and there may be leukopenia. One third of patients

may have reticulocytopenia at presentation.[138] The direct Coombs test will be positive. Any or all of these findings may be absent in mild disease.

Whether complement, IgG, or both are present on RBCs should be determined by the use of Coombs reagents that are specifically directed against IgG, IgA, or complement components. Occasionally, an autoimmune hemolytic anemia is suspected, but the direct Coombs test is repeatedly negative; in such cases, the level of autoantibody may be below the level of detectability for very active autoantibodies, such as subclass IgG3 autoantibodies, or the autoantibody may be IgA or IgM.[134]

Patients with evidence of hemolytic anemia should be screened for autoimmune diseases (e.g., systemic lupus erythematosus) and other forms of hemolysis, such as paroxysmal nocturnal hemoglobinuria, cold agglutinin disease, and paroxysmal cold hemoglobinuria.

Treatment Treatment of clinically affected patients is directed at decreasing autoantibody production and reducing the macrophagic attack on the RBCs. Initial therapy usually consists of 60 to 100 mg of prednisone a day, given in divided doses. This approach usually produces a slow decrease in antibody coating of RBCs and is thought to interfere with phagocytic attack on coated erythrocytes. A good response to corticosteroid use—indicated by a rise in the reticulocyte count and an improvement in hemoglobin and hematocrit—may be apparent within 1 or 2 days. Supplementation with 1 mg of folic acid a day is recommended.

After the initial response to therapy, which is usually satisfactory, the hemoglobin level and reticulocyte count may return to normal. The Coombs test is then repeated to determine whether the response has become weaker; if so, the prednisone dosage is tapered cautiously. Approximately 20% of patients remain well indefinitely, but the majority suffer from a chronic, treacherous disease that can produce sudden relapses with abrupt anemia. The prednisone should be titrated in accordance with the hemoglobin level, the reticulocyte count (elevation indicates continued hemolysis), and the direct Coombs titer; alternate-day therapy should be considered to minimize steroid side effects. If patients do not respond to standard prednisone therapy, high-dose dexamethasone (e.g., 40 mg/day orally for 4 consecutive days in 28-day cycles[139]) may be effective.

If the corticosteroid dose required for long-term therapy produces significant morbidity, one can proceed empirically either to splenectomy or to the use of immunosuppressive agents. Measurements of splenic sequestration of chromium-51 (^{51}Cr)-labeled erythrocytes do not reliably indicate the benefits of splenectomy. Splenectomy rarely results in extended remission but is valuable as a prednisone-sparing measure. After splenectomy, low-dose prednisone (5 to 10 mg/day) may stabilize the hemoglobin concentration.

The immunosuppressive agent azathioprine or cyclophosphamide can be used as an alternative to splenectomy. There is no reliable evidence to support the use of one of these agents over the other. For patients with very aggressive disease, cyclosporine has been used successfully.[140] Azathioprine should be started at a dosage of 100 to 200 mg a day; the peripheral blood count should be monitored with a view toward preventing reticulocytopenia or neutropenia. Cyclophosphamide is started at a dosage of 100 to 200 mg a day, with monitoring of blood counts and urine; however, because cyclophosphamide can cause therapy-related acute myeloid leukemia or myelodysplastic syndrome, its use should be limited [*see 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*].

Azathioprine or cyclophosphamide doses have to be adjusted to reduce the white cell count to about 3,000/mm^3. Improvement usually comes in 3 to 4 weeks. When a response occurs, the prednisone dose can be reduced and the hemoglobin level, reticulocyte count, and Coombs titer monitored to determine the minimally required therapy. For patients with very refractory disease, therapy with intravenous cyclophosphamide at doses used for allogeneic bone marrow transplantation has been tried. This approach is clearly myelotoxic, and its usefulness awaits further confirmation. High-dose intravenous IgG has been used to treat autoimmune hemolytic anemia. In one report, only one third of patients had a transient response, and doses larger than those used in idiopathic thrombocytopenic purpura (i.e., 1g/kg/day for 5 days) were required.[141,142]

There are anecdotal reports that rituximab is useful in treating refractory and relapsing cases.[143,144] However, a case of automimmune hemolytic anemia occurring after rituximab therapy for lymphoproliferative disorder has been reported.[145]

Patients with symptomatic anemia require an RBC transfusion, but often the blood bank reports an incompatibility. Many blood banks regularly perform a direct Coombs antiglobulin test on the recipient's RBCs. A patient who has free antibodies in the serum will exhibit very extensive and broad reactivity against donor panels of RBCs and will usually produce an incompatible major cross-match when tested with the antiglobulin reagent. If transfusions are needed to support cardiorespiratory and central nervous system functions, immediate consultation with the transfusion medicine service is recommended.[135] No patient should be allowed to die because the blood bank does not have a perfectly compatible unit of RBCs. If transfusion is clinically indicated, the physician should administer the best units of blood that are available, because it has been shown that these patients can tolerate even imperfectly matched RBCs.[146]

Drug-Related Immune Hemolysis

Drug-initiated immune hemolysis is often indistinguishable from autoimmune hemolytic anemia. There are two variants: the hapten type and the hemolysis that results from alteration of a membrane antigen.[147]

Hapten type Drugs such as the penicillins and the cephalosporins bind firmly to the erythrocyte membrane. In rare circumstances in which massive dosages of the drug (e.g., more than 10 million units of penicillin a day) are required, the protein-bound drug may act as a hapten and elicit an immune response. An IgG antibody that appears to be directed against the drug–RBC complex is produced[148,149]; this leads to a positive result on direct Coombs testing with the anti-IgG reagent and a negative result with the anti-C3d reagent. When the offending drug is stopped, hemolysis ends in a few days. In contrast, the drug may be bound loosely to produce a neoantigen that generates the immune response.[147] In this circumstance, the result of direct Coombs testing with the anti-C3d reagent is usually positive, and the result of testing with the anti-IgG reagent may be negative.

If the patient's serum is tested against normal cells (i.e., the indirect Coombs test is used), no reaction occurs unless the offending drug and a source of complement are first added to the normal RBCs. Stopping or switching the drug is effective in eliminating the hemolysis because the antibody is usually very specific.

Alteration of a membrane antigen Some drugs may alter a membrane antigen, thereby stimulating the production of IgG antibodies that cross-react with the native antigen. Methyldopa is the classic example of a drug that causes autoimmune hemolytic anemia. Other examples are levodopa, mefenamic acid, and procainamide. Drug administration leads to a positive direct Coombs test with anti-IgG reagents in 15% to 20% of treated patients, but hemolysis occurs in fewer than 1%. The eluted antibody is seen to be a classic IgG autoantibody directed against Rh components. The mechanism of hemolysis is identical to that of autoimmune hemolytic anemia.[150]

The NSAID diclofenac sodium has been reported to cause a devastating acute hemolytic anemia, with evidence of intravascular and extravascular hemolysis accompanied occasionally by shock, organ failure, and even disseminated intravascular coagulation.[151] Patients develop both RBC autoantibodies and drug-dependent antibodies. It is thought that diclofenac sodium binds to the surface of RBCs, forming neoantigens that lead to the generation of true autoantibodies, as well as drug-dependent antibodies. The direct Coombs test is positive with both the IgG and the C3d reagents. Additional antibody reactivity occurs with the addition of diclofenac sodium metabolites obtained from the urine of patients treated with the drug. Therapy consists of recognizing the cause, stopping the diclofenac sodium, and supporting the patient for several days until the process stops.[151]

Delayed Hemolysis of Transfused Erythrocytes

Blood is usually typed only for ABO and Rh-D antigens, but other antigens are also present on RBCs. Thus, a patient who receives extensive transfusions over 1 to 2 weeks may develop an antibody response to one or more of these other antigens. Kell, Duffy, Kidd, and Rh antigens other than D are the usual offenders. When the patient with antibodies receives RBCs expressing these antigens, an acute self-limited hemolysis, usually extravascular, may ensue. Clues are a history of transfusion, spherocytosis on peripheral smear, a positive direct Coombs test, and the recent appearance of an antibody in the patient's serum (positive indirect Coombs test). Usually, no therapy is required, but further transfusions should be cross-matched with the patient's serum [*see 5:X Transfusion Therapy*]. Similar problems arise with transplantation of bone marrow and other tissue.[152]

Cold Agglutinin Disease

Cold agglutinin disease has several variants. One rare variant affects young adults and usually occurs after infection with *Mycoplasma pneumoniae* or infectious mononucleosis, although several cases have also been reported in association with chronic falciparum malaria. A more common variant affects persons about 60 years of age and may present as idiopathic cold agglutinin disease, as a prodrome to a lymphoproliferative or an immunoproliferative disorder, or in association with an already established lymphoproliferative disorder.[153]

Pathophysiology Serologically, cold agglutinin disease is characterized by the presence of high titers of IgM agglutinins (> 1:1,000 and usually > 1:10,000) in serum. These antibodies are maximally active at 4° C, are capable of activating the complement sequence, and are directed against the polysaccharide antigens. Presumably, IgM reacts with erythrocytes circulating in the cooled blood of the nose, ears, and shins, where it fixes complement and then dissociates from the RBCs when they reach warmer areas of the body.

In the postinfectious variety of this disorder, IgM cold agglutinin is oligoclonal and short-lived. Conversely, the IgM is monoclonal in chronic idiopathic cold agglutinin disease or in cases associated with Waldenström macroglobulinemia, chronic lymphocytic leukemia, or other lymphomas. IgM predominantly contains λ light chains in patients with chronic idiopathic cold agglutinin disease or Waldenström macroglobulinemia; in patients with lymphoma, however, the IgM mainly contains κ light chains. Occasionally, the IgM cold agglutinin is detectable as an M protein spike on serum protein electrophoresis [*see 12:XV Chronic Lymphoid Leukemias and Plasma Cell Disorders*].

In the post-*Mycoplasma* variant, the mycoplasmas appear to bind to the RBC surface at the Ii antigen site. This receptor-ligand interaction results in the presentation of the I antigen in an immunogenic form.[154] *Listeria monocytogenes* contains the I antigen,[153] further supporting the idea that some infectious agents stimulate the naturally occurring cold agglutinins, as well as cause the postinfectious cold agglutinin disease.

Diagnosis The clinical syndrome of cold agglutinin disease is quite variable. Patients occasionally show only low titers of cold agglutinins and have no other symptoms or have a history of recent pneumonia. In patients with warm-and-cold autoimmune hemolytic anemia, the associated hemolysis tends to be severe and chronic. The RBCs of these patients are coated with IgG and complement components, whereas their serum contains a relatively low titer of cold agglutinin that acts at 30° C and perhaps even at temperatures up to 37° C.

The diagnosis is suggested by hemolytic anemia with acral signs and symptoms. It may be difficult to draw blood, and the RBCs may visibly agglutinate in a cold syringe and on the blood smear. Automated blood cell counters may count the agglutinated RBCs as single cells and thus report absurdly high values for the MCV and MCHC. Usually, the laboratory detects a broadly active cold agglutinin. The direct Coombs test is positive with anticomplement reagents but infrequently positive with anti-IgG.

Findings that support the diagnosis of idiopathic cold agglutinin disease include a high IgM cold agglutinin titer with broad thermal reactivity[134] and I specificity (reacting with erythrocytes from adults but not with cord erythrocytes), pure κ light-chain composition, occasionally an absolute serum IgM elevation, and an M protein pattern on serum protein electrophoresis. Investigation should be directed at discovering a possible lymphoma or other underlying disorder in these patients. Conversely, post-*Mycoplasma* and post–infectious mononucleosis cold agglutinins are polyclonal. The post–infectious mononucleosis antibody is usually directed against i antigens (cord RBCs).

Treatment The post-*Mycoplasma* or the post–infectious mononucleosis variant is usually mild and self-limited and requires no specific treatment. Patients with the idiopathic variety who have acral symptoms must change their way of life, either by moving to a warmer climate or by keeping their ears, nose, hands, and feet covered during cold weather. In severely anemic patients, transfusions with packed RBCs may be required; in such patients, careful cross-matching and warming of the blood is necessary to minimize cold agglutination.

Splenectomy and corticosteroids are generally of no benefit in controlling hemolysis associated with cold agglutinin disease. Presumably, complement-coated cells are removed to a substantial degree by hepatic rather than splenic macrophages, and the cells that produce IgM are relatively insensitive to the effects of

corticosteroids. Occasionally, however, high doses of corticosteroids (e.g., 100 mg of prednisone a day) have resulted in a reduction in the hemolytic rate in patients with relatively low titers of cold agglutinins. In the relatively rare variant caused by IgG cold agglutinins, corticosteroids and splenectomy may be of benefit. Use of penicillamine or other reducing agents containing sulfhydryl groups produces no benefit. Good responses are occasionally obtained by the use of chlorambucil at a dosage of 4 to 6 mg/day. Exchange transfusion and plasmapheresis appear to be logical therapies for acute disease, but further clinical studies are needed to evaluate these techniques. Interferon alfa, at a dosage of 3 million U/m^2 three times weekly, was reported to produce an impressive drop in cold agglutinin titer, with a decrease in serum IgM monoclonal protein and in acral symptoms over a 1-month period.[134] Treatment with rituximab in the doses used to treat non-Hodgkin lymphoma has been beneficial.[155,156]

Paroxysmal Cold Hemoglobinuria

Patients with the rare disorder of paroxysmal cold hemoglobinuria have cold-induced signs and symptoms of intravascular hemolysis. The hemolysis is associated with the presence of an IgG serum antibody that is directed against the RBC's P system. The IgG antibody is best demonstrated by the Donath-Landsteiner test; the serum is mixed either with the patient's own blood cells or with blood cells from a normal person. The mixture is chilled to 4° C. If the IgG antibody associated with this disorder is present, hemolysis occurs after warming to 37° C. In the past, paroxysmal cold hemoglobinuria was usually seen as a complication of syphilis, but it has recently been observed in association with viral infections and non-Hodgkin lymphoma.[157]

HYPERSPLENISM

Hypersplenic disorders constitute a diverse group of clinical conditions sharing the common features of splenomegaly and hemolysis. Splenic enlargement and hemolysis occur in many disorders, including hepatic cirrhosis with congestive splenomegaly, Gaucher disease, lymphoma, connective tissue disorders, Felty syndrome, sarcoidosis, tuberculosis, and other infectious diseases.

Pathophysiology

The spleen's unique structure accounts for several of the pathophysiologic features of hypersplenism. Splenic arterioles have a few direct branches leading to the sinusoids, but most of the terminal arterioles open into the splenic cords. Blood cells pass from the cords to the pulp through slits in the sinus walls; the slits have dimensions of about 1 by 3 μm.[158] Blood cells must squeeze through the longitudinal spaces, which are lined with reticular fibers, and between adventitial cells that are located outside the sinus. Macrophages and endothelial cells line the inside of the sinus. Repeated intimate contact occurs between blood cells and these macrophages.

Blood flow in the spleen is slow. The erythrocyte's pH and oxygen tension level fall, glucose is consumed, and the cell's metabolism is impaired. The hematocrit may increase, further elevating viscosity and resistance to flow. As a consequence, the blood cells are exposed to metabolic and mechanical stresses in the presence of macrophages and other leukocytes that can recognize cell membrane damage. As erythrocytes age, phagocytes remove defective surface areas, transforming the biconcave erythrocytes into rigid spherocytes or RBC fragments; these particles are later trapped and removed by the reticuloendothelial system. A big spleen has a greater than normal blood flow and exposes an unusually large proportion of blood cells to its culling activities. Thus, the problem in hypersplenism is essentially a quantitative one. A vicious circle may evolve in patients undergoing hemolysis, because hemolysis itself may cause splenomegaly.

Diagnosis

If the spleen is not palpable but the clinical situation is strongly suggestive of splenomegaly, ultrasonography or CT scanning may prove useful. Because blood cells other than erythrocytes are affected by a large spleen, the patient may be pancytopenic. Unless the underlying disease specifically involves the bone marrow, the marrow of patients with hypersplenism is generally hyperplastic because of rapid regeneration of all affected cell lines. The peripheral blood smear is not diagnostic of hypersplenism.

Treatment

If hypersplenism is producing clinically significant complications and if therapy for the patient's primary disease does not shrink the spleen, splenectomy may be necessary. Anemia, however, is not necessarily attributable to hypersplenism, irrespective of the size of the spleen. Hemodilution is another possible mechanism. Patients with massive splenomegaly who have very low hematocrit and hemoglobin values may have a normal RBC mass as assessed with the ^{51}Cr technique. Massive splenomegaly often is associated with an increase in plasma volume that results in extraordinary hemodilution. Moreover, greatly enlarged spleens may contain a pool of erythrocytes that constitutes as much as 25% of the total RBC mass—in contrast to normal spleens, which have no such RBC pool. In patients with splenomegaly who have a true decrease in RBC mass, the underlying disease may act to reduce RBC production by suppressing erythropoietin production rather than by accelerating destruction. Therefore, it is prudent to determine RBC mass before making the diagnosis of hypersplenism.

DRUGS AND TOXINS AS CAUSES OF HEMOLYSIS

Drugs Causing Oxidative Attack

Pathogenesis Dapsone, sulfasalazine, phenacetin, sodium perchlorate, nitroglycerin, phenazopyridine, primaquine,[100] paraquat, and vitamin K analogues can insert themselves into the oxygen-binding cleft of hemoglobin. By this action, such agents can generate oxidizing free radicals, such as superoxide, hydroxyl free radical, and peroxide. If the erythrocyte's protective reducing mechanisms are overwhelmed [*see Table 1*], hemoglobin is oxidized to form Heinz bodies and methemoglobin. Sulfhemoglobin is also produced by oxidative attack. The molecule contains a sulfur atom in the porphyrin ring, which gives it a blue-green color. The source of the sulfur atom is not clear, but the presence of sulfur in the heme ring makes it a poor oxygen transporter.[159] The RBC membrane may also suffer from oxidative attack. Damaged cells are removed in the reticuloendothelial system. Hemolysis is usually, but not invariably, extravascular, and Heinz bodies can be seen on a specially stained blood smear. The smear may also show the bite, hemiblister, or cross-bonded cells typical of oxidative attack on erythrocytes [*see Figure 4*]. Severe oxidative damage apparently causes hemoglobin to puddle at one side of the RBC, leaving a plasma membrane–enclosed hemighost in the remainder. Such hemighosts can be detected in the peripheral blood. Severe oxidative destruction is associated with increased methemoglobin levels and a decrease in RBC levels of GSH. The methemoglobin level is elevated. As little as 1.5 g/dl of methemoglobin or

0.5 g/dl of sulfhemoglobin can produce the physical finding of cyanosis. By contrast, 5 g/dl of reduced deoxyhemoglobin is required to produce comparable cyanosis.[100]

Nitrites can oxidize hemoglobin to methemoglobin. Consequently, the recreational use of butyl and isobutyl nitrites as stimulants, psychedelics, and aphrodisiacs has led to clinical problems. When inhaled in usual amounts, these agents may produce a mild to modest increase in methemoglobin, raising its concentration from the normal level of 1% to 2% to as much as 20%. More extensive inhalation or ingestion of these agents has induced severe methemoglobinemia, characterized by methemoglobin levels approaching 62%. Because methemoglobin does not carry oxygen, these high levels are accompanied by manifestations of tissue hypoxia such as headache, shortness of breath, lethargy, and stupor. Physical examination shows tachycardia, postural hypotension, and cyanosis; the venous blood is purple-brown.[160] If untreated, it is likely to be fatal.

Diagnosis Diagnosis is based on a history of exposure to an oxidant drug or other toxin, together with characteristic peripheral blood smear findings and elevated methemoglobin measurements.

Treatment Treatment should restore normal methemoglobin levels. Management starts with the identification and withdrawal of the offending agent. Patients who have severe methemoglobinemia should be treated immediately with 1 to 2 mg/kg of methylene blue; the agent is infused intravenously in a 1 g/dl solution over a 5-minute period. In the presence of the RBC enzyme NADPH-methemoglobin reductase and adequate amounts of the electron donor NADPH [*see Table 1*], methylene blue is rapidly reduced to leukomethylene blue. This product in turn quickly reduces methemoglobin to hemoglobin. Cyanosis is thereby reversed, and the patient should turn pink immediately after the infusion. Several hours later, however, the patient may again become cyanotic, presumably because nitrates released from tissues reenter the peripheral blood at that time. Readministration of methylene blue at a dosage of 1 mg/kg intravenously over a 5-minute period should restore normal hemoglobin levels.

Successful methylene blue therapy requires adequate supplies of NADPH. Patients who have abnormalities of the pentose phosphate pathway, such as G6PD deficiency, will not respond to this approach and should receive emergency exchange transfusions.[160] Patients with very high levels of methemoglobin (at least 60%) or those whose smears contain many hemighosts should undergo exchange transfusion, perhaps with hemodialysis.[100,160]

Lead-Induced Hemolysis

Lead exposure results in hypertensive encephalopathy, neuropathy, and hemolytic anemia characterized by coarse basophilic stippling in RBCs. The mechanism of lead-induced hemolysis is complex because the metal has several actions: it blocks heme synthesis, thus causing a buildup of RBC protoporphyrin; it produces a deficiency of pyrimidine 5′-nucleotidase[161]; and it attacks erythrocyte membrane phospholipids, producing potassium leak and interfering with Na^+,K^+-ATPase activity.

Diagnosis Screening for lead poisoning entails measuring the free erythrocyte protoporphyrin level (sometimes called the zinc protoporphyrin level), which is elevated because lead blocks the last step in heme synthesis. The diagnosis is confirmed by measuring blood and urine lead levels.

Treatment After the exposure to lead is stopped, use of a chelating agent such as edetate calcium disodium ($CaNa_2EDTA$) may be considered. Treatment is started with 0.5 to 1 g of intravenous $CaNa_2EDTA$, given over a period of 6 to 8 hours; the compound is given daily for 5 days.

After this initial course, 0.5 g of $CaNa_2EDTA$ is given as an intravenous bolus or intramuscular injection every 2 days for 2 weeks, during which time the urine lead levels are monitored. Alternatively, the initial 5-day course of $CaNa_2EDTA$ can be followed with oral penicillamine: 1 g a day is given for the first 7 days; the drug is withheld for the next 7 days; and during the final 7 days of the regimen, the dosage of 1 g a day is resumed and the urine lead level is measured at the end of the final day. Another study recommends giving 500 mg of penicillamine a day and continuing this dosage for 60 days after the patient has become asymptomatic.[162]

VENOMS AND PHYSICAL AGENTS AS CAUSES OF HEMOLYSIS

Agents Causing Enzymatic Attack

Classic examples of attacking enzymes are the snake-venom or clostridial lecithinases (e.g., phospholipase C). Such enzymes attack the phospholipids of the membrane bilayer and produce RBC fragmentation, spherocytosis, and intravascular and extravascular hemolysis. Disseminated intravascular coagulation and shock may occur. Prompt recognition and management of the primary disorder is critical, as is supportive therapy.

Venom from the brown spider, *Loxosceles intermedia,* releases sphingomyelinases and metalloproteinases that cleave the RBC membrane glycophorins. This in turn facilitates complement activation and lysis of affected RBCs.[163]

Physical Causes of Hemolysis

Freshwater drowning and accidental intravenous administration of sterile water can cause intravascular hemolysis by osmotic lysis. In such cases, RBCs swell and become spheroidal. Saltwater drowning can induce hemolysis by desiccating RBCs. Burns cause temperature-mediated denaturation of erythrocyte membrane polypeptides, resulting in hemolysis.

Infectious Diseases Causing Hemolysis

Malaria is the most important infectious cause of hemolysis. The resulting severe anemia causes the death of large numbers of pregnant women and 2- to 5-year-old children in sub-Saharan Africa. *Plasmodium* species, particularly *P. falciparum*, directly parasitize and destroy RBCs, but the anemia is a complex blend of impaired RBC production, hemolysis of parasitized and nonparasitized[130] RBCs, and ineffective erythropoiesis.[164] The diagnosis is made by pathognomonic findings on the blood smear; treatment is directed against the malarial parasite, with support of the circulation with RBC transfusions if required [*see 7:XXXIV Protozoan Infections*].

Other infectious causes of hemolysis Infection with *M. pneumoniae* and infectious mononucleosis can cause cold agglutinin hemolysis. Infection with *H. influenzae* type b can cause hemolysis. The major virulence factor of *H. influenzae*, polyribose ribosyl phosphate (PRRP), allows the organism to escape phagocytosis. When PRRP is released into the circulation, it binds to RBCs. The binding of anti-PRRP antibodies then leads to complement-dependent hemolysis.[165] Patients infected with

HIV or cytomegalovirus may have autoimmune hemolytic anemia (see above).[166]

Clostridial sepsis can be devastating; the appearance of free plasma hemoglobin or hemoglobinuria should suggest this often fatal infection. *Clostridium* species are capable of sudden, explosive growth; they can release many enzymes, including phospholipases and proteases, that digest RBCs, producing intravascular hemolysis.

Some infections can cause splenomegaly and hypersplenic hemolysis. Meningococcemia or overwhelming gram-negative septicemia often produces disseminated intravascular coagulation and microangiopathic hemolysis.

Babesiosis is caused by a parasite that invades RBCs and that is transmitted from its rodent reservoir by the same ixodid tick that carries Lyme disease and human granulocytic ehrlichiosis. This disease is being more frequently diagnosed, particularly in New England. Immunocompromised persons, such as those with HIV, are more likely to have chronic and severe infections. The diagnosis has been made on peripheral blood smears, but polymerase chain reaction methods are more sensitive.[167]

HEMOLYSIS ASSOCIATED WITH LIVER DISEASE

Anemia in patients with liver disease is often the result of a production defect rather than hemolysis, but cirrhotic patients may have congestive splenomegaly with hypersplenic hemolysis. Macrocytes (with or without B_{12} or folate deficiency) and target cells (caused by cholesterol elevation) are also common findings in such cases.

Spur cell anemia Severe liver disease, including alcoholic cirrhosis, may result in the formation of irregularly spiculated RBCs known as spur cells (acanthocytes).[168] Spur cells have alterations in their membranes (a decreased ratio of phospholipids to cholesterol[169]) that shorten their survival, resulting in hemolytic anemia.

OTHER CAUSES OF HEMOLYSIS

Copper Accumulation

In rare instances, Wilson disease, a metabolic disorder associated with excessive copper deposition, is first detected during a coincident episode of dramatic, acute hemolysis. The release of free copper into the serum and its subsequent entry into RBCs are thought to be the underlying hemolytic mechanism. In addition to affecting hexokinase levels, the intracellular copper appears to cause formation of oxygen radicals that react with and oxidize membrane components. Although no successful therapeutic intervention has been reported, penicillamine can be given at a dosage of 2 to 4 g once a day orally to reduce the free copper level. The administration of 1,000 to 2,000 IU of vitamin E (α-tocopherol) a day for several days may also be helpful if oxidative attack is an important factor.

Cardiopulmonary Bypass

Free plasma hemoglobin increases after cardiopulmonary bypass. The increase is thought to be caused by activation of the complement pathway, leading to deposition of the C5b-C9 attack complex on the RBC surface [*see 6:IV Disorders of the Complement System*].[170]

The author has served as a consultant for Tularek Corp. and Receptron, Inc., during the past 12 months.

V THE POLYCYTHEMIAS

Virginia C. Broudy, m.d.

Classification of the Polycythemias

Polycythemia, also called erythrocytosis, is an increase in the number of circulating red blood cells per volume of blood, as reflected by an elevated hematocrit or hemoglobin level. The three major categories of polycythemia are (1) relative polycythemia, (2) secondary polycythemia, and (3) primary polycythemia, or polycythemia vera.

In relative polycythemia, the red blood cell mass is normal but the plasma volume is decreased. Secondary polycythemia is caused by an elevated erythropoietin level. Polycythemia vera is a neoplastic stem cell disorder characterized by an autonomous overproduction of red blood cells and, often, of white blood cells and platelets [*see 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*].

Initial Evaluation

Patients are often asymptomatic, and the elevated hemoglobin or hematocrit level is usually discovered accidentally. When such an increase is found, it should be promptly evaluated to determine its cause [*see Figure 1*]. Any family history of polycythemia and the results of any previous hematocrit determinations should be obtained. History and physical examination findings suggestive of congenital heart disease, severe chronic obstructive pulmonary disease (COPD), or sleep apnea syndrome should be sought, and the presence or absence of splenomegaly should be determined. The results of the complete blood count, including the platelet count and white blood cell differential, should be critically reviewed for abnormalities. Findings of leukocytosis, thrombocytosis, an occasional circulating immature white blood cell, or increased basophils are suggestive of polycythemia vera and argue against secondary causes of erythrocytosis.

A hematocrit level of 60% or higher in a man or 57% or higher in a woman virtually always indicates a true increase in red blood cell mass (i.e., primary or secondary polycythemia). If the patient's hematocrit is below these values but above normal, a red blood cell mass study is required.[1] To perform this study, a sample of the patient's red blood cells is labeled with radioactive chromium (^{51}Cr) ex vivo and injected back into the patient. A second blood sample is then obtained to quantitate the concentration of ^{51}Cr-labeled red blood cells among the unlabeled red blood cells. In parallel, the patient is given an injection of albumin labeled with radioactive iodine (^{125}I) to measure the plasma volume. If a contraction of plasma volume is noted, the patient has relative polycythemia; if an increase in red blood cell mass is noted, the patient has true (i.e., primary or secondary) polycythemia. Once a relative or an absolute increase in red blood cell mass is documented, an exact diagnosis should be determined [*see Figure 1*].

Relative Polycythemia

Patients with relative polycythemia (Gaisböck syndrome) are often obese, hypertensive men who may also be heavy smokers[2]; they often are 45 to 55 years of age—a decade younger than typical for polycythemia vera patients [*see 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*]. It has been estimated that 0.5% to 0.7% of the healthy male population in the United States have relative polycythemia. Diuretic use for treatment of hypertension may exacerbate the deficit in plasma volume, and smoking-induced high carboxyhemoglobin levels or hypoxemia may also play a role.

Relative polycythemia is usually mild (hematocrit lower than 55%). In patients with a hematocrit lower than 60%, this diagnosis should be considered, and the red blood cell mass and plasma volume should be measured [*see Figure 1*] to avoid an extensive and ultimately frustrating workup for other causes of polycythemia. Patients with relative polycythemia fall into two major groups: (1) those with normal red blood cell mass and clearly decreased plasma volume and (2) those with red blood cell mass and plasma volume at the upper and lower range of normal, respectively. Behavior modification (e.g., an exercise regimen and smoking cessation) is recommended for these patients. Hematocrit returns to normal over time in approximately one third of patients.

Secondary Polycythemia

Secondary polycythemia occurs when erythropoietin production is increased as a result of chronic tissue hypoxia. Causes of tissue hypoxia include life at high altitude, high-affinity hemoglobin, cardiopulmonary disease, obstructive sleep apnea, obesity-hypoventilation syndrome, and high serum levels of carboxyhemoglobin. Polycythemia also occurs in some renal and hepatic disorders, in rare genetic disorders, and from treatment with androgens or erythropoietin.

Polycythemia caused by appropriate increases in erythropoietin production

Life at High Altitude

Initial human adaptation to high altitude includes increases in the respiratory rate, cardiac output, and the level of 2,3-bisphosphoglycerate to facilitate oxygen unloading from hemoglobin to the tissues [*see Figure 2*]. Within 6 to 24 hours after a person has ascended to a high altitude, erythropoietin levels increase, resulting in reticulocytosis within 24 to 48 hours. Over several days, serum erythropoietin levels return to normal, but the increase in hematocrit is sustained. In addition to the increase in red blood cell mass, a modest decrease in plasma volume occurs. A patient's travel history should be taken to determine the likelihood of high-altitude effect and thus possibly avoid having to conduct an extensive workup.

Life at high altitude, such as in the Rocky Mountains of North America or the Andes of South America, may result in chronic mountain sickness characterized by headaches, dizziness, mental slowing, dyspnea, and weakness. In such cases, individuals may have a hematocrit as high as 63% and are at risk for the development of pulmonary hypertension, early onset cardiovascular disease, and proteinuria. Treatment with low-dose angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril, 5 mg orally each day) can improve the hematocrit and renal function over 1 to 2 years.[3]

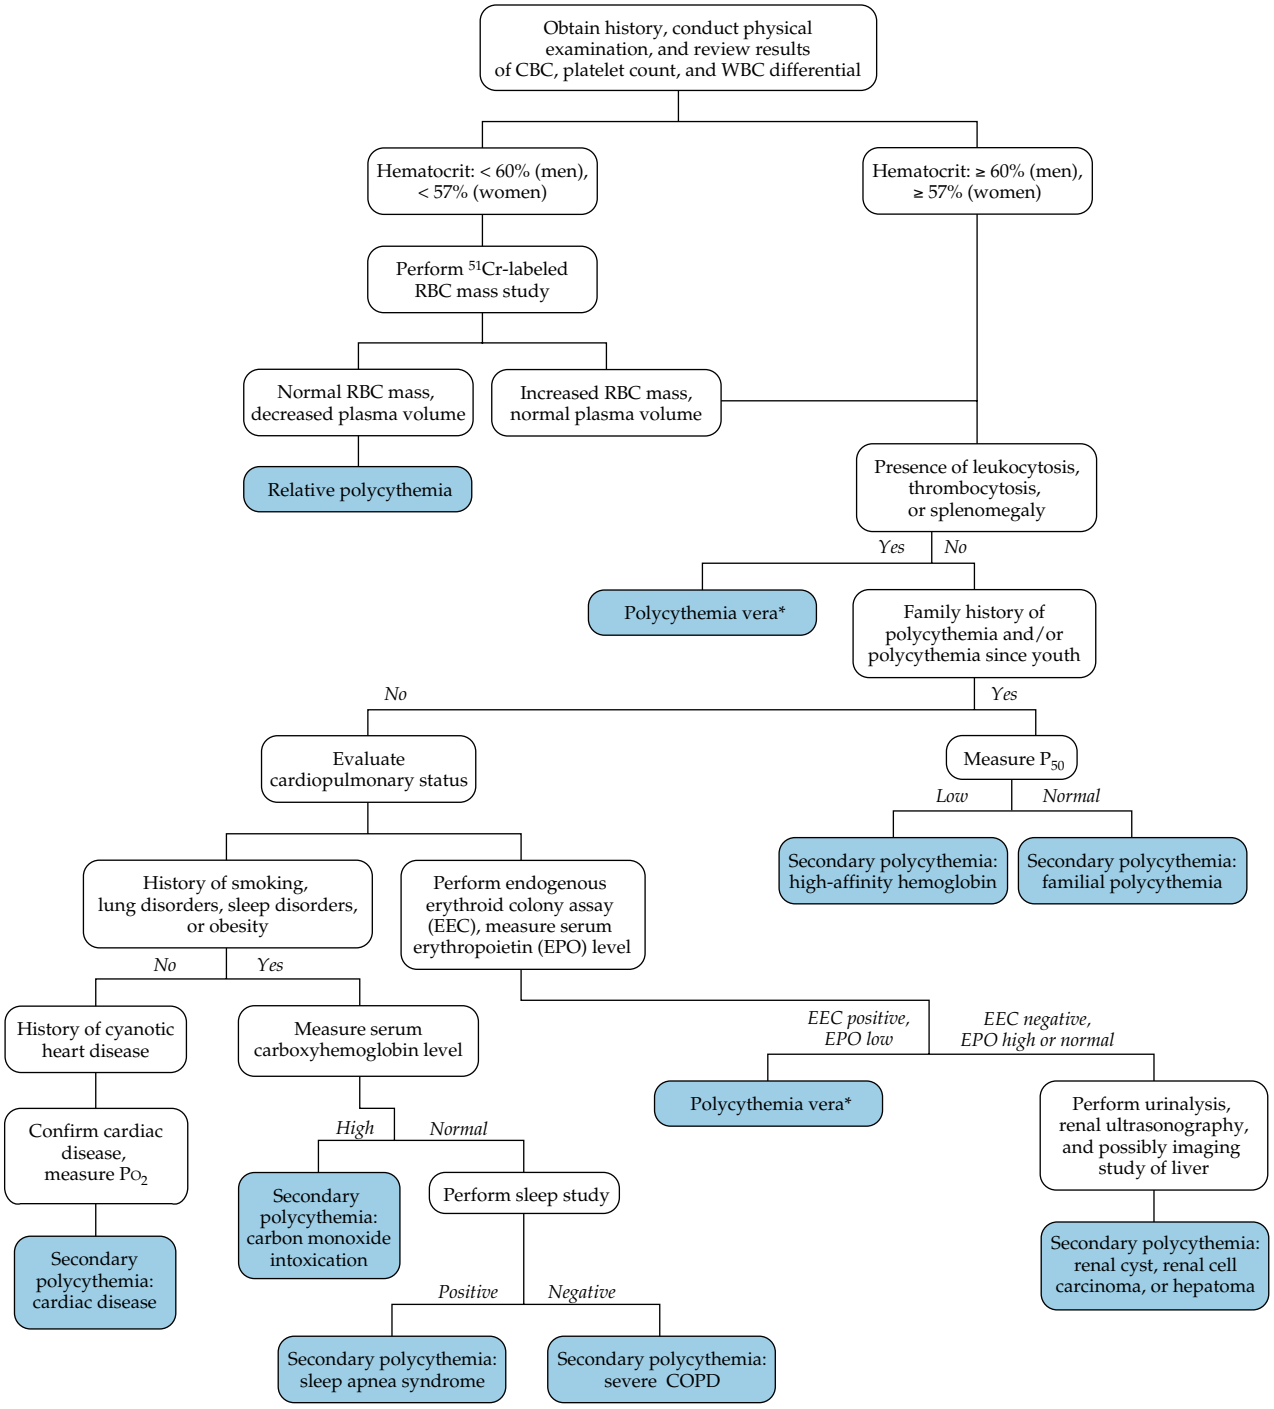

Figure 1 **This flowchart depicts an approach to the evaluation of a patient with polycythemia, as evidenced by an elevated hematocrit or hemoglobin level on routine complete blood count. (CBC—complete blood cell count; COPD—chronic obstructive pulmonary disease; EEC—endogenous erythroid colony; EPO—erythropoietin; RBC—red blood cell count; WBC—white blood cell count)**
***For coverage of polycythemia vera, see *12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*.**

High-Affinity Hemoglobin

High-affinity hemoglobin is caused by an amino acid substitution in either the α chain or, more commonly, the β chain of globin that impedes the normal conformational change during oxygen loading and unloading. This condition results in an impaired ability to release oxygen in the tissues, causing tissue hypoxia and increased erythropoietin production. More than 100 mutations causing high-affinity hemoglobin have been described. They are usually familial and are inherited in an autosomal dominant manner but are occasionally the result of spontaneous mutation. A review of the patient's medical history should show evidence of lifelong polycythemia. The hematocrit is usually less than 60%, and the white blood cell and platelet counts are normal. The partial pressure of oxygen at which hemoglobin is 50% saturated (P_{50}) should be measured; it is reduced in patients with high-affinity hemoglobin [*see Figure* 2].

Hemoglobin electrophoresis is usually not helpful, because many of the mutations that result in high-affinity hemoglobin are electrophoretically silent. However, the mutations can be identified by DNA sequencing. In rare instances, patients have congenital 2,3-bisphosphoglycerate mutase deficiency; the presentations of these patients are similar to those of patients with high-affinity hemoglobin. Patients with high-affinity hemoglobin or congenital 2,3-bisphosphoglycerate mutase deficiency usually have no symptoms of hyperviscosity and require no therapy. Phlebotomy decreases exercise tolerance in these patients and should not be used.

Cardiopulmonary Disease

Polycythemia caused by cardiopulmonary defects (e.g., Eisenmenger complex, univentricular heart, and tetralogy of Fallot) results from a failure to load oxygen onto hemoglobin adequately in the lungs.[4,5] The hematocrit may range from 60% to 75% and cause profound symptoms of hyperviscosity, including headache, dizziness, visual disturbances, fatigue, paresthesias, irritability, and decreased mental acuity. Platelet microparticles are overproduced in cyanotic congenital heart disease, especially when the hematocrit is greater than 60%; overabundance of these microparticles may contribute to the hemostatic abnormalities in these patients.[6] Some adults with cyanotic congenital heart disease have decompensated erythrocytosis, which is characterized by unstable, rising hematocrit and symptomatic hyperviscosity; these patients may benefit from phlebotomy.[5] Other adults with cyanotic congenital heart disease have compensated erythrocytosis, in which a stable (though elevated) hematocrit is maintained without overt symptoms of hyperviscosity; these patients do not require phlebotomy.[5] A practical approach is to cautiously phlebotomize patients whose hematocrits range from 60% to 65% and who have symptoms of hyperviscosity.[5] The extent of phlebotomy should be guided by the patient's symptoms. Acute dehydration, which exacerbates polycythemia, should be excluded from the diagnosis before phlebotomy is performed, and the volume of blood withdrawn should be replaced with isotonic saline. Iron deficiency should be avoided by the use of oral iron therapy if necessary because severe iron deficiency may alter red blood cell rheology and increase the risk of stroke.[7]

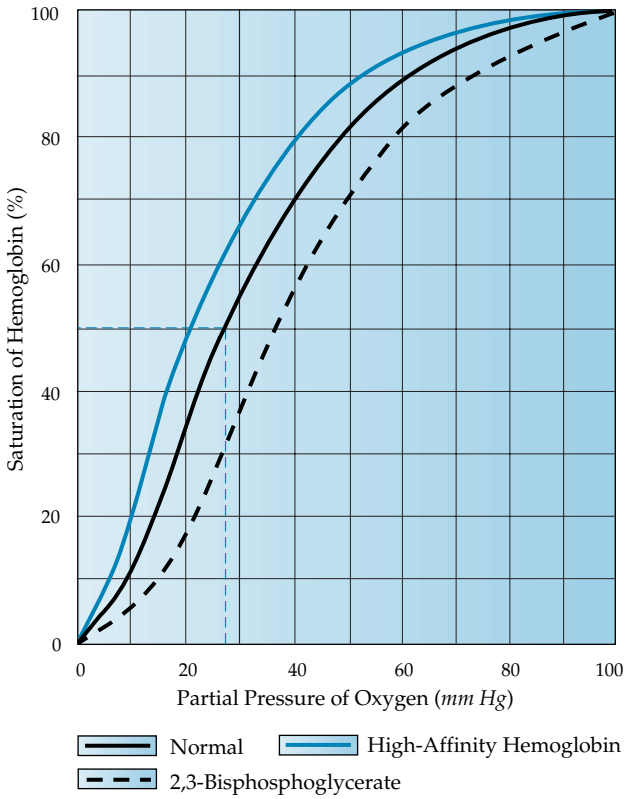

Figure 2 **Depicted is the oxygen-hemoglobin dissociation curve (solid black line). The partial pressure of oxygen at which hemoglobin is 50% saturated (P_{50}) is normally 27 mm Hg (broken blue lines). The presence of high-affinity hemoglobin shifts the curve to the left, reflecting impaired oxygen unloading in the tissues (solid blue line). An increase in the level of 2,3-bisphosphoglycerate—a feature of adaptation to high altitude—shifts the curve to the right, reflecting increased oxygen unloading in the tissues (broken black line).**

Severe COPD can be associated with polycythemia, although the clinical features of COPD usually predominate. In patients who continue to smoke, both hypoxemia and elevated carboxyhemoglobin levels may contribute to the development of polycythemia. Reduction of hematocrit in patients with significant polycythemia caused by COPD results in increased cerebral blood flow, relief from the symptoms of dizziness and headache that are associated with hyperviscosity, and dramatic improvement in mental alertness. In a study of seven patients with severe COPD and pulmonary hypertension, serial phlebotomy reduced pulmonary arterial pressure and improved exercise capacity.[8]

Obstructive Sleep Apnea

Sleep apnea syndrome is estimated to occur in 4% of middle-aged men and 2% of women and is underdiagnosed.[9] Risk factors include obesity, male sex, central body fat distribution, and a family history of obstructive sleep apnea.[10] The prevalence of sleep apnea syndrome increases as the body mass index increases. Recurrent episodes of upper airway collapse during sleep obstruct air movement, resulting in intermittent nocturnal hypoxemia. Patients may have a history of loud snoring, alternating with periods of silence lasting 10 seconds to 1 minute, followed by gasping sounds. Fragmented sleep results in excessive daytime sleepiness and impaired work performance and may increase the risk of motor vehicle accidents.[11] The hematocrit may be modestly increased in patients with severe obstructive sleep apnea, and this syndrome should be considered in patients with unexplained polycythemia. Nocturnal polysomnography with quantitation of the apnea-hypopnea index can establish the diagnosis. Management of this condition may include weight loss, nasal continuous positive airway pressure, and surgery[12] [*see 11:XIII Disorders of Sleep and 14:VI Ventilatory Control during Wakefulness and Sleep*].

Obesity-Hypoventilation Syndrome

Obesity-hypoventilation syndrome is also known as pickwickian syndrome, in reference to Charles Dickens' astute description of the obese coachboy who had excessive daytime sleepiness. Patients with this syndrome are usually morbidly obese (body mass index of 40 kg/m^2) and have chronic daytime hypoxemia and hypercapnia, in part because of a blunted ventilatory response to these stimuli.[13] Many of these patients also have nocturnal obstructive sleep apnea.[14] Hypoxemia provides the stimulus for increased erythropoietin production and polycythemia. Other clinical features associated with obesity-hypoventilation syndrome are daytime hypersomnolence and cor

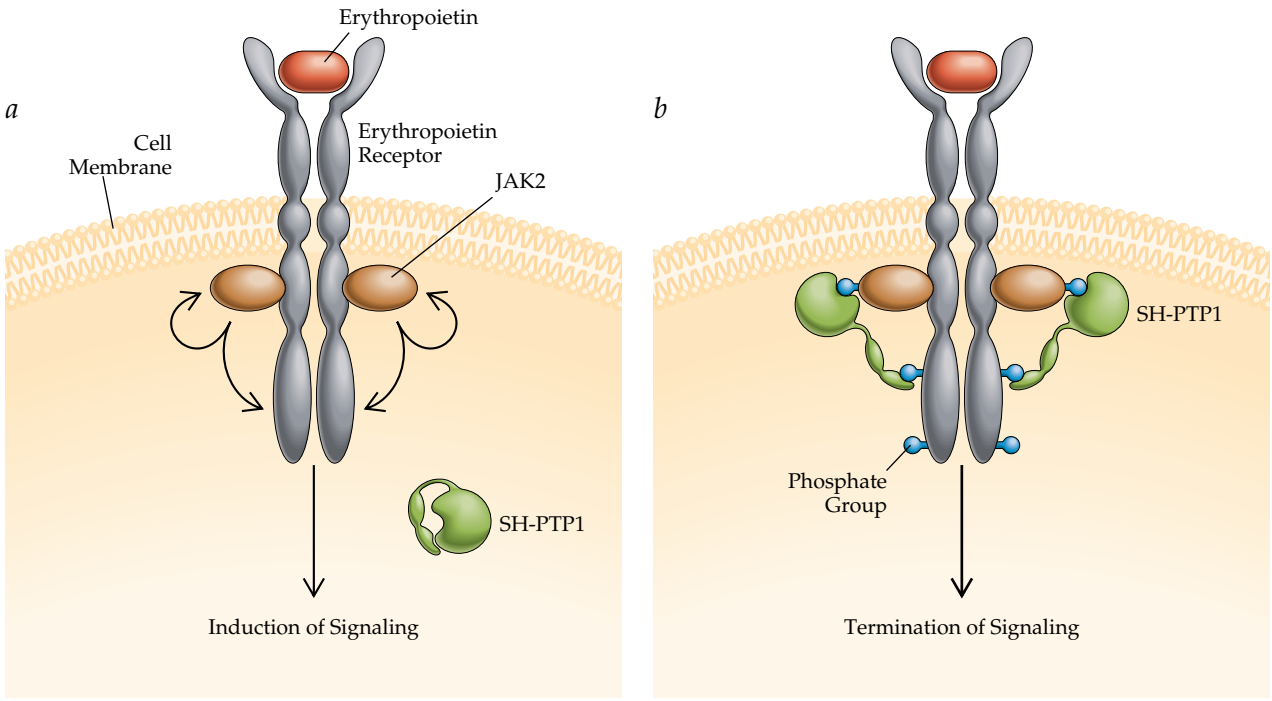

Figure 3 **(*a*) Binding of erythropoietin to the erythropoietin receptor on an erythroid progenitor cell triggers association and activation of the protein-tyrosine Janus kinase-2 (JAK2) and the initiation of signal transduction, stimulating growth of the erythroid progenitor cell. (*b*) Binding of the protein-tyrosine phosphatase SH-PTP1 results in dephosphorylation of JAK2 and termination of signal transduction.**

pulmonale. Management of this condition includes weight loss and progesterone therapy to stimulate the central respiratory drive [*see 14:VI Ventilatory Control during Wakefulness and Sleep*].

High Carboxyhemoglobin Levels

Long-term exposure to carbon monoxide results in chronic high carboxyhemoglobin levels [*see 8:I Management of Poisoning and Drug Overdose*]. Carbon monoxide binds to hemoglobin with an affinity 210 times greater than that of oxygen, decreasing the quantity of hemoglobin available for oxygen transport. Carbon monoxide binding also increases the affinity of the remaining heme groups for oxygen, shifting the oxygen-hemoglobin dissociation curve to the left [*see Figure 2*] and impairing the unloading of oxygen in the tissues. By these mechanisms, long-term carbon monoxide exposure can cause polycythemia. Cigarette and cigar smokers and persons with long-term occupational exposure to automobile exhaust in poorly ventilated areas (e.g., toll-booth operators, underground-garage attendants, and truck loaders) are at risk. The average carboxyhemoglobin level in the blood of nonsmokers is approximately 1% or less, whereas it is 4% in smokers and as high as 15% in heavy smokers.

Symptoms may include subtle neuropsychiatric abnormalities and exacerbation of angina (likely as a result of impaired myocardial oxygen delivery). The diagnosis can be established by measuring the percentage of carboxyhemoglobin in the blood. Because the half-life of carboxyhemoglobin is approximately 5 hours, the test should be done late in the day, when the patient has smoked the usual number of cigarettes or spent several hours in the work environment. Polycythemic smokers usually have both elevated red blood cell mass and decreased plasma volume. For smokers, the most effective therapy is smoking cessation; abnormal blood and plasma levels revert to normal within 3 months. No therapy is available for persons with occupational polycythemia, with the exception of avoidance of the workplace.

POLYCYTHEMIA CAUSED BY RENAL AND HEPATIC DISORDERS

Polycythemias arise when erythropoietin production is increased because of renal or, less often, hepatic disorders. In adults, approximately 90% of erythropoietin production occurs in the kidney, and 10% occurs in the liver. Because of the intricate regulation of erythropoietin production in the kidney, distortion of renal anatomy can result in polycythemia. Case reports document that renal cysts, hydronephrosis, focal glomerulonephritis, and Bartter syndrome can cause polycythemia. After renal transplantation, approximately 10% to 20% of patients have transient or persistent polycythemia. It is important to identify these patients, because they are at increased risk for arterial or venous thrombotic events and may require phlebotomy or ACE inhibitors.[15] In addition, primary malignancies of the kidney or liver can cause polycythemia. Polycythemia develops in approximately 3% of patients with renal cell carcinoma. Erythropoietin production by primary renal cell carcinoma or hepatoma tissues is the likely cause of polycythemia in these patients. In rare instances, focal nodular hyperplasia of the liver, hepatic or cerebral hemangiomas or hemangioblastomas,[16] uterine fibroids, adrenal adenomas, and pheochromocytomas have been reported to cause polycythemia. Mutations in the von Hippel–Lindau gene have been associated with cerebral hemangioblastomas or renal cell cancer, either as a part of the von Hippel–Lindau syndrome or as an acquired somatic mutation.[17]

FAMILIAL POLYCYTHEMIA

The familial polycythemias are rare diseases resulting from inborn mutations affecting hematopoietic or nonhematopoietic cells. The molecular mechanisms causing familial polycythemia may be different in different families, and mutations may be inherited in an autosomal dominant or recessive fashion.

A high frequency of autosomal recessive familial polycythemia is found in the Chuvash region of Russia.[18] Elegant

studies have demonstrated that a point mutation in the von Hippel–Lindau gene results in enhanced stability of hypoxia-inducible factor-1α, which regulates transcription of the erythropoietin gene.[19] Thus, Chuvash polycythemia is a congenital disorder of oxygen homeostasis. Chuvash polycythemia has also been identified in families of European or Asian descent.[20] Patients with Chuvash polycythemia present during the teenage years with headache, dizziness, fatigue, and dyspnea on exertion.[21] Affected members of these families have a high hematocrit (approximately 60%) and elevated levels of erythropoietin, and they have thromboembolism and cerebrovascular disorders, which shorten survival. Treatment is with phlebotomy.

In autosomal dominant familial polycythemia, abnormalities in the erythropoietin receptor have been identified in a small proportion of patients.[22-25] Erythropoietin initiates its biologic effects by binding to a specific receptor that is found on the surface of erythroid progenitor cells, precursor cells, and certain other types of cells. Binding triggers a cascade of events, including activation of the protein tyrosine Janus kinase-2 (JAK2) [*see Figure 3*]. Tyrosine phosphorylation of the erythropoietin receptor creates docking sites for other signal transduction molecules and for the protein-tyrosine phosphatase SH-PTP1, which dephosphorylates JAK2 and terminates signal transduction. In one large Finnish family with polycythemia, a point mutation in the erythropoietin receptor affecting SH-PTP1 rendered the erythroid progenitor cells hypersensitive to erythropoietin. Interestingly, one member of this family who had a hematocrit of 60% won three gold medals in cross-country skiing at the 1964 Winter Olympics. Another proportion of patients with autosomal dominant familial polycythemia have been found to have mutations in the erythropoietin receptor, resulting in deletion of the carboxyl terminus negative regulatory region of the receptor.[23-25] Individuals with autosomal dominant familial polycythemia have erythrocytosis that remains stable over time; they do not experience leukocytosis or thrombocytosis, and no long-term clinical consequences have been described.

POLYCYTHEMIA CAUSED BY DRUG USE

Androgens (e.g., testosterone) can cause polycythemia by stimulating erythropoietin production.[26] The elevation in hematocrit is usually mild, and hematocrit returns to normal 2 to 3 months after discontinuance of anabolic steroid use. Since recombinant human erythropoietin and darbepoetin have become available, concern has been raised that competitive athletes involved in endurance sports, such as bicycle racing, cross-country skiing, and long-distance running, might surreptitiously self-inject this drug to improve athletic performance.[27-29] Phlebotomy followed by blood doping is known to improve performance in runners and skiers. A similar increase in hematocrit can be achieved with erythropoietin injections, which can increase maximal exercise capacity. The unmonitored increase in red blood cell production may cause significant polycythemia, which, when coupled with exercise-induced dehydration, can have tragic consequences. Erythropoietin abuse has been linked to the deaths of competitive bicyclists.[27] The use of erythropoietin or darbepoetin to improve athletic performance is banned by the International Olympics Committee. Recombinant human erythropoietin can be detected in the urine by isoelectric focusing.[30]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII NONMALIGNANT DISORDERS OF LEUKOCYTES

David C. Dale, m.d.

Leukocytes, or white blood cells, protect the body against infections and participate in many types of immunologic and inflammatory responses. There are two main types of leukocytes: lymphocytes, which are responsible for antibody production and cell-mediated immunity, and phagocytes, which are responsible for the ingestion and killing of microorganisms. Neutrophils, monocytes, macrophages, and eosinophils are all phagocytes [*see Figure 1*]. Leukocytes interact with one another and modulate immune responses through the release of cytokines (interleukins and growth factors), enzymes, and vasoactive substances. This chapter covers the diagnosis of disorders of neutrophils, monocytes, and eosinophils and the treatment of neutropenia; the functions and disorders of lymphocytes are discussed elsewhere [*see Section 6 Immunology and Allergy*].

The White Blood Cell Count

The total white blood cell (WBC) count and differential count are often the first studies performed in evaluating a patient with a suspected infection or with susceptibility to infections. Most laboratories measure the WBC count using automated cell-counting techniques.[1] The normal WBC count ranges from 4,300 to 10,000/mm^3, with a median of 7,000/mm^3 [*see Table 1*]. A differential count gives the percentage for each type of leukocyte. The absolute count is determined by multiplying the total WBC count by this percentage (e.g., WBC × percent neutrophils = absolute neutrophil count). Because the blood level of each type of leukocyte is separately regulated, it is always better to use the absolute count rather than the percentage in assessing abnormalities.

Indications of the Presence of a Phagocytic Cell Disorder

Because the phagocytes, particularly neutrophils, represent the first line of defense against invading microorganisms, disorders in the number or function of these cells often result in an increased susceptibility to infection. A quantitative or qualitative disorder of phagocytic cells should be suspected when a patient has an increased number of bacterial or fungal infections, increasingly severe infections, or infections with unusual organisms.

Neutrophil Physiology

neutrophil production

Neutrophils are derived from the common stem cell, which also gives rise to erythrocytes, platelets, and other leukocytes. The proliferation and differentiation of the neutrophil precursors are governed by a family of regulatory cytokines. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) are two important cytokines affecting neutrophil production and function. G-CSF selectively stimulates progenitor cells to differentiate into neutrophils and rapidly increases blood neutrophils in hematologically normal individuals [*see Figure 2*].[2,3] GM-CSF stimulates progenitor cells to differentiate into neutrophils, eosinophils, monocytes, macrophages, and dendritic cells.[4] The life cycle of the neutrophil consists of bone marrow, blood, and tissue phases. Neutrophil production in the bone marrow takes approximately 10 to 14 days, and the bone marrow produces approximately 1×10^9 neutrophils/kg/day.[5] Most of the body's neutrophils are found in the bone marrow. The mitotic compartment, which contains about 20% of the total neutrophil pool, consists of myeloblasts (the earliest morphologically recognizable precursors), promyelocytes, and myelocytes. The postmitotic pool or maturation compartment—the metamyelocytes, bands, and mature neutrophils—contains about 70% of the body's neutrophils. The marrow neutrophils and bands are sometimes called the storage compartment or marrow reserve. As neutrophils mature, they develop the capacity to enter the blood through increasing deformability and through changes in the adhesion proteins on their surface membranes. Entry into the blood involves interactions of the mature cells and the endothelial cells of the marrow sinusoids that are not yet well understood. Agents that stimulate release of neutrophils from the marrow (e.g., G-CSF, GM-CSF, corticosteroids, or endotoxin administration) can result in a doubling of the blood neutrophil count within 3 to 5 hours. The peripheral blood contains fewer than 10% of the body's neutrophils. In the blood, the neutrophils are divided approximately evenly between the circulating pool and the marginating pool; these pools are in dynamic equilibrium. Cells in the marginating pool can be swept rapidly (within minutes) into the circulation by endogenous or exogenous epinephrine or as a result of exercise or any cause of rapid increase in cardiac output. This response, called demargination, can double the blood neutrophil count very rapidly and is also quickly reversible. The blood half-life of the neutrophils is approximately 6 to 10 hours. Neutrophils leave the blood and enter the tissues by migrating between endothelial cells and penetrating the capillary basement membrane. It is now believed that neutrophils that do not leave the circulatory system die by apoptosis and are removed by mononuclear phagocytes in the spleen, liver, and other tissues.[6]

neutrophil structure

As neutrophil precursors mature, their nuclear chromatin becomes condensed and segmented. Mature cells have no nucleoli, few mitochondria, and very little endoplasmic reticulum. The cytoplasm is filled with granules and glycogen. The primary granules, which appear at the myeloblast and promyelocyte stages, contain myeloperoxidase (MPO), proteases, defensins, and other antibacterial substances.[7,8] Secondary granules, produced primarily during the myelocyte stage, predominate in mature cells. They contain collagenase, lactoferrin, lysozyme, vitamin B_{12}–binding protein, and several other proteins. Small tertiary granules are also found in mature neutrophils. Neutrophils also may have cytoplasmic vesicles containing lactases, alkaline phosphatases, and components of nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase.

The surface of the neutrophil is replete with deep folds and ruffles. On the neutrophil surface, there are numerous receptors, including receptors for immunoglobulins (e.g., FcγRII [CD32],

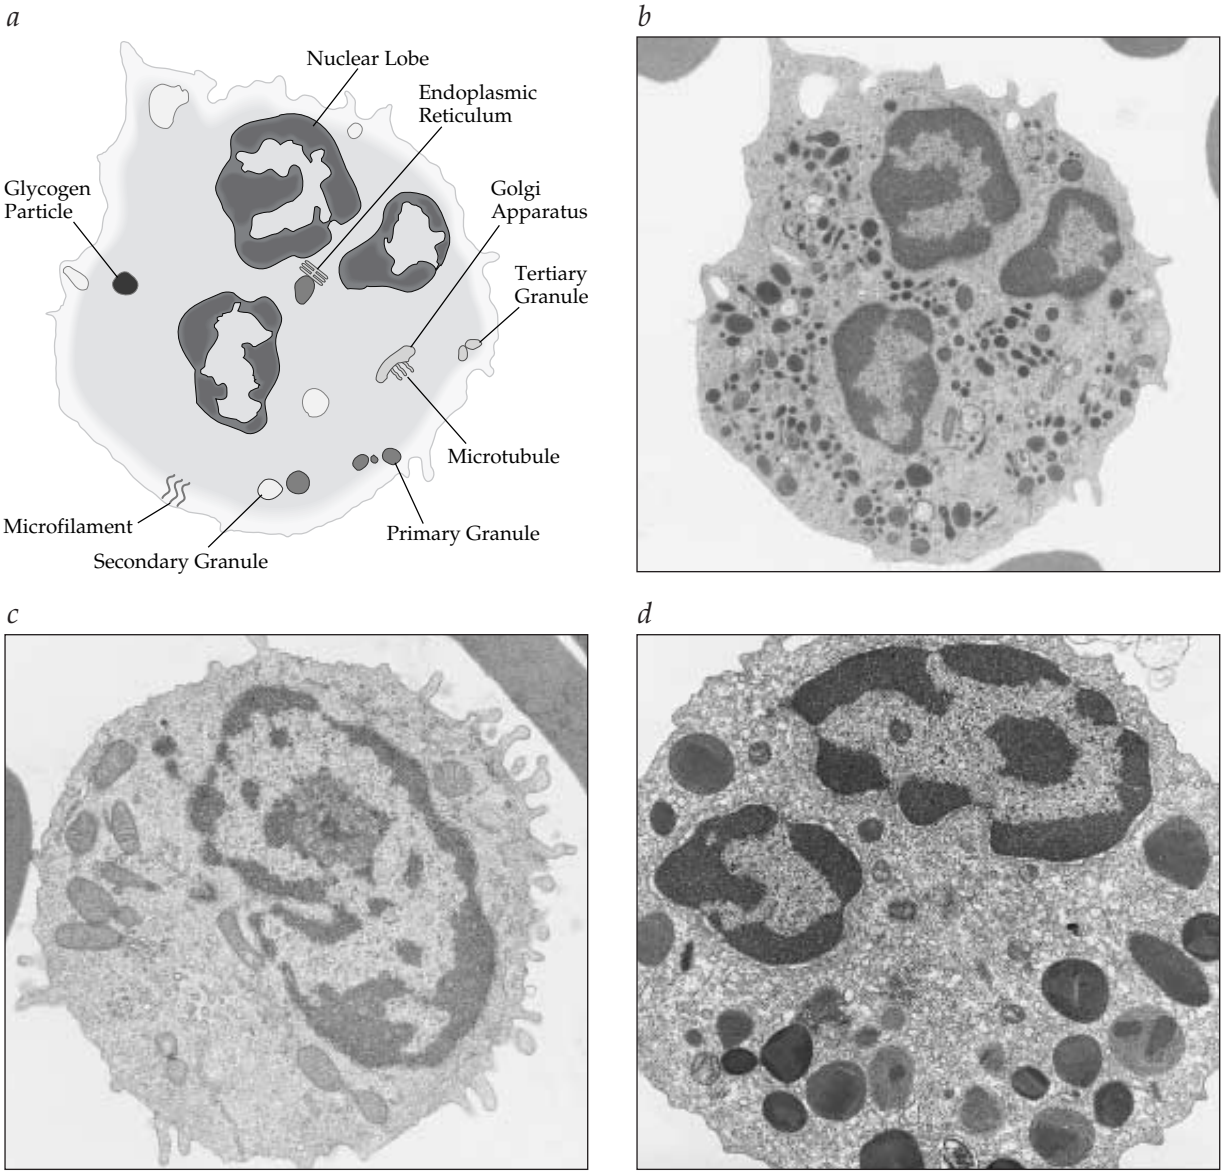

Figure 1 **Shown are a schematic diagram of a neutrophil (*a*), a corresponding electron micrograph of a neutrophil (*b*), and electron micrographs of a monocyte (*c*) and an eosinophil (*d*).**

FcγRIII [CD16]), complement (e.g., CR3 [CD11b18], CR1 [CD35]), chemokines, the colony-stimulating factors G-CSF and GM-CSF, Fas, tumor necrosis factor receptor (TNF-R), and the apoptosis-related receptors.[9]

The cytoskeleton of the neutrophil is composed of microtubules and microfilaments that are critical for phagocytic shape and movement, including migration through the vascular endothelium. The microfilaments, which consist primarily of actin polymers, are dispersed throughout the cytoplasm.[10]

NEUTROPHIL FUNCTION

The major function of neutrophils is to respond rapidly to microbial invasion to kill the invaders. This response has several distinct steps—adherence, migration, recognition, phagocytosis (or ingestion), degranulation, oxidative metabolism, and bacterial killing [*see Figure 3*]. Susceptibility to infection results from abnormalities in any one or a combination of these processes.

Adherence

For neutrophils to move to an inflammatory site, they must first adhere to a capillary wall.[11] Loose adherence is facilitated by L-selectins, such as sialyl-Lewis^x (sLe^x), on the neutrophil and E-selectin and P-selectin on capillary endothelial cells [*see Figure 4*]. Bacterial invasion increases local selectin expression and neutrophil accumulation. Other neutrophil surface proteins, called β_2 integrins, facilitate firmer adhesion to endothelial cells and interact with actin, myosin, and actin-binding proteins to initiate movement of neutrophils to the tissue.[11] The three proteins in this family have a common β subunit (CD18) and a different α subunit (CD11a, CD11b, or CD11c). There is generally increased expression of these proteins (e.g., CD 11b/C18) on neutrophils in response to inflammation. Concomitantly, there is increased expression of the intracellular adherence molecules (ICAMs) on the endothelial cells, with a net result of increased trafficking of neutrophils to the inflammatory focus.

Table 1 Normal Leukocyte Values in Peripheral Blood

Cell Type	Cells/mm³*		Percentage of Total Differential Count
	Median	Range	
All leukocytes (white blood cells)	7,000	4,300–10,000	100
Total neutrophils	4,000	1,800–7,200	55
Band neutrophils	500	100–2,000	10
Segmented neutrophils	3,500	1,000–6,000	45
Lymphocytes	2,500	1,500–4,000	36
Monocytes	450	200–900	6
Eosinophils	150	0–700	2
Basophils	30	0–150	1

*To calculate the number of cells/L, multiply by 10^6.

Chemotaxis

Chemotaxis, the directed movement of cells, occurs when neutrophils detect a chemoattractant at low concentrations and move up the concentration gradient toward its source, which is usually a site in the extravascular spaces.[12] Well-characterized stimulators of neutrophil chemotaxis are the complement proteins C5a, leukotriene B4, interleukin-8 (IL-8), and a family of small peptides, the chemokines. The trafficking of neutrophils from the blood is unidirectional; they do not return from the tissues to the circulation.

Recognition and Phagocytosis

At the site of inflammation, neutrophils utilize their immunoglobulin and complement receptors to recognize bacteria and other particles coated or opsonized by immunoglobulins or complement. Inflammation stimulates neutrophils to express increased numbers of the high-affinity IgG receptor FcγRI (CD64).[13] As the neutrophil internalizes a particle, a phagocytic vesicle, or phagosome, develops around it. This process stimulates degranulation and activates a burst of oxidative metabolism.

Degranulation

When the neutrophil is activated, the granule membranes come in contact with the plasma membranes surrounding the phagosome. The membranes fuse, which leads to the release of granule proteins into the phagosome and to the reorganization of the components of the critical NADPH oxidase system.[14]

Oxidative Metabolism and Bacterial Killing

Resting granulocytes are primarily anaerobic cells that rely on anaerobic glycolysis for adenosine triphosphate (ATP) production. Although chemotaxis, ingestion, and degranulation require

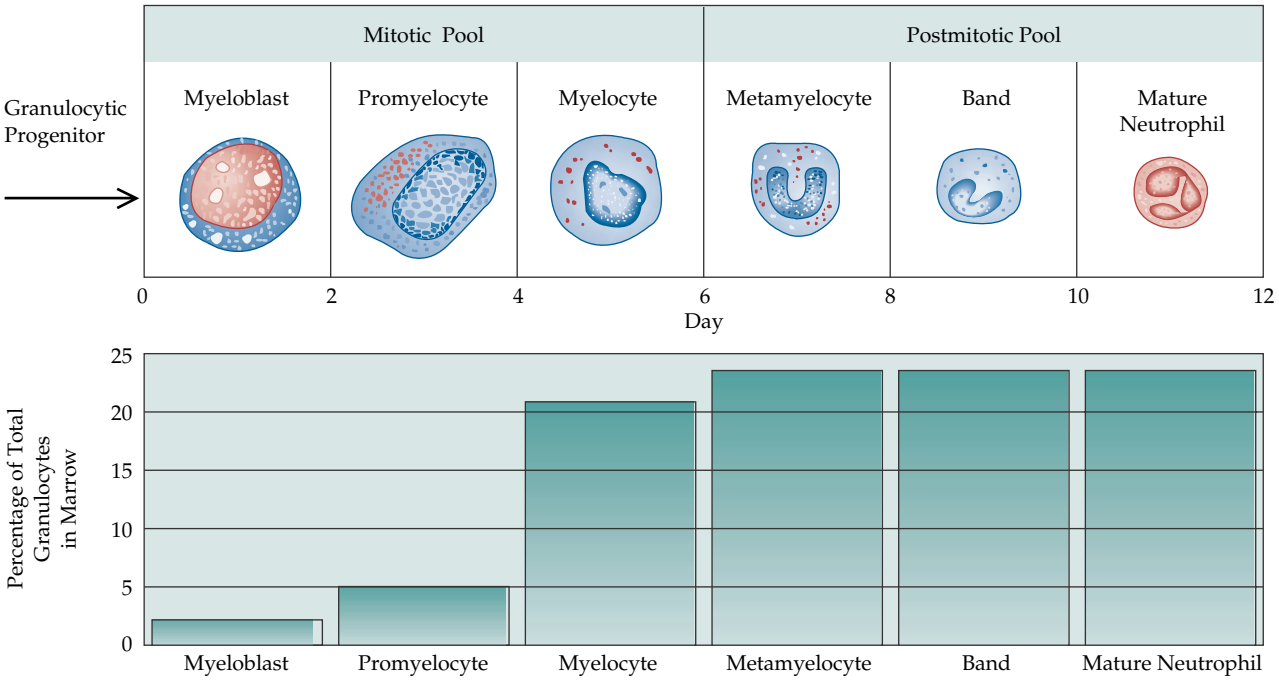

Figure 2 **The process of neutrophil maturation begins in the bone marrow (top). After about 12 days, approximately 10% of the mature neutrophils are released into the peripheral blood, where they have a half-life of approximately 6 to 10 hours. Eventually, the neutrophils migrate into the tissues by diapedesis. The percentage of neutrophils at each stage of development (bottom) ranges from about 2% at the myoblast stage to almost 25% at the mature neutrophil stage.**

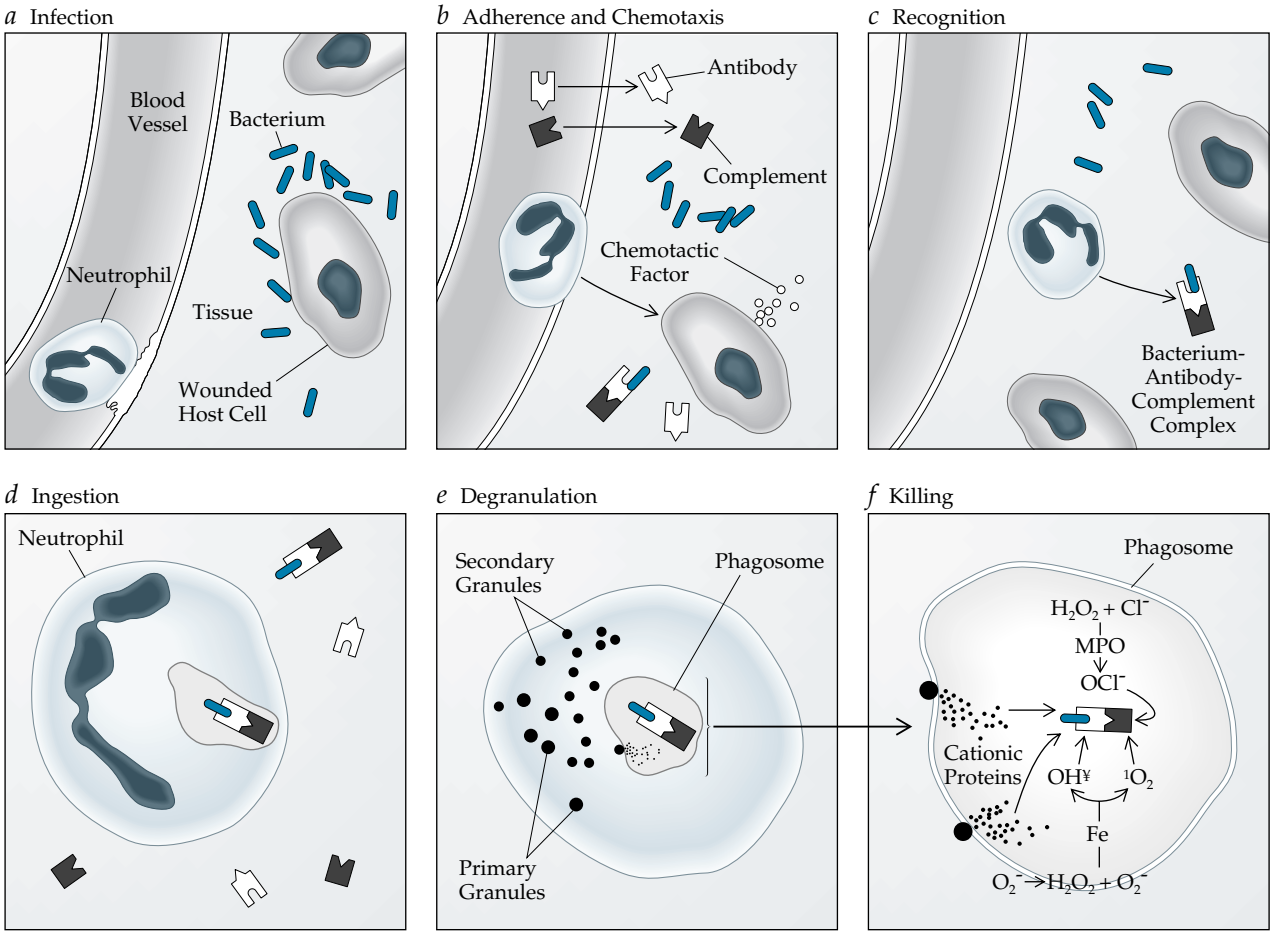

Figure 3 **The neutrophil response to bacterial invasion involves several stages. A bacterium infects a host cell and injures it (*a*). Bacterial products, antibodies, and complement cause the release of chemotactic factors, which activate a neutrophil in the adjacent blood vessel. The neutrophil adheres to the vessel wall and undergoes chemotaxis and diapedesis into tissue (*b*) to follow the chemoattractants to their sites of generation or expression. The neutrophil recognizes (*c*) and ingests (*d*) the bacterium-antibody-complement complex, forming a phagosome. The neutrophil then undergoes degranulation, a process in which granule membranes fuse with the plasma membrane (*e*). Degranulation releases various enzymes and enhances oxidative metabolism, the products of which are bactericidal (*f*). For example, hydrogen peroxide (H_2O_2), produced from superoxide (O_2^-), can interact with O_2^- in the presence of iron (Fe) to produce hydroxyl radicals ($OH\bullet$) and singlet oxygen ($^1O_2$), both of which are highly toxic to bacteria. In addition, H_2O_2 and chloride (Cl^-) combine in the presence of the myeloperoxidase (MPO) released in the phagosome to produce hypochlorite (OCl^-), which is also bactericidal.**

some energy, they also proceed quite well anaerobically. However, bacterial killing generally is associated with a rapid increase (within seconds) in oxygen use. This respiratory burst occurs as a result of the activation of an NADPH oxidase.[15] Before activation, the components of the oxidase are located separately in the plasma and granule membranes and in the cytosol. The membranes contain two components: $gp91^{phox}$ and $p22^{phox}$. The cytosol includes a p47 protein and a p67 protein. When the neutrophil is activated, the cytosolic proteins first associate and then combine with the membrane components to produce the complete NADPH oxidase. NADPH oxidase can reduce oxygen by one electron to superoxide O_2^-; in the process, NADPH is converted to $NADP^+$. The NADPH is then regenerated through the hexose monophosphate shunt. Dismutation of the superoxide in the presence of superoxide dismutase produces hydrogen peroxide (H_2O_2), which can then be converted to hydroxyl radical ($OH\bullet$). H_2O_2, O_2^-, and $OH\bullet$ are highly toxic. In addition, within the phagocyte vacuole, hydrogen peroxide and chloride (Cl^-) can combine in the presence of myeloperoxidase to produce hypochlorous acid (HOCl), which is bactericidal.[15] These products of the respiratory burst can also be released from the activated neutrophil and subsequently damage the surrounding cells and tissues.

Responses to and Production of Cytokines

The growth factors that affect neutrophil production, such as G-CSF and GM-CSF, also influence neutrophil function.[16] These cytokines upregulate stimulus-dependent NADPH oxidase activity and can enhance bactericidal and fungicidal activities. Although neutrophils contain very few ribosomes, they can respond to bacterial stimuli by synthesizing and secreting proinflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor–α (TNF-α); monocytes, however, produce much larger quantities of these substances.[17]

Disorders of Neutrophil Number

NEUTROPHILIA

Neutrophilia, or granulocytosis, is usually defined as a neutrophil count greater than 10,000/mm^3.

Etiology

Neutrophilia most often occurs secondary to inflammation, stress, or corticosteroid therapy. Cigarette smoking commonly causes neutrophilia as a result of inflammation in the airways and lungs. Malignancies, hemolytic anemia, and lithium therapy are less common causes. Neutrophilia is also associated with splenectomy. Extreme neutrophilia (i.e., neutrophil counts of more than 30,000 to 50,000/mm^3), often called a leukemoid reaction, occurs with severe infections, sepsis, hemorrhagic shock, and severe tissue injury of any cause. Neutrophilia is also seen in patients with leukocyte adhesion deficiency (LAD), a rare disease in which neutrophils accumulate in the blood because they lack either the integrin CD11b18 or the selectin sLe^x (CD15s) required to leave the circulation.[18]

Serious bacterial infections and chronic inflammation are usually associated with changes in both the number of circulating neutrophils and their morphology. Characteristic changes include increased numbers of young cells (bands), of cells with residual endoplasmic reticulum (Döhle bodies), and of cells with more prominent primary granules (toxic granulation). These changes are probably caused by the endogenous production of G-CSF or GM-CSF and are also seen with administration of these growth factors.

Primary neutrophilia (i.e., neutrophilia attributed to defects in proliferation and maturation of neutrophil precursors) occurs in patients with myeloproliferative disorders, such as chronic myeloid leukemia (CML) and polycythemia vera [*see 5:VI The Polycythemias*]. Hereditary and idiopathic neutrophilias have been described; they are benign and quite rare. One such uncommon idiopathic condition is Sweet syndrome, which is an acute febrile illness with painful cutaneous plaques and associated neutrophilia of any cause.[19] Neutrophilia is also associated with congenital abnormalities. For example, infants with Down syndrome can have transient leukemoid reactions that must be distinguished from congenital leukemia.[20]

Diagnosis

When neutrophilia cannot be readily attributed to an infection or inflammatory condition or to glucocorticosteroid therapy, the possibility of a myeloproliferative disease should be considered. The presence of splenomegaly, metamyelocytes, and myelocytes in the blood, together with increased basophils or eosinophils and a low leukocyte alkaline phosphatase (LAP) score, suggests CML [*see 12:XVII Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders*]. A high LAP score or the presence of toxic granulations usually suggests an underlying infection. When there is uncertainty, bone marrow aspiration and biopsy, chromosomal analysis, as well as marrow cultures for bacteria (e.g., *Salmonella, Brucella, Mycobacterium*, and fungi), are warranted. The results of these tests will enable the clinician to make a diagnosis of CML (or another myeloproliferative disorder), a granulomatous infection, inflammatory disease, or metastatic malignancy. If no such cause

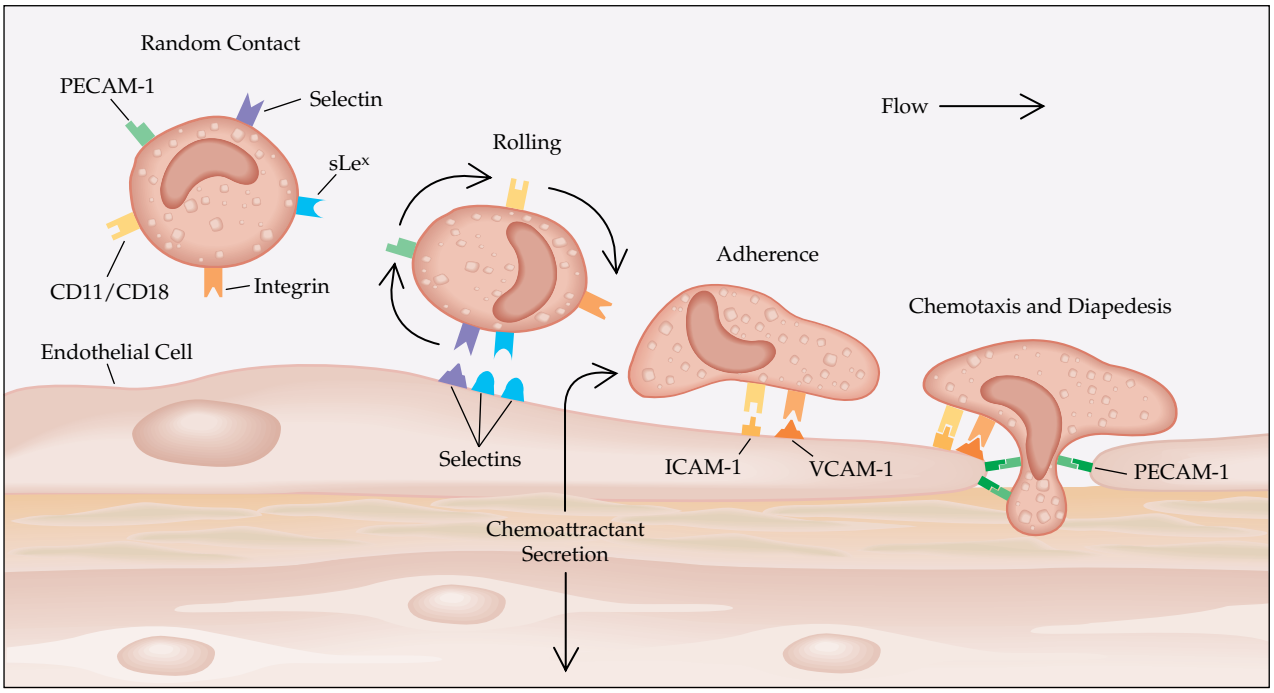

Figure 4 **Neutrophils in the peripheral blood exist in either the circulating or the marginating pool. The marginated neutrophils roll along a vessel wall, where their surface carbohydrates interact with selectins on the endothelial cells. After activation by chemotactic agents, the neutrophils change shape and change the affinity of their integrin molecules for endothelial cell intercellular adhesion molecules. The neutrophils then crawl and undergo diapedesis by interacting with platelet–endothelial cell adhesion molecules on the endothelial surface and by liberating hydrolases that permit passage of the neutrophils through the capillary basement membrane. (PECAM-1—platelet–endothelial cell adhesion molecule–1; sLe^x—sialyl-Lewis^x carbohydrate; ICAM-1—intercellular adhesion molecule–1; VCAM-1—vascular cell adhesion molecule–1)**

can be found in an otherwise healthy-appearing person, a diagnosis of idiopathic or familial neutrophilia may be considered, and repeated neutrophil counts can be performed at monthly intervals until the diagnosis is clarified.

Treatment

Except for the myeloproliferative syndromes, treatment of neutrophilia is not indicated. Neutrophil levels will return to normal when the inflammatory process is resolved.

NEUTROPENIA

Neutropenia is generally defined as a neutrophil count of less than 1,800/mm^3, which is two standard deviations below the normal mean. In some populations (e.g., Africans, African Americans, and Yemenite Jews), neutrophil counts as low as 1,000/mm^3, or 1.0×10^9/L, are probably normal.[21,22]

In otherwise healthy persons, the risk of bacterial infections is relatively low if the neutrophil count is greater than 500 mm^3, or 0.5×10^9/L—the level usually defined as severe neutropenia. When neutropenia develops after myelotoxic chemotherapy, the risk of infection is much greater, particularly in patients whose age and medical history (e.g., diabetes, heart failure, renal failure, previous chemotherapy, and HIV infection) also predispose them to infection.[22,23] Patients with neutropenia are also at greater risk for serious infections if they have disrupted mucosal or cutaneous barriers or are taking corticosteroids. Patients with neutropenia are at risk for infection by those pathogenic organisms that normally colonize body surfaces, particularly the skin, the oropharynx, and the GI tract. Thus, infections from staphylococci occur in neutropenic patients after breaks in the skin. Infection by mixtures of aerobic and anaerobic organisms of the oropharynx frequently causes gingivitis, pharyngitis, and sinusitis with neutropenia. Gram-negative bacilli often invade the blood from the GI tract in these patients. Antibiotic therapy, particularly therapy involving broad-spectrum antibiotics and protracted treatments, leads to colonization by resistant bacteria and to fungal infections.[24]

Etiology

Neutropenia may be a primary or secondary condition. Primary neutropenia is caused by abnormalities of neutrophil formation derived from hematopoietic stem cells in the bone marrow; disorders with this underlying pathogenesis include the myeloid malignancies and several congenital disorders [*see* Primary Forms of Neutropenia, *below*]. Secondary neutropenia may be caused by drug therapy, infections, and immunologic disorders, including autoimmune diseases. Secondary neutropenia is far more common than primary neutropenia. In all of these conditions, the risk of infection depends on the level of blood neutrophils and the capacity of the marrow to respond to an inflammatory stimulus and increase production of these cells. Usually if blood neutrophils are greater than 0.5×10^9/L, the risk of serious infection is relatively low.

Drug-induced neutropenia In aggregate, drug reactions are probably the most common cause of neutropenia in adults [*see Table 2*].[25,26] Many cancer chemotherapy drugs, some of which are also used as cytotoxic immunosuppressive agents (e.g., cyclophosphamide, methotrexate, and azathioprine), predictably cause dose-dependent neutropenia. The use of these agents requires careful attention to medical history, dosages, treatment schedules, and serial neutrophil counts to avoid serious and life-threatening toxicity. Other drugs cause neutropenia idiosyncratically. Many of these reactions probably occur because drugs can act as immunogens or as haptens, causing immunologic injury to neutrophils and their precursors. Other mechanisms of drug-induced neutropenia may involve direct toxicity of marrow cells in susceptible persons. Most patients recover from drug-induced neutropenia; the time for recovery can vary from 2 days to 2 weeks or more.

Infection-associated neutropenia Viral infections often cause mild neutropenia, especially in children. Such infections include measles and other viral exanthems, infectious mononucleosis, hepatitis, and HIV infection. The mechanisms are diverse. For example, in HIV infection, possible mechanisms include infections of the hematopoietic precursor cells and the marrow stromal cells, which lead to decreased production; induction of autoantibodies, which leads to accelerated turnover of mature neutrophils; and accelerated apoptosis of mature cells.[27] HIV-associated neutropenia generally develops late in AIDS and is often compounded by the use of antiviral agents (e.g., zidovudine, ganciclovir), antibiotics (e.g., sulfonamides), or the presence of hematologic malignancies (e.g., lymphoma, Kaposi sarcoma).[28] With other viral infections, the neutropenia is usually mild and without serious consequences. In rare instances, infectious mononucleosis causes severe hypoplasia, which has more severe consequences.[29] Neutropenia and anemia are common features of human parvovirus B19 infection.[30]

With severe bacterial infections, neutropenia occurs as a consequence of endotoxemia, which results in rapid neutrophil mobilization and turnover, especially in patients with a marrow reserve that is impaired because of previous chemotherapy, other drugs, or alcohol. In this setting, neutropenia generally portends a grave prognosis. Neutropenia occurs in parasitic infections associated with splenomegaly, such as kala-azar and acute malaria, presumably as a result of splenic trapping of the cells.

Autoimmune and idiopathic neutropenia Autoimmune neutropenia occurs as an isolated phenomenon or secondary to other autoimmune disorders.[31] For example, in patients with Evans syndrome, autoimmune neutropenia may be associated with immune thrombocytopenia and hemolytic anemia. The bone marrow cellularity in patients with autoimmune neutropenia is either normal or increased, with a relative decrease in the number of cells in the late stages of the neutrophil formation. The diagnosis of autoimmune neutropenia requires specific antineutrophil antibody tests.[32] The specificity of these tests probably varies considerably, and they are performed by a limited number of laboratories. It is often difficult to distinguish autoimmune neutropenia from cases otherwise categorized as idiopathic neutropenia. Neutropenia with antineutrophil antibodies also occurs in systemic lupus erythematosus,[33] Sjögren syndrome,[34,35] rheumatoid arthritis,[36] and Felty syndrome (i.e., rheumatoid arthritis, splenomegaly, and neutropenia).[37]

Patients with rheumatoid arthritis and neutropenia may have clonal expansion of large granular lymphocytes (usually $CD2^+$, $CD3^+$, $CD8^+$, and $CD57^+$ cells), which impair neutrophil production by excessive Fas ligand or interferon-gamma production.[38] Recent studies indicate that this same mechanism may be involved in cases diagnosed as idiopathic neutropenia.[39] The marrow typically shows increased lymphocytes with reduced neutrophils in the later stages of development. In most patients, the lymphocytosis is clonal and may evolve very gradually into a lymphoid malignancy.[40]

Table 2 Drugs Associated with Neutropenia

ANALGESICS
- Aminopyrine
- Dipyrone

ANTIBIOTICS
- Cephalosporins
- Chloramphenicol
- Clindamycin
- Doxycycline
- Flucytosine
- Gentamicin
- Griseofulvin
- Isoniazid
- Lincomycin
- Metronidazole
- Nitrofurantoin
- Penicillins
- Rifampin
- Streptomycin
- Sulfonamides
- Vancomycin

ANTICONVULSANTS
- Carbamazepine
- Ethosuximide
- Mephenytoin
- Phenytoin
- Primidone
- Trimethadione

ANTIHISTAMINES
- Brompheniramine
- Cimetidine
- Ranitidine
- Thenalidine
- Tripelennamine

ANTI-INFLAMMATORY AGENTS
- Fenoprofen
- Gold salts
- Ibuprofen
- Indomethacin
- Phenylbutazone

ANTIMALARIALS
- Amodiaquine
- Dapsone
- Hydroxychloroquine
- Pyrimethamine
- Quinine

ANTITHYROID DRUGS
- Carbimazole
- Methimazole
- Methylthiouracil
- Potassium perchlorate
- Propylthiouracil

CARDIOVASCULAR AGENTS
- Captopril
- Diazoxide
- Hydralazine
- Methyldopa
- Pindolol
- Procainamide
- Propranolol
- Quinidine

DIURETICS
- Acetazolamide
- Bumetanide
- Chlorothiazide
- Chlorthalidone
- Hydrochlorothiazide
- Methazolamide
- Spironolactone

HYPOGLYCEMIC AGENTS
- Chlorpropamide
- Tolbutamide

PHENOTHIAZINES
- Chlorpromazine
- Methylpromazine
- Prochlorperazine
- Promazine
- Thioridazine
- Trifluoperazine
- Trimeprazine

SEDATIVES AND NEUROPHARMACOLOGIC AGENTS
- Chlordiazepoxide
- Clozapine
- Desipramine
- Diazepam
- Imipramine
- Meprobamate
- Metoclopramide

MISCELLANEOUS AGENTS
- Allopurinol
- Colchicine
- Ethanol
- Levamisole
- Levodopa
- Penicillamine

In sarcoidosis, cirrhosis, and congestive splenomegaly of diverse causes, neutropenia and thrombocytopenia often occur concomitantly, presumably because of splenic sequestration. In most instances, the neutropenia is mild and without recognizable consequences.

Other secondary causes of neutropenia Neonates can have severe neutropenia because of transplacental transfer of maternal IgG antibodies to the FcγRIII (CD16) isotype (previously called NA-1 or NA-2) that is inherited from the infant's father.[41] This abnormality is transient, usually lasting less than 3 months. Transient severe neutropenia also can occur in an infant as a result of transplacental transfer of other antibodies (e.g., transfer of IgG) from a mother with autoimmune neutropenia. Pure white cell aplasia is a rare acquired condition characterized by a complete absence of myeloid precursors.[42] Pure white cell aplasia may be associated with a thymoma; if so, the aplasia may respond on removal of the thymoma. The short-term consequences of all these conditions depend primarily upon the level of blood neutrophils and the proliferative response of the marrow when inflammation or infections occur. The causes of other forms of neutropenia in children and adults are often difficult to establish and usually require referral to an expert hematologist.

Primary forms of neutropenia There are a number of congenital and inherited causes of neutropenia [*see Table 3*].

Diagnosis

Neutropenia is easily diagnosed by performing a white blood cell count and differential count. Patients with acute, severe neutropenia are often febrile and are frequently referred to as having acute febrile neutropenia. In this circumstance, attention is immediately focused on determining whether the patient has an infection, as well as focused on instituting empirical antibiotic therapy. Hematologic studies (e.g., bone marrow examination) are generally not necessary, because the cause of neutropenia is recognized from the patient's history, and it will resolve if the inciting cause has been eliminated.

Initial evaluation of patients with chronic neutropenia should include a careful family history and review of the incidence and severity of infections, including oral ulcers, gingivitis, cellulitis, and more serious problems. A complete blood count will reveal whether the neutropenia is isolated or associated with other hematologic abnormalities. Medications should be discontinued if they can be implicated as causes of the neutropenia. A bone marrow biopsy and aspirate are indicated if there is any question of a primary disease affecting the marrow (e.g., metastatic carcinoma, tuberculosis) or if myelodysplasia or a hematologic malignancy is suspected. Serologic testing for infectious mononucleosis, hepatitis, and HIV is often warranted, as is measurement of antinuclear antibodies and rheumatoid factor titers. Broader immunologic assessments (i.e., lymphocyte subtypes and immunoglobulin levels) are warranted if the history suggests a susceptibility to infections by viruses, parasites, or bacteria; and they are also useful to detect clonal proliferation of lymphocytes and to diagnose the large granular lymphocyte syndrome. Neutrophil mobilization with corticosteroids and demargination tests with epinephrine are rarely helpful.

Treatment of Neutropenia

Evidence-based guidelines for management and prevention of acute febrile neutropenia associated with cancer chemotherapy have been developed by the Infectious Diseases Society of America (www.idsociety.org) and the American Society of Clinical Oncology (www.asco.org). Other guidelines are also available (www.guideline.gov) [*see Table 4*]. In general, acute management of severe, idiosyncratic, drug-induced neutropenia should be similarly managed.[43,44]

Table 3 Intrinsic Disorders of Neutrophils That Cause Neutropenia

Disorder	*Inheritance*	*Clinical Features*	*Diagnosis*	*Treatment*
Congenital neutropenia (also known as infantile genetic agranulocytosis and Kostmann syndrome)	AD, AR, S Locus: 19p13.3	From birth, upper respiratory, lung, liver, and skin infections; mild anemia; thrombocytosis; a normal immune system; possible development of leukemia	Selective, severe neutropenia; marrow promyelocytes but few more mature cells; marrow eosinophils; normal chromosomes; possible G-CSF receptor defect Genetic testing: research only*	G-CSF (effective in most cases); bone marrow transplantation; prophylactic antibiotics
Myelokathexis	AD, S	Recurrent infections; severe leukopenia and neutropenia	Marrow cellularity normal with maturing, often binucleate neutrophils	G-CSF
Cyclic neutropenia (also known as cyclic hematopoiesis)	AD, S Locus: 19p13.3	Regular oscillations of blood cell counts, most prominently of neutrophil and monocyte counts	Serial CBCs show severe neutropenia that recurs regularly, usually every 21 days Genetic testing: research only*	G-CSF
Shwachman-Diamond syndrome	AR Locus: 7q11	Neutropenia with pancreatic insufficiency and sometimes with anemia or thrombocytopenia	Neutropenia with malabsorption caused by pancreatic enzyme deficiency; tests for cystic fibrosis negative Clinical testing available*	G-CSF; pancreatic enzymes
Chédiak-Higashi syndrome	AR, S Locus: 1q42	Recurrent infections; partial albinism; lymphoproliferative syndrome; neutropenia; thrombocytopenia	Giant cytoplasmic granules; defective neutrophil migration and bacterial killing Genetic testing: research only*	Antibiotics; vitamin C; bone marrow transplantation
Reticular dysgenesis and congenital immunodeficiency syndromes with neutropenia	AR, S	From birth, severe infections with severe leukopenia	Neutropenia; hypogammaglobulinemia; T cell and B cell deficiencies	Bone marrow transplantation; immunoglobulin therapy; G-CSF for neutropenia
Dyskeratosis congenita	AR Locus: Xq28; 3q21-q28	Severe infections; skin hyperpigmentation; dystrophic nails; leukoplakia	Skin changes associated with severe neutropenia Clinical testing available*	Prophylactic antibiotics

* See GeneTests (http://www.geneclinics.org) for laboratory directory.

AD—autosomal dominant AR—autosomal recessive CBC—complete blood count G-CSF—granulocyte colony-stimulating factor S—sporadic cases

Treatments for chronic neutropenia vary with the severity of neutropenia and the pattern of susceptibility to infection. Mild or moderate neutropenia (i.e., counts above 0.5×10^9/L, determined by serial counts over several weeks) rarely requires treatment. The neutropenia in Felty syndrome often responds to splenectomy and weekly doses of methotrexate.[45,46] With few other exceptions, long-term use of corticosteroids, γ-globulin injections, androgens, and splenectomy is not indicated for management of chronic neutropenia. With suspected infections, short-term, broad-spectrum antibiotic therapy is indicated, usually initiated after culture of blood and other body fluids for bacteria. Long-term antibiotic therapy is of unproven benefit in preventing infections, and it carries the risk of colonization by antibiotic-resistant organisms. G-CSF, usually in doses of 1 to 5 mg/kg/day, is of proven benefit for the treatment of congenital, idiopathic, and cyclic neutropenia and hastens the recovery of marrow from neutropenia after cancer chemotherapy.[47] G-CSF and GM-CSF have been widely used to treat other forms of chronic neutropenia, including the neutropenia associated with HIV infection.

Disorders of Neutrophil Function

In patients who have recurrent, severe, or unusual infections but who have a normal number of neutrophils, the presence of a neutrophil function disorder must be considered. Neutrophil function disorders are caused by defects in neutrophil adherence, chemotaxis, degranulation, or oxidative metabolism [*see Table 5*].

The evaluation of patients with confirmed, recurrent, or unusual infections is first to review the family history and then to examine the patient [*see Figure 5*]. A complete blood count and examination of the granulocytes in a blood smear can show neutrophilia or neutropenia, specific granule deficiency, or giant granules such as those that occur in Chédiak-Higashi syndrome. Evaluation of immunoglobulin levels (IgG, IgM, IgA, and IgE) and complement levels (C3 and CH_{50}) are also potentially helpful, especially if there is a pattern of infection by encapsulated bacteria or unusual organisms. After these considerations, neutrophil function should be evaluated with the nitroblue tetrazolium (NBT) test, superoxide production assays, and chemotactic assays. The NBT test and superoxide assays can determine whether a patient has chronic granulomatous disease (CGD), severe glucose-6-phosphate dehydrogenase (G6PD) deficiency, or a glutathione-pathway disorder[14]; chemotactic assays can be used to confirm the diagnosis of Chédiak-Higashi syndrome and acquired chemotactic defects.[12] Leukocyte adhesion deficiency types I and II are diagnosed by flow cytometry.[11] If the results of all of these tests are normal, ingestion assays using the patient's serum and cells and staining for MPO may be helpful. In this manner, all of the known neutrophil function abnormalities can be diagnosed, often with the aid of specialty consultations and a research laboratory.[48]

Monocytes and Macrophage Physiology

Monocytes and macrophages play critical roles in homeostasis and in host defense mechanisms. Monocytes and macro-

Table 4 Guidelines for Management and Prevention of Febrile Neutropenia[43]

Management

- Take careful history and conduct thorough physical examination of the patient
- Examine patient carefully for portal for bacterial or fungal infections
- Culture blood and other appropriate body fluids
- Start antibiotics immediately
  - Monotherapy (e.g., ceftazidime or imipenem) or duotherapy (e.g., an aminoglycoside, such as gentamicin, with a β-lactam drug that is effective against *Pseudomonas,* such as piperacillin
  - Add vancomycin if there is a significant risk of gram-positive sepsis
- Adjust antibiotic therapy after 3 days, depending on the results of cultures and the patient's clinical status
- Switch low-risk patients to oral therapy
- Continue broad-spectrum therapy for severely ill patients*
  - Consider antifungal treatments
  - Consider colony-stimulating factors as an adjunct to antibiotics for febrile neutropenia in severely ill, high-risk patients†

Prevention

- Primary prophylaxis with G-CSF reduces incidence of febrile neutropenia by ~50% when the risk of febrile neutropenia is ~40%‡
- Use G-CSF or GM-CSF as a preventive strategy for patients who have had their treatment reduced or experienced a delay in treatment because of an episode of febrile neutropenia or a prolonged period of neutropenia
  - Consider reducing the intensity of chemotherapy

Note: further information can be found at the following Web sites: www.idsociety.org, www.asco.org, and www.guidelines.gov.
*Resolution of illness generally follows resolution of neutropenia.
†For most patients with febrile neutropenia, CSF therapy has no proven benefit.
‡Administration of G-CSF or GM-CSF is not routinely indicated in previously untreated patients.
G-CSF—granulocyte colony-stimulating factor GM-CSF—granulocyte-macrophage colony-stimulating factor

phages perform tissue maintenance functions, such as clearance of particles—including bacteria—from the blood and removal of old red blood cells. They process antigens by interacting with T cells and B cells and are essential for containment of mycobacterial, parasitic, fungal, and viral infections.

MONOCYTE-MACROPHAGE DEVELOPMENT

Monocytes develop from hematopoietic progenitor cells in the bone marrow. Once the progenitor cells are committed to a monocyte lineage, they develop morphologically into monoblasts, then promonocytes, and then monocytes. Monocytes are present in the bone marrow and blood. They are the precursors for the tissue mononuclear phagocyte system (including alveolar, peritoneal, and splenic macrophages), Kupffer cells, osteoclasts, dendritic cells, and Langerhans cells. In addition to having phagocytic capabilities, monocytes and macrophages play a central role in the immune response through the generation of numerous cytokines, including growth factors for white blood cells.

With the exception of the alveolar macrophages, which are uniquely dependent on aerobic metabolism for energy production, monocytes and macrophages are facultative anaerobes. Phagocytosis by monocytes and macrophages is associated with an oxidative burst and stimulation of the hexose monophosphate shunt. Adhesion, chemotaxis, and activation are similar for monocytes and neutrophils, although macrophages are better than neutrophils at phagocytosis and perform chemotaxis less rapidly and efficiently. Macrophages are also capable of oxygen-independent bactericidal activity that may depend on lytic activity. Stimulated macrophages are capable of producing nitric oxide. Macrophages are capable of secreting many cytokines, growth factors, and acute-phase reactants.

Monocytes and macrophages present antigen to T cells in association with major histocompatibility complex (MHC) class II molecules. This association occurs in the lysosomes of a mononuclear cell before the MHC class II molecules are expressed on the cell surface. Monocytes and macrophages are involved in antibody-dependent and antibody-independent cell-mediated cytotoxicity. The cytotoxicity involves oxidative metabolism, the production of nitric oxide and cytokines, and the secretion of cytotoxic mediators.

Macrophages play a key role in metabolizing high-molecular-weight proteins, glycoproteins, and other material and are intimately involved in the destruction of senescent and killed cells. They also are required for angiogenesis and wound healing and are able to induce neovascularization and endothelial cell proliferation. Given these diverse products and functions, macrophages are involved in many metabolic, infectious, inflammatory, and degenerative diseases.

Increases in blood monocytes (usually less than two times the normal level or less than $1.0 \times 10^9/L$) are a common feature of chronic inflammatory diseases and malignancies. Higher counts should raise concern about a hematologic malignancy (e.g., monocytic or myelomonocytic leukemia) [*see 12:XVI Acute Leukemia*].

Disorders of Monocytes and Macrophages

HISTIOCYTIC SYNDROMES

Histiocytic syndromes are a group of malignant and nonmalignant disorders in which the macrophages and dendritic (Langerhans) cells are the principal cells of abnormality.[49] The malignant disorders include acute monocytic leukemia, monocytic sarcoma, and histiocytic sarcoma. The nonmalignant disorders include the Langerhans cell histiocytosis (LCH) syndromes and the hemophagocytic syndromes, such as sinus histiocytosis with massive lymphadenopathy, hemophagocytic lymphohistiocytosis (HL), and infection-associated hemophagocytic syndrome (IAHS).

Langerhans Cell Histiocytosis Syndromes

The LCH syndromes include solitary eosinophilic granuloma, multifocal eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease.[49,50] These disorders predominantly affect children 1 to 15 years of age but also occur in young adults. The LCH syndromes represent a continuum of disease that has been divided on the basis of histologic studies, age at diagnosis, extent of disease, and organ involvement. The signs and symptoms of the LCH syndromes depend on the specific organs involved.[51] The bones, skin, teeth, gingival tissue, ears, endocrine organs, lungs, liver, spleen, lymph nodes, and bone marrow can all be involved and become dysfunctional as a result of cellular infiltration.[52] For example, diabetes insipidus is caused by histocyte infiltration of the pituitary gland,[53] and Erdheim-Chester disease is a multisystem disease characterized by histiocyte infil-

Table 5 Selected Disorders of Neutrophil Function

	Disorder	*Inheritance*	*Clinical Features*	*Diagnosis*	*Treatment*
Adherence defects	Leukocyte adhesion deficiency I	AR Locus: 21q22.3	Neutrophilia with recurrent severe infections; failure of pus formation; delayed umbilical cord separation	Decreased neutrophil adherence and migration; CD11/CD18 deficiency Clinical testing available*	Bone marrow transplantation; antibiotics
	Leukocyte adhesion deficiency II	S, possibly AR	Neutrophilia with recurrent infections	Neutrophils lack surface sLe^x and have deficient adherence	Bone marrow transplantation; antibiotics
	Actin polymerization defect	AR, S	Recurrent severe infections	Defective neutrophil migration and ingestion of bacteria	Bone marrow transplantation; antibiotics
Granule defects	Chédiak-Higashi syndrome	AR, S Locus: 1q42	Recurrent infections; partial albinism; lymphoproliferative syndrome; neutropenia; thrombocytopenia	Giant cytoplasmic granules; defective neutrophil migration and bacterial killing Genetic testing: research only*	Antibiotics; vitamin C; bone marrow transplantation
	Specific granule deficiency	S, possibly AR	Recurrent infections, especially sinopulmonary and skin infections	Absence of specific (secondary) granules in neutrophils; abnormal neutrophil migration and respiratory burst	Antibiotics
Respiratory burst defects	Chronic granulomatous disease	AR or X-linked CYBA locus: 16q24 CYBB locus: Xp21.1 NCF1 locus: 7q11.23 NCF2 locus: 1q25	Recurrent skin, pulmonary, and liver abscesses	Severely defective respiratory burst; NBT test; abnormality in one of four subunits of NADPH oxidase Clinical testing available*	Interferon gamma; antibiotics
	Glucose-6-phosphate dehydrogenase deficiency	X-linked Locus: Xq28	Recurrent bacterial infections; hemolytic anemia	Reduced levels of glucose-6-phosphate dehydrogenase Clinical testing available*	Antibiotics
	Myeloperoxidase deficiency	AR	Mild, if any, susceptibility to infection	Reduced levels of myeloperoxidase	Generally none indicated

tration of many tissues.[54] LCH with solitary and multifocal eosinophilic granuloma is found predominantly in older children and young adults; more infiltrative disease is common in younger patients.[55] On presentation, patients with solitary lesions may have an inability to bear weight, or they may have tender swelling caused by tissue infiltrates that overlie a sharply marginated bony lesion. Diagnosis is usually made by demonstration of dendritic cells, eosinophils, and giant cells present in a biopsy specimen; electron microscopy and immunostaining may be helpful for further classification.

Treatment of local LCH is sometimes unnecessary; when it is necessary, surgery or local radiation therapy can be curative.[50-55] LCH syndromes respond to chemotherapeutic agents, including vinblastine, methotrexate, 6-mercaptopurine, etoposide, or 2-chlorodeoxyadenosine (cladribine). There is a long-term risk of secondary or treatment-related malignancies in these patients.

Sinus Histiocytosis with Massive Lymphadenopathy

Sinus histiocytosis with massive lymphadenopathy, or Rosai-Dorfman disease, is characterized by chronic, painless, massive lymphadenopathy that usually involves the cervical nodes and less frequently involves the axillary, hilar, peritracheal, or inguinal nodes.[56] It occurs in both adults and children. Extranodal disease in the respiratory tract, bones, orbits, skin, liver, and kidneys is present in almost 30% of patients. The disease is usually benign, but significant morbidity and even death may result if massive tissue invasion of the liver, kidneys, lungs, and other critical structures occurs. Patients are usually of African descent, and the incidence of this disease is highest in Africa and the West Indies.

The affected lymph nodes show marked sinusoidal dilatation and follicular hyperplasia with proliferation of foamy histiocytes and multinucleated giant cells in the sinuses. The etiology of this disorder is unknown and may be related to abnormal immune regulation. Attempts at treatment should be reserved for special circumstances that are potentially life threatening. Surgery, irradiation, corticosteroids, vinblastine, and cyclophosphamide have all been administered with varying degrees of success.

Hemophagocytic Lymphohistiocytosis

HL is a rapidly fatal disorder, occurring as a familial or acquired condition; it is characterized by fever, pancytopenia, hepatic dysfunction, and activated macrophages, which overproduce inflammatory cytokines.[57] Family studies suggest that a portion of cases are attributable to mutations in the perforin gene.[58,59] The disease is usually diagnosed in young children; however, secondary forms of HL account for numerous cases in adults and occur in association with bacterial, fungal, and parasitic infections and exposure to various drugs. Treatment is diffi-

cult. Chemotherapy may be helpful. If the disease is associated with infection, treatment with appropriate antimicrobials may resolve the disorder.

LYSOSOMAL STORAGE DISEASES

Monocytes and macrophages play a role in tissue remodeling and the removal of senescent cellular debris, and lysosomes are the organelles that perform these functions; therefore, enzymatic abnormalities that involve lysosomal constituents result in disorders of storage that are related to macrophage function. These disorders, usually diagnosed in early childhood, include the mucopolysaccharidoses, the glycoproteinoses, the sphingolipidoses, and the neutral lipid storage diseases [*see Table 6*]. Enzymatic defects have been described for most of these disorders, and diagnosis depends on demonstrating the enzymatic abnormality in macrophages or histiocytes. Most of these defects result from

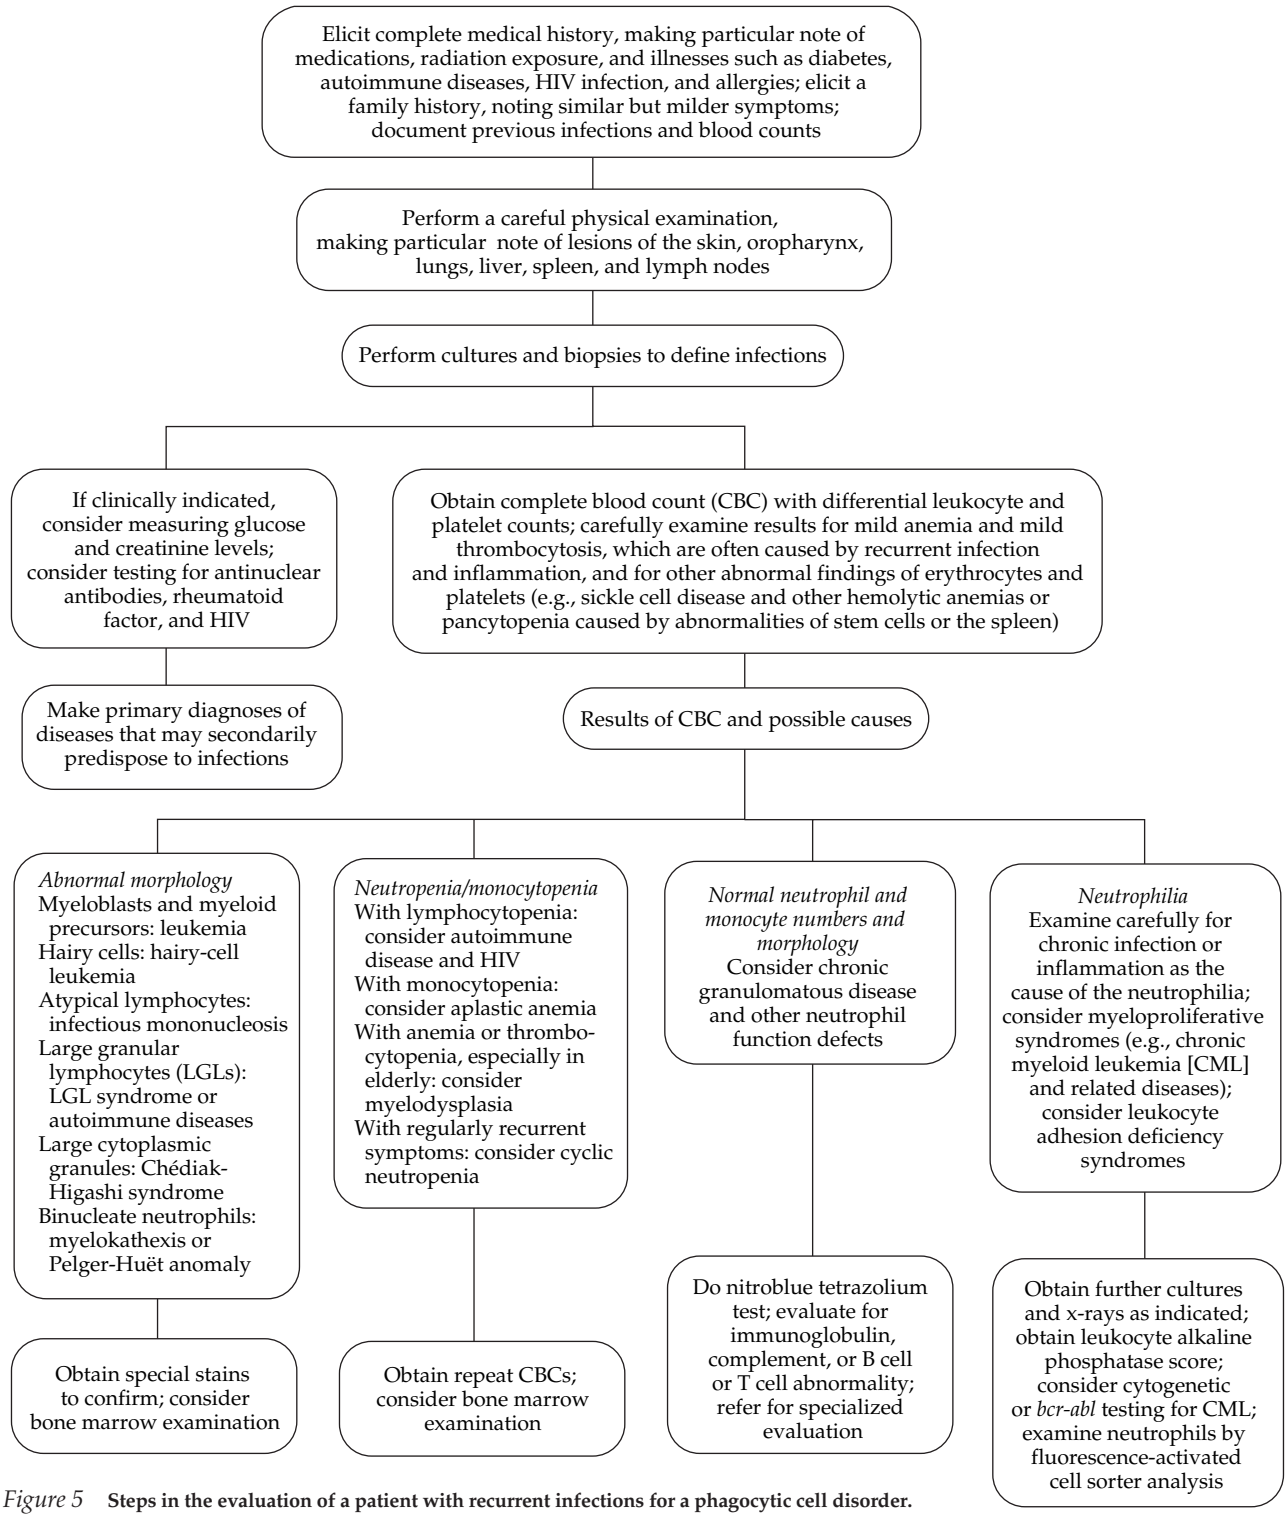

Figure 5 **Steps in the evaluation of a patient with recurrent infections for a phagocytic cell disorder.**

Table 6 Lysosomal Storage Diseases

Disease (Common Name)	*Inheritance*	*Enzymatic Defect*	*Organs and Tissues Involved*	*Stored Material*
Mucopolysaccharidoses (MPS)				
MPS IH (Hurler syndrome)	AR; locus: 4p16.3	α-L-Iduronidase	Liver, spleen, brain, heart, cornea, bone (mild and severe variants)	Dermatan sulfate, heparan sulfate
MPS II (Hunter syndrome)	Locus: Xq28	Iduronate-2-sulfatase	Liver, spleen, brain, heart, bone	Dermatan sulfate, heparan sulfate
MPS III				
(Sanfilippo A syndrome)	Locus: 17q25.3	Heparan *N*-sulfatase	Brain, liver, spleen, heart, bone	Heparan sulfate
(Sanfilippo B syndrome)	Locus: 17q21	α-*N*-Acetylglucosaminidase	Brain, liver, spleen, heart, bone	Heparan sulfate
(Sanfilippo C syndrome)	Chromosome 14	Acetyl-coenzyme A:α-glucosaminide *N*-Acetyltransferase		
MPS IV				
(Sanfilippo D syndrome)	Locus: 12q14	*N*-Acetylglucosamine-6-sulfatase		
(Morquio A syndrome)	Locus: 16q24.3	*N*-Acetylgalactosamine-6-sulfatase	Bone, cornea	Keratan sulfate, chondroitin 6-sulfate
(Morquio B syndrome)	Locus: 3p2	β-Galactosidase	Bone, cornea	Keratan sulfate
MPS VI (Maroteaux-Lamy syndrome)	Locus: 5q11-q13	*N*-Acetylgalactosamine-4-sulfatase	Bone, cornea, liver, spleen, heart (moderate and severe variants)	Dermatan sulfate
MPS VII (Sly syndrome)	Locus: 7q21	β-Glucuronidase	Brain, liver, spleen, bone, coronary arteries	Dermatan sulfate, heparan sulfate, chondroitin 4-sulfate, chondroitin 6-sulfate
Glycoproteinoses				
Mannosidosis	AR; locus: 19cen-q12	Lysosomal α-mannosidase	Brain, liver, spleen, bone (several variants)	Mannose-rich oligosaccharides
Fucosidosis	Locus: 1p34	Glycoprotein α-fucosidase	Brain, liver, spleen, heart, skin (several variants)	Fucose-containing oligosaccharides
Aspartylglucosaminuria	Locus: 4q32-q33	Aspartylglucosaminidase	Brain, liver, spleen, bone, heart	Aspartylglucosamine-containing peptides
Sialidosis	Locus: 6p21.3	Glycoprotein neuraminidase (sialidase)	Brain, liver, spleen, bone, retina (several variants)	Sialylated glycopeptides
Galactosialidosis	Locus: 20q13	Protector protein deficiency, combined neuraminidase (sialidase) and β-galactosidase deficiency	Brain, liver, spleen, bone (several variants)	GM_1 ganglioside, sialylated glycopeptides
Mucolipidosis II (I-cell disease)	Locus: 4q21-q23	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bone, connective tissue	Glycoproteins, glycolipids
Mucolipidosis III (Pseudo-Hurler polydystrophy)	?	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bone, connective tissue	Glycoproteins, glycolipids
Mucolipidosis IV (sialolipidosis)	Locus: 19p13.3-p13.2	Mucolipin 1	?	?
Sphingolipidoses				
(Gaucher disease type I [nonneuronopathic])	AR; locus: 1q21	Acid β-glucosidase, glucocerebrosidase	Liver, spleen, bone, bone marrow (highly variable phenotype)	Glucosylceramide
(Gaucher disease type 2 [acute neuronopathic])		Acid β-glucosidase, glucocerebrosidase	Brain, brain stem, liver, spleen, bone marrow, lungs	Glucosylceramide, glucosylsphingosine
(Gaucher disease type 3 [sub-acute neuronopathic])		Acid β-glucosidase, glucocerebrosidase	Brain, liver, spleen, bone marrow, lungs (variable phenotype)	Glucosylceramide, glucosylsphingosine

(*continued*)

point mutations or genetic rearrangements at a single locus of the gene that codes for a single lysosomal hydrolase.

The two types of therapy for lysosomal storage diseases that are currently available are cellular transplantation and enzyme therapy.[60] Gaucher disease was formerly treated with bone marrow transplantation, but it is currently treated with alglucerase, an α-mannosyl–terminated glucocerebrosidase. Bone marrow transplantation for the other lysosomal storage diseases is investigational and has yielded mixed results.

Eosinophil Physiology

Eosinophils can enhance or suppress acute inflammatory reactions and mediate responses to helminthic infection, allergy, and certain tumors.[61] Like neutrophils, eosinophils are capable of phagocytosis, but eosinophils are primarily secretory cells. Most of the functions they perform require the release of granule contents or reactive oxygen species. The eosinophils respond to unique chemotactic agents and growth factors that permit their accumulation at sites of inflammation.

EOSINOPHIL STRUCTURE

The granules of eosinophils contain strongly basic proteins and stain intensely with acid dyes. They have a striking and unique appearance on electron microscopy [*see Figure 1*]. The granules consist of an electron-dense core surrounded by a relatively radiolucent matrix; eosinophil peroxidase is active in the matrix. The dense core has a crystalloid structure and contains eosinophil cationic proteins (ECPs), major basic proteins (MBPs), and eosinophil-derived neurotoxins. MBPs and ECPs are capa-

Table 6 (continued)

Disease (Common Name)	*Inheritance*	*Enzymatic Defect*	*Organs and Tissues Involved*	*Stored Material*
Metachromatic leukodystrophy (MLD)				
Infantile MLD	Locus: 22q13.3-qter	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
Juvenile MLD	Locus: 10q22	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
Adult MLD		Arylsulfatase A, saposin B deficiency	Brain, peripheral nerves	Sulfatide
Pseudodeficiency		Partial arylsulfatase A	Normal	None
Multiple sulfatase deficiency		Unknown primary defect, multiple lysosomal and nonlysosomal sulfatase deficiencies	Brain, liver, spleen, bone	Sulfatide, dermatan sulfate, heparan sulfate
Gangliosidoses				
GM_2 gangliosidoses				
Infantile Tay-Sach disease (TSD)	Locus: 15q23-q24	Hexosaminidase A (α chain)	Brain	GM_2 ganglioside
Juvenile TSD		Hexosaminidase A (α chain)	Brain	GM_2 ganglioside
Adult TSD		Hexosaminidase A (α chain)	Brain	GM_2 ganglioside
Activator deficiency	Locus: 5q31-q33	GM_2 activator	Brain	GM_2 ganglioside
Sandhoff disease		Hexosaminidase B and A (β chain)	Brain, liver, spleen, bone	GM_2 ganglioside, globoside
GM_1 gangliosidoses	Locus: 3p21	β-Galactosidase	Brain, liver, spleen, bone	GM_1 ganglioside, keratan sulfate
Neutral sphingolipidoses				
Fabry disease	Locus: Xq22	α–Galactosidase A	Kidney, vascular endothelial system, heart, central nervous system vessels	Globotriaosylceramide
Schindler disease	Locus: 22q11	α-*N*-Acetylgalactosaminidase	Brain (probably several variants)	*N*-Acetylgalactosamine–linked oligosaccharides
Krabbe disease	Locus: 14q31	Galactocerebrosidase	Brain	Galactocerebroside
Niemann-Pick disease				
(Niemann-Pick A disease [infantile])	Locus: 11p15.4-p15.1	Sphingomyelinase	Brain, liver, spleen, lungs	Sphingomyelin
(Niemann-Pick B disease [late-onset])	Locus: 18q11-q12 (C1)	Sphingomyelinase	Liver, spleen, lungs	Sphingomyelin
(Niemann-Pick C disease)	Locus: 18q11-q12 (C2)			
Neutral lipid storage diseases				
Wolman disease	Locus: 10q24-q25	Lysosomal acid lipase	Liver, spleen, adrenal glands, bone marrow	Cholesteryl esters, triglycerides
Cholesterol ester storage disease	Locus: 10q23	Lysosomal acid lipase	Liver, spleen, blood vessels	Cholesteryl esters
Farber disease		Ceramidase	Brain, joints, tendons, skin, liver	Ceramide

ble of inflicting considerable damage to parasites such as schistosomula by binding to and disrupting their cell membranes. In addition, MBPs enhance the adherence of eosinophils and neutrophils to schistosomula.[62]

EOSINOPHIL FUNCTION

Eosinophils respond to a variety of chemotactic factors that enable them to enter tissues and carry out their functions. Some chemokines and chemotactic factors, such as C5a, *N*-formylmethionyl–containing peptides, and leukotriene B_4, stimulate both eosinophils and neutrophils. Several chemotactic stimuli, however, are highly specific for eosinophils. Among these eosinophil-specific stimuli are platelet-activating factor (PAF), eosinophil chemotactic factor of anaphylaxis, and a variety of parasite-derived factors. Responses to PAF, one of the most potent activators of normal eosinophils, include chemotaxis, adherence, enhanced binding of IgE, production of superoxide, release of granule proteins, and synthesis of prostanoids.

Both the production and activation of eosinophils are affected by GM-CSF, IL-5, and IL-3. IL-5 appears to be critical for eosinophil production and deployment.[63] Exposure to low doses of IL-5 also specifically primes eosinophils for later actions by other stimulants. Once activated, the eosinophils have enhanced generation of reactive oxygen species, enhanced glucose utilization and transport, increased oxygen consumption, a reduced cell surface charge, and activation of acid phosphatases in specific granules.

Eosinophils enhance the immune response to helminths. They perform this function by binding to the surface of both larval and adult forms, by damaging target cells through oxygen-dependent mechanisms that are similar to those of neutrophils, and by damaging cell surfaces by releasing granule proteins such as MBP and ECP. Although the release of these proteins similarly damages normal tissues and tumor cells, these interactions between eosinophils and host cells are less well understood. Eosinophils also produce cytokines that enhance the in-

flammatory response.[64] The presence of eosinophilia in patients with Hodgkin disease appears to be a function of the production of IL-5 by Reed-Sternberg cells. Eosinophils contribute to the fibrosis of the nodular sclerosis type of Hodgkin disease by producing transforming growth factor–β1.

Disorders of Eosinophil Number

EOSINOPHILIA

Evaluation of the patient with eosinophilia (eosinophil count > 700/mm^3) is difficult because the causes of this disorder are multiple and diverse.[65] Common causes of secondary eosinophilia include allergic disorders, infections caused by parasites and other organisms, dermatologic diseases, pulmonary diseases, collagen vascular disease, neoplasms, and immunodeficiency diseases. There are also myriad uncommon causes, such as eosinophilic gastroenteritis, inflammatory bowel disease, chronic active hepatitis, pancreatitis, and hypopituitarism.

HYPEREOSINOPHILIC SYNDROME

The term hypereosinophilic syndrome (HES) is often used for patients with chronic eosinophilia of unknown cause.[66] The criteria used to diagnose HES are an unexplained eosinophil count of greater than 1,500/mm^3 for longer than 6 months and signs or symptoms of infiltration of eosinophils into tissues. Recent evidence points to a mutation in chromosome 4 that results in linkage of the *Rhe* gene and the *PDGFRα* gene.[67]

The clinical features of HES are rash, fever, cough, dyspnea, diarrhea, and peripheral neuropathy. Patients may have chronic congestive heart failure, valvular abnormalities, and distinctive, fibrous, biventricular endocardial thickening with mural thrombi.[66] The blood smear of a patient with HES usually reveals normal mature eosinophils of typical morphology; however, the presence of hypogranulation and cytoplasmic vacuoles has been reported. The total leukocyte count is typically 10,000 to 30,000/mm^3, 30% to 70% of which are eosinophils. The bone marrow is generally hypercellular, with eosinophils constituting 25% to 75% of the marrow elements.

HES can usually be distinguished from malignant disorders associated with eosinophilia, such as acute or chronic eosinophilic leukemias.[68] Allergic reactions must also be excluded; the exclusion of such a reaction is usually based on the history, physical examination, and review of current medications. Because many drugs may generate an allergic reaction accompanied by eosinophilia, all nonessential medication should be discontinued before the patient is evaluated.

Parasitic infections, most commonly with such tissue-invasive helminths as filariae and *Strongyloides, Trichinella, Schistosoma,* and *Toxocara* species, frequently present with eosinophilia. To eliminate parasitosis as the cause of eosinophilia, multiple stool samples and a small bowel aspirate are recommended, particularly in patients who are at particular risk for infection (e.g., those who frequently travel, those who are exposed to animals, and those who have immunodeficiencies). If these test results are negative, serologic assays, radiologic tests, and peripheral blood and bone marrow smears should be performed to exclude the presence of connective tissue diseases, occult lymphoproliferative syndromes and solid tumors, and hematologic malignancies, respectively. In patients with possible cardiac involvement, an echocardiogram should be performed.

Therapy is directed toward lowering the eosinophil count and correcting specific symptoms. If symptoms involving the lungs or the heart are present, prednisone at a dosage of 1 mg/kg/day should be given for 2 weeks, followed by 1 mg/kg every other day for 3 months or longer. If this treatment fails or if an alternative is necessary to avoid steroid side effects, hydroxyurea at a dosage of 0.5 to 1.5 g/day should be given to lower the WBC count to less than 10,000/mm^3 and the eosinophil count to less than 5,000/mm^3. Study findings suggest that treatment with imatinib mesylate is effective.[69] Alternative agents include interferon alfa, cyclosporine, and etoposide.

Table 7 Causes of Lymphocytosis

Lymphoproliferative disorders (primary lymphocytosis)
Leukemia
Acute lymphocytic leukemia
Chronic lymphocytic leukemia
Hairy-cell leukemia

Basophil and Mast Cell Physiology

Basophils and mast cells are important in immediate hypersensitivity reactions, asthma, urticaria, allergic rhinitis, and anaphylaxis.[70] They are derived from a common hematopoietic progenitor cell in the bone marrow and are stimulated by soluble mediators, primarily IgE, to release granule contents and arachidonic acid metabolites from their plasma membranes.

The cytoplasmic granules of both basophils and mast cells contain sulfated glycosaminoglycans; in normal basophils, the sulfated glycosaminoglycans are predominantly heparin. The sulfated glycosaminoglycans are the granule contents that are primarily responsible for the intense staining of the basophil. Most, if not all, of the circulating histamine in the body is synthesized by the basophil and stored in its granules. Degranulation causes the release of histamine, which mediates many immediate hypersensitivity effects and which, because it is a potent

eosinophil chemoattractant, draws eosinophils to the site of degranulation. Other substances that are released on basophil degranulation include additional eosinophil chemotactic factors and a variety of arachidonic acid metabolites, the most important of which is leukotriene C_4. In addition, the cell membranes of basophils contain high-affinity IgE receptors, the number of which tends to be increased in allergic persons.

Disorders of Basophil Number

BASOPHILIA

Basophilia (basophil count > 150/mm^3) is seen in myeloproliferative disorders, such as CML, polycythemia vera, and myeloid metaplasia; after splenectomy; in some hemolytic anemias; and in Hodgkin disease. The basophil count can also be increased in patients with ulcerative colitis or varicella infection. Although basophils and mast cells are involved in immediate hypersensitivity reactions and basophils are often seen in areas of contact dermatitis, basophilia is not seen in patients with these disorders.

Lymphocyte Physiology

Lymphocytes (e.g., B cells and T cells) are also derived from hematopoietic stem cells. These cells develop and mature in the bone marrow, thymus, spleen, and lymph nodes and in other specialized lymphoid tissues [*see Section 6 Immunology and Allergy*].

Disorders of Lymphocytes

LYMPHOCYTOSIS

Lymphocytosis in adults is defined as an absolute lymphocyte count greater than 4,000/mm^3. In children with the disease, lymphocyte counts are higher than in adults and may be as high as 20,000/mm^3 in the first year of life. The blood film of any patient with lymphocytosis should be carefully examined to determine the morphology and diversity of the lymphocytes (e.g., reactive lymphocytes, large granular lymphocytes, blasts, or smudge cells).

Lymphocytosis can be either primary or secondary. Primary lymphocytosis, often called lymphoproliferative disease, is caused by dysregulation in the production of lymphocytes. The primary lymphocytoses include the leukemias (e.g., chronic lymphocytic leukemia, acute lymphocytic leukemia, hairy-cell leukemia, or large granular lymphocyte leukemia), the lymphomas, and monoclonal B cell lymphocytosis [*see Table 7*].

The reactive, or secondary, lymphocytoses are conditions that involve absolute increases in lymphocytes caused by physiologic or pathophysiologic responses to infection, inflammation, toxins, cytokines, or unknown agents. The most common causes of reactive lymphocytosis are viral infections: Epstein-Barr virus, cytomegalovirus, herpes simplex virus, varicella-zoster virus, rubella, human T cell lymphotropic virus type I (HTLV-I), HIV, adenovirus, or one of the hepatitis viruses is frequently responsible for the disease. Other pathogens that produce lymphocytosis are *Toxoplasma gondii* and, in children, *Bordetella pertussis* (which causes the lymphocyte count to rise to as high as 70,000/mm^3). Lymphocytosis is also associated with stress and consequent release of epinephrine, such as that seen in patients who have had cardiovascular collapse, septic shock, sickle cell crisis, status epilepticus, trauma, major surgery, drug reactions, or hypersensitivity. Persistent lymphocytosis may be seen in patients with autoimmune disorders, sarcoidosis, hyposplenism, or cancer and in those who are long-term cigarette smokers.

Table 8 Causes of Lymphocytopenia

- Inherited
  - Congenital immunodeficiency diseases
    - Severe combined immunodeficiency
      - Adenosine deaminase deficiency
      - Purine-nucleoside phosphorylase deficiency
      - Reticular dysgenesis
    - Ataxia-telangiectasia
    - Wiskott-Aldrich syndrome
    - Cartilage-hair hypoplasia
  - Idiopathic CD4$^+$ T lymphocytopenia
- Acquired
  - Infection
    - Viral (e.g., with HIV, a hepatitis virus, influenza virus, or respiratory syncytial virus)
    - Bacterial (e.g., typhoid fever, pneumonia, sepsis, or tuberculosis)
  - Aplastic anemia
  - Autoimmune diseases
  - Hodgkin disease
  - Sarcoidosis
  - Renal failure
  - Protein-losing enteropathies
  - Chylous ascites
  - Zinc deficiency
  - Chronic alcohol ingestion
  - Immunosuppressive agents (e.g., antithymocyte globulin, corticosteroids, chemotherapeutic agents, and radiation)

LYMPHOCYTOPENIA

Lymphocytopenia is defined as a total lymphocyte count less than 1,000/mm^3. Because in adults 80% of lymphocytes are T cells, most cases of lymphocytopenia are caused by a reduction in the T cell count. The mechanisms of lymphocytopenia are often unknown, and the causes are usually differentiated as inherited or acquired.

Inherited lymphocytopenias are usually caused by congenital immunodeficiency diseases. These diseases include severe combined immunodeficiency (e.g., adenosine deaminase deficiency, purine-nucleoside phosphorylase deficiency, and reticular dysgenesis), ataxia-telangiectasia, Wiskott-Aldrich syndrome, and cartilage-hair hypoplasia [*see Table 8*]. In addition, some persons have idiopathic CD4$^+$ T cell lymphocytopenia.

Acquired lymphocytopenia can be seen in patients with viral infections, such as HIV infection, hepatitis, influenza, and respiratory syncytial virus infection; in patients with certain bacterial infections, such as typhoid fever, pneumonia, sepsis, and tuberculosis; and in patients with aplastic anemia, autoimmune diseases, Hodgkin disease, sarcoidosis, renal failure, protein-losing enteropathies, and chylous ascites. Zinc deficiency and long-term alcohol ingestion are also associated with lymphocytopenia. Finally, immunosuppressive agents, such as antithymocyte globulin, corticosteroids, chemotherapeutic agents, and radiation, also produce lymphocytopenia.

The author has received grants for clinical research from and served as consultant for Amgen Inc.

X TRANSFUSION THERAPY

W. Hallowell Churchill, m.d.

Transfusion medicine developed rapidly, owing to several key discoveries and technical advances. These include the discovery of blood group antigens and the understanding of the host immune response to these antigens, the development of methods of anticoagulation and storage of blood, and the creation of plastic bags that allow sterile fractionation of whole blood into components. The potential of blood to act as an agent of disease transmission has heavily shaped both the donation process and transfusion practice.[1] Decisions about whether to transfuse must involve weighing the benefits against the risks. This chapter provides a basis for these decisions, including indications for blood-component use, complications of transfusion therapy, and methods of reducing risks during the collection, processing, and preparation of blood components.

Blood Donation

The donation process for either whole blood or special products, such as single-donor platelets (SDPs) obtained by apheresis, is designed to protect both the donor and the recipient. For example, persons weighing less than 110 lb (49.9 kg) are excluded from donation because they have too small a blood volume to donate blood safely. Donors taking drugs that would impair recovery from a vasovagal donor reaction may also be excluded in some locales. Recipient safety is promoted by excluding donors who are at risk for viral or bacterial infections or are taking medications that could cause reactions or impair the function of donated blood products.

autologous and directed donation

Autologous donations and directed donations are two strategies adopted by patients seeking to minimize their real or perceived risk of infection from blood products.

Autologous Donation

In autologous donation, patients deposit their own blood and then receive that blood if they need transfusion therapy. This eliminates the infectious and sensitization risks associated with allogeneic blood. Absolute contraindications to autologous donation are tight aortic stenosis, unstable angina, and active bacterial infection.[2] Low hemoglobin levels and poor venous access frequently limit the number of units that can be collected. With the increasing safety of allogeneic blood, the rationale for autologous donation may ultimately depend on the importance of the possible modulation of recipient immune function associated with allogeneic transfusion rather than the avoidance of blood-borne infections.

Directed Donation

Directed donation is donation for a specific recipient. It usually involves donations made by friends or family members of the intended recipient. It is based on the assumption that transfusions involving donors selected by the recipient carry lower risk of infections than transfusions involving donors from the general population. However, available prevalence data show that the risk of infectious disease from directed donors is no different from that of first-time donors.[3] The current risk of infection via transfusion is so low [*see Table 1*] that justification for directed donor programs depends primarily on patient preferences or on the need for a selected donor serving as the only source of blood products to reduce the recipient's risk from exposure to multiple donors. The latter form of directed donation is most appropriate for neonatal transfusions, in which one of the biologic parents may provide all the needed blood products.[4]

screening procedures

The combination of improved donor selection and postdonation testing has greatly decreased the infectious risks of allogeneic blood [*see Table 1*]. Predonation donor screening to identify clinical and lifestyle characteristics associated with higher incidences of infection has produced the biggest decrease in the risk of transfusion-transmitted disease.

postdonation testing

Postdonation testing is essential in identifying donors likely to transmit blood-borne infections who are missed in the initial screening process.

Screening for Hepatitis Viruses

Hepatitis C Screening for hepatitis C began in 1990 with the availability of a single antigen-based enzyme-linked immunosorbent assay (ELISA). This assay, together with second- and third-generation assays, their associated confirmatory tests, and nucleic acid testing (NAT) for viral RNA or DNA, has reduced the per-unit risk of hepatitis C virus (HCV) transmission to less than 0.0001% (1 per 1.6 million to 1 per 1.935 million).[5,6] Before these tests were available, the risk per unit was about 4%. Improved hepatitis C testing has eliminated the need for surrogate tests, such as the measurement of alanine aminotransferase (ALT) levels and testing for antibody to hepatitis B virus (HBV) core antigen. However, the test for antibody to HBV core antigen is still used to detect recently infected donors who lack measurable circulating HBV antigen.[7]

The epidemiology of HCV is still poorly understood. Approximately 20% to 25% of persons found to be HCV positive have no known risk factors.[8] Sexual transmission occurs with enough frequency to warrant evaluation of partners and appropriate use

Table 1 Estimated Risk of Infection per Transfused Blood Product[5,6]

Virus	*Risk in Year 2000*	*Risk in Year 2003*
Human immunodeficiency virus type 1/type 2 (HIV-1/2)*	1 in 660,000	1 in 2,135,000
Human T cell lymphotropic virus type I/type II (HTLV-I/II)†	1 in 641,000	1 in 2,993,000
Hepatitis B	1 in 63,000	1 in 205,000
Hepatitis C	< 1 in 103,300	1 in 1,935,000

*Risk with p24 antigen testing and HIV antibody testing.
†Approximately 67% of infections resulting from transfused blood products are infections with HTLV-II.

of methods of barrier protection.[9] Heterosexual transmission of HCV may be asymptomatic; a donor who was infected via sexual contact but has not yet developed detectable antibodies is a potential risk to the blood supply. Therefore, persons who are sexual partners of known HCV-infected persons may be excluded from donation. Donors found to be ELISA positive for HCV should have supplemental tests, such as the second-generation and third-generation recombinant immunoblot assays (RIBA-2, RIBA-3). Donors with positive supplemental test results are likely to have a chronic HCV infection and require further clinical evaluation.[10] Donors with negative supplemental test results probably had false positive screening results and may be eligible for reentry into the allogeneic donor pool after 6 months.[11] The infection status of donors with indeterminate supplemental results is best resolved by testing for HCV RNA; those with only a single band on the most sensitive supplemental test (RIBA-3) have a less than 4% chance of having circulating HCV RNA.[12]

Gene amplification methods for detecting HCV RNA are used on all blood products before release for transfusion. These tests directly detect the presence of virus before antibody development and are responsible for the current minuscule risk of HCV transmission.[6] Correlation studies have shown that only 80% of samples with confirmed serologic positive results for HCV are also NAT positive. This is consistent with previous estimates of the prevalence of HCV-positive persons who have cleared the virus.[6]

Hepatitis B Transmission of other forms of hepatitis by blood products is extremely rare. Modern testing methods and eliminating the practice of paying whole blood donors have reduced HBV infections to about one in 205,000 units transfused.

Hepatitis A Because the viremic phase of hepatitis A lasts about 17 days in humans before signs and symptoms develop, hepatitis A transmission from single-donor products is extremely rare. Pooled products, such as factor concentrates, however, carry a substantially higher risk.[13]

Hepatitis D Hepatitis D is a defective virus that requires HBV to produce fulminating hepatitis; it is a concern only for patients already infected with HBV.

Hepatitis G The flavivirus hepatitis G, now shown to include several strains, is present in about 4.5% of normal donors. It is transmitted from mother to infant, sexually, and by blood.[14] Circulating hepatitis G RNA is removed after the recipient develops antibodies, which makes the recipient resistant to further infection.[15] HGV has not been linked to any form of clinical hepatitis in children or adults. It is an example of a blood-borne virus without known pathogenicity; as yet, there is no clear reason to remove it from the blood supply.

Screening for Retroviruses

All blood products are screened for HIV-1, HIV-2, human T cell lymphotropic virus type I (HTLV-I), and HTLV-II. Data obtained nationally from American Red Cross donors indicate that the infection risk has been reduced from two per 100 transfusions to about one per 2 million transfusions because of the exclusion of high-risk donors and the postdonation testing for HIV-1 and HIV-2 antibodies and NAT for viral RNA or DNA.[5]

To have predictive value, the ELISA screening test for HIV must be confirmed by Western blot assay. Studies based on polymerase chain reaction (PCR) data, culture data, and donor review all indicate that donors with negative or indeterminate Western blot results are seldom, if ever, HIV positive.[16] A follow-up study of donors who were ELISA positive and whose Western blot results were indeterminate demonstrated that positive ELISA results persisted in about 45% of cases. Of these, 84% still had indeterminate Western blot results, but none were shown to be HIV positive by PCR.[17,18] There have been occasional false positive results of Western blot assays in low-risk donors.[19] The possibility of a false positive result should be remembered when one is counseling low-risk donors who have had unexplained positive results on Western blot testing; these false positive results must always be confirmed by careful clinical follow-up. Data since the introduction of NAT show that less than 6% of confirmed serologic positive results will be NAT negative. On the other hand, only 1.5% of NAT screen reactives were Western blot indeterminate or negative. Virtually none of these NAT reactives were confirmed by discriminatory NAT testing or PCR.[6]

The prevalence of HTLV-I and HTLV-II in United States donors was about 0.03% in 1995. Data from 2001 suggest that the prevalence has been reduced to about 0.01%; about two thirds of these HTLV-positive patients have HTLV-II.[5] Several longitudinal studies have defined the clinical consequences of HTLV-I/II infection[20-22]; they are useful in advising donors who have had positive or indeterminate test results. In a prospective, longitudinal study comparing seropositive blood donors with seronegative blood donors, both viruses were associated with an increase in the incidence of some infectious diseases. No cases of adult T cell leukemia or lymphoma were identified; myelopathies, though rare, were associated with both HTLV types.[22] The risk of HTLV-I/II transmission by blood products is one per 2,993,000.[5] As with HIV, laboratory studies and epidemiologic investigations of HTLV-I/II indicate that patients with positive screening-test results and negative or indeterminate supplemental-test results are unlikely to have clinical sequelae and that the positive results are most likely false positives.[23]

False Positive Test Results during Donor Screening

The causes of false positive test results for HCV and retroviruses are poorly understood. Flu vaccines administered in 1992 were associated with an increase in false positive results for these viruses.[24] However, the proteins responsible for cross-reactivity have not yet been identified. Tests for low-prevalence infections, even tests with excellent specificity and sensitivity, will always be associated with a substantial proportion of false positive results. Consequently, test characteristics, as well as culture and PCR results, can provide reassurance for donors who are not at risk but who have had positive screening-test results and negative or indeterminate confirmatory-test results. As PCR technology improves, it will probably become the most reliable means of establishing whether a positive result represents infection or is a false positive result.

Emerging Infectious Diseases

Until either screening tests or sterilization procedures become available, epidemiologic considerations are the only possible protective strategy against newly recognized infections.[25] For example, transmission of West Nile virus by blood products has led to new donor questions to eliminate donors at risk for this disease, and a nucleic acid–based test for all donated units was introduced in June 2003.[26] In the case of prion diseases such as

variant Creutzfeldt-Jakob disease (vCJD), the restrictions put in place have led to a loss of 4% to 5% of active blood donors and caused transient shortages of certain products such as albumin and immune globulin. In Great Britain, the first case of possible transfusion-transmitted vCJD was reported in December 2003.[27] The report identified 48 recipients of blood from a total of 15 donors who had developed vCJD. In one recipient, symptoms of the disease developed 6.5 years after the possible exposure, a time frame consistent with human-to-human vCJD transmission. The authors estimated the chance of this patient having contracted vCJD independent of the transfusion to be between one in 15,000 and one in 30,000. Recent estimates of the incidence of new vCJD diagnoses in the United Kingdom suggest that there will be fewer than 200 cases from 2001 to 2005 and fewer than 100 cases from 2006 to 2010.[28] Thus, although the current donor restrictions seem prudent, it is important that donors rejected because of epidemiologic risk for vCJD understand the low probability that they actually have a health problem.

Pretransfusion Testing

ANTIGEN PHENOTYPING

Blood recipients are routinely tested to establish their ABO phenotype and Rh type. Establishing ABO type is essential because isoagglutinins (antibodies) against A or B antigens not present on a person's red cells are acquired during the first 2 years of life. These IgM antibodies will cause an immediate hemolytic reaction if ABO-incompatible red cells are transfused.

The terminal carbohydrate on these antigens determines specificity in the ABO system, with type A being associated with *N*-acetylgalactosamine and type B being associated with a terminal galactose. Persons with type O lack both of these terminal sugars. These residues are added by a glycosyltransferase, which was thought to be either nonfunctional or absent in type O persons. Yamamoto and colleagues[29] used molecular techniques to prove that glycosyltransferase in type O persons is very similar to the transferase in type A persons. The type O glycosyltransferase is nonfunctional because of a single base deletion that produces a frameshift and a downstream stop codon.

All methods of ABO typing depend on demonstrating that the antigens found on the red cells are consistent with the expected isoagglutinins [*see Table 2*]. Molecular methods to determine ABO genotype are available.[30] D antigen specificity typing in the Rh system is done because of this antigen's potency as an immunogen. Antibodies to the D antigen are the most important cause of isoimmune hemolytic disease of newborns. Rh antigens are membrane glycolipids or glycoproteins. Antibodies against antigens of this class, which includes the Rh, Duffy, Kell, Kidd, and Lutheran systems, will usually cause shortened red cell survival. In contrast to antigens with carbohydrate-mediated specificity, glycolipid and glycoprotein antigens do not stimulate antibody formation unless the transfusion recipient was previously exposed to allogeneic red cells either from transfusion or from fetal red cells during pregnancy or delivery.

D antigen typing is also done using agglutination techniques. In some cases, less antigenic forms of the D antigen, called weak D, require an antiglobulin reagent to enhance detection. Structural studies of the complementary DNA associated with the major Rh antigens (D, Cc, and Ee) have provided probes for direct genotyping.[31] Molecular methods of prenatal Rh type determination have revealed that most Rh-negative persons lack the *D* gene. Some persons with the weak D phenotype have mosaic *D* genes because of exchange with some of the exons of the *CcEe* gene.

Because the genotypes of many of the clinically relevant red cell antigens are now known, it should now be possible to predict red cell phenotype by DNA analysis. Reid and colleagues[32] were able to correctly predict the red cell phenotype in 60 multitransfused patients by DNA analysis of each patient's white blood cells. This approach, although not yet generally available, will be useful for recently transfused patients, for whom circulating allogeneic red cells complicate antigen phenotyping.

SCREENING FOR ANTIBODIES

In addition to identifying patient ABO and D red cell phenotypes, blood banks must screen serum for red cell–specific antibodies, which can cause serious reactions with transfused red cells. Screening involves testing serum against indicator type O red cells displaying all the clinically important red cell antigens. Positive reactions are detected by adding an antiglobulin reagent (Coombs reagent) to the incubated mixture of type O red cells after it has been washed free of serum. Any observed agglutination is from the reaction of the antiglobulin reagent with antibody adsorbed on the surface of the indicator red cells [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*]. Agglutination of the indicator red cells indicates the presence of other antibodies, which require identification. The absence of agglutination excludes all antibodies except those against antigens so rare that they are not displayed on the indicator red cells.

Use of type-specific blood removes the risk of ABO incompatibility. There is, however, a residual risk of an immunologic reaction from the antibodies to other red cell antigens; such antibodies are present in about 3% to 5% of a random population and in 10% to 15% of persons who were recently transfused or women with a history of pregnancy. Screening for antibodies reduces the frequency of reactions to about 0.06%. Performing a full crossmatch, in which the recipient's serum is tested against the red cells actually being transfused, is of negligible additional benefit, because it excludes only technical errors and the rare antibody that is not detected by the screening. Therefore, a full crossmatch is performed only for persons already known to have made antibodies, because such persons are more likely to form additional antibodies if they are further stimulated by red cell transfusion.

Patients who may receive allogeneic red cells who either have had a transfusion or have become pregnant within the past 3 months must be tested for new antibodies every 3 days. There is no consensus concerning how long the interval should be between patient specimen collection and use of the specimen in pretransfusion testing for patients not recently exposed to red cells. Commonly, specimens are accepted 14 to 28 days before the

Table 2 ABO Typing

Blood Type	*Erythrocytes plus Anti-A Serum*	*Erythrocytes plus Anti-B Serum*	*Antibodies in Patient's Serum*
A	+	0	Anti-B antibodies
B	0	+	Anti-A antibodies
AB	+	+	No antibodies
O	0	0	Anti-A and anti-B antibodies

+—agglutination 0—no agglutination

date for use. However, one study showed that no new antibodies appeared in paired specimens collected up to 1 year apart, suggesting that a longer acceptance interval may be possible.[33]

Blood Components

Most blood donations undergo a fractionation process that allows each component to be used for specific indications. Whole blood can be fractionated into red cells (which contain most of the leukocytes), platelet concentrates (which contain some leukocytes), and plasma [*see Table 3*]. Plasma can be further subdivided into coagulation components and albumin. Each whole-blood unit can potentially support many recipients and clinical needs, maximizing use of each donation.

After 24 hours' storage, whole blood contains no active platelets, and after 2 days, it is deficient in factors V and VIII. Therefore, except for some autologous blood programs that use whole blood rather than packed red cells, use of whole blood has now been almost completely supplanted by therapy employing specific blood components.

RED BLOOD CELLS

The anticoagulant used determines the shelf life of red cells [*see Table 3*]. Citrate-phosphate-dextrose (CPD) with the addition of adenine (CPDA-1) increases storage time from 28 days to 35 days. Most red cells are now stored in CPD to which extra nutrients have been added, which increases storage time to 42 days. This additive solution sometimes contains additional saline, which can be removed if units with very high hematocrits (~70%) are needed.

To prevent transfusion reactions or to delay alloimmunization, red cells are further processed by leukocyte reduction (see below) or washing to remove plasma proteins. Current filter technology reduces white cell counts to less than 5×10^6 cells per unit, a concentration that is sufficient to reduce febrile transfusion reactions and delay alloimmunization and platelet refractoriness. Washing red cells removes the plasma, leaving less than 0.5 ml per unit, a degree of plasma depletion usually effective in treating allergic transfusion reactions. Leukocyte filtration and washing red cells usually shorten the product shelf life to 24 hours, because these procedures require breaking the seal on the plastic bag that contains the red cells, thereby increasing the risk of bacterial contamination. Leukocyte reduction can be accomplished during collection, immediately after collection in the blood bank, or at the bedside during product infusion. Prestorage or laboratory filtration is preferred to bedside filtration.[34] Universal leukoreduction has been implemented in Canada and Europe, but it is not yet required in the United States because of concerns regarding cost-effectiveness.

Table 3 Characteristics of Blood Products and Indications for Use

Product	*Volume (One Unit)*	*Hematocrit (Hct) or Platelet Count*	*White Cell Count*	*Shelf Life*	*Donors per Unit*	*Storage Outside Blood Bank*	*Indication*
Whole blood	450–500 ml (± 10%)	Hct 35–45	$3–5 \times 10^9$	With additive solution, 42 days; with CPDA-1, 35 days; with CPD, 28 days	1	2°–6° C	Massive transfusion if available; exchange transfusions in newborns younger than 3 days
Red cells	With additive solution, 350 ml; with CPD, 250 ml	If additive solution used, Hct 55; if CPD used, Hct 70	$1–2 \times 10^9$	Same as whole blood	1	Same as whole blood	To increase oxygen-carrying capacity; to maintain volume and oxygen-carrying capacity when bleeding
Platelet concentrates	40 ml	$8–9 \times 10^{10}$	$2–6 \times 10^7$	5 days	1/U; given as pool of 5–6 U	Room temperature	For major bleeding or surgical procedures, when platelet count is < 50,000–100,000 μl; for prophylaxis in nonbleeding patients, when platelet count is < 10,000 μl; for bleeding that is refractory to SDPs, when HLA-matched or crossmatched platelets are not available
Single-donor platelets	200–250 ml	$3–5$ ml $\times 10^{11}$	Depends on method of collection	5 days	1	Room temperature	Same as platelet concentrates, but SDPs are preferred because of lower donor exposure
Fresh frozen plasma (FFP)	200–250 ml	—	$< 1 \times 10^5$	1 yr; 24 hr when thawed	1	2°–6° C	Multiple coagulation factor deficiency from bleeding or DIC; reversal of warfarin therapy; factor XI deficiency when factor XI concentrates are unavailable; treatment of TTP
Cryoprecipitate	10–20 ml; pool of 10 U ~ 200 ml	—	$< 1 \times 10^5$	1 yr; 24 hr when thawed	1/U; given as pool of 10 U	2°–6° C wet ice	Replacement of fibrinogen when acutely depleted or when patient cannot tolerate volume load of equivalent amount of FFP (1 pool of cryoprecipitate = 4 FFP); fibrin glue (usually only 1 unit); replacement of von Willebrand factor if concentrate is not available; replacement of factor XIII; replacement for qualitatively abnormal fibrinogen

CPD—citrate-phosphate-dextrose CPDA-1—CPD with adenine DIC—disseminated intravascular coagulation FFP—fresh frozen plasma HLA—human leukocyte antigen SDPs—single-donor platelets TTP—thrombotic thrombocytopenic purpura

Freezing is an alternative method for storing red cells. Red cells can be kept in a cryoprotectant (usually glycerol) for 10 years. Freezing is therefore ideal for storing rare units or autologous units from persons with rare blood types, for whom it is difficult to find compatible allogeneic red cells. When a unit is at the end of its liquid storage shelf life, the cells can be rejuvenated with fresh media and nutrients; they can then be frozen and stored. To be used, frozen red cells must be thawed and the glycerol removed, so preparation time for this product is longer than for products stored in the liquid state. Thawed, deglycerolized red cells generally must be transfused within 24 hours.

PLATELETS

Platelets can be provided either as platelet concentrates from a number of blood donors or from a single donor. SDPs are collected by a continuous apheresis process that removes platelets and returns all other blood components. A single transfusion of platelet concentrates usually consists of platelets derived from four to six units of donated whole blood, which is about the same number of platelets contained in one SDP product. The advantage of SDP therapy is the reduced risk of blood-borne infection and antigen exposure, because the product is from one donor rather than from four to six; disadvantages are a longer collection time, greater cost, and often limited supply. The potential advantages of each of these products have been summarized in a review.[35] ABO Rh–compatible platelets should be used when possible, because studies have shown significantly better therapeutic results from compatible transfusions.[36]

PLASMA

Fresh plasma, frozen within 8 hours of collection (FFP), contains all the procoagulants at normal plasma concentrations. After thawing, it can be kept for 24 hours at 2° to 6° C and will retain 3 to 4 mg/ml of fibrinogen and 1 IU/ml of all the other coagulation components.

Solvent/detergent-treated plasma (S/D plasma) was formerly available as an alternative to FFP with lower infectious risks. However, in 2002 this product was withdrawn from the market by the manufacturer, presumably because of lack of demand for the product and evidence of selective inactivation of certain plasma components. Alternative methods of postcollection sterilization of single units of plasma are becoming available. The main advantage of a postdonation sterilization process is that it protects patients from blood-borne infections, including ones that are not yet recognized. Potential disadvantages are cost and less effectiveness than FFP.

Cryoprecipitate consists of the cryoproteins recovered from FFP when it is rapidly frozen and then allowed to thaw at 2° to 6° C. These cryoproteins include fibrinogen, factor VIII, von Willebrand factor, factor XIII, and fibronectin. About 40% of the components in FFP are recovered. The cryoproteins are suspended in a small amount of plasma that contains ABO isoagglutinin at the concentration found in normal plasma. A pool of 10 units of cryoprecipitate (each derived from one unit of FFP) contains an amount of fibrinogen equivalent to four units of FFP but in one fourth to one fifth the volume. Consequently, a cryoprecipitate pool permits more rapid replacement of fibrinogen than FFP but has the disadvantage of more donor exposures. After the cryoprecipitate is removed from FFP, the residual product is known as cryopoor plasma. Once frozen, cryopoor plasma has the same shelf life as FFP.

Transfusion of Red Cells

INDICATIONS FOR ALLOGENEIC TRANSFUSION

Acute Blood Loss

The decision whether to use red cells depends on the etiology and duration of the anemia, the rate of change of the anemia, and assessment of the patient's ability to compensate for the diminished capacity to carry oxygen that results from the decrease in red cell mass. Management of acute anemia caused by bleeding or operative blood loss will differ from management of chronic anemia to which the patient has adapted. However, the question underlying any red cell transfusion is whether there is sufficient oxygen delivery to tissues for current needs.

Compensatory mechanisms for acute blood loss include adrenergic response, leading to constriction of venous beds, which improves venous return; increased stroke volume, tachycardia, or both; and increased peripheral resistance, which eventually redistributes blood flow to essential organs. Also contributing to the maintenance of intravascular volume is the shifting of fluid to the intravascular space; this shifting occurs relatively rapidly from the extravascular space and more slowly from the intracellular to the extravascular space.[37]

A decrease in blood volume has distinct effects on oxygen delivery, depending on the volume of blood lost and the functioning of the compensatory cardiovascular responses. Restoration of intravascular volume, usually with crystalloid, ensures adequate perfusion of peripheral tissue and is the first treatment goal for a patient with acute blood loss. Whether red cell transfusion is required depends on the extent of blood loss and the presence of comorbid conditions that may limit host response to the blood loss. The American College of Surgeons has correlated blood loss with clinical findings. Loss of up to 15% of total blood volume (class I hemorrhage) usually has little effect; this amount is the maximum permitted in normal blood donation. A class II hemorrhage (15% to 30% loss) results in tachycardia, decreased pulse pressure, and, possibly, restlessness. A class III hemorrhage (30% to 40% loss) leads to obvious signs of hypovolemia; mental status often remains normal. Red cell transfusion is usually indicated when blood loss exceeds 30% in a patient without other significant comorbid conditions. However, the presence of serious cardiac, peripheral vascular, or pulmonary disease can lower this threshold. For example, anemic patients with significant coronary artery disease are more likely to have serious postoperative myocardial complications.

The threshold for red cell transfusion has been evaluated in two randomized, controlled trials. In one study of transfusion after coronary artery bypass, patients who received transfusions for hemoglobin levels below 8 g/dl did no worse than control patients who received transfusions for hemoglobin levels below 9 g/dl.[38] The other trial compared outcomes in critical care patients who received transfusions when their hemoglobin level fell below either 7 g/dl or 10 g/dl.[39] Enrollment in this study was limited to patients who were euvolemic at entry and whose hemoglobin levels were from 7 to 9 g/dl; patients who had undergone routine cardiac procedures or who were actively bleeding upon entry to the intensive care unit were excluded. There was no statistical difference in 30-day mortality for these two groups. However, in the subgroups of patients younger than 55 years and patients whose illness was less severe, as defined by standardized clinical criteria, Kaplan-Meier survival estimates were significantly better in the patients who were not transfused

Table 4 Indications for Platelet Transfusion

Platelet Count (μl)	*Indication for Transfusion*
< 10,000	All patients, even if asymptomatic
< 20,000	Coagulation disorder or minor bleeding
< 50,000–100,000	Major bleeding or surgical procedure

unless hemoglobin levels dropped below 7 g/dl. These results are provocative, but they must be interpreted cautiously. They do suggest that more restrictive transfusion policies may be safely adopted for selected patients. However, the enrollment criteria may have biased the findings, and this calls into question the applicability of these findings to other settings.

Chronic Anemia

In the chronically anemic patient, an increase in red cell 2,3-diphosphoglycerate leads to a shift in the oxygen dissociation curve and improved delivery of oxygen to tissues. This adaptation augments the mechanisms for improved oxygen delivery described above. Indications for transfusion depend on clinical assessment of the adequacy of oxygen delivery and are also guided by the etiology of the anemia. If the anemia can be reversed with iron, folic acid, or vitamin B_{12}, transfusion therapy is indicated only in patients with clinical findings that cannot be tolerated while endogenous red cell mass is being regenerated. Patients with chronic renal disease are typically deficient in erythropoietin. Replacement therapy with exogenous erythropoietin [*see 5:III Anemia: Production Defects*] often obviates transfusion. Patients with anemia that is a result of chronic disease such as rheumatoid arthritis, malignancy, or AIDS may also respond to erythropoietin.[40,41]

Relatively little is known about transfusion thresholds in specific medical illnesses. An observational trial has addressed the effect of anemia on the 30-day mortality of elderly patients hospitalized with acute myocardial infarction. Mortality was reduced in those patients who were transfused to a hematocrit of 30% to 33%, but transfusion had little or no effect on patients who presented with a hematocrit already in the 30% to 33% range.[42]

INDICATIONS FOR AUTOLOGOUS TRANSFUSION

Whether the criteria for autologous transfusion should be the same as that for allogeneic transfusion remains unresolved. Although the risk associated with autologous blood is less than that associated with allogeneic blood, it is not zero. Errors in labeling, storage, and processing can still occur. For these reasons, many argue that uniform standards based on oxygen delivery should apply, regardless of the blood source. Others, citing the reduced risk, advocate returning most or all of the predeposited units to the patient. There is no clinical evidence that either transfusion policy is associated with better or worse patient outcomes.[43]

Intraoperative and postoperative blood salvage can also help limit allogeneic blood use. Blood salvage is employed in procedures associated with the shedding of large volumes of blood; it involves returning concentrated red cells to the patient after those cells have been washed. Preoperative isovolemic hemodilution (PIH) is a process in which blood collected immediately before surgery is returned as needed postoperatively. This strategy has been shown to be a cost-effective alternative to preoperative autologous donation in patients undergoing radical prostatectomy.[44] PIH would be particularly useful if an oxygen-carrying blood substitute were available to replace the autologous blood that is removed. Until it is clear that the cardiovascular risks associated with acute hemodilution do not outweigh the risks associated with allogeneic blood, this approach should be considered with caution.

Transfusion of Platelets

In general, the decision to transfuse platelets rests on the answers to two questions: (1) Is the thrombocytopenia the result of underproduction or increased consumption of platelets? and (2) Do the existing platelets function normally?

INDICATIONS FOR TRANSFUSION

Low Platelet Count

Thrombocytopenia can result from decreased production caused by marrow hypoplasia or from increased consumption caused by conditions such as idiopathic thrombocytopenic purpura (ITP). In a patient with ITP, surviving platelets are larger and younger and function better than would be expected given the platelet count; platelet transfusion is largely avoided or minimized for such a patient. In contrast, with hypoplasia, platelet function is more severely impaired, and the risk of bleeding is relatively higher. Thus, the decision to transfuse patients who have hypoproliferative thrombocytopenia is generally based on their platelet count and is initiated prophylactically when the count drops below a certain threshold. Published consensus guidelines provide an excellent summary of all aspects of platelet therapy.[45]

Studies have shown that the prevalence of bleeding increases significantly below a threshold of about 10,000 platelets/μl in otherwise asymptomatic patients.[46] The desire to avoid allogeneic donor exposure, cost concerns, and increasing platelet demand have encouraged the use of transfusion policies similar to the policy proposed by Wandt and colleagues [*see Table 4*].[45,46]

Nonfunctioning Platelets

Platelet function is the second criterion for the transfusion of platelets. Transfusion is appropriate in a bleeding patient whose platelet count is adequate but whose platelets are nonfunctional as a result of medications such as aspirin or nonsteroidal anti-inflammatory drugs or as a result of bypass surgery. In a bleeding patient, if platelet dysfunction is from inherited or acquired defects, transfusion is indicated to provide a minimum number of normal platelets. Platelet function is abnormal in uremic patients, and definitive treatment requires correction of the uremia. Some studies suggest that interventions that increase von Willebrand factor levels, such as desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]) conjugated estrogen, or cryoprecipitate, may favorably influence platelet function in uremia.[47] In vitro evidence suggests that DDAVP may improve platelet dysfunction caused by glycoprotein IIb/IIIa (GPIIb/IIIa) inhibitors (e.g., eptifibatide, abciximab, tirofiban) or aspirin.[48]

CONTRAINDICATIONS TO PLATELET TRANSFUSION

Proper investigation of the causes of thrombocytopenia will identify clinical situations in which platelets should be withheld because they contribute to evolution of the illness. These disorders include thrombotic microangiopathies such as TTP, hemolytic-uremic syndrome, and HELLP syndrome (hemolysis, elevated liver enzymes, and a low platelet count). Posttransfu-

sion purpura is usually unresponsive to platelet transfusion but may respond to plasma exchange or intravenous immunoglobulin (IVIg). Platelet transfusions will not help patients with autoimmune thrombocytopenia (e.g., ITP), but they also will not harm them.

RESPONSE TO PLATELET TRANSFUSIONS

Both platelet and host factors influence the response to platelet transfusions. Length of in vitro storage, storage temperature, adequacy of oxygenation, and extent of pretransfusion manipulation all influence in vivo survival. Important host factors that influence survival are temperature, splenomegaly, ABO compatibility, and immune status.

A transfusion of appropriately stored fresh platelets—whether pooled concentrates or SDPs—should contain about 6,000/μl to 10,000/μl platelets per unit (5.5×3^{10} platelets). Thus, in an unsensitized 75 kg (165 lb) recipient, each unit should yield an increment of about 60,000 platelets/μl. When needed, a posttransfusion count is usually obtained after 1 hour but can be obtained as early as 10 minutes after transfusion. A patient is considered refractory to platelet transfusions when the 1-hour posttransfusion increment is less than 10,000 platelets/μl after the patient is given 3.3×10^{11} platelets.

PLATELET TRANSFUSIONS IN REFRACTORY CASES

Platelets have platelet-specific antigens, human leukocyte antigens (HLA), and blood group antigens. Immune response to any of these can contribute to platelet unresponsiveness. Platelet surfaces have only class I HLA antigens, of which only HLA-A and HLA-B are clinically important. Polymorphic antigens are found in association with each of the major platelet proteins: HPA1a/2a (formerly called $Pl^{A1/A2}$) and Pen on glycoprotein IIIa, Bak system on glycoprotein IIb, and Br and Ko on glycoproteins Ia and Ib. Each of these antigen groups is associated with isoimmune neonatal thrombocytopenia. The prevalence of antibodies to platelet-specific antigens is increased for patients sensitized to HLA antibodies; therefore, antibodies to both sets of epitopes may contribute to refractoriness in patients who fail to respond to HLA-matched platelets.[49]

Treating a patient refractory to platelet transfusions involves addressing nonimmune causes (e.g., fever, sepsis, bleeding, and disseminated intravascular coagulation [DIC]) and providing recently collected ABO-compatible products. If these strategies fail, minimization of the effects of HLA antibodies or platelet antigens through HLA typing, platelet crossmatching, or both is indicated.[50] Selecting platelets matched at the HLA-A and HLA-B loci may improve responsiveness in about half of patients with positive HLA antibody screens. Unless contraindicated because of transplant considerations, an empirical trial of donations from family members may also be helpful.

In one study undertaken to determine the best method of treating refractory cases, platelet selection by crossmatching was compared with selection by HLA criteria. Selection by crossmatching was equivalent to HLA selection and yielded better results.[51] Another study found that crossmatched platelets provided equivalent platelet increments that were independent of the grade of HLA match.[52] Although these results are promising, the effectiveness of selection either by HLA and crossmatching or by crossmatching alone is often limited by nonimmune host factors. Additionally, these techniques are not yet routinely available.

Modifying the effects of alloimmunization is difficult. IVIg can improve platelet increments but not platelet survival. An analysis of IVIg therapy found that about 50% of alloimmunized patients appeared to benefit from such therapy.[50] Plasma exchange is of limited value because it is difficult to remove IgG antibodies. In some patients, the HLA antibodies responsible for refractoriness may regress over time, so it is important to periodically retest for them. If the HLA antibody screen becomes negative, a trial of non–HLA-matched platelets is warranted.

All in all, the best strategy is prevention, which can be achieved by avoiding unnecessary transfusions and using only leukocyte-depleted products. A randomized, prospective trial of how best to prevent alloimmunization of newly diagnosed patients with acute myeloid leukemia showed equivalent rates of alloimmunization and platelet refractoriness for filtered platelet concentrates, filtered SDPs, and ultraviolet B–irradiated platelets.[53] However, leukocyte reduction did not prevent secondary immune responses in patients already sensitized through either pregnancy or transfusion.[54]

Transfusion of Fresh Frozen Plasma, Plasma Derivatives, and Recombinant Products

FRESH FROZEN PLASMA

Despite a paucity of indications for FFP use, roughly two million units are transfused annually[55] [*see Table 3*]. FFP is most appropriate for replacing the multiple coagulation deficiencies that result from massive transfusion, liver disease, warfarin toxicity, or acute or chronic DIC. In addition, it can be used to treat thrombotic microangiopathies and specific factor deficiencies when factor concentrates are not available. After one blood volume exchange using only red cells, plasma components are diluted to about 40% of their original concentration; after two blood volume exchanges, plasma components are diluted to 15%. Prothrombin time (PT) and partial thromboplastin time (PTT) become prolonged when coagulation components are lower than 30%, but abnormal bleeding from dilution usually does not occur until these values are less than 17% of normal. Microvascular bleeding associated with a PT and PTT greater than 1.5 times normal is an indication for FFP.[56] Whether FFP replacement is needed when PT and PTT are over 1.5 times normal but not associated with bleeding is less clear-cut; paracentesis and thoracentesis did not cause increased bleeding in patients with PT and PTT that were up to twice normal values.[57]

The FFP dose depends on whether or not a consumptive process is being treated in addition to hemodilution. For hemodilution, 15 ml/kg will usually be sufficient. However, if consumption is occurring, the dose is best guided by the effect of treatment on PT and PTT. If fibrinogen is lower than 80 mg/dl, cryoprecipitate may be required to rapidly increase fibrinogen. However, four units of FFP can be used in most cases to provide the same amount of fibrinogen as one pool of cryoprecipitate. Urgent reversal of the effects of warfarin can usually be accomplished with about 5 to 10 ml/kg of FFP.

Factor XI concentrates, which still have some thrombogenic potential, are available but not yet licensed in the United States.[58] Therefore, FFP is the treatment for factor XI deficiency. FFP is not used to replace antithrombin III, because a purified concentrate is available.[59]

Thrombotic microangiopathies [*see 5:XIII Hemorrhagic Disorders*] are treated with either FFP transfusions or, more often, plasma exchange with either FFP or cryopoor plasma.[60] Studies suggest that cryopoor plasma may be an alternative to FFP in the

treatment of TTP.[61] The dose of either product is usually equal to a plasma volume exchange of 1.0 to 1.5, which is carried out daily until clinical improvement occurs.

FACTOR VIIA

Recombinant activated factor VII was approved in 1999 for the treatment of bleeding episodes in patients with hemophilia A or B who have antibodies (inhibitors) to factor VIII or IX, respectively. Factor VIIa is also the treatment of choice for the rare patient with factor VII deficiency, whether acquired—as, for example, a consequence of liver disease—or inherited. It is not approved for this purpose, however. In addition, factor VIIa is useful in activation of the coagulation tissue factor pathway. For patients with inhibitors, factor VIIa is given at a dosage of 90 μg/kg as a slow I.V. push over 2 to 5 minutes; the dosage is repeated every 2 hours, as needed. For factor VII deficiency, the dosage is 20 to 30 μg/kg given as a slow I.V. push over 10 minutes; given in this manner, factor VIIa treatment will reduce the PT to normal within 20 minutes after administration. Depending on the clinical setting, the PT will become prolonged again 3 to 4 hours after treatment.

Off-label use of this product to treat uncontrolled hemorrhage in patients who do not have a preexisting bleeding disorder and who are unresponsive to FFP is becoming more common.[62] However, it is important not to use factor VIIa in patients with DIC, because VIIa may exacerbate the DIC. The high cost of this product and its potential for contributing to DIC should limit its use to carefully selected patients for whom other alternatives are not available.

FACTOR VIII CONCENTRATES

The introduction of plasma-derived factor VIII concentrates in the 1960s brought a significant improvement in the treatment of hemophilia A. Unfortunately, these concentrates were derived from large donor pools, and contamination of the factor with HBV, HVC, and, especially, HIV resulted in the widespread transmission of these infections in the hemophilia community. Since 1980, new methods of heat sterilization, solvent/detergent treatment, and immunoaffinity purification have yielded an array of factor concentrates that are highly purified and unable to transmit these infections. The efficacy of these viral-inactivation methods has been validated by using reverse transcription and PCR studies to measure HCV RNA in factor VIII concentrates; HCV RNA was present in 100% of products before treatment but was undetectable after treatment. Besides reducing the risk of infection, use of high-purity factor VIII concentrates may be associated with better preservation of patients' cell-mediated immunity. The 1980s also saw the advent of recombinant factor VIII concentrates.

The factor VIII preparation Humate-P is also rich in von Willebrand factor and is approved for the treatment of von Willebrand disease. This product has the major advantage of being free of the risks of infection associated with cryoprecipitate. If Humate-P is not available, the factor VIII preparations Alphanate or Koate-DVI may be used, but they are not approved for this purpose and their efficacy is uncertain.

The advances in safety and purity of factor VIII concentrates, especially in the case of the recombinant products, have increased the cost per unit fivefold to 10-fold. Recombinant products are used primarily for newly diagnosed patients with hemophilia who have not been exposed to plasma products. Work is just beginning on modifying these recombinant products to make them more effective by reducing immunogenicity and prolonging circulation time.[63]

The possibility that a nonhuman source of factor VIII would be useful in the treatment of patients with acquired factor VIII inhibitors led to the development of a highly purified porcine factor VIII concentrate. This was shown to be effective for patients whose anti–factor VIII antibody does not cross-react with the porcine product.[64] About one third of patients develop antibodies to the porcine product, which limits its usefulness for repeat treatments.

FACTOR IX CONCENTRATES

Factor IX complex concentrates contain about equal amounts of the vitamin K–dependent factors II, VII, IX, and X. These preparations are available in several degrees of purity, but all have the disadvantage of being thrombogenic when used for extended periods or in patients with liver disease. Highly purified factor IX, prepared by immunoaffinity chromatography, is free of this complication and is the product of choice in treating factor IX deficiency.[65] Activated prothrombin complex concentrates (Autoplex-T and FEIBA) have been used to bypass the need for factor VIII in selected patients with hemophilia A and acquired inhibitors. This provides an alternative for patients who do not respond to porcine factor VIII [*see 5:XIII Hemorrhagic Disorders*].

Transfusion of Granulocytes

Studies have shown granulocyte transfusion to be effective in the treatment of neutropenic patients. Transfusion of granulocytes in doses in the range of 8.3×10^{10} can be obtained by apheresis of donors who have been pretreated with granulocyte colony-stimulating factor (G-CSF) and a single dose of dexamethasone. Granulocyte transfusions at these dose levels have been shown to produce measurable, sustained increments in neutrophils, even into the normal range. The indications and clinical benefits of granulocyte transfusion at these higher doses are still being determined. Randomized trials are required to fully define the clinical efficacy of granulocyte transfusions. After collection, granulocytes must be stored at room temperature and irradiated to prevent transfusion-associated graft versus host disease. Crossmatching should be done to ensure compatibility.[66]

Transfusion of Immune Globulin

Many human immune globulin preparations are available. Immune serum globulin, administered intramuscularly, is used to treat chronic immunodeficiency disease and for prevention or alleviation of measles. Hepatitis A can now be prevented by vaccination [*see 4:VII Acute Viral Hepatitis*]. Alternatively, a traveler who will spend less than 3 months in an endemic area can receive 0.02 ml/kg of immune serum globulin. Hepatitis B immune globulin is used for postexposure prophylaxis against HBV infection [*see CE:V Adult Preventive Health Care*]. It is prepared from plasma with high titers of antibody to hepatitis B surface antigen. Rh_0(D) immune globulin is used to prevent the development of anti-Rh_0 (anti-D) antibodies in Rh-negative women who have just given birth, undergone amniocentesis, or aborted, if the biologic father is thought to be Rh positive.

Intravenous administration of human immune globulin promptly elevates circulating IgG levels and is preferable to intramuscular administration. Several preparations of IVIg are

available to treat chronic immunodeficiency disease[67] [*see 6:VIII Deficiencies in Immunoglobulins and Cell-Mediated Immunity*]. The intravenous dosage for such deficiency syndromes is 0.2 g/kg/mo but can be raised to 0.3 g/kg/mo or the agent can be given more often if needed.

The most common side effects of IVIg therapy—headache, nausea, and fever—usually respond to symptomatic treatment and reduction of the infusion rate. Rarer and potentially more severe side effects are anaphylactic reactions, hemolysis from anti-A and anti-B antibodies, and acute renal failure. Renal failure has been attributed to osmotic nephrosis caused by the high sucrose concentration in many IgG preparations.[68,69] In one study, aseptic meningitis was the most common of the serious side effects, with a frequency of 11% (95% confidence interval, 4% to 23%); patients with a history of migraine had a significantly higher incidence of aseptic meningitis.[70]Aseptic meningitis usually occurs within 24 hours after administration and does not respond to a reduction of the infusion rate. Patients may be required to stay in the hospital for symptomatic treatment; if further treatment is needed, changing the lot or preparation of IVIg may alleviate this side effect. Current manufacturing practices eliminate HCV from IVIg preparations.

Transfusion of Stem Cells

Stem cell transplantation, initially pioneered for use in leukemia, is used to treat a number of life-threatening, malignant, hereditary, and immunologic disorders [*see 12:XV Chronic Lymphoid Leukemias and Plasma Cell Disorders*].

Complications of Transfusions

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are classified as immediate or delayed, depending on their pathophysiology. Immediate hemolytic reactions are the result of a preexisting antibody in the recipient that was not detected during pretransfusion testing. Delayed hemolytic reactions are the result of an anamnestic response to an antigen to which the recipient is already sensitized. The renewed antigenic stimulation in a person already primed by previous antigenic exposure results in recrudescence of antibody to levels that can cause hemolysis. This is in contrast to an immune response during primary sensitization, which seldom causes hemolysis, because antibody levels develop at a much slower rate.

Patients with sickle cell disease are more likely than others to become alloimmunized and to have delayed hemolytic transfusion reactions, which often occur in association with recrudescence of an occlusive pain crisis. These reactions are occasionally associated with severe hemolysis involving autologous, as well as allogeneic, red cells. The cause of these episodes is unknown but has been attributed to so-called bystander hemolysis associated with abnormal function of CD59 (MIRL, membrane inhibitor of reactive lysis), transfusion-associated marrow suppression, or both.[71]

Diagnosis of Hemolytic Reactions

The pathophysiologic differences between immediate and delayed hemolytic transfusion reactions account for some of their differences in clinical findings. Fever is a common sign associated with both immediate and delayed hemolytic transfusion reactions.

Clinical evidence of hemolysis is likely to be more severe in immediate hemolytic reactions and may include back pain, pain along the vein into which the blood is being transfused, changes in vital signs, evidence of acute renal failure, and signs of developing DIC. These findings are probably caused by immune complexes activating the complement and kinin systems, by the direct effects of red cell stroma on kidney function, and possibly by the release of inflammatory cytokines such as interleukin-1β (IL-1β), IL-6, and tumor necrosis factor (TNF).[72]

In delayed hemolytic reactions, hemolysis with hemoglobinemia and hematuria (sometimes associated with renal failure) also occurs, but it is less common and generally less severe. In many delayed hemolytic transfusion reactions, the only clinical findings may be a newly positive Coombs test result, the appearance of a new antibody against red cell antigens that are not present on the recipient's red cells, or both. When hemolysis is absent, these reactions are sometimes called delayed serologic transfusion reactions. At the Mayo Clinic, two surveys sought to identify the relative incidence of both kinds of delayed transfusion reactions. The most recent survey, covering the period from 1993 to 1998, revealed a relative increase in delayed serologic transfusion reactions and an associated decrease in delayed hemolytic reactions, with overall increases in the incidence of these reactions. The earlier survey, which covered the period from 1980 to 1992, revealed an association between delayed transfusion reactions and the presence of antibodies to Jk^a and Fy^a or antibodies with multiple specificity; this association was not found in the later survey. These changes probably result from improved systems for identifying clinically significant nonhemolytic antibodies.[73]

In some cases, antiglobulin testing may yield positive results after all the transfused cells have been cleared, often with only complement being detected on the red cells. This finding has been attributed to autoimmune hemolysis after the delayed transfusion reaction.

Treatment of Hemolytic Reactions

As soon as a hemolytic transfusion reaction is suspected, the transfusion should be immediately discontinued. The diagnosis can be confirmed or excluded by sending the remaining blood product, together with a freshly drawn posttransfusion specimen, to the blood bank. The blood bank rechecks all records, confirms the patient's type and antibody screen, checks for evidence of hemoglobin in the plasma, and rechecks the crossmatch and antiglobulin test results. These tests will confirm or disprove the diagnosis and identify the antibody causing the immediate hemolytic reaction, when present. Until these studies have been completed, any further blood products can be given only with the approval of the blood bank's medical director.

The side effects of an acute hemolytic transfusion reaction can be managed by supporting renal blood flow with furosemide and supporting tubular urine flow with mannitol; treating shock, if required, with pressors; and giving platelets and FFP as needed to control coagulopathy if DIC develops. Intravenous steroids may be useful. Until the antibody causing the immune hemolysis is identified, only type O red cells and AB plasma should be used.

Managing delayed transfusion reactions is simpler because of the slower tempo at which these reactions develop. The diagnosis requires identifying a new antibody against red cell antigens and searching for clinical evidence of hemolysis. Treatment requires replacement with the appropriate antigen-negative blood

products. Acute renal failure and DIC are unlikely but would be managed as described for immediate hemolytic reactions. The severe, atypical delayed transfusion reactions sometimes found in patients with sickle cell disease may require steroids and transfusion support.

Prevention of Hemolytic Reactions

Prevention of immediate and delayed hemolytic transfusion reactions depends on recognizing their respective proximate causes. Immediate hemolytic reactions are usually caused by technical errors made during the procurement or processing of blood specimens, during pretransfusion testing, or during product infusion. In a review of transfusion-related deaths reported to the Food and Drug Administration between 1990 and 1998, approximately 50% were caused by clerical errors that led to transfusion of ABO-incompatible blood, a rate virtually unchanged since reporting began in 1976.[74] Prevention of immediate transfusion reactions is best accomplished by following protocols for obtaining specimens from patients in adequate time before transfusion and checking to see that blood products are appropriate for the intended recipient.

Delayed transfusion reactions are the result of an anamnestic response of antibodies from a previous transfusion (or pregnancy) that are not present in detectable levels at the time the specimen is crossmatched. A careful transfusion history can best prevent delayed hemolytic reactions. Many patients will know whether there were difficulties involving blood obtained for transfusion. If a patient has a history of difficulty with crossmatches, the blood bank can obtain the details from the institution responsible for the previous transfusion. A proper transfusion history can uncover patients likely to have antibodies that the blood bank would not detect. For example, antibodies to Jk^a and Fy^a are characteristically hard to identify because they are quick to rise on stimulation and fall equally rapidly, making later detection difficult.

FEBRILE TRANSFUSION REACTIONS

Nonhemolytic febrile transfusion reactions occur in 1% to 2% of all transfusions and are more likely to occur after platelet transfusions. Until recently, febrile transfusion reactions were attributed to recipient antibody reactions against HLA antigens on donor leukocytes in the transfused product. It is now believed that cytokines produced during storage may also contribute to these reactions.[75] This conclusion is based on observations that platelet products associated with transfusion reactions have higher levels of inflammatory cytokines such as IL-1β, TNF, IL-6, and IL-8 in the supernatant than are found in platelets that do not cause febrile transfusion reactions.[75]

Diagnosis of Febrile Reactions

Febrile reactions are characterized by the development of fever during transfusion or within 5 hours after transfusion. These reactions may be limited to an increase in body temperature of 1° to 2° F but are often associated with chills and rigors.

The differential diagnosis for a patient undergoing a nonhemolytic febrile transfusion reaction should always include unrecognized sepsis. When febrile reaction is suspected, immediate management consists of discontinuing the transfusion, obtaining appropriate cultures, and returning the product to the blood bank. The blood bank obtains cultures from the product and verifies that no errors have occurred in its preparation. The probability that a febrile transfusion reaction has occurred is influenced by the type of product, the number of white cells contained therein, and the transfusion history of the recipient. Febrile reactions to products that have few or no white cells, such as deglycerolized red cells or FFP, are unusual. Unmodified whole blood and red cells contain between 1.3×10^9 and 3×10^9 white cells and are much more likely to cause febrile reactions. In the case of platelets, reactions can be from cytokines made during in vitro storage or from bacterial contamination.

Treatment of Febrile Transfusion Reactions

Febrile transfusion reactions are usually self-limited and respond to symptomatic management with antipyretics. However, symptoms may be of sufficient magnitude to require the use of 50 to 75 mg of meperidine by intravenous bolus. To prevent further occurrences, leukocyte-depleted products are indicated for patients who have had two or more febrile transfusion reactions.

Prevention of Febrile Reactions

Newer designs of filters for leukocyte reduction should decrease the white cell content to below the threshold for febrile transfusion reactions. Because inflammatory cytokines may be involved in febrile transfusion reactions, methods are being implemented to accomplish leukocyte reduction either during or after collection but before storage. In a study comparing products that underwent leukocyte reduction either before storage or at the bedside, significantly fewer febrile reactions occurred in patients receiving prestorage leukocyte-depleted products; there was no difference in the number of allergic reactions.[76]

Prestorage leukocyte reduction is particularly important for platelets because platelets are stored at room temperature and accumulate significantly more cytokines than do red cells, which are refrigerated. Febrile transfusion reactions are also more likely with older products. In one study, platelets that were used after they were in storage for 3 days or less were found to cause significantly fewer febrile transfusion reactions than platelets that were used after longer storage periods.[77] Unfortunately, testing for infectious diseases often takes 2 to 3 days, during which time the product cannot be used. It is therefore impractical to rely on younger products to reduce the risk of febrile transfusion reactions. Other benefits of leukocyte reduction are prevention of HLA alloimmunization; prevention of transmission of leukocyte-bound viruses such as cytomegalovirus (CMV), Epstein-Barr virus, HTLV-I, and HTLV-II; and, possibly, reduction of immune modulation.[78]

Whether these advantages justify leukocyte reduction for all blood products remains an unsettled issue because it is unclear whether the benefits justify the associated increased costs. Managing patients who continue to have febrile reactions after receiving leukocyte-depleted products is a clinical problem for which there are no clear solutions. In addition to premedication with steroids, use of HLA-matched products for patients demonstrated to have HLA antibodies may be helpful. Occasionally, use of washed products is beneficial.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) usually presents as bilateral pulmonary infiltrates within 4 hours after transfusion.[79] The clinical and radiographic picture is that of normal-pressure acute respiratory distress syndrome (ARDS); therefore, the differential diagnosis is sufficiently broad to make the possible causal role of transfusion often go unnoticed. Current evidence suggests that TRALI is associated with the interaction of

antibodies (HLA class 1 or class 2 antibodies, antimonocyte antibodies, or antigranulocyte antibodies), with the corresponding antigens on monocytes or granulocytes. A recent study found such associations in 14 of 16 TRALI patients.[80,81] These interactions cause endothelial injury, alveolar exudation, and the associated clinical findings of ARDS.

A second form of TRALI that involves two clinical events has been proposed.[82-84] In this two-event model, which is based on clinical findings and rat lung studies, the first step is the priming of neutrophils by mediators that arise in certain clinical settings (e.g., recent surgery, massive transfusion, cytokine therapy, or infection).[82] The primed neutrophils adhere to pulmonary endothelium and are activated by a second event, such as exposure to biologically active lipids from blood products.

Diagnosing TRALI depends on excluding cardiac and other causes of ARDS. Demonstration of antileukocyte antibodies helps confirm the diagnosis, but their absence does not exclude TRALI in the appropriate clinical setting. Early diagnosis is important because most patients will improve within 24 hours after conservative treatment is initiated. Unfortunately, a minority of patients develop TRALI associated with severe pulmonary edema and fluid filling the trachea, for which no effective therapy exists.

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions are more common than febrile nonhemolytic transfusion reactions, occurring in 3% to 4% of transfusions. Allergic transfusion reactions usually present as pruritus and urticaria. A small percentage of patients have anaphylactoid symptoms, including wheezing, bronchospasm, and, occasionally, true anaphylaxis.[85] These reactions had been attributed to an immune response to plasma proteins. However, a 1999 study suggested that they may instead be provoked by increased levels of RANTES (regulated on activation, normal T cell expressed and secreted), an inflammatory chemokine that is stored in platelet alpha granules and accumulates during storage.[86] This is an intriguing hypothesis, because RANTES is known to affect eosinophil and basophil function.

In most cases, symptoms of allergic reactions are local and do not require discontinuance of the transfusion if they are controlled with antihistamines. There is, however, no means as yet to identify the rare patient who will progress to anaphylaxis.[85] It is known that IgA deficiency is associated with an increased likelihood of anaphylaxis, but many patients who are IgA deficient never have any difficulty.

For most patients with urticaria, which seldom progresses to anaphylaxis, management is symptomatic. However, patients known to be IgA deficient should receive cells that have been washed to remove plasma. When plasma products are required, they should be administered in a facility equipped to manage anaphylactic reactions. Using IgA-deficient plasma can minimize the risk, but such plasma is difficult to obtain and may require drawing from a rare donor pool, testing family members, or both.

ATYPICAL TRANSFUSION REACTIONS

Occasionally, patients have reactions that do not fit the categories already defined but clearly seem related to blood transfusion. These reactions have mainly consisted of severe hypotension after platelet infusions. No allergic features are present. The reactions are associated with blood-product infusions through a negatively charged leukocyte reduction filter, and they often occur in patients who are receiving angiotensin-converting enzyme (ACE) inhibitors. A recent study suggests that such reactions may be caused by excessive accumulation of des-Arg9-bradykinin. This metabolite of bradykinin is known to be vasoactive and to be metabolized by ACE.[87] Clinical observations suggest that atypical hypotensive reactions are more likely to occur in patients receiving ACE inhibitors during plasma exchange, hemodialysis, low-density lipoprotein apheresis, IgG-affinity column apheresis, and desensitization immunotherapy. These findings have led to the suggestion that ACE inhibitors should be withheld for 24 hours before any of these procedures are initiated. Such reactions are sufficiently rare that it may be adequate to limit this restriction to patients who have already experienced one of these reactions.[88]

TRANSFUSION-ASSOCIATED GRAFT VERSUS HOST DISEASE

The diagnosis of transfusion-associated graft versus host disease (TA-GVHD) should be considered in any patient who presents after transfusion with fever, skin rash, and diarrhea and has pancytopenia and abnormal results on liver function tests.[89] Signs and symptoms in neonates are similar to those in adults, but fever and rash develop later: in adults, fever occurs after a median of 10 days after transfusion; in neonates, fever occurs after 28 days, with rash appearing 1 to 2 days later.[90] TA-GVHD is a much-feared consequence of transfusion therapy because mortality approaches 100%. It results from transfusing immunocompetent lymphocytes into a recipient who is unable to reject the allogeneic cells. Reaction of the transfused lymphocytes with host antigens leads to the multiple manifestations of TA-GVHD.

TA-GVHD is best prevented by identifying potentially susceptible recipients. Patients who are at significant risk for TA-GVHD include premature infants receiving large doses of allogeneic lymphocytes, patients with congenital defects in cellular immunity or immunity resulting from illness or chemotherapy, and patients who are unable to reject infused cells because of shared antigens with the allogeneic lymphocytes. Patients undergoing autologous or allogeneic bone marrow transplantation are particularly at risk. Many case reports document the association of Hodgkin disease with TA-GVHD, which occurs presumably as a result of acquired defects in T cell immunity. The intensive chemotherapy that is used to treat leukemia, high-grade lymphomas, and solid tumors may also set the stage for TA-GVHD. However, no cases have been identified in AIDS patients. One hypothesis explaining this surprising finding is that the HIV-mediated injury to $CD4^+$ T cells blocks the development of TA-GVHD.[91]

Patients whose risk for TA-GVHD is a result of receiving transfusions from a homozygous donor of a shared haplotype are the hardest to identify a priori. Donor lymphocytes are not rejected by the recipient but do respond to the nonshared recipient haplotype. This mechanism probably accounts for the majority of cases of TA-GVHD. The chances of receiving haplotype-homozygous blood from an unrelated donor vary with different populations. In Japan, the risk for adults may be as high as 1 in 874; it is estimated to be 1 in 102 in neonates because of the use of fresh whole blood from family members.[92] In France, the risk is estimated to be 1 in 16,835. In the United States, the risk for the white population is thought to be about 1 in 7,147. Risk increases if first-degree relatives are donors.

Once patients at risk are identified [*see Table 5*], pretreatment of all cellular transfused products with gamma radiation is indicated. On the basis of in vitro studies, the current recommended

Table 5 Patients for Whom Irradiated Blood Products Are Recommended

- Fetuses and neonates
- Patients with congenital immunodeficiency
- Allogeneic and autologous bone marrow transplantation patients
- Recipients of some solid-organ transplants*
- Patients with hematologic malignancies†
- Patients with nonhematologic malignancies, especially if undergoing intensive chemotherapy‡
- Recipients who may share haplotypes with donor§

*No consensus, but most agree that heart, liver, and lung recipients should receive irradiated products, whereas recipients of renal allografts do not require irradiated blood.
†Patients with low-grade lymphomas and leukemias in remission may not require irradiated products. Applying restriction to all lymphoma and leukemia patients avoids mistakes.
‡Except for immunosuppression from intensive chemotherapy, there is no consensus.
§Donors in this group include directed donors and first- and second-degree relatives.

dose is 2,500 cGy, which does not affect red cell function or platelet survival if administered immediately before transfusion.[93] However, irradiated red cells stored for 42 days show significant increases in plasma potassium and hemoglobin and a small but significant decrease in cell survival. Consequently, recommended storage after irradiation is only 28 days; most institutions prefer to irradiate immediately before product release when possible. Platelets have normal storage survival 5 days after irradiation and can be irradiated at regional centers before distribution. Leukocyte reduction may provide some protection against TA-GVHD, which is related to the dose of lymphocytes. However, filtration alone is not preventive and must never be used as a substitute for gamma irradiation. Because of the risk associated with a one-way HLA match, blood-bank standards require that family members' blood and blood of directed donors be irradiated.

Treatment of TA-GVHD remains ineffective. Prevention by providing irradiated blood products to all recipients may become the most practical solution to this complication.[94]

BACTERIAL AND PROTOZOAN INFECTIONS

Platelets are associated with the majority of cases of transfusion-related sepsis because the platelets are stored at room temperature.[95] Controlling this problem requires improved disinfection of skin, better detection of subclinical infection, and development of methods for storage at lower temperatures or postcollection sterilization. If sepsis is suspected in patients who have been given red cells, the possibility of *Yersinia enterocolitica* infection should be considered.[96] This organism can grow in the cold, iron-rich environment provided by stored red cells. When such infections occur, the blood is almost always at least 2 weeks old; this period corresponds to the time needed for the usually small initial inoculum to reach clinically significant amounts. Malaria infections have been almost completely eliminated by predonation screening. *Trypanosoma cruzi* can cause a chronic parasitic infection; the incidence of blood-borne transmission has increased to the point that pretransfusion testing for it may soon be needed. Spirochetes cannot be transmitted by products that have been stored longer than 80 hours and are no longer considered a clinically significant source of blood-borne infection.

CYTOMEGALOVIRUS INFECTION

CMV is a common blood-borne infection of no clinical consequence to healthy, immunocompetent recipients, but it can be a severe problem for patients with either acquired or congenital immunodeficiency [*see Table 6*]. Judged on the basis of screening for antibody to CMV, more than 40% of healthy donors may have the potential to transmit CMV.

There are two approaches to preventing CMV transmission. The first is to use CMV antibody–negative products. The second, more practical approach is to use leukocyte-reduced products, because CMV is transmitted only by leukocytes. On the basis of a prospective, randomized study of more than 500 transplant patients, products that have undergone leukocyte reduction to the current standard of fewer than 0.5×10^6 leukocytes per milliliter are considered to be as effective as seronegative products in preventing CMV infection.[97] It is unclear which product provides the best protection against transfusion-associated CMV infection.[98] Direct comparisons between seroconversion rates after transfusion of prestorage leukocyte-depleted products and seroconversion rates after transfusion of CMV-negative products are required to settle this issue.

IMMUNE MODULATION AS A RESULT OF TRANSFUSION

Evidence that transfusions result in modulation of host immunity has come from studies of transplantation, cancer recurrence, and posttransfusion infection rates. The effect was first observed in cadaver-kidney transplantation; patient survival was shown to increase with increased transfusions. Although this benefit became less important with the introduction of cyclosporine, Opelz and colleagues[99] found increased cadaver-graft survival in transfused recipients whose immunosuppression regimen included cyclosporine.

The hypothesis that immune modulation is related to infused white cells has been supported by studies in animal models and by clinical observations of tumor recurrence and posttransfusion infection rates. Bordin and colleagues[100] have shown in a rabbit model that the number of pulmonary metastases is increased by allogeneic blood transfusions but not by blood from syngeneic littermates. This effect of allogeneic blood is abrogated by prestorage leukocyte reduction but not by poststorage reduction. Randomized clinical studies of posttransfusion infection and cancer recurrence have produced conflicting results.[101] The conflicting data concerning the magnitude and clinical relevance of transfusion-induced immunomodulation need to be resolved. If leukocyte reduction is shown to reduce posttransfusion infections and cancer recurrence, the argument for universal leukocyte reduction of cellular blood products, which is already strong, would become irrefutable. Until this matter is settled, the possible immunomodulatory effect of blood transfusion is another reason to avoid allogeneic blood transfusion whenever possible.

Table 6 Patients for Whom Cytomegalovirus-Negative Blood Products Are Recommended

- Neonates, especially if weight is less than 1,200 g
- Pregnant women, as a means of preventing primary intrauterine infections
- Recipients of solid-organ transplants, especially when the recipient and the organ donor are both CMV negative
- Patients with severe combined immunodeficiency

Apheresis

Apheresis therapy is the converse of transfusion therapy; it entails treating disease by removing plasma, specific antibodies, or cells. It has been tried in a broad spectrum of diseases [*see Table 7*]. Therapeutic apheresis has real risks and may provide little benefit. It is usually an acute intervention that is only transiently effective, unless the underlying problem is being treated effectively. Consequently, it is important to identify criteria for both starting and stopping such treatment. Indications for apheresis that are approved by the American Association of Blood Banks and the American Society for Apheresis have been summarized.[102]

INDICATIONS FOR APHERESIS THERAPY

Neurologic Diseases

Neurologic diseases whose pathogenesis may be antibody mediated are now the most common indications for plasma exchange. Myasthenia gravis occurs when antibodies to acetylcholine receptors cause abnormal neuromuscular transmission. Reductions in these antibody titers from plasma exchange are associated with clinical improvement. A randomized trial compared the use of plasma exchange with the use of IVIg therapy in the treatment of myasthenia gravis; the investigators noted a trend toward better results with plasma exchange, but this trend was not statistically significant.[103] Similar findings were reported from much larger studies of Guillain-Barré syndrome, which is thought to be caused by antibodies to myelin. Two large series comparing plasma exchange with current best therapy showed faster improvement with the addition of plasma exchange. Randomized comparisons of plasma exchange and IVIg in the treatment of Guillain-Barré syndrome have shown these approaches to be equivalent; no additional benefit from using both therapies was shown.[104,105]

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an autoimmune disorder that causes proximal and distal weakness; it has a progressive or relapsing course and is sometimes associated with monoclonal gammopathies. CIDP responds to plasma exchange, except in patients with distal weakness and associated IgM monoclonal gammopathies[106,107]; such patients respond poorly to all modalities of therapy.[108] IVIg therapy and plasma exchange have been shown to be comparably effective in CIDP.[109]

The use of plasma exchange in multiple sclerosis remains controversial. Meta-analysis of six controlled trials of plasma exchange provided some evidence of benefit, but the authors concluded that the subgroups of patients likely to benefit needed further definition.[110] A randomized study of plasma exchange in patients with acute inflammatory demyelinating central nervous system disease showed a significant benefit from the therapy. However, patients continued to have problems with relapse.[111]

Hematologic Diseases

Leukapheresis The hematologic diseases that require apheresis are those associated with obstruction of vascular flow by cells or the blockage of flow by proteins as a result of increased viscosity or cryoprecipitation; antibody-mediated diseases that lead to destruction of the formed elements of the blood; and thrombotic microangiopathies.

Leukostasis is a function of cell number and cell type. Myeloblasts are more likely to cause stasis than are an equivalent number of lymphocytes in a patient with chronic lymphocytic leukemia. Unless pulmonary or cerebral leukostasis is severe enough to cause progression in clinical findings, hydroxyurea is the treatment of choice. It will usually decrease the cell count sufficiently within 24 hours. However, when clinical findings demand improvement within 4 to 8 hours, leukapheresis in addition to hydroxyurea is usually needed.

Red cell exchange Red cell exchange has been used to treat acute chest crises, stroke, and priapism, and it is sometimes used to prepare patients with sickle cell disease for surgery. In these patients, the indications for red cell exchange, versus simple transfusion, are poorly defined. For example, in an analysis of causes and outcomes in acute chest syndrome, simple transfusions were used instead of red cell exchange in about two thirds of patients.[112] Many believe that red cell exchanges should be reserved for patients with progressive pulmonary disease or for those who fail to respond to transfusions. Using Rh and Kell antigen–compatible red cells reduces the incidence of alloimmunization from 7% to 1%[113] and should be standard practice. Red cell exchange leads to less iron accumulation than transfusion therapy, which is an advantage in the treatment of patients with sickle cell disease who require long-term therapy, such as those who have a history of stroke.[114]

Plasma exchange The concentration of paraprotein influences plasma protein viscosity, as does its heavy-chain class. IgM is the largest plasma protein and is nearly 100% intravascular; it is most likely to cause hyperviscosity. IgA and IgG3 are more likely to aggregate and are associated with hyperviscosity more often than other IgG subclasses. As in leukostasis, the choice between plasma exchange and chemotherapy is guided mainly by the clinical symptoms and their rate of progression.

Table 7 Indications for Plasma Exchange

Indications Based on Randomized Trials	*Indications Based on Consensus and on Case Reports*	*Possible Indications*
	Myasthenia gravis	
	Hyperviscosity	Pemphigus vulgaris
Guillain-Barré syndrome	Hemolytic-uremic syndrome	Goodpasture syndrome
Chronic inflammatory polyneuropathy	Persistent HELLP syndrome	Autoimmune hemolytic anemia
Peripheral neuropathy associated with MGUS	Posttransfusion purpura	Antibody to coagulation factors
Thrombotic thrombocytopenic purpura	Cryoglobulinemia	Idiopathic thrombocytopenic purpura
	Vasculitis	Cold agglutinin disease
	Familial hypercholesterolemia	

HELLP—hemolysis, elevated liver enzymes, and low platelet count MGUS—monoclonal gammopathy of unknown significance

Plasma exchange can lower viscosity within hours, whereas most chemotherapy requires days. Acute-onset renal failure caused by myeloma proteins can be improved by lowering the plasma concentration of paraprotein, but more data are needed for this to be considered an established indication.[115]

Despite the role that antibody and immune complexes play in hematologic cytopenia, there are no well-controlled studies supporting the use of plasma exchange. The available case reports usually describe the role of plasma exchange as being that of backup after failure of more established therapies. FFP or cryopoor plasma is used in replacement therapy for thrombotic microangiopathies. Case reports suggest that patients with severe preeclampsia, HELLP syndrome, or both may benefit from plasma exchange with FFP replacement if they fail to improve after delivery.[116]

Antibody-Mediated Renal, Muscular, and Cutaneous Diseases

Despite promising reports from case studies, controlled trials of patients with pemphigus vulgaris,[117] polymyositis, dermatomyositis,[118] and Goodpasture syndrome[119] have raised doubts concerning the value of plasma exchange. However, plasma exchange does appear to be valuable in stopping pulmonary hemorrhage in Goodpasture syndrome.

Immune Complex Diseases

The only indication for plasma exchange in rheumatoid arthritis and systemic lupus erythematosus is severe vasculitis that does not respond to other therapies.

Metabolic Diseases

Plasma exchange and selective removal of low-density lipoproteins (LDLs) have both been used to treat familial hypercholesterolemia [*see 9:II Diagnosis and Treatment of Dyslipidemia*]. Selective removal of LDLs can be accomplished by immunoadsorption, heparin precipitation, or dextran sulfate cellulose absorption, whereas plasma exchange causes significant reduction of both LDLs and HDLs.

COMPLICATIONS OF PLASMA EXCHANGE

The complications associated with plasma exchange are best divided into problems related to apheresis machines and problems related to venous access, type of replacement fluids, and anticoagulant. Apheresis machines accomplish cell and plasma separation by either centrifugation or membrane filtration. All systems monitor air and access pressure, allowing air emboli to be eliminated and access problems to be promptly recognized. Excess transmembrane pressure may cause red cell hemolysis, which leads to increased hemoglobin in the separated plasma. The majority of complications associated with plasma exchange result from the replacement fluid and anticoagulant used. Plasma removed by exchange is commonly replaced with 5% albumin, which carries no risk of infection and does not increase the citrate return but does dilute coagulation factors, causing mild coagulopathy for 24 to 48 hours. On an every-other-day treatment schedule, coagulation abnormalities are usually not clinically significant, but they may become significant if the patient is on a daily treatment schedule. Using FFP prevents dilutional coagulopathy but increases risks of blood-borne infection and allergic reactions. Peripheral venous access is often inadequate to maintain the required flow rates of 45 to 80 ml/min, necessitating central venous access with a large, double-lumen catheter; life-threatening or fatal complications from central catheter placement have been reported.[120] Catheter malfunction should always be considered when a patient shows clinical evidence of hypovolemia, shock, or both while undergoing plasma exchange. The majority of complications, however, are side effects of the citrate anticoagulant. These can include paresthesias, abdominal cramps, and, in rare instances, cardiac arrhythmias or seizures. Citrate toxicity is usually managed easily by slowing the return rate and providing extra calcium, either orally or sometimes intravenously. Patients with renal failure who receive large amounts of citrate may develop a profound metabolic alkalosis.[121]

Future Prospects for Transfusion Therapy

The evolution of transfusion practice has been a steady progression from whole blood to fractionated products designed for specific therapies. The search for a practical replacement for red cells that would allow stable storage, provide adequate oxygen delivery, and be free of significant toxins has been long and filled with substantial obstacles. Hemoglobin-based substitutes are most promising, but they still have problems with purification, adequate oxygen unloading, and potential toxicity. Chemically modified bovine hemoglobin is currently in phase-3 clinical trials and is probably closest to licensure. In the case of coagulation components, recombinant products are beginning to provide highly specific treatment of clinical problems that are poorly managed by current therapy. Bioengineering holds the promise of improving the effectiveness of current recombinant products.[62] Recombinant factor VIIa provides specific therapy for deficiency states and an alternative approach for patients with high-titer factor VIII inhibitors. Recombinant antithrombin III provides specific replacement for patients with congenital deficiency. The off-label use of these products is increasing and brings with it the need for careful studies of cost-effectiveness, which are only beginning to emerge.

A major change in transfusion practice may evolve from the availability of cytokines that can modify endogenous production. Erythropoietin has changed the treatment of anemia associated with chronic renal disease; as a result, many dialysis patients no longer require transfusions. Erythropoietin can also facilitate patients' self-banking their blood for anticipated surgical needs. In some cases, erythropoietin use is accepted by Jehovah's Witness patients, thereby allowing such patients to undergo surgical procedures that would otherwise not be possible. The availability of myeloid growth factors has contributed substantially to the development of methods for collection, and it is possible that mobilizing leukocytes with growth factors can increase the effectiveness of granulocyte transfusions. Thrombopoietin may in time be used to enhance platelet apheresis collections. The immunomodulatory effects of blood transfusion are in the early stages of description. It may be that a better understanding of the mechanisms underlying immunomodulation will permit using these effects to therapeutic advantage, such as to induce tolerance to a transplanted organ or to downregulate antibody production.

Even in an era of accelerating change, certain aspects of transfusion medicine will remain constant. The blood donor remains a kingpin who cannot be replaced by recombinant methodology. Transfusion practice has improved in safety, but there will always be residual risks. Each transfusion will always require careful assessment of whether the risks to the recipient of the transfusion will exceed the risks of going without. Further decre-

ment of these risks will require new systemic approaches for improving the collection of specimens, selecting patients for transfusion of specific products, and continuing education of clinicians who make transfusion decisions.[122]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XI HEMATOPOIETIC CELL TRANSPLANTATION

Frederick R. Appelbaum, m.d.

Because hematopoietic stem cells can be collected from the peripheral blood, bone marrow, and umbilical cord blood, the term bone marrow transplantation is being replaced by the more inclusive term hematopoietic cell transplantation. With transplantation, an abnormal but nonmalignant lymphohematopoietic system can be replaced with a healthy one, making transplantation an effective therapy for a variety of nonmalignant diseases (e.g., severe combined immunodeficiency disease, Wiskott-Aldrich syndrome, aplastic anemia, thalassemia, sickle cell anemia, and Gaucher disease). In addition, hematopoietic cell transplantation is used to treat a variety of malignancies because it allows administration of higher and potentially more effective doses of chemotherapy and radiotherapy that would otherwise cause unacceptable myelosuppression. Allogeneic transplantation also confers its own antitumor effects beyond those of chemoradiotherapy. Worldwide, an estimated 48,000 patients underwent hematopoietic cell transplantation in 2002.[1]

The Hematopoietic Stem Cell

Three features of the lymphohematopoietic system make transplantation feasible: its regeneration capacity, the homing of stem cells to sites that promote survival and proliferation, and the ability of stem cells to survive, with little damage, the freezing and thawing process entailed in cryopreservation. In mice, a single hematopoietic stem cell can reconstitute a lethally irradiated recipient.[2] In humans, transplantation of considerably less than 10% of a donor's marrow regularly results in complete and sustained replacement of the recipient's entire lymphohematopoietic system, including red cells, platelets, granulocytes, T cells, and B cells, as well as pulmonary alveolar macrophages, Kupffer cells of the liver, osteoblasts, Langerhans cells of the skin, and microglial cells of the brain. Studies suggest that transplanted hematopoietic cells rarely differentiate into hepatic, epithelial, or mucosal cells.[3,4]

The mechanisms of homing are not entirely understood, but a remarkably high percentage of transplanted primitive hematopoietic cells are retained in the marrow shortly after intravenous injection. Cell adhesion molecules on marrow endothelial cells, termed selectins, which bind to carbohydrate-based ligands on early hematopoietic cells, may be responsible.

The human hematopoietic stem cell expresses distinctive surface antigens. One of these, the CD34 antigen, is expressed on only 1% to 5% of normal adult bone marrow cells, but when marrow is cultured in vitro, virtually all colonies derive from the CD34+ population. Successful transplantation in humans can be carried out using only positively selected CD34+ cells. Over 90% of CD34+ cells also express CD38, but the 10% that are CD34+ and CD38– are the population best able to support long-term hematopoiesis in vitro and are thus considered a more primitive population. The most primitive subset of these cells stain poorly with Rh123, a mitochondrial dye. These cells also lack known markers of B cell or T cell lineage and are therefore said to be lineage negative.

Types of Hematopoietic Stem Cell Transplantation

Hematopoietic cell transplantation can be categorized according to the relation between the donor and the recipient and according to the anatomic source of the stem cell. Hematopoietic stem cells for transplantation may derive from bone marrow, peripheral blood, or umbilical cord blood and may be harvested from a syngeneic, allogeneic, or autologous donor.

SYNGENEIC TRANSPLANTATION

Identical twins are the best possible donors of stem cells. When syngeneic donors are used, neither graft rejection nor graft versus host disease (GVHD) will develop in the recipient. Syngenicity is easily established by DNA typing, using one of two techniques—either restriction fragment length polymorphisms (RFLPs) or variable nucleotide tandem repeats. Only about one in 100 patients undergoing transplantation will have an identical twin.

ALLOGENEIC TRANSPLANTATION

Allogeneic transplantation, which involves a related or unrelated donor, is more complicated than syngeneic or autologous transplantation (see below) because of immunologic differences between donor and host. With allogeneic hematopoietic cell transplantation, in which the immune system of the patient is provided by the graft, the clinical concerns are not only with the prevention of graft rejection by host cells surviving the pretransplant preparative regimen but also with the prevention of donor cells from causing immune-mediated injury to the patient (i.e., GVHD).

Immunologic reactivity between donor and host is largely mediated by immunocompetent cells that react with human leukocyte antigens (HLAs), which are encoded by genes of the major histocompatibility complex. HLA molecules display both exogenous peptides (e.g., from an infecting virus) and endogenous peptides, presenting them to T cells, an important step in the initiation of an immune response. If two persons do not share the same HLA antigens, T cells taken from one person will react vigorously to the mismatched HLA molecules on the surface of the cells from the other. These are reactions against so-called major HLA determinants. Even when two persons who are not identical twins have identical HLA types, the endogenous peptides presented by the HLA antigens will differ, triggering a response against so-called minor HLA determinants.

The genes encoding HLA class I and class II antigens are tightly linked and tend to be inherited together as haplotypes with low recombination frequencies. For any given patient, there is a 25% probability that any one sibling has inherited the same paternal and maternal haplotype, making the siblings identical with regard to HLA genotype. Given that the average number of children per family in the United States is slightly more than two, the average chance that a patient has an HLA-matched sibling is approximately 35%. The formula for calculating the probability that a patient has an HLA-identical sibling is $1 – (0.75)^n$, where n equals the number of siblings.

Allogeneic transplantation has been performed using HLA-identical sibling donors, other matched and mismatched family-member donors, and matched unrelated donors. The best re-

sults have been achieved with HLA-identical sibling donors. With transplantation from family-member donors who are identical for one haplotype but mismatched for a single locus (i.e., HLA-A, HLA-B, or HLA-D) on the other haplotype, the survival rate is nearly equal to that with HLA-identical donors, although there is a higher incidence of GVHD.[5] Transplants using family-member donors mismatched for two or more loci have worse results—a higher incidence of GVHD and graft rejection and a lower probability of survival.[5]

Because of the highly polymorphic nature of HLA antigens, the probability that two unrelated persons will match is extremely low. Matched unrelated donor transplantation was first performed in the late 1970s. The broader application of this technique was made feasible by the creation of large donor registries in the late 1980s. Since then, the number of unrelated-donor transplantations has rapidly increased [*see Figure 1*]. Currently, more than seven million healthy persons have volunteered to serve as marrow donors in the United States alone, making the odds of finding an unrelated donor matched for HLA-A, HLA-B, and HLA-D approximately 50%. On average, it takes about 3 months from the time a search is initiated to identify a donor and begin transplantation. In 2002, approximately 2,100 unrelated-donor transplantations were performed in the United States.[6]

Results of early transplantations suggested that GVHD was more common and graft rejection more frequent with unrelated donors than with related donors matched for HLA compatibility.[7] The difference in incidence of GVHD may be partially explained by the increased disparity in minor HLA determinants in unrelated individuals. Undetected disparities in HLA types between supposedly matched unrelated donor-recipient pairs may also have contributed to the increased incidence of GVHD. Before 1998, HLA typing for HLA-A, HLA-B, and HLA-C was conducted using serologic methods. Since then, studies using automated direct sequencing of these genes have demonstrated allele-level mismatching in 30% of pairs previously defined as HLA identical.[8,9] Such mismatching in class I antigens has been shown to be associated with increased GVHD, whereas mismatches at class II have been shown to be associated with an increased risk of graft rejection. Currently, outcomes of transplantations using fully matched donors approach those seen with matched sibling transplants in many disease categories.

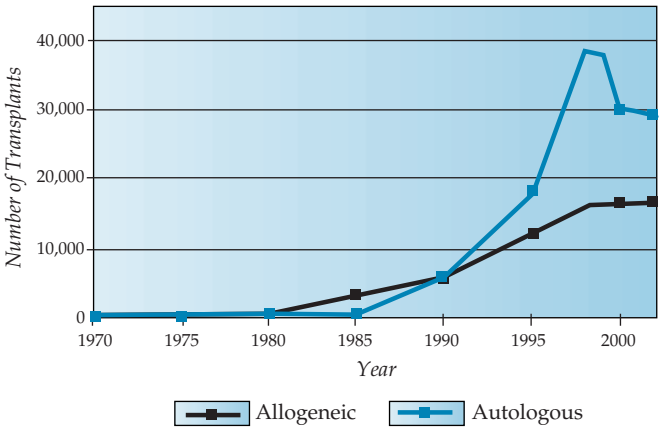

Figure 1 **Depicted are the estimated total numbers of allogeneic and autologous hematopoietic stem cell transplantations performed worldwide from 1970 to 2002, according to estimates of the International Bone Marrow Transplant Registry. The drop in autologous transplantations in 1999 was due to decreased transplantation for breast cancer, whereas the flattening in growth of allogeneic transplantation is the result of fewer transplantations for chronic myelogenous leukemia since the introduction of imatinib mesylate.**

AUTOLOGOUS TRANSPLANTATION

Compared with allogeneic transplantation, autologous transplantation has the advantage of avoiding GVHD and associated complications; disadvantages are that the autologous cells lack the antitumor effect of an infusion of allogeneic leukocytes (the so-called graft versus tumor effect) and may contain viable tumor cells. Removal of tumor cells by use of antibodies to tumor-specific antigens together with complement, toxins, or immunomagnetic beads is very efficient, reducing the number of tumor cells 1,000-fold to 10,000-fold.[10] Other methods of purifying stem cells that are currently under investigation are antibody adherence and flow techniques that select normal hematopoietic stem cells while leaving tumor cells behind; in vitro treatment of the autologous cells with selective chemotherapeutic agents; and in vitro culturing to selectively grow hematopoietic cells. Gene-marking studies have demonstrated that remaining tumor cells can contribute to relapse[11]; however, it remains unknown which, if any, methods of cell purification can prevent relapse. Further, many of the techniques result in delayed hematologic and immunologic recovery after transplantation. Several retrospective analyses suggest that in vitro marrow treatment may be effective in acute myeloid leukemia (AML) and B cell non-Hodgkin lymphoma, but sufficiently large prospective, controlled studies have not been published.[10]

PERIPHERAL BLOOD CELL TRANSPLANTATION

Hematopoietic stem cells normally circulate in the peripheral blood, albeit at very low numbers. Early experiments in animal models showed that at least 10 times more mononuclear cells are needed to rescue animals from lethal total body irradiation when the cells are collected from peripheral blood rather than from marrow of untreated animals. Initial attempts to use peripheral blood stem cells as a source of hematopoietic grafts were complicated by the large number of collections (phereses) required—often seven or more—and by slow engraftment. Subsequently, it was shown that a marked increase in the number of hematopoietic progenitors in the blood, measured either as hematopoietic colony-forming units or as CD34+ cells, occurs during recovery from previous chemotherapy or shortly after exposure to hematopoietic growth factors.[12,13] This led to studies of the use of peripheral blood stem cells as a substitute for marrow. These studies were initially conducted in the autologous setting because peripheral blood stem cell collections contain a large number of T cells, which could induce GVHD if the collections were used for allogeneic transplantation. In the autologous setting, cells sufficient in number to achieve engraftment can usually be collected with one to three leukaphereses of 4 hours' duration after treatment of the patient with granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF). The exact mechanism by which myeloid growth factors cause the remarkable increase in number of peripheral blood stem cells is unclear; however, recent murine studies suggest that myeloid growth factors activate neutrophils to release serine proteases, and serine proteases in turn proteolytically cleave vascular adhesion molecules in the marrow, releasing hematopoietic stem cells.[14] If more than 2.5 million CD34+ cells/kg are collected and subsequently used for

autologous transplantation, recovery to 500 granulocytes/mm^3 within 12 days after transplantation and recovery to 20,000 platelets/mm^3 within 14 days after transplantation almost always occur.[15] This rate of recovery is significantly faster than the rate with autologous marrow stem cells [*see Figure 2*]. Although it is not yet known whether peripheral blood is more likely or less likely than marrow to be contaminated with transplantable tumor cells, mobilized peripheral blood has almost entirely replaced marrow as the source of stem cells for autologous transplantation.

Peripheral blood stem cells have also been used for allogeneic transplantation. Initial studies with G-CSF–mobilized peripheral blood stem cells from HLA-identical matched donors suggested that they engraft more rapidly, and the incidence of acute GVHD did not appear to be greater than would be expected with marrow, despite the transplantation of at least 10 times more mature T cells.[16] Randomized trials have confirmed that the use of peripheral blood stem cells accelerates engraftment without increasing the incidence of acute GVHD.[17-19] Although the incidence of chronic GVHD may be somewhat higher with peripheral blood stem cells, the incidence of tumor recurrence appears to be less and overall disease-free survival tends to be higher with use of peripheral blood stem cells, particularly in patients with higher-risk leukemias.[17-19]

UMBILICAL CORD BLOOD TRANSPLANTATION

Umbilical cord blood is rich in CD34+ cells, and these cells can thus serve as an alternative source of stem cells. The first human umbilical cord blood transplantations were performed in the late 1980s for patients with Fanconi anemia. In a series of 44 children treated with cord blood from siblings, the speed of myeloid engraftment was similar to that seen with marrow transplantation, but platelet recovery was slower.[1] The incidence of GVHD was 6%, which was low; this probably reflected both the young ages of the recipients and the fact that umbilical cord blood is relatively devoid of mature T cells. Subsequently, several studies were undertaken that entailed banking unrelated umbilical cord blood and using it for subsequent transplantation.[19] A summary of the first 562 unrelated cord blood transplants facilitated by the New York Blood Center's program reported engraftment in approximately 80% of patients, but the time to engraftment was significantly prolonged—24 days for neutrophils and 72 days for platelets.[20] A close relation was found between the number of nucleated cord blood cells infused and the incidence and speed of engraftment. The overall incidence of severe acute GVHD was 23%.

Currently, umbilical cord blood is used as the source of stem cells for between 15% and 20% of pediatric allogeneic transplantations. Because the rates of graft failure and transplant-related death increase as the cell dose per kilogram of cord blood drops, umbilical cord blood is rarely used for adult transplantation. Advantages of umbilical cord blood as a source of stem cells include an apparent ability to use donors with greater HLA disparity, a seemingly lower risk of GVHD, and the rapid availability of stored unrelated units. Disadvantages include slower engraftment, a higher incidence of graft failure, slower immune reconstitution, and a trend toward higher disease-recurrence rates. Studies comparing the outcomes of matched unrelated donors with those of unrelated cord blood transplants have, in some cases, shown equivalent survival, but others have shown a trend toward improved survival with the use of unrelated marrow donors.[21]

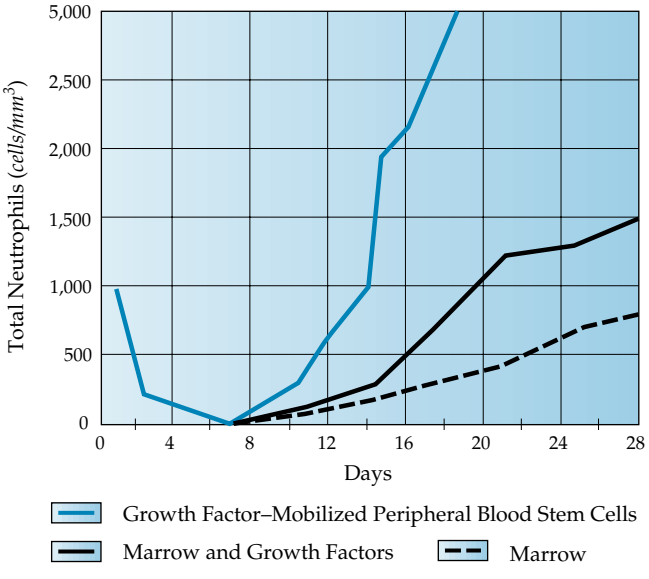

Figure 2 **Shown are the typical patterns of myeloid recovery after hematopoietic stem cell transplantation using marrow alone, marrow plus posttransplant myeloid growth factors, and growth factor–mobilized peripheral blood stem cells.**

Transplantation Procedure

PREPARATIVE REGIMENS

A preparative regimen is administered before hematopoietic stem cells are transplanted. The purpose of this regimen is to eliminate the abnormal or malignant cells causing disease and to suppress the immune system sufficiently to avoid graft rejection. The appropriate regimen for any particular patient is determined by the disease to be treated, the age and health of the patient, and the source of the stem cells to be grafted.

At one extreme, patients undergoing transplantation for the treatment of severe combined immunodeficiency disease with stem cells from an HLA-matched sibling require no preparative regimen, because there are no abnormal cells to eliminate (the disease being caused by a lack of normal cells) and because the patients' immune systems are already sufficiently suppressed to avoid graft rejection. Patients with aplastic anemia lack a normal hematopoietic system but are sufficiently immunocompetent to reject allogeneic marrow if no immunosuppression is given. In this setting, treatment with high-dose cyclophosphamide plus antithymocyte globulin is sufficiently immunosuppressive to ensure engraftment as long as the donor is an HLA-identical sibling. When the transplant is from an unrelated donor, greater immunosuppression is required; thus, low-dose total body irradiation is often added to the treatment. When transplantation is used to treat diseases characterized by an abnormal but nonmalignant population of cells, such as thalassemia and sickle cell anemia, the preparative regimen must eliminate the abnormal population and suppress the patient's immune system. To accomplish this, high-dose busulfan is often added to cyclophosphamide in the preparative regimen.

In developing preparative regimens for transplantation to treat malignancies, most investigators have focused on the use of agents that are highly active against the malignancy being treated and whose dominant dose-limiting toxicity in the nontransplant setting is myelosuppression. Thus, the therapies most commonly used are alkylating agents (e.g., cyclophosphamide,

busulfan, thiotepa, melphalan, carmustine), etoposide, cytarabine, and total body irradiation.

High-dose preparative regimens are typically used when allogeneic transplantation is performed to treat malignancy; however, the allogeneic graft-versus-tumor effect suppresses tumor growth independent of the preparative regimen, which has led investigators to ask whether less intensive, nonmyeloablative regimens may be effective and less toxic. Allogeneic engraftment has been achieved with lower-dose regimens that combine fludarabine with busulfan, cyclophosphamide, or total body irradiation. In one study, for example, patients with hematologic malignancies were treated with fludarabine and 200 cGy of total body irradiation, with encouraging results.[22] Complete responses were achieved in a variety of malignancies, particularly in patients with more indolent hematologic malignancies, with much less toxicity than seen with standard transplant approaches.[22] The decreased toxicity associated with this approach has permitted its study in patients 70 years of age and older. The appropriate role of nonmyeloablative transplants in the treatment of specific malignancies is still being defined.[22,23]

STEM CELL COLLECTION AND INFUSION

Marrow is usually obtained from the donor's anterior and posterior iliac crests with the donor under spinal or general anesthesia. A total marrow volume equivalent to 10 to 15 ml/kg is withdrawn; withdrawal of marrow volume is limited to 3 to 5 ml at each aspiration site to avoid excessive dilution with peripheral blood circulating within the iliac crest. The marrow is filtered through 0.3 mm and 0.2 mm screens to remove bone spicules and fat. The marrow may require further in vitro treatment to remove other cells, such as donor red cells to prevent a hemolytic transfusion reaction in the setting of ABO incompatibility; donor T cells to prevent GVHD; and tumor cells from autologous marrow (see above). The risks associated with marrow donation are small; in one series, there were six serious but nonfatal complications out of 1,220 consecutive marrow donations.

Peripheral blood stem cells are usually collected by use of continuous-flow apheresis from donors previously treated with hematopoietic growth factor alone or, in the case of autologous transplantation, after chemotherapy plus treatment with growth factors. Attempts are made to collect a minimum of 5×10^6 CD34+ cells/kg; there is consistent rapid engraftment with this dose.[15]

Marrow and peripheral blood stem cell infusions are usually well tolerated, though patients sometimes develop fever, cough, or mild shortness of breath. Slowing the infusion usually alleviates these symptoms.

ENGRAFTMENT

The rate of engraftment depends on the source of the stem cells, the choice of prophylaxis against GVHD, and whether hematopoietic growth factors are used. The most rapid engraftment is seen with peripheral blood stem cells; in this setting, engraftment is typically achieved by day 12. In marrow or umbilical cord blood transplantation, the granulocyte count usually reaches 100 cells/mm^3 by about day 16 and 500 cells/mm^3 by day 22. The rate of myeloid recovery can be accelerated by 4 to 6 days with the use of G-CSF or GM-CSF after marrow transplantation, but posttransplant growth factors have less of an effect when mobilized peripheral blood is the source of transplanted stem cells [*see Figure 2*].[24] The use of methotrexate after allogeneic transplantation delays recovery by an average of 4 days. Platelet recovery generally occurs shortly after granulocyte recovery.

Complications of Transplantation

EARLY DIRECT TOXICITIES OF THE PREPARATIVE REGIMEN

Pretransplant preparative regimens are associated with a substantial array of toxicities, which vary considerably depending on the specific regimen used. For example, nausea, vomiting, and mild skin erythema develop immediately in almost all patients after the standard cyclophosphamide–total body irradiation regimen. Occasionally, hemorrhagic cystitis is seen despite bladder irrigation or therapy with a sulfhydryl compound (MESNA); in rare instances (fewer than 2% of cases), acute hemorrhagic carditis develops. Oral mucositis inevitably develops about 5 to 7 days after transplantation, usually requiring narcotic analgesia. Patient-controlled analgesia provides the greatest patient satisfaction and, surprisingly, results in a lower cumulative dose of narcotics. Within 10 days after transplantation, complete alopecia and profound granulocytopenia have developed in most patients.

Veno-occlusive disease of the liver (also referred to as sinusoidal obstruction syndrome) is a serious complication of high-dose chemoradiotherapy; it develops in approximately 10% to 20% of patients.[25] Veno-occlusive disease of the liver, characterized by the development of ascites, tender hepatomegaly, jaundice, and fluid retention, may occur at any time during the first month after transplantation; the peak incidence occurs at around day 16. Histologic features of veno-occlusive disease of the liver include concentric narrowing or fibrous obliteration of terminal hepatic venules and sublobular veins and necrosis of zone 3 hepatocytes [*see Figure 3*]. Predisposing factors are pretransplant hepatitis of any cause and the use of more intensive conditioning

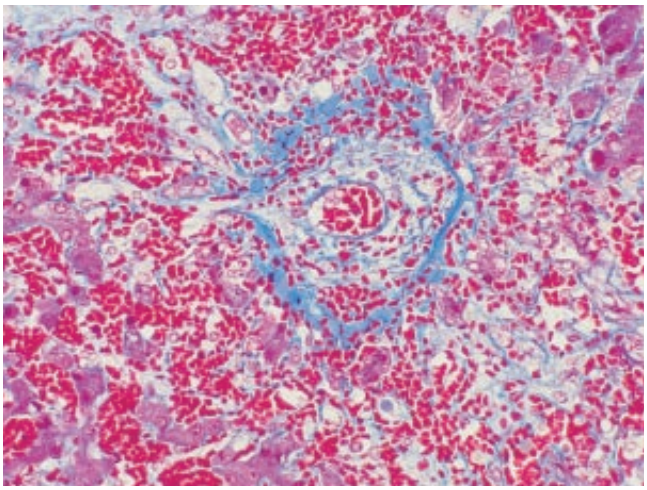

Figure 3 **Photomicrograph of a liver biopsy stained with Trichrome shows the typical changes of veno-occlusive disease of the liver. A sublobular vein is outlined by dense, blue connective tissue in the outer adventitial layer. There is marked narrowing of the lumen of the vein by a widened and edematous subendothelial zone containing trapped red cells and loose extracellular matrix. The hepatocyte cords surrounding the vein are necrotic, and the intervening sinusoids are hemorrhagic. Deposition of coagulants in the sinusoids and in the subendothelial zone of the vein obstructs outflow of blood from the liver, producing sinusoidal hypertension and hepatomegaly.**

regimens. Although the precise sequence of events leading to the clinical presentation of veno-occlusive disease is unknown, direct cytotoxic injury to hepatic venular and sinusoidal endothelium occurs early on, with subsequent deposition of fibrin and the development of a local hypercoagulable state. Direct cytotoxic injury to zone 3 hepatocytes is a contributing factor. Approximately 30% of patients who develop veno-occlusive disease of the liver die as a result of the disease, with progressive hepatic failure leading to a terminal hepatorenal syndrome. Antithrombotic and thrombolytic agents, including prostaglandin E_1 and tissue plasminogen activator, with or without heparin, have been evaluated as treatment. These therapies have been associated with significant toxicities, and randomized trials demonstrating efficacy are lacking. It has been reported that defibrotide, a polydeoxyribonucleotide, may benefit patients with veno-occlusive disease.[26]

Most pneumonias that occur after transplantation are caused by microbial agents, but idiopathic interstitial pneumonia occurs in up to 5% of patients.[27] Most experts consider idiopathic interstitial pneumonia to be a direct toxicity of intensive chemotherapy, but evidence for a role of soluble cytokines is growing. Biopsies reveal some cases to be characterized by diffuse alveolar damage, whereas other cases have a more clearly interstitial component. Treatment with high-dose glucocorticoids is often attempted, but randomized trials evaluating their efficacy have not been performed.

LATE DIRECT TOXICITIES OF THE PREPARATIVE REGIMEN

Direct complications of chemoradiotherapy seen late after transplantation include a decreased growth rate in children and a delay in the development of secondary sex characteristics. Most children will have a deficiency in growth factor and should undergo replacement therapy. Ovarian failure develops in most postpubertal women. Azoospermia develops in most men. Aseptic osteonecrosis occurs in as many as 10% of transplant patients, particularly in those with chronic GVHD necessitating corticosteroid treatment. Similarly, cataracts develop in 10% to 20% of patients; the risk is higher in patients who take steroids to treat chronic GVHD.[28]

Patients treated with high-dose chemoradiotherapy and hematopoietic cell transplantation are at increased risk for the development of secondary malignancies.[29,30] The risk is highest in patients receiving T cell–depleted marrow and those who receive multiple cycles of highly immunosuppressive drugs after transplantation to treat GVHD; in such cases, a high incidence of Epstein-Barr virus–associated lymphoproliferative disease is seen. A smaller increase is seen in the incidence of solid tumors after transplantation, with a 2.9% 10-year cumulative rate. The actuarial incidence of myelodysplasia after autologous transplantation for non-Hodgkin lymphoma and Hodgkin disease may be as high as 10%.[31]

GRAFT FAILURE

Although complete and sustained engraftment is the general rule after transplantation, marrow function does not return in some cases; and in other cases, after temporary engraftment, marrow function is lost. Graft failure after autologous transplantation can result from marrow damage before harvesting, during ex vivo treatment, during storage, or after exposure to myelotoxic agents after transplantation.[32] Infections with cytomegalovirus (CMV) or human herpesvirus type 6 may also result in poor marrow function. Graft failure after allogeneic transplantation may be the result of immunologically mediated graft rejection and is more common after conditioning regimens that are less immunosuppressive, in recipients of T cell–depleted marrow, and in recipients of HLA-mismatched marrow.

The treatment of graft failure begins with removal of all potentially myelosuppressive agents. A reasonable second step is to attempt a short trial of a myeloid growth factor (GM-CSF or G-CSF); 40% to 50% of patients respond.[33] Identification of persistent host lymphocytes in peripheral blood or marrow of the patient suggests immunologic rejection. These patients should receive further immunosuppression before a second transplant is performed. Several studies have reported successful second transplants after a regimen of cyclophosphamide and antithymocyte globulin or a regimen of anti-CD3 antibody and high-dose steroids.

GRAFT VERSUS HOST DISEASE

When allogeneic T cells that are transferred with the graft or that develop from it react with targets of the genetically different host, GVHD results.[34] GVHD that develops within the first 3 months after transplantation is categorized as acute and is characterized by an erythematous maculopapular skin rash that, unlike many rashes, often appears on the palms and soles [*see 2:VI Cutaneous Adverse Drug Reactions*]. Acute GVHD is also characterized by persistent anorexia or diarrhea, or both, and by liver disease, evidenced by increased levels of bilirubin, alanine and aspartate aminotransferases, and alkaline phosphatase. Also characteristic of acute GVHD is epithelial damage to the skin, liver, and intestines [*see Figure 4*]. Skin, liver, and endoscopic intestinal biopsies are the usual methods of establishing a diagnosis, and they may reveal damaged epidermis and hair follicles, segmental disruption in small bile ducts, and intestinal mucosal ulceration caused by destruction of intestinal crypts. Clinical

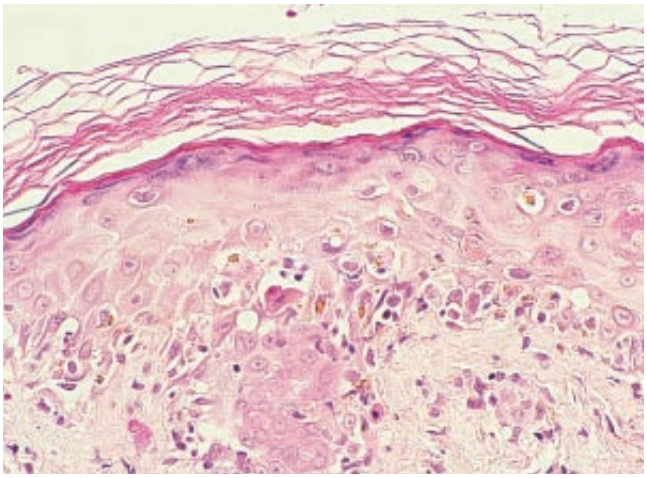

Figure 4 **This photomicrograph of a skin biopsy stained with hematoxylin and eosin demonstrates the features of acute graft versus host disease of the skin. Both intercellular edema (spongiosis) and intracellular edema (reticular degeneration) of the lower epidermis are evident. Mononuclear cells are scattered throughout the epidermal area along with many bodies that have undergone apoptosis, including dead epidermal cells with hypereosinophilic cytoplasm and dense basophilic pyknotic nuclei. The inflammatory process has produced incontinence of melanin pigment into the papillary dermis, as well as coarse intraepidermal blocks of melanin, leading to hyperpigmentation. Because the apoptosis and basal layer damage are extensive, the epidermis will become grossly scaly and will possibly slough.**

staging of acute GVHD is determined by the extent of involvement of skin, liver, and gut [*see Table 1*]. The incidence of acute GVHD increases in older patients, in recipients of mismatched marrow, and in patients unable to receive full doses of the drugs used to prevent GVHD.[35]

Two general approaches are used to prevent acute GVHD: use of immunosuppressive agents during the early posttransplant period and removal of T cells from the transplanted cell population. Methotrexate alone and cyclosporine alone are equally effective as prophylaxis, but their use in combination is more effective. Prednisone, FK 506 (tacrolimus), rapamycin, and mycophenolate mofetil have also been used in various combinations.[36] Removal of T cells from the allogeneic marrow is effective in preventing acute GVHD, but in most circumstances, it has been associated with an increased incidence of graft rejection and leukemic relapse. Accordingly, several potential therapies are now under study, including partial T cell depletion and complete T cell depletion followed by the reintroduction of a fraction of the T cells. Once acute GVHD develops, it can be treated with glucocorticoids, antithymocyte globulin, and monoclonal antibodies targeted against T cells or their receptors.

GVHD that develops or persists 3 months or more after transplantation is termed chronic GVHD. Chronic GVHD has features in common with collagen vascular diseases, including a malar rash, sclerodermatous changes, sicca syndrome, arthritis, obliterative bronchiolitis, and, in some cases, bile duct degeneration and cholestasis. Chronic GVHD develops in 20% to 40% of patients, more often in older patients and in those who previously had acute GVHD.[37] Prednisone, cyclosporine, or the two in combination is the usual treatment[38]; in some studies, azathioprine or thalidomide was useful.[39] In most patients, chronic GVHD eventually resolves and immunosuppressive therapy can be withdrawn, but 1 to 3 years of treatment may be required. Patients with chronic GVHD who are on immunosuppressive therapy are susceptible to bacterial infections and should receive prophylactic antibiotics.

INFECTIOUS DISEASES

During the first 2 to 3 weeks after transplantation, all patients are severely granulocytopenic. To reduce the risk of disseminated bacterial infections, posttransplantation patients are usually placed on broad-spectrum antibiotics once they become granulocytopenic. In addition, the prophylactic administration of fluconazole reduces the incidence of *Candida albicans* infection.[40] The treatment of patients who become febrile despite prophylactic antibiotic and antifungal therapy is a difficult challenge; in such cases, therapy is guided by individual aspects of the patient's condition and by the institution's experience. For example, if fever develops in a patient who received prophylactic treatment with levofloxacin, the subsequent choice of antibiotic might be guided by whether an intra-abdominal source of infection is suspected, in which case meropenem or imipenem is appropriate therapy; when intra-abdominal infection is not a concern, ceftazidime might be selected.[41] If fever persists for more than 72 hours, amphotericin B or voriconazole is often added to the treatment regimen.[42] Granulocyte transfusions can be effective in treating specific infections, particularly now that donors can be treated with G-CSF before donation to greatly increase the number of granulocytes that can be collected and transfused.[42] There is no established role, however, for prophylactic granulocyte transfusions. Laminar airflow isolation can reduce the incidence of infection but has no impact on survival in transplant patients treated for malignancy. With current methods of supportive care, the risk of death from an infectious cause during the period of granulocytopenia is less than 5%.

In the past, CMV infection frequently occurred after transplantation, particularly in recipients of allogeneic marrow. It has been shown, however, that primary CMV infection can be prevented in CMV-seronegative patients by the use of CMV-seronegative blood products. In CMV-seropositive patients, treatment with ganciclovir as soon as virus excretion is evident can diminish the incidence of CMV-associated disease and death, but in some patients, CMV disease develops before or at the same time as viral excretion is noted. Ganciclovir prophylaxis beginning at the time of engraftment can prevent the development of CMV infection in most patients, but ganciclovir causes significant marrow suppression in at least 10% of patients.[43] At most centers, after transplantation, peripheral blood is monitored for the development of CMV antigenemia, and prophylaxis with ganciclovir is initiated only if and when patients test positive for the presence of CMV antigen. Foscarnet is effective for patients who develop CMV antigenemia or infection despite ganciclovir therapy or for patients who cannot tolerate ganciclovir.

Herpes simplex virus infection, when not prevented, contributes to the severity of early oral mucositis and esophagitis. However, the prophylactic use of acyclovir at a dosage of 250 mg/m^2 I.V. every 8 hours can prevent herpes simplex virus reactivation in almost all seropositive patients.

Pneumocystis carinii once caused pneumonia in 5% to 10% of patients after transplantation, but now this complication can be prevented in virtually all patients by first treating the patient with oral trimethoprim-sulfamethoxazole for 1 week before transplantation and then resuming treatment 2 days a week once engraftment occurs and continuing it for as long as immunosuppressive therapy is given. Desensitization should be attempted in patients with allergic reactions to trimethoprim-sulfamethoxazole. Dapsone (50 mg p.o., b.i.d.), although not as effective as trimethoprim-sulfamethoxazole, can serve as a substitute but must be avoided in patients with glucose-6-phosphate dehydrogenase deficiency.

Table 1 Clinical Staging of Acute Graft versus Host Disease*

Stage	*Skin Changes*	*Liver*	*Gut*
I	Maculopapular rash < 25% body surface	Bilirubin 2–3 mg/dl	Diarrhea 500–1,000 ml/day
II	Maculopapular rash 25%–30% body surface	Bilirubin 3–6 mg/dl	Diarrhea 1,000–1,500 ml/day
III	Generalized erythroderma	Bilirubin 6–15 mg/dl	Diarrhea > 1,500 ml/day
IV	Desquamation and bullae	Bilirubin > 15 mg/dl	Pain and ileus

*Overall severity ranges from mild skin involvement (stage I) to severe multiorgan involvement, usually with a fatal outcome (stage IV).

Table 2 Disease-Free Survival after Hematopoietic Stem Cell Transplantation

Disease	*Five-Year Disease-Free Survival (%)*
Chronic myeloid leukemia	
Chronic phase	60–70
Accelerated phase	30–40
Blastic phase	15–20
Acute myeloid leukemia	
First remission	40–70
Second remission	30
Chronic lymphocytic leukemia	50
Acute lymphocytic leukemia	30–50
Multiple myeloma	35
Non-Hodgkin lymphoma	
After first relapse, chemosensitive tumors	40–50
Hodgkin disease	
First treatment after standard treatment	40–70
Advanced disease	15–30
Myelodysplastic syndromes	45
Severe aplastic anemia	> 90
Thalassemia major	70–90
Fanconi anemia	50–70
Sickle cell disease	50–90
Severe combined immunodeficiency disease	90
Breast cancer (stage IV disease)	10–30

More than 3 months after transplantation, patients are still at risk for varicella-zoster virus infections and, if they have chronic GVHD, for recurrent bacterial infections. Varicella-zoster virus infection usually occurs initially as localized disease (i.e., herpes zoster, or shingles), but it can disseminate; disseminated infection is often fatal if left untreated. Thus, patients with localized varicella-zoster virus infection should be treated with acyclovir to prevent dissemination. Many centers now routinely place all allogeneic transplant recipients on prophylactic acyclovir therapy for the first year after transplantation. In an effort to reduce late bacterial infections, many centers place patients with chronic GVHD receiving immunosuppression on daily trimethoprim-sulfamethoxazole therapy.

Hematopoietic Stem Cell Transplantation for Specific Diseases

TREATMENT OF IMMUNODEFICIENCY STATES

The widest experience in treating immunodeficiency with hematopoietic stem cell transplantation has been in the treatment of severe combined immunodeficiency disease.[44] When current techniques of supportive care are used, the expected outcome of transplantation from an HLA-identical donor is excellent, with a better than 90% probability of long-term survival [*see Table 2*]. In patients without matched donors, transplantation from a haplotype-mismatched parent results in engraftment and survival longer than 2 years in 50% to 70% of patients. The experience in the treatment of Wiskott-Aldrich syndrome and other immunodeficiency states is limited. Cures have been noted in more than half of patients, with the best results seen in patients who undergo transplantation when they are younger than 5 years.

TREATMENT OF NONMALIGNANT DISEASES OF HEMATOPOIESIS

Aplastic Anemia

Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin, together with the use of methotrexate and cyclosporine for GVHD prophylaxis, is a very effective regimen for patients with aplastic anemia. Current results suggest a cure rate greater than 90% [*see Table 2*].[45] Results with mismatched or unrelated matched donors are somewhat worse; therefore, patients with aplastic anemia who are without sibling donors are often given a trial of immunosuppressive therapy before transplantation.

Thalassemia

Marrow transplantation from an HLA-identical sibling after a preparative regimen of busulfan and cyclophosphamide can cure from 70% to 90% of patients with thalassemia major [*see Table 2*]. The best results have been obtained in patients who undergo transplantation before they develop hepatomegaly or portal fibrosis and who have been given adequate iron chelation therapy. In one study of 121 such patients, the probabilities of survival and disease-free survival 5 years after transplantation were 95% and 90%, respectively.[46] Prolonged survival can also be achieved with aggressive chelation therapy, but transplantation remains the only curative treatment. Fewer than 30% of patients with thalassemia have an HLA-identical sibling. Selection of alternative donors of hematopoietic stem cells (i.e., unrelated persons or HLA-nonidentical family members) has been aided by the establishment of worldwide donor registries, by improvements in the methods of controlling GVHD, and by prevention of fungal and cytomegalovirus infection.

Sickle Cell Anemia

Experience in transplantation for sickle cell disease is small but growing. In a European study of 100 patients with sickle cell disease who received transplants from HLA-matched siblings, the survival rate at 4 years was 88%, and disease-free survival was 80%.[47] In a study of 59 patients in the United States, similar rates were reported—93% and 84%, respectively.[48]

Other Nonmalignant Diseases

Hematopoietic stem cell transplantation has been used successfully to treat a variety of other nonmalignant but nonetheless fatal diseases. Included in this group are congenital disorders of white cells, including Kostmann syndrome, chronic granulomatous disease, neutrophil actin defects, leukocyte adhesion deficiency, and Chédiak-Higashi syndrome. Congenital anemias, including Fanconi anemia and Blackfan-Diamond anemia, are likewise treatable with hematopoietic stem cell transplantation.[49,50] Osteopetrosis is a rare inherited disorder caused by an inability of the osteoclast to resorb bone. Because the osteoclast is a specialized macrophage derived from the marrow, it follows that osteopetrosis can be treated with marrow transplantation.

A final category of treatable nonmalignant diseases are storage diseases caused by enzymatic deficiencies, including Maroteaux-Lamy syndrome, metachromatic leukodystrophy, Gaucher disease, Hurler syndrome, and Hunter syndrome [*see 5:VII Nonmalignant Disorders of Leukocytes*]. Transplantation for these disorders has not been universally successful, but treatment early in the disease course, before irreversible end-organ damage occurs, increases the chance for a successful outcome. Studies have recently been done on the use of transplantation in the treatment of severe autoimmune disorders. These studies are based on the demonstration that transplantation can cure autoimmune diseases in some animal models and on the observation that some patients with coexistent hematologic malignancies and autoimmune disorders have been cured of both with transplantation.[51]

TREATMENT OF MALIGNANT DISEASES

Acute Myeloid Leukemia

Allogeneic marrow transplantation cures 15% to 20% of patients with AML in whom induction therapy fails and, indeed, is the only therapy that can cure such patients.[52] Thus, all patients 55 years of age or younger with newly diagnosed AML should have their HLA type determined, as should their families, soon after diagnosis to enable transplantation for those in whom induction therapy fails. Allogeneic transplantation can cure approximately 30% of patients in second remission and 35% of patients in untreated first relapse—situations that are clear indications for the procedure, because these results are superior to those achieved without transplantation.[53,54] The best results with allogeneic transplantation for AML are obtained in patients undergoing transplantation in first remission, in whom a cure rate of 40% to 70% is reported [*see Table 2*].

In 14 prospective studies, the cure rate with marrow transplantation for patients with HLA-matched siblings ranged from 40% to 64%, whereas the cure rate with chemotherapy for patients without HLA-matched siblings ranged from 19% to 24%, suggesting that allogeneic transplantation is the preferred form of postremission therapy for younger patients with AML and a matched sibling.[55-57] However, important advances have been made in both chemotherapy and transplantation since many of these studies were conducted. Further, it remains untested whether transplantation in first remission is superior to a regimen of initial chemotherapy followed by transplantation as salvage therapy.

In several phase II studies, autologous transplantation for patients with AML in first or second remission yielded results not dissimilar to those achieved with allogeneic transplantation. In general, relapse rates after autologous transplantation have been substantially higher than those seen with allogeneic transplantation, but the mortality associated with transplant-related complications has been lower. Several large trials compared allogeneic transplantation, autologous transplantation, and aggressive chemotherapy as postremission therapy for patients with AML in first remission. The European Organization for Research and Treatment of Cancer compared these therapies in 333 patients with AML in first remission and found the rate of disease-free survival at 4 years to be 54% with allogeneic transplantation, 49% with autologous transplantation, and 30% with continued chemotherapy.[58] In a recent update of a similarly designed American Intergroup study, the estimated rate of survival at 5 years was 52% with allogeneic transplantation, 42% with autologous transplantation, and 39% with chemotherapy.[59] In a study from the United Kingdom Medical Research Council, patients with AML in first remission who had been treated with three cycles of postremission therapy were randomized either to receive no further therapy or to undergo autologous transplantation in first remission.[60] The group who underwent transplantation had a lower relapse rate, and the rates of disease-free survival and overall survival were improved. The benefits of allogeneic transplantation over autologous transplantation or chemotherapy are most apparent for patients with high-risk AML, as determined by cytogenetic risk status and other prognostic factors.[59]

Acute Lymphocytic Leukemia

As with AML, allogeneic transplantation can cure 15% to 20% of patients with acute lymphocytic leukemia (ALL) in whom induction therapy fails or in whom chemotherapy-resistant disease develops; thus, these patients are candidates for the procedure. The results of transplantation for patients in second remission are better, with cure rates of 30% to 50% [*see Table 2*]. However, further intensive chemotherapy also can cure some patients who suffered an initial relapse. This is particularly true for children who experience a relapse more than 18 months after initial induction chemotherapy. In a study comparing the use of allogeneic transplantation in 255 children with the use of chemotherapy in an equal number of children, the rates of disease-free survival at 5 years were found to be 40% in transplant patients and 17% in chemotherapy patients. The relative benefits of transplantation were similar for children with short and long initial remissions. Thus, allogeneic transplantation can be recommended for all patients with ALL in second complete remission who have appropriate donors.[61]

Allogeneic transplantation for ALL in first remission results in long-term disease-free survival in 40% to 70% of adult patients. In a retrospective study comparing these results with those achieved with chemotherapy, no clear advantage could be found for either approach.[62] In the largest prospective, randomized study published to date (involving 572 patients), the 10-year survival rate for those undergoing allogeneic transplantation was 46%; for those undergoing autologous transplantation, 34%; and for those receiving continued chemotherapy, 31%.[63] In standard-risk patients, there was no difference in outcome between the three approaches (i.e., 10-year survival of 49% with allogeneic transplantation, 49% with autologous transplantation, and 40% with chemotherapy), whereas for high-risk patients, allogeneic transplantation provided the best results (44% versus 10% versus 11%). Because children with ALL, in general, respond well to chemotherapy, there is no role for transplantation at first remission except for those with very high risk disease (e.g., Philadelphia chromosome–positive ALL).[64]

Myelodysplastic Syndromes

The myelodysplastic syndromes are generally considered to be incurable except with marrow transplantation. In some patients, the myelodysplastic syndromes have a relatively indolent course, and transplantation can be safely withheld until the disease progresses. However, once significant granulocytopenia (fewer than 1,000 cells/mm^3) or thrombocytopenia (fewer than 40,000 cells/mm^3) develops or the proportion of blast cells in the marrow exceeds 5%, transplantation should be seriously considered, because without transplantation, the expected survival time is short. When an HLA-matched sibling is available to

serve as a donor, the chance of long-term survival with transplantation is roughly 55%, with better results being obtained in younger patients and in those who receive transplants earlier in the course of their disease.[65] Similar results have been reported with matched unrelated donor transplants.[66] No role has been established for autologous transplantation in the myelodysplastic syndromes, but this is a current focus of research.

Chronic Myeloid Leukemia

Allogeneic and syngeneic marrow transplantation are the only forms of therapy known to cure chronic myeloid leukemia (CML). Five-year disease-free survival rates are 15% to 20% for patients who undergo transplantation in blast crisis, 30% to 40% for patients who undergo transplantation during the accelerated phase, and 60% to 70% for patients who undergo transplantation during the chronic phase [*see Table 2*].

Time from diagnosis influences the outcome of transplantation during the chronic phase. The best results are obtained in patients who receive transplants within 1 year of diagnosis; progressively worse results are seen the longer the procedure is delayed.[61] Previous exposure to busulfan is an adverse risk factor for transplantation.[67] A growing number of patients between 55 and 65 years of age with CML have undergone transplantation, with results not significantly worse than those seen in younger patients.[68] Although the initial experience with the use of unrelated-donor transplantation in CML was substantially worse than the experience with matched-sibling transplantation, more recent results at some centers have demonstrated a 70% probability of disease-free survival at 3 years.[69]

The overall role of hematopoietic cell transplantation in CML has become more complex with the introduction of imatinib mesylate, a very effective, relatively nontoxic oral agent used for treatment of CML.[70] Imatinib does not result in complete, molecular-level remissions in most patients, and therefore, many investigators would agree that early allogeneic transplantation remains the treatment of choice for younger patients with matched donors. For older patients or those without appropriate donor matches, an initial trial of imatinib is generally preferred.

Chronic Lymphocytic Leukemia

Use of marrow transplantation in chronic lymphocytic leukemia (CLL) has received only limited attention, probably because of the indolent nature of the disease and its propensity to occur in older patients. Of the small number of patients receiving allogeneic transplantation, many have had complete remissions, and approximately half have remained disease free.[71,72] However, the transplant-related mortality in this group of patients has been substantial. The number of patients treated with autologous transplantation is limited.[71,73] Complete remissions have been achieved, some of which appear to be sustained. Further study is needed to determine whether transplantation significantly improves long-term outcome in CLL.

Non-Hodgkin Lymphoma

Patients with disseminated intermediate or high-grade non-Hodgkin lymphoma in whom conventional therapy fails can seldom be cured without transplantation. High-dose therapy followed by autologous or allogeneic marrow transplantation can cure a substantial number of such patients. A number of studies have documented cure rates of 40% to 50% in patients who receive transplants after an initial relapse and whose tumors remain sensitive to chemotherapy [*see Table 2*].[74] In one randomized study of 216 patients, the 5-year disease-free survival rate for patients who underwent autologous transplantation for chemosensitive disease was 46%, compared with 12% for patients in the chemotherapy group ($P = 0.001$). Cure rates decrease substantially once the disease becomes resistant to conventional-dose chemotherapy.[74] A poor performance status and large tumor bulk are additional adverse risk factors. As in other diseases, patients who receive transplants of allogeneic marrow have a lower relapse rate but a higher risk of nonrelapse mortality than patients who receive transplants of autologous marrow.[75]

For most categories of intermediate- and high-grade non-Hodgkin lymphoma, the outcomes for allogeneic and autologous transplantation appear roughly similar, though an advantage has been suggested for the use of allogeneic transplantation in patients with lymphoblastic lymphoma. The role of transplantation for patients in first remission is unsettled. Of the randomized studies that have thus far been performed, some have found a significant benefit, some have found no benefit, and others have found a benefit only for the subgroup of patients with intermediate-to-high risk disease or high-risk disease.[76,77]

Autologous marrow transplantation has also been studied in patients with low-grade disease. The probabilities of survival at 3 years after transplantation have averaged 83% for patients who undergo transplantation in first remission, 65% for patients in first relapse or second remission, and 50% for patients with more advanced disease. Whether these results are superior to what could be achieved with therapies that do not involve transplantation has not been demonstrated in prospective, randomized trials. Further, late relapses have been seen after autologous transplantation, raising questions about the possibility of cure, but studies of allogeneic transplantation in patients with low-grade disease have shown long-term disease-free survival in some of these patients.

Hodgkin Disease

The results of transplantation for Hodgkin disease mimic those for non-Hodgkin lymphoma. A substantial number of patients in whom first-line chemotherapy for Hodgkin disease has failed can be cured with salvage transplantation. Results of treatment for recurrent Hodgkin disease have been shown to be better when transplantation is performed in patients who have chemotherapy-sensitive disease with minimal tumor bulk and a good performance status. In this setting, cure rates of 40% to 70% have been reported [*see Table 2*]. As with non-Hodgkin lymphoma, lower relapse rates but higher nonrelapse mortality are seen with the use of allogeneic stem cells than with the use of autologous stem cells.[78] There is currently no established role for transplantation for patients in first remission, though pilot studies in patients with high-risk disease are being performed.

Multiple Myeloma

Allogeneic marrow transplantation has been used to treat patients with multiple myeloma. For patients with multiple myeloma in whom first-line therapy has failed, allogeneic transplantation has achieved overall survival rates averaging 35% at 5 years[*see Table 2*]. An important finding is that there appears to be a plateau in the rate of disease-free survival, suggesting that although some of these patients were cured, transplant-associated complications were substantial and occurred more frequently than in most other hematologic malignancies.[79] With improvements in supportive care measures, the outcome of allogeneic transplantations for multiple myeloma has improved.[80]

Autologous transplantation has also been studied. There is less evidence that this approach can lead to long-term cure, at least with current techniques. However, when employed before patients have developed resistant disease, autologous transplantation can result in a substantial reduction in tumor burden and, in many cases, at least temporary complete remission. In two large randomized studies, the addition of high-dose chemotherapy and autologous transplantation to the initial treatment regimen led to significantly longer disease-free survival and greater overall survival than that which occurred with conventional chemotherapy alone.[81,82] A strategy of autologous transplantation followed by nonmyeloablative allogeneic transplantation has been applied with very encouraging early results.

Other Hematologic Malignancies

Long-term survival has been documented after allogeneic marrow transplantation in patients with hairy-cell leukemia, myelofibrosis, and various myeloproliferative syndromes, but the number of patients reported in any one disease category is small.

Breast Cancer

In women with stage IV breast cancer, high-dose chemotherapy followed by autologous transplantation results in a higher rate of complete remission than standard-dose chemotherapy. Studies of a large number of patients have reported disease-free survival at 5 years to be 10% to 30% [*see Table 2*].[83] In patients who underwent transplantation for stage IV disease, the highest rates of progression-free survival (32%) were seen in patients who received transplants after they had achieved a complete response to conventional chemotherapy; lower rates were seen in patients with partially responding disease (13%) or progressive disease (7%). Although these results appear to be superior to those achieved with standard-dose chemotherapy, longer follow-up and the completion of randomized trials are needed to determine whether patients who achieved complete response are cured and whether this percentage of patients is truly higher than that seen with standard-dose chemotherapy. On the basis of these initial high response rates, high-dose chemotherapy followed by autologous transplantation has been increasingly studied in patients with earlier-stage disease. Pooled registry results show a 42% 3-year disease-free survival for patients who received transplants for inflammatory breast cancer and a 74% 3-year disease-free survival for women with high-risk (> 10 nodes) stage II disease. On the basis of these results, randomized trials were initiated to test whether autologous transplantation would lead to improved cure rates for women with high-risk disease. Two such trials have been published: the Netherlands trial and an Eastern Cooperative Oncology Group study. In the Netherlands trial, high-dose alkylating therapy followed by transplantation improved relapse-free survival rates in patients with stage II or III disease and 10 or more positive nodes.[84] In an Eastern Cooperative Oncology Group study, the use of intensive chemotherapy reduced the risk of relapse of disease but did not improve disease-free survival rates.[85]

Testicular Cancer

Although standard-dose chemotherapy for testicular cancer is very effective, conventional regimens fail in 30% to 40% of cases. High-dose chemotherapy with autologous marrow support has resulted in a 2-year disease-free survival of approximately 20% in patients with advanced recurrent disease—a rate seemingly better than that achieved with conventional approaches.[86]

Other Solid Tumors

The utility of high-dose chemotherapy with autologous stem cell support for several other solid tumors, including ovarian cancer, small cell lung cancer, neuroblastoma, and pediatric sarcomas, is being studied. As in virtually all other situations, best results occur in patients with limited tumor bulk in whom the tumor remains sensitive to conventional-dose chemotherapy. Randomized trials evaluating the usefulness of transplantation in these settings have not been reported.

Treatment of Posttransplant Relapse

Patients with malignancies who experience relapse after autologous transplantation occasionally respond to further conventional-dose chemotherapy, particularly when the interval from transplantation to relapse is long. There are more options available to the patient who experiences relapse after allogeneic transplantation. Patients with CML frequently respond to interferon therapy, and other patients occasionally respond to withdrawal of immunosuppression. Patients who experience relapse after allogeneic transplantation sometimes respond to nonirradiated donor lymphocyte infusions. In a summary of 258 patients reported by a European registry, complete responses were seen in 75% of patients with CML, 38% with myelodysplasia, 24% with AML, and 15% with myeloma.[87] Responses were seldom seen in ALL. The major complications of posttransplant donor lymphocyte infusions have been GVHD and myelosuppression, both of which can be severe or fatal. Starting the transfusion with a low cell dose and then gradually increasing the dose can lessen the risk of severe toxicity. A second hematopoietic cell transplant can occasionally be effective, particularly in younger patients and in patients who experience a longer interval from first transplant to relapse and who do not have advanced disease.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Hemostasis, the process of blood clot formation, is a coordinated series of responses to vessel injury. It requires complex interactions between platelets, the clotting cascade, blood flow and shear, endothelial cells, and fibrinolysis.

Platelet Plug Formation

Platelets are activated at the site of vascular injury to form a plug to stop bleeding. Physiologic platelet stimuli include adenosine diphosphate (ADP), epinephrine, thrombin, and collagen. ADP and epinephrine are relatively weak platelet stimulators; thrombin and collagen are strong agonists. Thrombin activation is mediated by G protein–coupled protease-activated receptors (PAR),[1] specifically PAR-1 and PAR-4. Thrombin cleaves the external domain of the PAR to initiate transmembrane signaling [*see Figure 1*].[2] Platelet responses to ADP require the coordinated activation of two G–protein–coupled receptors, P2Y1 and P2Y12, which lead to activation of phospholipase C and suppression of cyclic adenosine monophosphate (cAMP) formation, respectively. Antiplatelet drugs such as ticlopidine and clopidogrel block activation of P2Y12.[3] There are also specific receptors for epinephrine, thromboxane A_2, and collagen.

Platelet activation involves four distinct processes: adhesion (deposition of platelets on subendothelial matrix); aggregation (cohesion of platelets); secretion (release of platelet granule proteins); and procoagulant activity (enhancement of thrombin generation) [*see Figure 2*].

ADHESION

Platelet adhesion is primarily mediated by the binding of platelet surface receptor glycoprotein (GP) Ib-IX-V complex to the adhesive protein von Willebrand factor (vWF) in the subendothelial matrix.[4] Deficiency of GPIb-IX-V complex or vWF leads to two congenital bleeding disorders, Bernard-Soulier disease and von Willebrand disease, respectively [*see 5:XIII Hemorrhagic Disorders*]. Other adhesive interactions (e.g., binding of platelet collagen receptor GPIa-IIa to collagen fibrils in the matrix) also contribute to platelet adhesion.[5]

AGGREGATION

Platelet aggregation involves binding of fibrinogen to the platelet fibrinogen receptor (i.e., the GPIIb-IIIa complex). GPIIb-IIIa (also termed aIIbb3) is a member of a superfamily of adhesive protein receptors, called integrins, which are found in many different cell types. It is the most abundant receptor on the platelet surface. GPIIb-IIIa does not bind fibrinogen on nonstimulated platelets. After platelet stimulation, GPIIb-IIIa undergoes a conformational change and is converted from a low-affinity fibrinogen receptor to a high-affinity receptor in a process termed inside-out signaling. Fibrinogen, a divalent molecule, serves to bridge the activated platelets [*see Figure 3*]. The cytosolic portion of the activated GPIIb-IIIa complex binds to the platelet cytoskeleton and can mediate platelet spreading and clot retraction (in a process termed outside-in signaling).[6] Congenital deficiency of GPIIb-IIIa or fibrinogen leads to Glanzmann thrombasthenia and afibrinogenemia. The GPIIb-IIIa–fibrinogen pathway is the final common course for platelet aggregation. Blockade of this pathway is the basis of an important class of antiplatelet drugs.

PROTEIN SECRETION

After stimulation, platelet granules release ADP and serotonin, which stimulate and recruit additional platelets; adhesive proteins such as fibronectin and thrombospondin, which reinforce and stabilize platelet aggregates; factor V, a component of the clotting cascade; thromboxane, which stimulates vasoconstriction; and growth factors such as platelet-derived growth factor (PDGF), which stimulate proliferation of smooth muscle cells and mediate

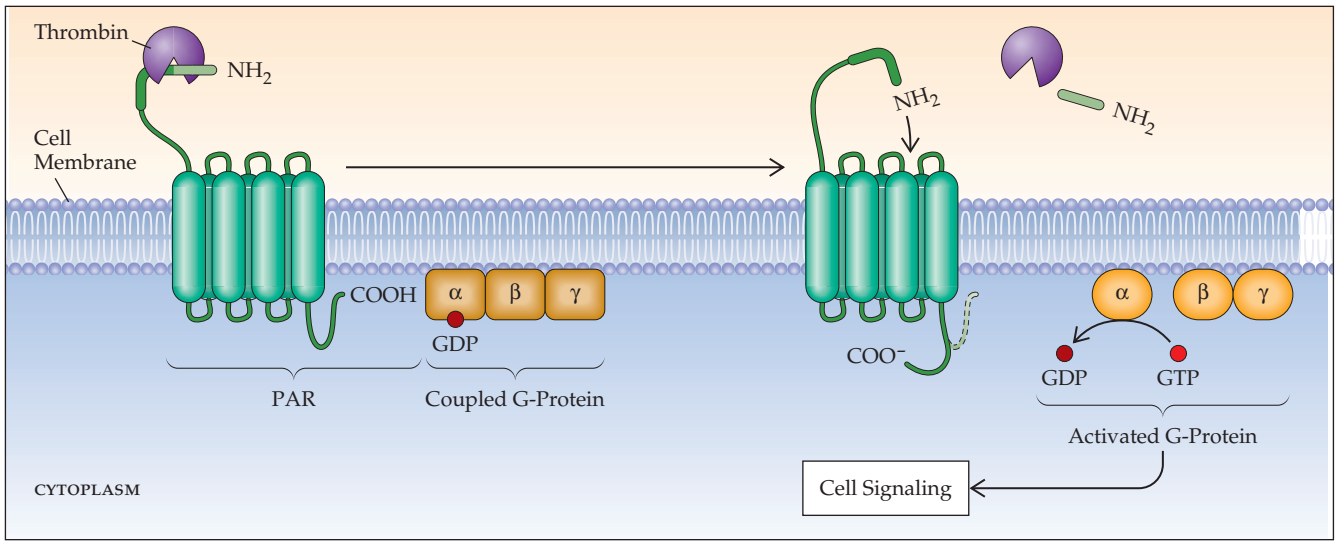

Figure 1 **Thrombin activation is mediated by G protein–coupled protease-activated receptor (PAR). Thrombin cleaves the NH_2-terminal exodomain of the PAR, exposing a new NH_2 terminus, which then serves as a tethered ligand to bind intramolecularly to the body of the receptor to initiate transmembrane signaling.**

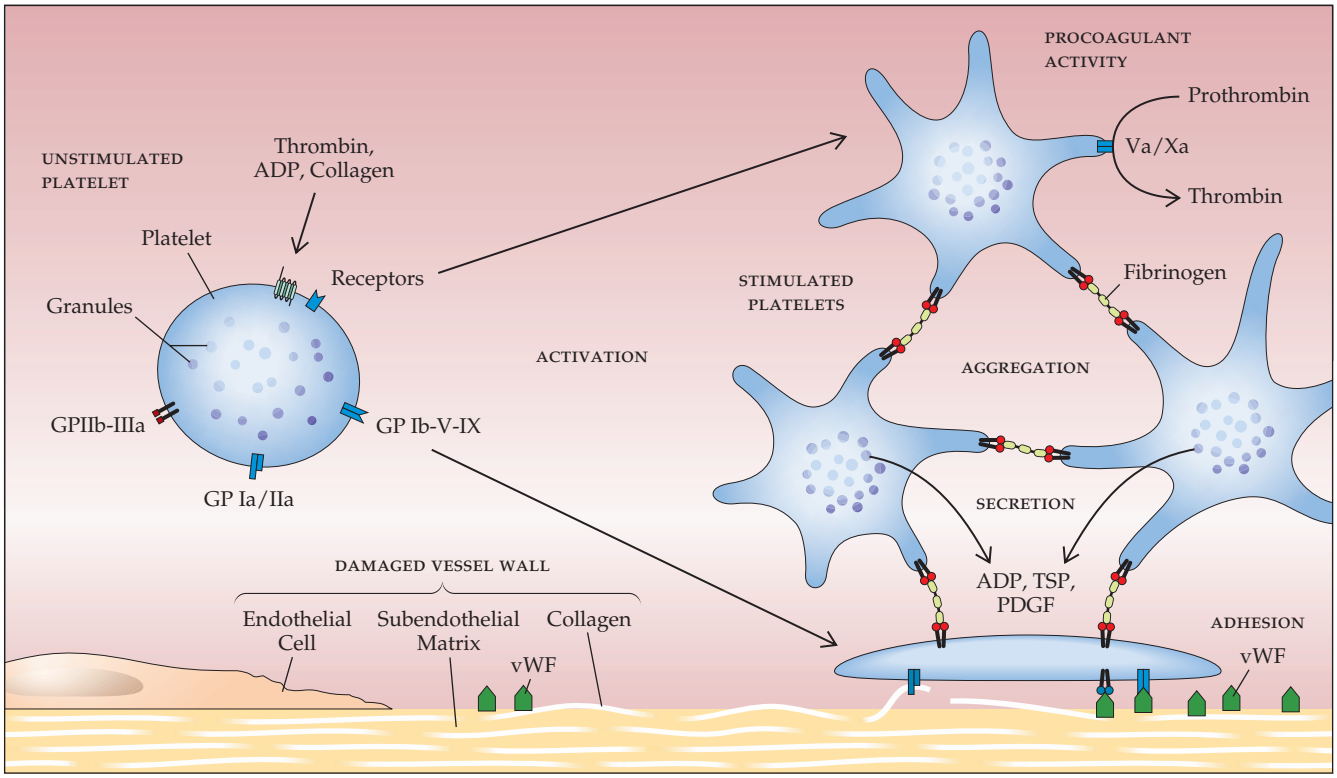

Figure 2 **After platelets are activated, they undergo significant morphologic changes, producing elongated pseudopods. They also become extremely adhesive. The functional response of activated platelets involves four distinct processes: adhesion (deposition of platelets on subendothelial matrix); aggregation (cohesion of platelets); secretion (release of platelet granule proteins); and procoagulant activity (enhancement of thrombin generation).**

tissue repair. PDGF may also contribute to the development of atherosclerosis and reocclusion after coronary angioplasty.

PROCOAGULATION

Platelet procoagulation involves the assembly of the enzyme complexes of the clotting cascade on the platelet surface. It is an important example of the close interrelationship between platelet activation and the activation of the clotting cascade.

Clotting Cascade

The central feature of the clotting cascade is the sequential activation of a series of proenzymes (zymogens) to enzymes, ultimately generating fibrin and reinforcing the platelet plug. Another key feature, amplification, ensures rapid response for effective hemostasis but demands tight regulation to prevent untoward thrombosis.

The clotting cascade is usually depicted as comprising intrinsic and extrinsic pathways [*see Figure 4*]. The intrinsic pathway is initiated by the exposure of blood to a negatively charged surface (e.g., glass), whereas the extrinsic pathway is activated by tissue factor or thromboplastin. Both pathways converge on the activation of factor X, which then activates prothrombin (factor II) to thrombin, the final enzyme of the clotting cascade.

Although this classic view of the clotting cascade has been useful in the interpretation of clotting times, it is not completely accurate. Patients who are severely deficient in factor XII—as well as many patients deficient in factor XII—do not bleed clinically, which indicates that the initiation part of the intrinsic pathway (the contact phase) is not important in vivo. It is now established that generation or exposure of tissue factor at the wound site is the primary physiologic event that initiates clotting [*see Figure 4*].[7] Tissue factor functions as a cofactor that is absolutely required by factor VII/factor VIIa to initiate clotting. Factor VIIa activates factor X directly and indirectly via the activation of factor IX. This dual pathway of factor X activation is necessary apparently because of the limited amount of tissue factor generated in vivo and the presence of the tissue factor pathway inhibitor (see below), which, when complexed with factor Xa, inhibits the tissue factor/factor VIIa complex.

All of the procoagulants are synthesized in the liver except vWF, which is synthesized in megakaryocytes and endothelial cells. The vitamin K–dependent procoagulants are prothrombin, factor VII, factor IX, and factor X; the vitamin K–dependent anticoagulants are protein C and protein S. For these factors, the formation of α-carboxyglutamic acid residues by vitamin K–dependent carboxylation of glutamic acid residues endows them with calcium-binding properties and the ability to interact with phospholipid membrane surfaces, which are required for biologic activity.[8]

INTERACTION BETWEEN ACTIVATED PLATELETS AND THE CLOTTING CASCADE

There is an extremely close interaction between the clotting cascade and activated platelet surface in vivo. When platelets are activated, anionic lipids become exposed on the platelet surface, and factor V (stored in platelet granules) is released and bound on the anionic lipids. The factor V on the platelet surface is acti-

vated to factor Va and acts as an assembly site for the binding of factor Xa (enzyme) and prothrombin (substrate) known as the prothrombinase complex. At the assembly site, thrombin generation by the prothrombinase complex is approximately 300,000 times more efficient than thrombin generation by fluid-phase factor Xa and prothrombin alone, and the platelet plug keeps the thrombin localized. Factor Xa bound on factor Va is also relatively protected from inhibition by circulating inhibitors such as antithrombin III (AT-III) (see below). Similar enzyme complex assembly applies to the activation of factor X by factor VIIIa (cofactor) and factor IXa (the intrinsic tenase). The result of these processes is efficient amplification and localization of clotting.

Control Mechanisms

Coagulation is modulated by a number of mechanisms: dilution of procoagulants in flowing blood; removal of activated factors through the reticuloendothelial system, especially in the liver; and control by natural antithrombotic pathways. At least seven separate and distinct control systems modulate each phase of hemostasis and protect against thrombosis, vascular inflammation, and tissue damage [*see Table 1*]. Antithrombin III, protein C, protein S, and tissue factor pathway inhibitor (TFPI) collectively regulate the clotting cascade; prostacyclin and nitric oxide modulate vascular and platelet reactivity; ecto-ADPase inhibits platelet recruitment; and fibrinolysis removes the fibrin clot.

ANTITHROMBIN III–HEPARAN SULFATE SYSTEM

Antithrombin III is a circulating plasma protease inhibitor. It inhibits thrombin and factor Xa, the two key enzymes in the clotting cascade. AT-III also inhibits activated factor XII and factor XI. In the absence of the glycosaminoglycan heparin, AT-III inhibits thrombin and factor Xa relatively slowly (complete inhibition requires a few minutes). When present, heparin binds to a discrete binding site on AT-III that causes a conformational change in AT-III, which then inhibits thrombin instantaneously and irreversibly. This augmentation of the inhibition of thrombin and factor Xa is the basis for the therapeutic use of heparin as an anticoagulant. Heparan sulfate proteoglycans on the luminal surface of endothelial cells appear to activate AT-III in a manner similar to that of heparin [*see Figure 5*].[9]

Thus, the endothelial surface is normally coated with a layer of AT-III that is already activated by the endogenous heparan sulfate. Because 1 ml of blood can be exposed to as much as 5,000 cm^2 of endothelial surface, the AT-III–heparan sulfate system is poised to rapidly inactivate any thrombin in the general circulation.

PROTEIN C AND PROTEIN S–THROMBOMODULIN SYSTEM

Thrombomodulin is an integral membrane protein found on the luminal surface of the vascular endothelium in the microcirculation. The binding of thrombin to thrombomodulin results in a remarkable switch in thrombin's substrate specificities: it no longer clots fibrinogen or activates platelets [*see Figure 6*]. On the other hand, it acquires the ability to activate protein C in plasma.[10] A distinct endothelial receptor for protein C has been found that enhances the activation of protein C by the thrombin-thrombomodulin complex.[11] Activated protein C degrades factor Va and factor VIIIa, the two cofactors responsible for the assembly of the prothrombinase and intrinsic tenase complex in the clotting cascade. Protein S serves as a cofactor for activated protein C. Deficiencies of AT-III, protein C, and protein S are important causes of a hypercoagulable state.

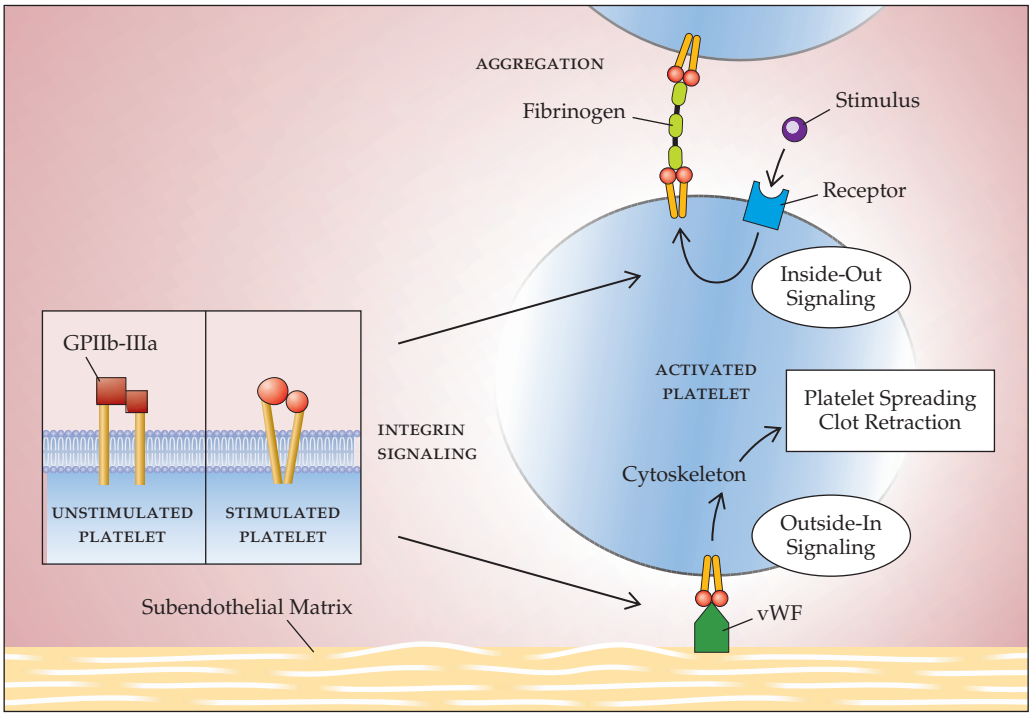

Figure 3 **Platelet aggregation involves binding of the divalent molecule fibrinogen to the platelet fibrinogen receptor (the GPIIb-IIIa complex). After platelet stimulation, GPIIb-IIIa is converted from a low-affinity fibrinogen receptor to a high-affinity receptor (inside-out signaling). The cytosolic portion of the activated GPIIb-IIIa complex can mediate platelet spreading and clot retraction (outside-in signaling).**

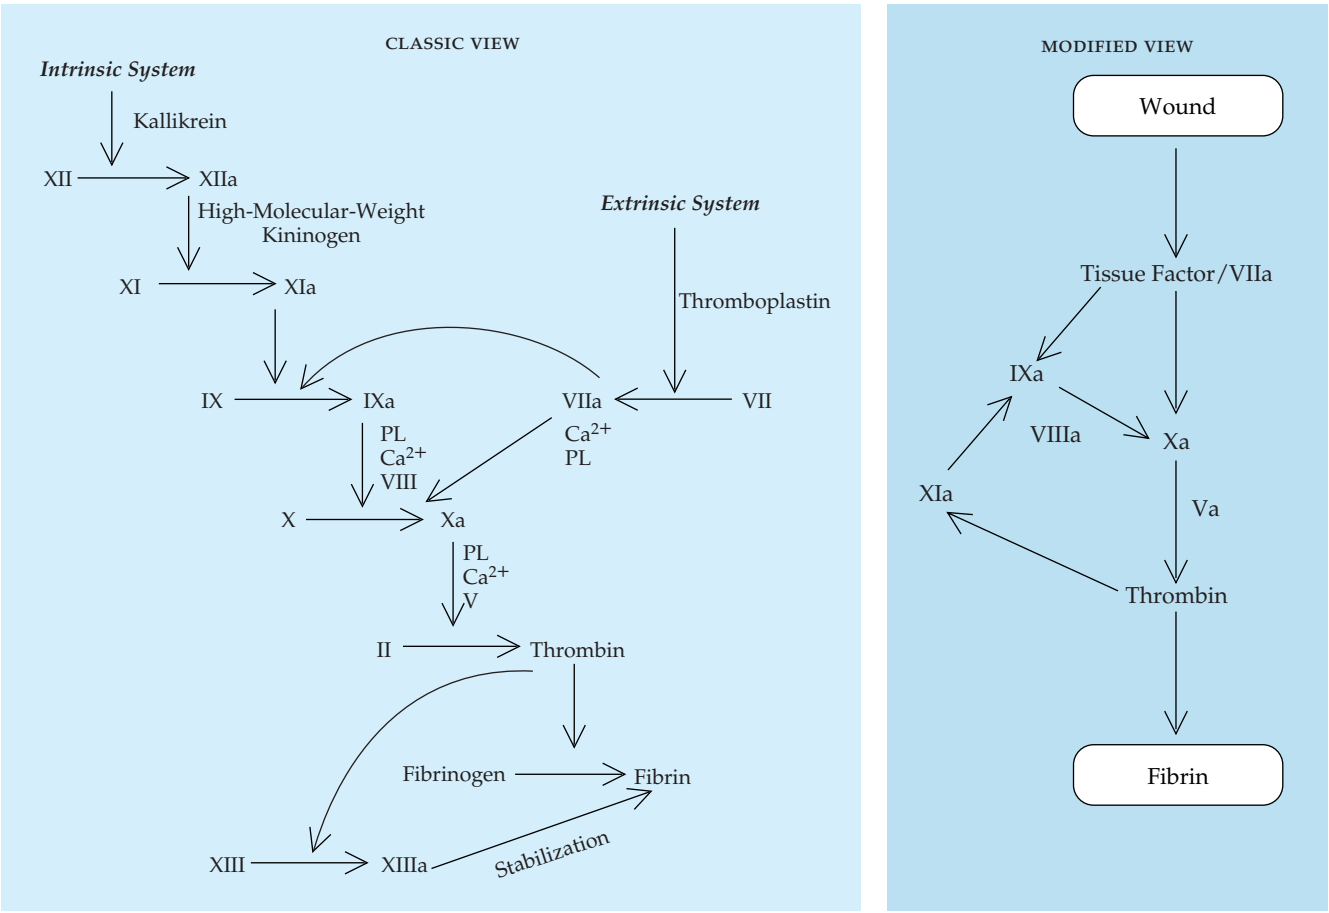

Figure 4 **In the classic view of the clotting cascade (*left*), the intrinsic pathway is initiated by the exposure of blood to a negatively charged surface (e.g., glass) and the extrinsic pathway is activated by tissue factor or thromboplastin. In the modified view (*right*), generation or exposure of tissue factor at the wound site is the primary physiologic event that initiates clotting.**

Protein C and protein S both show some structural similarity to the vitamin K–dependent clotting factors (prothrombin, factor VII, factor IX, and factor X). Protein S circulates in two forms: a free form, in which it is active as an anticoagulant, and a bound, inactive form, in which it is complexed to C4b-binding protein of the complement system. C4b-binding protein acts as an acute-phase reactant. The resultant increase in inflammatory states reduces the activity of free protein S, enhancing the likelihood of thrombosis.

TISSUE FACTOR PATHWAY INHIBITOR

Tissue factor pathway inhibitor is a circulating plasma protease inhibitor that is synthesized by the microvascular endothelium. Unlike AT-III, TFPI has a very low plasma concentration. TFPI inhibits factor Xa. The TFPI/factor Xa complex becomes an effective inhibitor of tissue factor/factor VIIa, thus mediating feedback inhibition of tissue factor/factor VIIa [*see Figure 7*]. Animal studies have shown that depletion of the endogenous TFPI sensitizes the animals to the development of disseminated intravascular coagulation induced by tissue factor or endotoxin.[12]

TFPI is primarily synthesized by the microvascular endothelium. Approximately 20% of TFPI circulates in plasma associated with lipoproteins; the majority remains associated with the endothelial surface, apparently bound to the cell-surface glycosaminoglycans. The plasma level of TFPI is greatly increased after intravenous administration of heparin. This release of endothelial TFPI may contribute to the antithrombotic efficacy of heparin and low-molecular-weight heparin. Recombinant TFPI is now in early clinical trials.[13]

PROSTACYCLIN

Upon cell perturbation, the fatty acid arachidonic acid is released from cell membrane phospholipids by phospholipase A_2. The enzyme prostaglandin endoperoxide H synthase-1 (PGHS-1) converts arachidonic acid into prostaglandin endoperoxides

Table 1 Natural Antithrombotic Mechanisms of Endothelial Cells

Regulation of clotting cascade	Tissue factor pathway inhibitor Antithrombin III Protein C/Protein S
Modulation of vessel and platelet reactivity	Prostacyclin Nitric oxide
Inhibition of platelet recruitment	Ecto-ADPase (CD39)
Removal of fibrin clot	Fibrinolysis

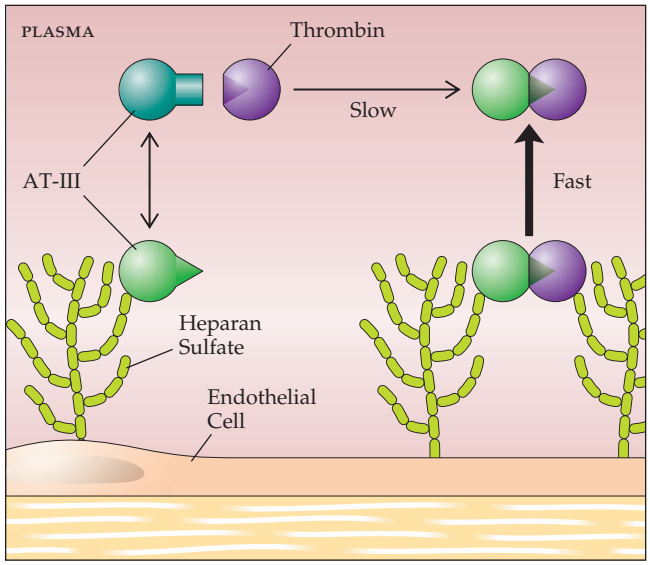

Figure 5 **In the absence of heparan sulfate (HS), antithrombin III (AT-III) inhibits thrombin slowly. When HS is present, it binds to a specific site on AT-III that causes a conformational change in AT-III, allowing it to reach the active site of thrombin and inhibit the enzyme instantaneously. HS also binds to a specific site on thrombin, positioning it for optimal inhibition by AT-III.**

and finally to thromboxane A_2 (TXA_2) in platelets and prostacyclin (PGI_2) in endothelial cells. TXA_2 and PGI_2 have opposite functions. TXA_2 is a potent stimulator of platelet aggregation and causes vasoconstriction, whereas PGI_2 inhibits platelet aggregation and induces vasodilatation. PGI_2 functions by activating adenylate cyclase, which leads to an increase in intracellular cAMP [*see Figure 8*].

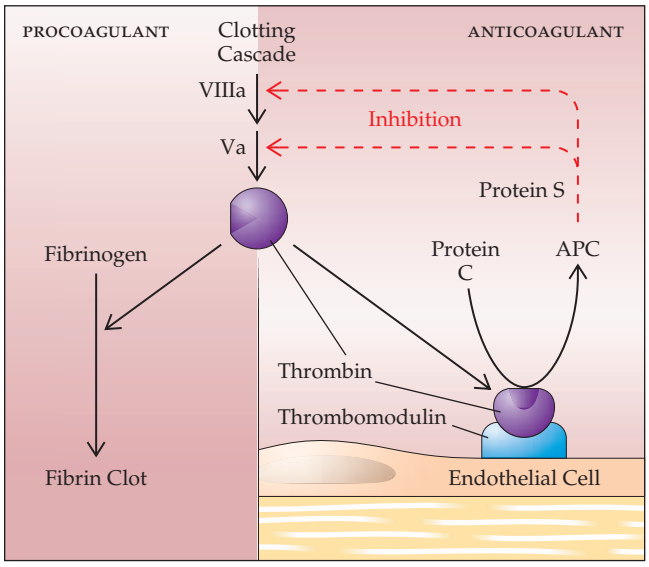

Figure 6 **The protein C/protein S pathway is complementary to the AT-III pathway. When thrombin binds to thrombomodulin, thrombin undergoes a conformational change and no longer clots fibrinogen or activates platelets. However, it acquires the ability to activate protein C in plasma. Protein S serves as a cofactor for activated protein C. Activated protein C degrades activated factors V and VIII, the two cofactors in the clotting cascade.**

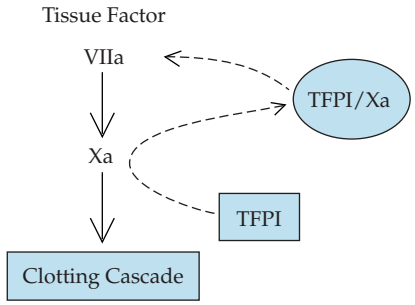

Figure 7 **Tissue factor pathway inhibitor (TFPI) binds to and inhibits factor Xa. After binding to factor Xa, TFPI undergoes a conformational change. The TFPI/factor Xa complex then mediates feedback inhibition of tissue factor/factor VIIa.**

Cyclooxygenase-1 and Cyclooxygenase-2

Cyclooxygenase-1 (COX-1) is the constitutive isoform of PGHS. Cyclooxygenase-2 (COX-2) is an inducible isoform of PGHS. COX-2 is undetectable in most tissues. However, it can be rapidly induced in response to growth factors, endotoxins, and cytokines in endothelial cells and monocytes (although not in platelets).[14] Recent evidence indicates that endothelial COX-2 is a major source of PGI_2 under physiologic conditions in humans, perhaps because of continual COX-2 induction by hemodynamic shear in the circulation.[15] Aspirin acetylates and irreversibly inhibits both COX-1 and COX-2. Other nonsteroidal anti-inflammatory drugs (NSAIDs) also inhibit COX-1 and COX-2, although not permanently. Selective COX-2 inhibitors are now available as a new generation of NSAIDs.[16]

Because aspirin irreversibly inhibits COX-1 and because platelets cannot make new COX-1, brief exposure to aspirin will permanently inhibit TXA_2 production for the life span of affected platelets.

NITRIC OXIDE

Nitric oxide (NO) is formed from L-arginine in endothelial cells. NO stimulates guanylate cyclase, leading to an increase in cyclic guanosine monophosphate (cGMP) in target cells; causes vasodilatation; and inhibits platelet adhesion and aggregation [*see Figure 8*].[17] NO is rapidly destroyed by hemoglobin and thus functions as a local (i.e., paracrine) hormone. Intravenous infusion of an arginine analogue that blocks NO production leads to an immediate and substantial rise in blood pressure. This phenomenon suggests that NO is released continually and basally to regulate vascular tone (in contrast to the production of PGI_2, which is more stimulus-responsive). There is significant synergism between NO and PGI_2. Formation of NO is catalyzed by NO synthases, which exist in different isoforms in various tissues. In addition to regulating vascular events, NO has a wide range of biologic effects (e.g., neurotransmittal function in the central nervous system).

ECTO-ADPase (CD39)

CD39 is an integral membrane protein found on the endothelial cell surface. It is an active enzyme that rapidly hydrolyzes ADP to AMP, thus functioning as a cell-bound ecto-ADPase. It limits the recruitment of additional platelets into the growing platelet plug by removing ADP released from the dense granules of activated platelets and from damaged erythrocytes and endothelial cells.[18]

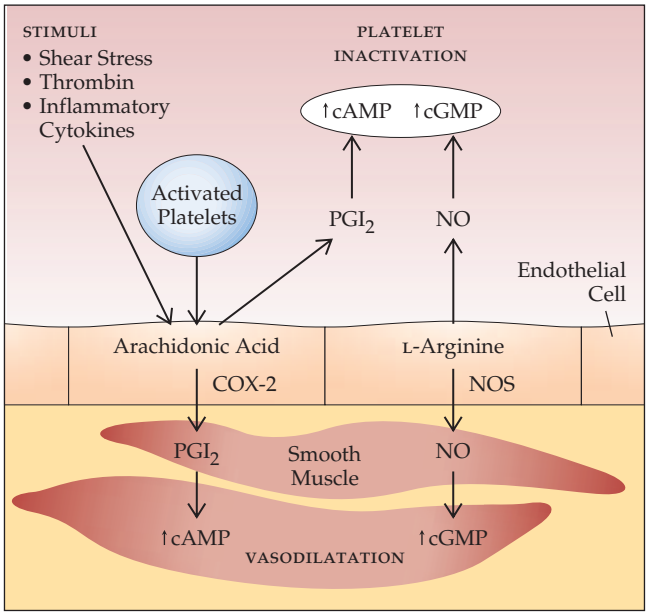

Figure 8 **Significant synergism exists between nitric oxide (NO) and prostacyclin (PGI_2), leading to platelet inactivation and vasodilatation. The enzyme prostaglandin endoperoxide H synthase–1 (PGHS-1) converts arachidonic acid into PGI_2 in endothelial cells. PGI_2 activates adenylate cyclase, which leads to an increase in intracellular cyclic adenosine monophosphate (cAMP), inhibiting platelet aggregation and inducing vasodilatation. NO, formed from L-arginine, stimulates production of cyclic guanosine monophosphate (cGMP). Cyclooxygenase-2 (COX-2) is the induced isoform of PGHS; its formation presumably results from hemodynamic shear in the circulation. NO formation is catalyzed by NO synthases (NOS).**

FIBRINOLYSIS

Tissue plasminogen activator (t-PA) is released from perturbed endothelial cells near the site of vascular injury. t-PA converts plasminogen to plasmin. Like the AT-III interaction with thrombin, which is accelerated in the presence of endothelial cell surface heparan sulfate, generation of plasmin takes place optimally on a surface (in this case, the fibrin clot). Both t-PA and plasminogen bind to fibrin (via recognition of lysine residues), which facilitates plasmin generation and localized fibrinolysis [*see Figure 9*].

Plasmin cleaves the polymerized fibrin strand at multiple sites, releasing fibrin degradation products. One of the major fibrin degradation products is D-dimer, which consists of two D domains from adjacent fibrin monomers that have been cross-linked by activated factor XIII [*see Figure 10*]. Plasmin has a broad substrate specificity and, in addition to fibrin, cleaves fibrinogen and a variety of plasma proteins and clotting factors. Plasmin bound on the fibrin clot is protected from inactivation, whereas plasmin released into the circulation is rapidly inactivated by plasma α_2-antiplasmin. Thus, localized fibrinolysis is achieved, but nonspecific plasmin degradation of plasma proteins is prevented. In rare cases, patients have bleeding problems caused by a congenital deficiency in α_2-antiplasmin.

Urokinase is the second physiologic plasminogen activator. It is present in high concentration in the urine. Although t-PA is largely responsible for initiating intravascular fibrinolysis, urokinase is the major activator of fibrinolysis in the extravascular compartment. Urokinase is secreted by many cell types in the form of prourokinase, also termed single-chain urokinase-type plasminogen activator (scu-PA). Prourokinase is converted to urokinase by plasmin. Urokinase lacks fibrin specificity in converting plasminogen to plasmin, whereas prourokinase displays such specificity.

The major physiologic inhibitor of t-PA and urokinase plasminogen activator (u-PA) is plasminogen activator inhibitor-1 (PAI-1).[19] Substantial amounts of PAI-1 are found in platelets. PAI-1 is also released from endothelial cells. PAI-1 deficiency is associated with bleeding diathesis, usually related to trauma or surgery.[20] A second inhibitor, PAI-2, is normally secreted by monocytes. During pregnancy, PAI-2 levels are greatly increased because of synthesis by the placenta. The biologic importance of PAI-2 remains to be established.

Thrombin-Activatable Fibrinolysis Inhibitor

Plasma carboxypeptidase is a newly recognized thrombin-activatable fibrinolysis inhibitor (TAFI) [*see Figure 11*].[21,22] TAFI is the second known physiologic substrate for the thrombin-thrombomodulin complex. One may envisage that after the initial fibrin clot is formed by thrombin at the site of a vascular wound, thrombin binds to thrombomodulin on the nearby intact endothelial surface. The thrombomodulin-bound thrombin leads to the generation of activated protein C, which dampens the clotting cascade and prevents excessive thrombin generation. At the same time, the thrombomodulin-bound thrombin activates TAFI, thus slowing down the lysis of the existing clot. In hemophilia, the decreased generation of thrombin may lead to suboptimal activation of TAFI and result in premature clot lysis, which contributes to the delayed bleeding observed in these patients.[22] Whether excessive TAFI activity leads to thrombosis is unknown at present.

Overview of Blood Coagulation

The clotting cascade is initiated by the exposure of tissue factor at a vascular wound, which leads to the generation of thrombin and the deposition of a fibrin clot [*see Figure 12*]. Simultaneously, the damaged endothelium releases t-PA, which converts plasminogen to plasmin, which then lyses the clot.

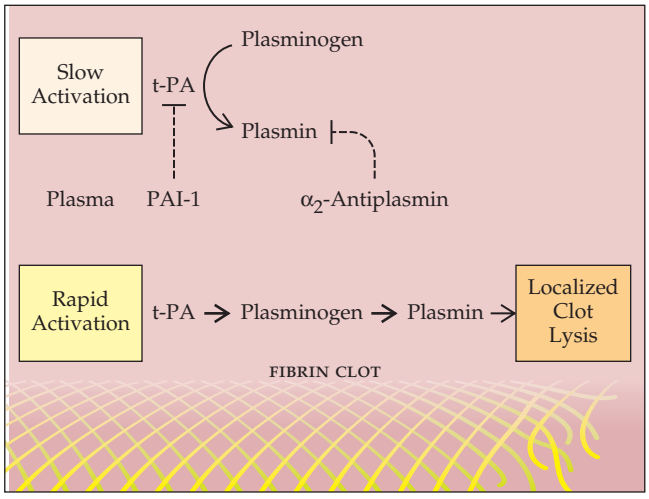

Figure 9 **Tissue-type plasminogen activator (t-PA), released from perturbed endothelial cells near an injured blood vessel, converts plasminogen to plasmin. Free plasmin is rapidly inactivated by plasma α_2-antiplasmin; plasmin bound to the fibrin clot is protected from inactivation.**

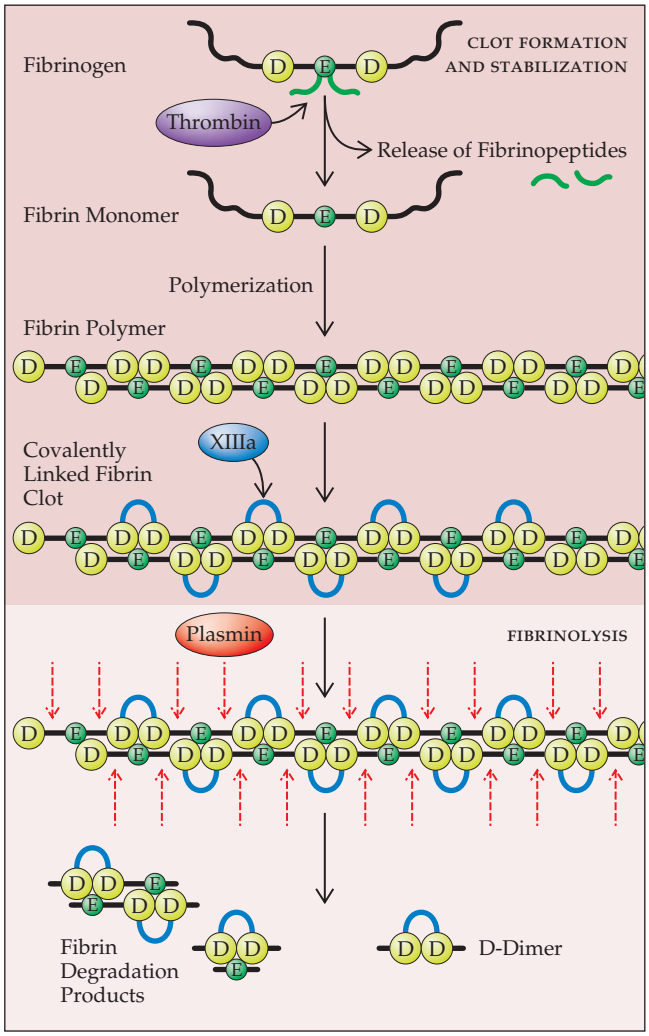

Figure 10 **The transformation of fibrinogen to fibrin is initiated by thrombin cleavage of fibrinopeptides A and B from the E domains of fibrinogen to form fibrin monomer. The cleavage apparently changes the overall negative charge of the E domain to a positive charge. This change in charge permits the spontaneous polymerization of fibrin monomers, because the positively charged E domain assembles with the negatively charged D domains of other monomers. The polymer is initially joined by hydrogen bonds. Thrombin activates factor XIII, which catalyzes the formation of covalent bonds between adjacent D domains in the fibrin polymer. Plasmin cleaves the polymerized fibrin strand at multiple sites and releases fibrin degradation products, including D-dimer.**

Both pathways are regulated: TF/factor VIIa is regulated by the TFPI/factor Xa complex, and thrombin is regulated by protein C and protein S. Similarly, the activity of t-PA is regulated by PAI-1. Thrombin and plasmin are under the control of their respective inhibitors, AT-III and α_2-antiplasmin. When these two pathways work in coordinated symmetry, a clot is laid down to stop bleeding, and clot lysis and tissue remodeling follow. Diminished thrombin generation (as in factor VIII deficiency) or enhanced plasmin production (as in α_2-antiplasmin deficiency) causes hemorrhage [*see 5:XIII Hemorrhagic Disorders*]. Conversely, excessive production of thrombin (as in AT-III or protein C deficiency) leads to thrombosis [*see 5:XIV Thrombotic Disorders*].

Heterogeneity of Endothelial Cells and Vascular Bed–Specific Hemostasis

Although the endothelium is generally considered to be a distinct, homogeneous organ system, there are significant differences between arterial, venous, and capillary endothelial cells in terms of morphology and disease susceptibility. Recent studies have shown distinct sets of proteins that mark the arterial and venous endothelial cells from the earliest stages of angiogenesis. Ephrin-B2, an Eph family transmembrane ligand, marks arterial but not venous endothelial cells. Conversely, Eph-B4, a receptor tyrosine kinase for ephrin-B2, marks veins but not arteries.[23]

It is also likely that endothelia from different vascular beds are not identical.[24] For example, the high endothelium in the postcapillary venules of lymph nodes and Peyer patches regulates the circulation of lymphocytes from blood to lymphatics and peripheral tissues. Specific adhesive protein receptors and matrix proteins are highly expressed in these high endothelial venules. The specialized endothelium representing the blood-brain barrier is another example.

These differences between arterial and venous endothelial cells and the vascular bed–specific endothelium may partly account for their different susceptibilities to thrombosis. For example, whereas AT-III and protein C deficiencies are usually associated with deep vein thrombosis of the lower extremities, thrombosis of portal and hepatic veins is frequently associated with myeloproliferative diseases.[25] In both conditions, the underlying defect is a systemic hypercoagulable state, and yet there is a clear predisposition of thrombosis to specific vascular beds. Thus, clinical thrombosis is attributable to an imbalance between systemic prothrombotic stimuli and local antithrombotic mechanisms [*see 5:XIV Thrombotic Disorders*].

Platelet Production and Thrombopoietin

Platelets are derived from megakaryocytes, which arise from pluripotent myeloid stem cells. Platelet production is controlled

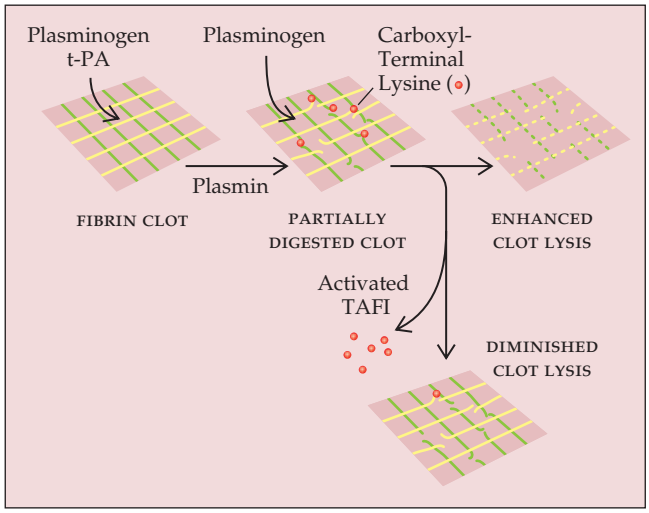

Figure 11 **Plasma carboxypeptidase is a thrombin-activatable fibrinolysis inhibitor (TAFI). When fibrin is degraded by plasmin, new carboxyl-terminal lysines are exposed in the partially digested clot. These lysines provide additional sites for plasminogen incorporation and activation in the clot, setting up a positive feedback loop in clot lysis. Thrombin activates carboxypeptidase-B in plasma, which removes the exposed carboxyl-terminal lysines and prevents further plasminogen incorporation into the clot.**

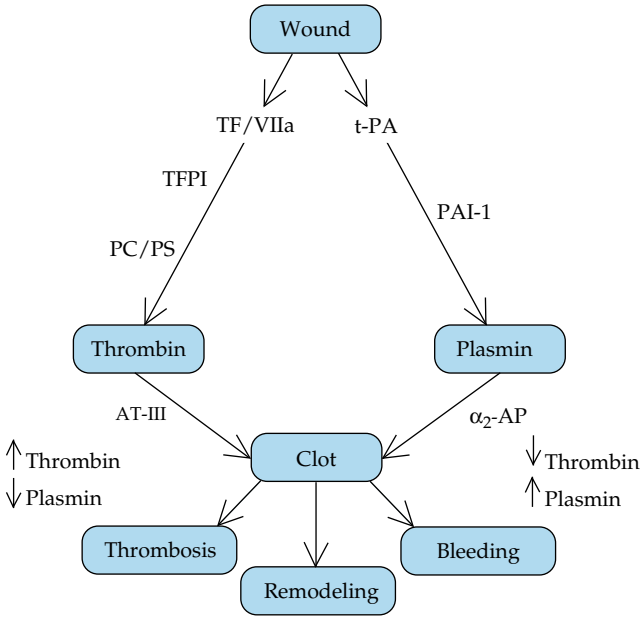

Figure 12 **Exposure of tissue factor at a vascular wound initiates the clotting cascade. Generation of thrombin and deposition of a fibrin clot occur simultaneously with release of t-PA from the damaged epithelium and conversion of plasminogen to plasmin. Plasmin then lyses the clot. When these two pathways work in coordinated symmetry, a clot is laid down to stop bleeding, and clot lysis and remodeling follow. (α_2-AP—α_2-antiplasmin; AT-III—antithrombin III; PAI-1—plasminogen activator inhibitor–1; PC/PS—protein C/protein S; TF—tissue factor; TFPI—tissue factor pathway inhibitor; t-PA—tissue-type plasminogen activator)**

by a thrombopoietin that is involved in the final maturation of the megakaryocyte. Thrombopoietin has multiple actions in megakaryocyte development.[26] It shares some structural homology with erythropoietin and is produced principally by the liver. It increases the size and number of megakaryocytes, stimulates the expression of platelet-specific markers, and is a potent megakaryocyte colony-stimulating factor. Although thrombopoietin is clearly a key factor, stem cell factor (also called kit ligand), interleukin-3 (IL-3), IL-6, and IL-11 all play contributory roles in controlling megakaryocytopoiesis.

Megakaryocytes undergo endomitosis, in which nuclear divisions occur without cell division and are followed by nuclear fusion, to yield a cell with a chromosomal content of 8n, 16n, or 32n. The megakaryocyte cytoplasm then changes into a series of thin, cylindrical strands that eventually fragment into small pieces of megakaryocytes, called proplatelets, that are released into the circulation. Megakaryocyte volume correlates with ploidy and cytoplasmic maturity; the largest megakaryocytes produce the greatest number of platelets. Large platelets called megathrombocytes are seen in the peripheral blood in thrombocytopenic states, especially in idiopathic thrombocytopenic purpura [*see 5:XIII Hemorrhagic Disorders*]. These megathrombocytes probably are young proplatelets and account for the increase in mean platelet volume that occurs during response to or recovery from acute thrombocytopenia.

Platelets entering the circulation survive about 8.5 to 10 days and have a half-life of about 4 days. Approximately 30% to 40% of the platelets are present in a splenic pool that can freely exchange with the circulation. When the need for platelets arises, production can increase sevenfold to eightfold. Because there is no marrow pool of platelets waiting to be released, meeting increased requirements for platelets may require a few days. Platelets have receptors for thrombopoietin and remove it from plasma, and the platelet mass functions as a major thrombopoietin regulator.[27] In states of megakaryocyte hypoplasia and thrombocytopenia, little thrombopoietin is metabolized and the plasma thrombopoietin level rises, leading to increased production of megakaryocytes and platelets. In the setting of thrombocytosis, thrombopoietin metabolism increases, lowering the plasma thrombopoietin level and decreasing platelet production.

Coagulation Tests and Their Use

TESTS OF COAGULATION CASCADE

Most coagulation tests measure the time required for fibrinogen from plasma to form fibrin strands, which can be detected by either optical or electrical devices. Prolongation may represent a low factor concentration, inactive factor or factors, or the presence of inhibitors.

Partial Thromboplastin Time

The partial thromboplastin time (PTT), sometimes termed the activated PTT (aPTT), tests the intrinsic coagulation system. A negatively charged surface (e.g., kaolin or silica), followed by cephalin, is added to whole plasma to activate factors XII and XI. The PTT is most sensitive to abnormalities and deficiencies in the sequence of the coagulation cascade before factor X activation. The PTT is also quite sensitive to the action of heparin. It is used to monitor and adjust anticoagulant therapy with regular heparin but not with low-molecular-weight heparins.

Prothrombin Time

The prothrombin time (PT) is a test of the extrinsic system. It detects deficiencies in fibrinogen, factor II (prothrombin), factor V, factor VII, and factor X. Tissue factor is added to whole plasma, leading to fibrin formation, normally in 9 to 12 seconds. Results are usually reported using the international normalized ratio (INR). The INR is calculated by using the following equation:

$$\text{INR} = (\text{Log patient PT} \,/\, \text{Log control PT})^{C}$$

where C represents the international sensitivity index (ISI). In this way, the thromboplastin used in an individual laboratory, with its specific ISI, is calibrated against a standard reference thromboplastin, and the PT is reported as an INR.[28] The presence of a lupus anticoagulant may also interfere with the PT.[29]

Dilute Russell Viper Venom Time

Russell viper venom contains an enzyme that activates factor X; therefore, the dilute Russell viper venom time (DRVVT) measures the common pathway of the clotting cascade. It is sensitive to the presence of a lupuslike anticoagulant that inhibits the phospholipid-dependent prothrombinase complex.

Thrombin Time

The thrombin time (TT) is used to test abnormalities of the conversion of fibrinogen to fibrin. It can be prolonged because of hypofibrinogenemia, abnormal fibrinogen (dysfibrinogen), or the presence of inhibitors (e.g., fibrin degradation products) that interfere with fibrin polymerization. The clinical factors com-

monly associated with prolonged TT are severe liver disease, disseminated intravascular coagulation, and heparin therapy.

Reptilase Time

Reptilase is a thrombinlike enzyme that converts fibrinogen to fibrin. The reptilase time (RT) is prolonged under conditions similar to those for prolonged TT, with one significant difference: reptilase is not inhibited by the AT-III–heparin complex. Therefore, RT is not prolonged by heparin. A long thrombin time and normal RT suggest a heparin effect.

Fibrinopeptide A

Thrombin activates fibrinogen by splitting off two peptides, fibrinopeptide A (FPA) and FPB, from the Aα and Bβ chain of fibrinogen and converting fibrinogen to fibrin monomer. Measurement of FPA in the blood can be used as an index of thrombin activity in vivo. Because the clotting cascade can be activated during the blood-sample collection, however, precautions are required in the measurement and interpretation of FPA levels.

Fibrinogen

The fibrinogen level in plasma can be measured either antigenically or more commonly by clotting assays. The results are reported in mg/dl.

D-Dimer and Fibrin-Fibrinogen Degradation Products

Fibrinogen degradation products (FDP) and fibrin-fibrinogen split products (FSP) result from plasmin degradation of fibrinogen and fibrin clot [*see Figure 9*]. D-dimer is released by the plasmin-mediated degradation of fully polymerized fibrin. Plasmin cleavage of fibrinogen or soluble fibrin monomer does not yield the D-dimer. Thus, elevated D-dimer is a specific measure of intravascular fibrin deposition and plasmin degradation characteristic of disseminated intravascular coagulation. The D-dimer test has largely replaced the FSP test.

Factor XIII

Factor XIII is the only clotting factor whose activity is not assessed in PT or PTT because the end point for both tests is the formation of fibrin polymers, irrespective of whether these polymers are cross-linked covalently by activated factor XIII. Factor XIII deficiency may be suspected in an infant who has significant bleeding after circumcision or, more rarely, in an adult patient who has unexplained bleeding.

Plasminogen and α_2-Antiplasmin

The activation of the plasminogen-plasmin system can be inferred from the findings of a long TT, a low plasma fibrinogen level, and an elevated D-dimer level. Another crude test used to measure plasminogen-plasmin activation is the euglobulin lysis time. The sensitivity and specificity of this test is not well defined, however. During extensive thrombosis and fibrinolysis, both plasminogen and α_2-antiplasmin (the physiologic inhibitor of plasmin) are consumed. The direct measurement of plasma levels of plasminogen and α_2-antiplasmin is sometimes useful to assess the extent of fibrinolysis and the requirement for replenishment of these plasma proteins using fresh frozen plasma.

TESTS OF PLATELETS AND OF PLATELET FUNCTION

Peripheral Blood Smear Evaluation

This examination provides quick, definitive information to confirm or question a platelet count. Normally, there are eight to 12 platelets per high-power field (1,000 × magnification), corresponding to a normal platelet count of 150,000 to 300,000/ml. The smear also shows platelet granularity and whether megathrombocytes are present.

Bleeding Time

This test primarily measures platelet function. A spring-loaded device is used to make a standard skin incision on the forearm. A prolonged bleeding time with platelets greater than 100,000/ml suggests impaired function. The bleeding time is difficult to standardize, and a normal bleeding time does not predict the safety of surgical procedures or accurately predict hemorrhage.[30] It should not be used as a general screening test in a preoperative setting. Although once used in the screening of patients for von Willebrand disease or certain platelet function disorders, for these purposes bleeding time has been largely replaced by the platelet function–100 assay (PFA-100).

Platelet Function Assay–100

PFA-100 is a newly developed automated test for platelet function. Citrated whole blood is aspirated through a capillary tube under high shear onto a membrane coated with collagen and epinephrine or collagen and ADP in which a central aperture is made. The time it takes for blood flow through the membrane to stop is denoted as closure time and is a measure of platelet function. The closure time is prolonged in patients with von Willebrand disease or other platelet functional defects.[31] PFA-100 should be considered the first-line test for platelet function disorders.

Platelet Aggregometry

Platelet aggregometers are photometric devices for recording the transmission of light through a suspension of platelets. When platelets aggregate, light passes through the suspension more readily. To test aggregation, dilute concentrations of platelet agonists (e.g., ADP, epinephrine, collagen, and ristocetin) are added to citrated platelet-rich plasma. With the weak agonists, such as ADP and epinephrine, the initial primary wave of aggregation is followed by a secondary wave. The secondary wave reflects the induction of the platelet release reaction, in which platelet granule contents are released to augment further platelet aggregation. A suboptimal secondary wave is seen with platelet storage pool defects in which either platelet granule content is diminished or its release activity is impaired. The latter is commonly associated with aspirin intake or uremia-related thrombocytopathy. Patients with von Willebrand disease will have a suboptimal platelet aggregation response to ristocetin but a normal response to the other agonists. Platelet aggregation testing is labor intensive and expensive and should be performed only in clinical coagulation laboratories that do this test regularly.

TESTS OF INHIBITORS OF HEMOSTASIS

Mixing Studies

A prolonged clotting time (e.g., PTT of 60 seconds [normal, 28 to 30 seconds]) can be caused by either a clotting factor deficiency or an inhibitor. An inhibitor is generally an antibody directed against a specific clotting factor or against a phospholipid-protein complex, the so-called lupus anticoagulant [*see 5:XIV Thrombotic Disorders*]. In a mixing study, one volume of a patient's plasma is mixed with an equal volume of normal plasma. The resulting mixture will provide at least 50% of a deficient factor and

correct the abnormality. If the problem is caused by an inhibitor, the resulting plasma mixture still has a prolonged clotting time. A mixing study should always be done when a prolonged clotting time is noted.

Antithrombin III

Bioassays and immunoassays are available for assessing AT-III activity. A functional assay is preferable to an antigenic assay.

Protein C and Protein S

Functional and immunologic methods are available. Because protein C and protein S are vitamin K dependent, their measurement can be problematic in patients taking warfarin. It is best to measure protein C or protein S when the patient has been off warfarin for 3 to 4 weeks.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XIII PLATELET AND VASCULAR DISORDERS

Lawrence L. K. Leung, m.d.

Bleeding or bruising that is spontaneous or excessive after tissue injury may be caused by abnormal platelet number or function, abnormal vascular integrity, coagulation defects, fibrinolysis, or a combination of these abnormalities. This chapter addresses hemorrhagic disorders associated with quantitative or qualitative platelet abnormalities and disorders associated with blood vessels. Hemorrhagic disorders associated with abnormalities in coagulation (e.g., von Willebrand disease and hemophilia) are covered elsewhere [*see 5:XV Coagulation Disorders*].

Approach to the Patient with a Bleeding Disorder

A bleeding disorder may be suspected when a patient complains of excessive bruising or bleeding that often occurs secondary to trauma. The clinical evaluation of a patient with a suspected bleeding disorder begins with a careful history. Assessment of the presenting complaint may suggest where in the hemostatic process a defect is located and whether the defect is inherited or acquired—information that contributes to a rational approach to laboratory evaluation.

PATIENT HISTORY

Bleeding History

Patients suspected of having a bleeding disorder should be questioned about past bleeding problems, bleeding outcomes after surgeries and tooth extractions, character of menses, and dietary habits that might predispose to deficiencies of vitamin K, vitamin B_{12}, and folic acid. The patient should also be questioned about sexual activity, anemia, transfusions, recurrent infections, connective tissue diseases, malignancies, liver and kidney diseases, immunocompromised states, and drug use [*see* Medication History, *below*].

Many healthy people consider their bleeding and bruising to be excessive, whereas patients with underlying von Willebrand disease, the most common hereditary bleeding disorder, often fail to identify their bleeding symptoms.[1] Given the variability in patients' perceptions of bleeding, as well as the lack of a uniform clinical measure of bleeding severity, a dialogue between the patient and the physician is essential for the evaluation of a bleeding disorder. It is therefore necessary to ask for specific information from patients about bleeding and bruising: (1) If the patient is easily bruised, what size are the bruises? (2) If the patient has had surgery, were blood transfusions needed? (3) If the patient had a wisdom tooth extracted, were return visits required for packing, suturing, or transfusion? The response to trauma is an excellent screening test. A history of surgical procedures, tooth extractions, or significant injury without abnormal bleeding is good evidence against the presence of an inherited hemorrhagic disorder.

The type of bleeding is informative and may suggest the underlying disorder [*see Table 1*]. Active bleeding can be caused by a localized anatomic lesion or an underlying bleeding diathesis. Mucosal bleeding, with recurrent epistaxis, gum bleeding, ecchymoses, and menorrhagia, is suggestive of von Willebrand disease or other platelet disorders. Deep-tissue bleeding (e.g., hemarthrosis and painful muscle hematomas) is more commonly seen in hemophilia and clotting factor deficiencies. Patients with clotting factor deficiencies may have delayed bleeding, presumably because the initial platelet thrombus provides immediate hemostasis but is not properly stabilized by the fibrin clot.

Medication History

A careful history of medication use is a critical aspect of the diagnostic evaluation. The patient should be questioned about use of recreational drugs, prescribed medications, over-the-counter medications, and herbal products. Aspirin use is of particular importance. Aspirin can partially impair platelet function and trigger bleeding symptoms in a patient with mild underlying von Willebrand disease. Because several hundred drug formulations contain aspirin (often with no indication of aspirin content in the product name), identification of aspirin as the cause of a hemorrhagic disorder can be difficult.

LABORATORY EVALUATION

The laboratory evaluation begins with general screening tests, such as platelet count, bleeding time (BT), prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin time (TT). These tests are supplemented with specific tests that define platelet or clotting factor abnormalities. Specific tests include examination of the peripheral blood smear; platelet aggregation in response to adenosine diphosphate (ADP), epinephrine, collagen, and ristocetin; platelet release assays; coagulation factor assays; and assessment of factor XIII activity via clot solubility testing [*see 5:XII Hemostasis and Its Regulation*].

In many patients with a bleeding disorder, the likely diagnosis will be suggested from the history and physical examination; the diagnosis can then be confirmed with the appropriate specific tests. When the diagnosis is not immediately apparent, three initial tests should be performed: platelet count, PT, and aPTT. The pattern of results provided by these tests suggests a diagnosis that can then be confirmed with specific testing [*see Table 2*].

Both the PT and aPTT provide a global assessment of the clotting cascade: the PT measures the extrinsic pathway, and the aPTT measures the intrinsic pathway [*see 5:XII Hemostasis and Its Regulation*]. Prolongations of both the PT and the aPTT suggest a clotting defect in the final common portion of the cascade that involves either factor X, factor V, prothrombin, or fibrinogen.

A prolonged PT with a normal aPTT is most commonly seen in a patient taking warfarin; in the absence of warfarin, these test results will indicate either factor VII deficiency or, more rarely, an inhibitor against factor VII.

A prolonged aPTT with a normal PT has a broader differential diagnosis. This combination of test results may denote the presence of an inhibitor against a clotting factor or a deficiency of one of the clotting factors in the intrinsic pathway. It is important to perform a repeat aPTT with equal volumes of the patient's plasma and normal plasma (a mixing study). If the normal plasma does not correct the prolonged aPTT, an inhibitor exists (e.g., a lupuslike anticoagulant or an inhibitor directed against a specific clotting factor). If the normal plasma corrects the prolonged aPTT, the patient has a clotting factor deficiency involving factor XII, factor XI, factor VIII, factor IX, or, more rarely, prekallikrein

Table 1 Clinical Manifestations of Hemorrhagic Disorders

Manifestation	*Bleeding Disorder*	
	Platelet Defect	*Clotting Factor Deficiency*
Site of bleeding	Skin, mucous membranes (gingivae, nares, genitourinary tract)	Deep in soft tissues (joints, muscles)
Petechiae	Present	Absent
Ecchymoses	Small, superficial	Large, palpable
Hemarthroses, muscle hematomas	Rare	Common
Bleeding after minor cuts	Common	Rare
Bleeding after surgery	Immediate, mild	Delayed, severe

or high-molecular-weight kininogen. Because the clinical presentations of these clotting factor deficiencies are quite different (e.g., factor VIII and factor IX deficiencies are X linked, frequently with a positive family history), correlation with the clinical setting should be sought and the specific clotting factor levels subsequently determined [*see 5:XV Coagulation Disorders*]

Thrombocytopenia

Thrombocytopenia, a decreased platelet count, is a common clinical finding that may be caused by decreased platelet production or accelerated platelet removal. Accelerated platelet removal may result from immunologic mechanisms, nonimmunologic mechanisms, or sequestration of platelets in the spleen [*see Table 1*]. Thrombocytopenia can range from a transient, isolated finding to a severe, life-threatening condition.

DIAGNOSTIC EVALUATION

Clinical Manifestations

Patients with thrombocytopenia may be asymptomatic; in these patients, the finding of a low platelet count may be first detected on a routine complete blood count. The most common symptomatic presentation of thrombocytopenia is bleeding—characteristically, mucosal and cutaneous. The hallmark of thrombocytopenia is nonpalpable petechiae, which reflect bleeding probably from capillaries or postcapillary venules [*see Table 1*]. Petechiae usually are only a few millimeters in diameter and occur at sites of increased intravascular pressure, such as over the lower extremities and on the oral mucosa, and at sites constricted by certain types of clothing, such as brassiere straps. Purpura, more extensive subcutaneous bleeding, may occur with a confluence of petechial lesions. Palpable purpura indicates an additional component of vascular inflammation and suggests underlying systemic vasculitis, such as cryoglobulinemia. Thrombocytopenia also leads to mucosal bleeding; deep-tissue bleeding is less common.

Laboratory Tests

Blood count and peripheral smear Laboratory examination should start with the complete blood count and examination of the peripheral smear. The importance of examination of the peripheral smear for estimation of platelet numbers, morphology, and the presence or absence of platelet clumping, as well as evaluation of associated white and red blood cell changes, cannot be overemphasized.

Normally, there are eight to 12 platelets per high-power field (×1,000 magnification), corresponding to a normal platelet count of 15,000 to 30,000/μl. There is no clearly demarcated level of platelets above which patients can be considered safe from bleeding. In general, a platelet count greater than 20,000/μl is considered safe; platelet counts of 10,000/μl or below may be tolerated in nonsurgical patients [*see 5:X Transfusion Therapy*]. Patients with idiopathic thrombocytopenic purpura bleed less at a given platelet level than patients with aplastic anemia [*see* Idiopathic Thrombocytopenic Purpura, *below*]. Presumably, the larger, younger platelets are more effective in hemostasis. The risk of intracranial hemorrhage usually directs therapy.

Elderly patients and patients with coexistent illnesses bleed more than young patients and patients with thrombocytopenia alone. An associated disorder, such as liver dysfunction or connective tissue disease, increases the risk of serious bleeding.

In the initial laboratory evaluation, the complete blood count will establish whether the thrombocytopenia is a single disorder or is associated with anemia or leukopenia, which suggests a production defect as the underlying cause [*see* Platelet Production Defects, *below*]. If thrombocytopenia is an isolated finding, the physician should confirm the platelet count by repeating the complete blood count. A falsely low platelet count can be the result of in vitro platelet clumping caused by the presence of cold-dependent or ethylenediamenetetraacetic acid–dependent agglutinins. Examination of the blood smear and a repeat platelet count in a citrated or heparin-anticoagulated blood sample will resolve this problem.[2]

The peripheral smear may reveal morphologic abnormalities in platelets and indicate the presence of polychromatophilia, neutropenia, lymphopenia, spherocytosis, blastomycosis, or fragmented microangiopathic erythrocytes. The mean platelet volume, as determined by automated blood cell counters, may provide an additional clue to the cause of the thrombocytopenia. Low platelet volumes (< 6.4 femtoliters) suggest poor production, whereas larger volumes suggest rapid platelet regeneration or dysplastic platelet production.

Bone marrow aspirate and biopsy When accelerated platelet removal appears to be the cause of the patient's thrombocytopenia, a rapid differential diagnosis should be made [*see Table 3*]. A bone marrow aspirate and biopsy will be very helpful in narrowing the diagnosis. Usually, thrombocytopenia with an abundance of normal megakaryocytes in the marrow is the result of accelerated platelet removal.[3] Normally, platelets survive for 10 days and have a half-life of about 4 days; in accelerated-removal states, such as idiopathic thrombocytopenic purpura, the

Table 2 Typical Results of Tests for Hemostatic Function in Bleeding Disorders

Disorder	*PC*	*PT*	*aPTT*
Thrombocytopenia	Low	Normal	Normal
Platelet function abnormalities	Normal	Normal or low	Normal
Vascular purpuras	Normal	Normal	Normal
von Willebrand disease	Normal	Normal	Long
Hemophilia A	Normal	Normal	Long
Disseminated intravascular coagulation	Low	Long	Long

aPTT—activated partial thromboplastin time PC—platelet count
PT—prothrombin time

platelet half-life may be as short as 30 to 60 minutes. The platelet count will then reflect the balance between accelerated platelet removal and compensatory megakaryopoiesis.

Platelet survival studies are not generally available and are not usually necessary to determine whether accelerated platelet removal is occurring. Infusion of random-donor platelets can be used as a diagnostic and therapeutic procedure. When accelerated platelet removal is responsible for the thrombocytopenia, transfusion with six platelet packs only slightly elevates the platelet count, which then returns to baseline values in less than 24 hours. This therapeutic test becomes unreliable, however, if the patient has been previously alloimmunized by blood or platelet transfusions or by multiple pregnancies.

PLATELET PRODUCTION DEFECTS

Inadequate Platelet Production Due to Stem Cell Destructon

Disorders that injure stem cells or prevent their proliferation frequently cause thrombocytopenia. These disorders affect multiple hematopoietic cell lines, and the resulting thrombocytopenia is accompanied by varying degrees of anemia and leukopenia.

Diagnosis Diagnosis of a platelet production defect is readily established by examination of a bone marrow aspirate and biopsy. The finding of a hypoplastic marrow in which the total cellularity is reduced, along with a decrease in megakaryocytes, implies aplastic or hypoplastic anemia. The first presumption of a cause in these cases is drug toxicity. A marrow that is fibrosed or infiltrated with leukemic or other malignant cells represents the syndrome of pancytopenia from infiltrated marrow.

A marrow aspirate and biopsy sample showing normal cellularity and normal maturation of the erythroid and myeloid precursors, with decreased numbers of apparently normal megakaryocytes, suggest that the patient has ingested a drug, such as ethanol, that specifically affects the megakaryocytic progenitor cells.[4] Ethanol also produces ineffective megakaryopoiesis. In vitamin B_{12} deficiency and folate deficiency, all three marrow cell lines are affected. The marrow smear shows many large hyperlobated megakaryocytes. Some myeloproliferative disorders are characterized by ineffective megakaryopoiesis with bizarre binucleate megakaryocytes.

TREATMENT

If a drug is the suspected cause of the thrombocytopenia, it should be discontinued. Specific replacement is required for deficiencies of vitamin B_{12} and folate. When the thrombocytopenia is causing significant bleeding, platelet transfusion will be required until the situation resolves [*see 5:X Transfusion Therapy*].

Interleukin-11 (IL-11), which plays a contributory role in megakaryopoiesis, has been approved for secondary prophylaxis against thrombocytopenia after chemotherapy[5]; however, it has limited efficacy and is associated with moderate toxicity.[6] Two forms of recombinant thrombopoietin—one full length and one with a truncated form—have undergone extensive clinical trials. Both types are potent stimulators of megakaryocyte growth and platelet production and are effective in reducing the thrombocy-

Table 3 Causes of Thrombocytopenia

Type	*Disorder*	*Cause*
Platelet production defect	Marrow aplasia or hypoplasia, pancytopenia	Radiation, cytotoxic drugs, idiopathic
	Marrow infiltration, pancytopenia	Cancer (leukemia, lymphoma), fibrosis
	Selective impairment of platelet production	Drugs (ethanol, gold, trimethoprim-sulfamethoxazole, sulfonamides, thiazides, phenylbutazone); infections (childhood rubella, HIV)
	Ineffective megakaryopoiesis	Vitamin B_{12} deficiency, folic acid deficiency, myelodysplastic syndrome, alcohol abuse
Accelerated platelet removal	Immune destruction	Autoantibodies (idiopathic thrombocytopenic purpura, systemic lupus erythematosus, lymphoproliferative disease); proven drug antibodies (quinidine, quinine, heparin, GPIIb-IIIa antagonists); infections (infectious mononucleosis, HIV, gram-negative septicemia, malaria); suspected drug antibodies (thiazide diuretics, acetaminophen, cimetidine, aminosalicylic acid); posttransfusion purpura
	Nonimmunologic removal	Disseminated intravascular coagulation, preeclampsia, vasculitis, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, HELLP syndrome, severe bleeding, platelet washout after massive transfusion, giant hemangioma, gram-negative septicemia
	Hypersplenism	Enlarged spleen from various causes

HELLP—hemolysis, elevated liver enzymes, low platelet count

topenia after nonmyeloablative chemotherapy. They have, however, elicited antibody formation; even more worrisome, use of the truncated form has led to the development of functionally neutralizing antibodies that cross-react with the endogenous thrombopoietin.[6] Thrombopoietin mimetics are now in clinical trials.

Inadequate Platelet Production Due to Low Thrombopoietin Level

Moderate thrombocytopenia, generally in the 50,000 to 100,000/μl range, is commonly seen in patients with cirrhosis, which has been conventionally ascribed to platelet sequestration caused by hypersplenism. In addition, there is evidence that low-grade disseminated intravascular coagulation (DIC) occurs in cases of severe liver disease. Impaired clearance of fibrin degradation products may interfere with platelet function and fibrin polymerization. In one study, patients with advanced cirrhosis and thrombocytopenia were found to have low-normal serum levels of thrombopoietin (TPO). Serum TPO levels increased rapidly after orthotopic liver transplantation, and normalization of thrombocytopenia occurred within 14 days after transplantation, irrespective of the change in spleen size.[7] The data indicate that the liver is a major site of TPO production, and decreased hepatic TPO production accounts for a significant part of the thrombocytopenia in liver disease.

ACCELERATED PLATELET REMOVAL DUE TO IMMUNE DESTRUCTION

Idiopathic Thrombocytopenic Purpura

The estimated incidence of idiopathic thrombocytopenic purpura (ITP) is 50 to100 new cases per million persons per year, equally distributed between children and adults.[8,9] ITP typically appears in young women. Predisposing diseases and contributing factors may include infectious mononucleosis and other acute viral illnesses, Graves disease, and Hashimoto thyroiditis,[10] as well as antiphospholipid antibody syndrome.[11] For ITP patients who have antiphospholipid antibody, the outcomes, courses, and response to therapy do not differ from those of other ITP patients.

Pathophysiology ITP is an autoimmune disorder characterized by rapid platelet destruction that is caused by the presence of antibodies against the patient's own platelets. These autoantibodies bind to specific proteins on the platelet surface, and the antibody-coated platelets are removed by the reticuloendothelial system, especially in the spleen. The immunoglobulin on the platelet membrane is usually IgG (most commonly, IgG1). In some patients, only IgG2, IgG3, or IgG4 is present on the platelet surface, suggesting oligoclonality.[12] Immunoglobulin on the platelet membrane is frequently directed against the platelet glycoprotein (GP) IIb-IIIa, the receptor complex that mediates fibrin-ogen binding and platelet aggregation; fortunately, most of these antibodies are not capable of functionally neutralizing the GPIIb-IIIa complex. Less frequently, the immunoglobulin is directed against the GPIb complex.[13] Thrombopoietin levels are normal in ITP, indicating a normal or increased megakaryocyte mass (in contrast to a high thrombopoietin level in aplastic anemia).[14] The marrow may respond to the thrombocytopenia by increasing platelet production. In many cases, however, the marrow response is suboptimal, probably because the antiplatelet antibodies also react with megakaryocyte cell surface antigens. The platelets produced in ITP are usually large and functional, which may account for the clinical observation that most patients with ITP do not have significant clinical bleeding.

Clinical features The onset of ITP is usually insidious. History and physical examination are usually negative except for the presence of petechiae, most commonly in the lower extremities. Clinical bleeding is usually mild, consisting of purpura, epistaxis, gingival bleeding, and menorrhagia. Blood blisters (wet purpura) in the mouth indicate the presence of severe thrombocytopenia. Retinal hemorrhages are uncommon. The spleen is usually not palpable. The presence of a palpable spleen raises the possibility of systemic lupus erythematosus (SLE), lymphoma, infectious mononucleosis, or hypersplenism from underlying chronic liver disease.

Laboratory evaluation The peripheral smear is usually normal; the few platelets that are present are large and well granulated. The presence of hypochromia suggests iron deficiency from chronic blood loss; spherocytes raise the possibility of associated autoimmune hemolysis (Evans syndrome); and red blood cell fragments (schistocytes) suggest DIC, thrombotic thrombocytopenic purpura (TTP), or hemolytic-uremic syndrome (HUS). The marrow shows abundant megakaryocytes; erythroid and myeloid precursors remain normal. Results of tests for SLE are negative. Platelet-associated IgG (PA-IgG) levels are elevated; however, because platelets normally contain IgG in their α-granules, PA-IgG does not distinguish between antiplatelet antibodies, immune complexes deposited on platelet surfaces, and antibodies released from the platelet granules and bound on its surface. Therefore, tests for PA-IgG are not useful in the diagnosis of ITP, unless the tests are performed by special research laboratories that measure platelet antigen-specific antibodies.[15]

Differential diagnosis The differential diagnosis of ITP includes a falsely low platelet count resulting from ethylenediamenetetraacetic acid (EDTA)–dependent or cold-dependent agglutinins that cause in vitro platelet clumping (diagnosed by reexamination of the platelet count in a citrated or heparin-anticoagulated blood sample); the gestational thrombocytopenia of pregnancy (usually a mild problem that is not associated with increased bleeding risk [*see* Idiopathic Thrombocytopenic Purpura in Pregnancy, *below*]); myelodysplastic syndrome (usually associated with anemia and leukopenia); and underlying lymphoproliferative disease.

Course and prognosis ITP is a relatively benign disorder that has a mortality of approximately 1% to 5%; most deaths in adult cases result from intracranial bleeding. Acute ITP is usually confined to children and young adults and is frequently preceded by a viral illness. Permanent spontaneous remission occurs in less than 3 months. Chronic ITP, the usual adult variety, refers to disease that persists for more than 3 months. Although spontaneous remissions and relapses do occur in chronic ITP, long-term spontaneous remissions are uncommon. On the other hand, the long-term prognosis of ITP is benign, even in refractory cases, when these patients are managed properly.[16]

Treatment The treatment of ITP depends on the age of the patient; disease severity; whether petechiae are present alone or with moderate or severe mucosal or central nervous system bleeding; and whether the patient is pregnant.[17]

The American Society of Hematology has released an evidence-based practice guideline for the management of ITP,[15] which can be summarized as follows:

1. Patients with platelet counts above 50,000/μl do not routinely require treatment.
2. Treatment is indicated in patients with platelet counts below 20,000 to 30,000/μl and in patients with platelet counts below 50,000/μl who have significant mucosal bleeding or risk factors for bleeding (e.g., hypertension, peptic ulcer disease, or a vigorous lifestyle).
3. Patients with platelet counts below 20,000/μl need not be hospitalized if they are asymptomatic or if they have only mild purpura.

Patients with asymptomatic mild or moderate thrombocytopenia (i.e., platelet count > 50,000/μl) do not require active therapy. They may be followed and simply alerted to report any mucosal bleeding or crops of new petechiae. Avoidance of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) is strongly advised. The role of *Helicobacter pylori* eradication in the management of ITP is controversial. It may have a limited value in improving the thrombocytopenia in young patients who have evidence of *H. pylori* infection and have relatively mild thrombocytopenia (i.e., 30,000 to 70,000/μl) of short duration (< 2 years). *H. pylori* eradication is not useful in patients with chronic severe ITP.[18]

For patients with moderate mucosal bleeding, therapy is begun with prednisone at a dosage of 60 to 100 mg/day in divided doses. Corticosteroids interfere with the macrophage attack on platelets and eventually reduce the amount of antiplatelet antibody produced by splenic and marrow lymphoid cells. A study showed that a 4-day course of high-dose dexamethasone (40 mg daily) achieved a high remission rate (85%) in newly diagnosed ITP patients; of those patients who responded to therapy, 50% had a sustained response.[19] This remarkably high rate of long-term response after a single course of dexamethasone will require confirmation and longer follow-up.

Unless bleeding is severe, the patient need not be hospitalized. Heavy physical activity, particularly any activity that involves the Valsalva maneuver, should be avoided so as not to increase intracranial pressure. The avoidance of aspirin and other NSAIDs should be emphasized. If required, red blood cell transfusions can be given; however, it is rarely necessary to transfuse platelets in such cases.

The platelet count usually rises several days to 2 to 3 weeks after the start of therapy. When the platelet count reaches normal levels, the prednisone dose can be tapered over a 3- to 4-week period. Although complete long-term remissions with prednisone alone have been reported, sustained complete response after therapy occurs in fewer than 10% of patients.

Splenectomy, usually performed by laparoscopy, is indicated if platelet counts remain below 30,000/μl after 4 to 6 weeks of steroid therapy or when the platelet count begins to fall again after the tapering of steroid. The procedure produces long-standing remission in about 65% of patients with ITP. It is best to administer intravenous immune globulin (IVIg) a few days before splenectomy so that the patient will have a platelet count of at least 30,000 to 50,000/μl at the time of surgery. Generally, a full course of IVIg therapy (1 g/kg/day for 2 days or 0.4 g/kg/day for 5 days) is not required when given as preparation for splenectomy. IVIg will produce a transient increase in the platelet count in the majority of patients, but it is a very expensive therapy. The platelet count usually begins to rise on the first postoperative day, often overshooting normal values by the second week. Pneumococcal, *Haemophilus influenzae*, and meningococcal vaccines should be administered 1 to 2 weeks before surgery.

If the patient is elderly or frail and hence may not survive splenectomy, the disease may be controlled by administration of the minimum amount of corticosteroids required to raise the platelet count to 30,000 to 50,000/μl, a level above which severe bleeding rarely occurs. Because patients with ITP who are classified as therapeutic failures generally do well clinically, the role of such potentially dangerous agents as cyclophosphamide and azathioprine in the management of such cases should be evaluated on a case-by-case basis.

Severe mucosal or CNS bleeding is a true medical emergency requiring hospitalization. Red cells are transfused as required, and prednisone is administered immediately, beginning with a 100 mg dose and then continuing at a level of 25 mg every 6 hours. A full course of IVIg should be administered, and transfusion with 8 to 10 units of random-donor platelets should be carried out when the infusion of the first dose of IVIg, usually given over approximately 60 minutes, is complete. The platelet transfusion after the infusion of IVIg produces a greater and more durable increase in the platelet count. Side effects include generalized aches, headache, flushing, fever, and chills. When severe uterine bleeding occurs, a single 25 mg dose of conjugated estrogen can be administered intravenously to control the hemorrhage. It should be emphasized that the benefit of IVIg is usually transitory and lasts only a few days. Plans for splenectomy should follow this emergency therapy.

The mechanism of action of IVIg is not completely understood. It may produce reticuloendothelial blockade by blocking the IgG-Fc sites on the monocyte-macrophages. Highly specific anti-idiotype antibodies may also block the binding of platelet autoantibodies to the platelet GPIIb-IIIa antigen.[20] Studies indicate that the catabolic rate of IgG is mediated by a new receptor for the Fc component of IgG, termed FcRn (neonatal Fc receptor, so named because it was initially identified in neonatal intestinal epithelium), on the vascular endothelial cells. Normally, IgG, but not IgM, that enters the cell through the process of pinocytosis is protected from catabolic breakdown by binding to the FcRn. After the administration of high-dose IVIg, this receptor is presumably saturated, permitting the degradation of the pathologic antibody to occur in proportion to its concentration in plasma.[21]

Refractory Idiopathic Thrombocytopenic Purpura

About 40% of ITP patients are characterized as refractory; they either remain severely thrombocytopenic after splenectomy and corticosteroid therapy or go into remission but later experience a relapse. Approximately 25% to 40% of patients will have a relapse 5 to 10 years after an initially successful splenectomy.[16] Because serious hemorrhage is uncommon with platelet counts above 30,000/μl, it is often prudent to accept an incomplete response and not proceed to more toxic forms of management. Immunosuppressive agents are generally the mainstay of therapy at this stage. However, it should be emphasized that there are no large randomized studies to address this difficult problem and that generally these patients should be referred to a hematologist.

There are several major treatment alternatives for refractory patients. Rituximab, a chimeric anti-CD20 monoclonal antibody, when administered at 375 mg/m^2 I.V. once weekly for 4 weeks, produces a lasting and substantial response in approximately one third of patients with chronic refractory ITP; however, long-

term follow-up is limited.[22] The majority of the responses occur within 8 weeks after the first infusion. The therapy is generally well tolerated, with most of the side effects (i.e., fever, chills, mild hypotension, and bronchospasm) being infusion related and occurring during or after the first infusion. Rituximab produces a profound and prolonged peripheral B cell depletion in all patients, which can last for more than a year, but serious infection is rare. Azathioprine (100 to 150 mg/day orally) or, alternatively, cyclophosphamide (100 to 150 mg/day orally) plus prednisone (40 to 60 mg/day orally) can be given, but this therapy requires weekly monitoring of complete blood count and platelet count. Prednisone may be tapered and azathioprine or cyclophosphamide adjusted to avoid severe leukopenia. A frequent mistake is to discontinue the therapeutic trial prematurely. Both azathioprine and cyclophosphamide are myelosuppressive and should be given in sufficient dosages to cause a mild leukopenia, with a white blood cell count of approximately 3,000/μl, and both have been associated with development of myelodysplastic syndrome and acute myeloid leukemia. After 1 month, alternate-day prednisone therapy should be considered to avoid steroid side effects. Because of the concern of long-term marrow toxicity associated with azathioprine and cyclophosphamide, rituximab should be considered the first-line therapy in refractory ITP patients, if treatment is indicated.

Another alternative is antibody therapy with intermittent courses of IVIg at the dosage schedules described (see above). The cost of this therapy and the usual short-lived response make it an unattractive choice. Anti-D antibody has been used successfully in $Rh^+(D^+)$ patients with ITP; in the presumed mechanism of action, the antibody-coated red blood cells block Fc receptors on macrophages and prevent the accelerated removal of platelets. Other therapeutic options include vincristine, vinblastine,[23] danazol,[24] high-dose dexamethasone, cyclosporine, interferon alfa, and plasmapheresis.

In the refractory splenectomized patient, it is important to check for the continued presence of Howell-Jolly bodies and the possibility of an accessory spleen. The disappearance of Howell-Jolly bodies suggests the presence of a remaining accessory spleen or a regenerated spleen.

Patients with clinically significant thrombocytopenic bleeding can also benefit from fibrinolysis inhibitor ε-aminocaproic acid (EACA). EACA can be given at 2 to 3 g orally four times daily until hemostasis is achieved.

HIV-Related Idiopathic Thrombocytopenic Purpura

HIV-1–related ITP appears to have a pathophysiology that is somewhat different from that of non–HIV-associated ITP, in that the antigenic specificity for the antiplatelet antibody is different. Two major antigenic determinants have been identified—a linear peptide in the platelet membrane GPIIIa and a cleavage product of talin, a platelet cytoskeletal protein, that can be generated by HIV-1 protease.[25,26] In patients with HIV infection, platelets also contain increased amounts of IgG, IgM, complement, and immune complexes. Platelet survival is moderately short, and platelet production is impaired, especially at the later stages of the disease.[27]

The use of immunosuppressive agents in HIV-infected patients is hazardous. If the drop in the platelet count is modest, no therapy is needed. When the thrombocytopenia is severe, a short course of prednisone can be administered, followed by splenectomy.

Acute thrombocytopenic hemorrhage in HIV-associated ITP may be managed with high-dose IVIg, similar to the management of other ITPs. Chronic HIV-associated ITP may respond to oral zidovudine (AZT) or other antiviral therapies [*see 7:XXXIII HIV and AIDS*]. Anti-D antibody, dapsone, and interferon have also been used with some success.[28-30] Patients who refuse splenectomy or who are thought to be poor surgical candidates may respond to low-dose splenic irradiation.[31]

Idiopathic Thrombocytopenic Purpura in Pregnancy

Mild thrombocytopenia, generally in the range of 110,000 to 150,000/μl and seldom below 70,000/μl, occurs in 5% of healthy pregnant women. When thrombocytopenia is observed for the first time during pregnancy, the differential diagnosis must include preeclampsia [*see Table 3*]. If other diagnoses can be excluded, the diagnosis is gestational thrombocytopenia (incidental thrombocytopenia of pregnancy); it requires no management.[32] If the diagnosis of ITP is made, the the patients is considered to be at high risk for complications. The platelet counts should be monitored regularly and closely, especially in the third trimester, because in many pregnant women with ITP, thrombocytopenia progressively worsens over the course of the pregnancy. The therapeutic choices are limited because splenectomy may cause spontaneous abortion and immunosuppressive agents may damage the developing fetus; therefore, therapy is usually limited to corticosteroids or IVIg. Because corticosteroids increase the risk of preeclampsia and gestational diabetes, IVIg is the drug of choice. Generally, no treatment is required until the platelet count has fallen to 20,000 to 30,000/μl or there is clinical bleeding. Typically, a single dose of IVIg (1 g/kg I.V. over 6 hours) will raise the platelet count to above 50,000/μl in the majority of patients, which will last for 3 to 4 weeks. Repeated doses can be given if necessary. In cases of severe thrombocytopenic hemorrhage, however, all of the available therapies should be used to protect the life and well-being of the mother.

Because the antiplatelet autoantibody in ITP has broad specificity and is almost always an IgG, it can cross the placenta and produce thrombocytopenia in the fetus. During a vaginal delivery, the pressure applied to the head of a thrombocytopenic fetus may induce an intracranial hemorrhage. Concern about this occurrence led many experts in the past to recommend early cesarean sections in women with a history of ITP or active disease. No data exist, however, to support this recommendation, and a much more conservative approach is now generally accepted. Most pregnant women with ITP undergo vaginal deliveries; cesarean sections are performed only for obstetric indications.

There is no correlation between maternal platelet count and the infant's platelet count. A mother with a history of ITP who has a normal platelet count can deliver a thrombocytopenic neonate (~10% incidence). Alternatively, a thrombocytopenic mother can have an infant with a normal platelet count. Measurement of maternal antiplatelet antibody is of no clinical utility. The best predictor of thrombocytopenia in a neonate is the mother's previous experience of giving birth to an infant with neonatal thrombocytopenia.[33] Neonatal severe thrombocytopenia—defined as a platelet count at birth that is less than 20,000/μl—is uncommon (1% to 5% of births), and severe bleeding complications are rare (< 1%).[34,35] The occurrence of neonatal severe thrombocytopenia is also unpredictable. The risk of intracranial hemorrhages in these infants is low (< 1%), and it cannot be reduced by cesarean section.[36] Percutaneous umbilical blood sampling is generally not recommended. Many infants who are born to mothers with ITP will have a decrease in platelet count after delivery, with a nadir on day 2; the infant's platelet

count should be monitored daily for several days.[32] Maternal ITP is not a contraindication to breast-feeding.

Thrombocytopenic Purpura with Lymphomas and Systemic Lupus Erythematosus

Patients with SLE, Hodgkin disease, or non-Hodgkin lymphoma can present with a clinical picture identical to that seen in ITP. The diagnostic approach and therapy are the same in these cases as they are in ITP. Splenomegaly with splenic sequestration, marrow infiltration with malignant cells, and recent antineoplastic or immunosuppressive therapy should be excluded. Patients with SLE or lymphoma may have Evans syndrome, in which ITP is associated with autoimmune hemolytic anemia. The management of Evans syndrome is the same as that of ITP and autoimmune hemolytic anemia.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is characterized by acute onset of severe thrombocytopenia, often with a platelet count below 10,000/μl, accompanied by clinical bleeding. It may occur from 2 to 10 days after a transfusion of packed red blood cells or platelet-containing components. Almost all of the affected patients are multiparous women. Such disorders as septic thrombocytopenia, DIC, and heparin-induced thrombocytopenia must be considered in the differential diagnosis. The thrombocytopenia usually lasts for about 4 weeks. Because platelet transfusions are usually futile and sometimes precipitate severe systemic responses, they should be avoided if possible.

The pathophysiology of PTP is not completely understood. In most cases, the patient has been exposed to platelet alloantigens during pregnancy or as a result of a transfusion. Most patients with this disorder have antibodies to the human platelet antigen–1 (HPA-1), a polymorphic epitope present on platelet surface GPIIIa. The HPA-1 has two isoforms, HPA-1a and HPA-1b (previously PLA-1 and PLA-2). In the United States, approximately 98% of the white population, 99% of the African-American population, and 99% of the Asian-American population are homozygous for HPA-1. Patients in whom PTP develops are usually HPA-1a negative and HPA-1b positive. The patient has been sensitized to the HPA-1a antigen, most frequently during pregnancy, and reexposure to HPA-1a platelets during red cell transfusion leads to an anamnestic response and the destruction of the foreign platelets. It is puzzling that alloantibody directed against an antigen present on foreign platelets results in destruction of the patient's autologous platelets, which do not express the HPA-1a antigen. There is evidence suggesting that the HPA-1a antigen becomes soluble and attaches to the HPA-1a–negative platelets. Alternatively, exposure to foreign platelets may induce the formation of a true autoantibody against the endogenous platelets. The HPA-1a/HPA-1b polymorphism accounts for 80% to 90% of PTP. However, the presence of an alloantibody is necessary but insufficient for the development of PTP. Some patients with anti–HPA-1a antibodies become refractory to platelet transfusions but do not have PTP.[37] In addition, the incidence of PTP is far less common than might be predicted by the 1% to 2% of the general population who are homozygous for HPA-1b.

Confirmation of the diagnosis of PTP requires serologic studies demonstrating the presence of anti–HPA-1a antibody and a homozygous HPA-1b genotype. Several rapid platelet genotyping techniques based on the polymerase chain reaction have been developed. Homozygous deficiency of platelet CD36 (glycoprotein IV) occurs in 3% to 5% of Asians and Africans, and alloantibody against CD36 has also been found to be associated with PTP.[38] There are no controlled clinical trials evaluating therapy for PTP because of the limited number of cases. IVIg, used at doses similar to those used in the treatment of ITP, is efficacious in about 80% of cases. Plasmapheresis is also efficacious, but it is more cumbersome than IVIg administration. Use of high doses of corticosteroids is not consistently effective.[39] Transfusion of HPA-1a–negative platelets may provide some transient benefit in life-threatening bleeding situations.[40]

Drug-Induced Immune Platelet Destruction

Drug-induced immune platelet destruction is indistinguishable from ITP. The bone marrow shows abundant megakaryocytes, and special laboratories can detect the presence of antidrug antibodies.

Quinidine and quinine purpura The pathogenic antibodies in cases of quinidine and quinine purpura develop as early as 12 days after exposure to the offending agent. In most cases, drug-dependent antibodies to platelet surface GPIb-IX have been identified in patients' sera.[41] The antibodies are drug dependent because they bind to the platelets only in the presence of quinine or quinidine. Presumably, the binding of the drugs to these platelet surface glycoproteins induces new antigenic sites on the proteins that are recognized by the antibodies.

The agent (quinidine or quinine) should be withdrawn in such cases. Neither corticosteroid therapy nor emergency splenectomy is of documented benefit in purpura induced by these agents. Plasmapheresis to remove the drug and antibodies would appear to be a logical treatment, but there are no systematic studies of its effectiveness. Transfused platelets are removed as rapidly as the recipient's own platelets. Treatment with prednisone and IVIg in a dose similar to that used in ITP is recommended. Platelet transfusion after IVIg infusion may be given to control life-threatening bleeding.

A quinine-induced thrombocytopenia that is closely followed by the development of HUS has been recognized. Quinine-dependent antibodies to platelets, as well as to endothelial cells, have been found in patients' sera.[42] Even the small amount of quinine in tonic water seems to be sufficient to trigger recurrent bouts of the syndrome. Other drugs that may occasionally produce drug-dependent thrombocytopenia include dipyridamole and trimethoprim-sulfamethoxazole.[43]

Heparin-induced thrombocytopenia Heparin-induced thrombocytopenia (HIT) is a frequent cause of drug-induced thrombocytopenia in hospitalized patients. Despite the presence of modest to moderate thrombocytopenia, HIT is rarely associated with bleeding but is associated with significant and sometimes fatal thrombosis [*see 5:XIV Thrombotic Disorders*].

Gold-induced thrombocytopenia Gold salt therapy for rheumatoid arthritis produces thrombocytopenia, which is sometimes severe, in 1% to 3% of patients. There are drug-induced autoantibodies that target platelet membrane GPV, but the presence of gold is not required for their reactivity.[44] Most patients respond to therapy with 60 mg of prednisone daily. IVIg is also efficacious.

Cocaine-associated thrombocytopenia An ITP-like syndrome has been reported in intravenous cocaine users. They

have been shown to respond to an approach similar to that employed in patients with ITP.[45]

Thrombocytopenia caused by GPIIb-IIIa receptor antagonists Three parenteral GPIIb-IIIa antagonists—abciximab, eptifibatide , and tirofiban—have been approved for use in the treatment of acute coronary artery syndrome and as adjunctive therapy in coronary angioplasty. In contrast to the low platelet counts in other types of drug-induced thrombocytopenia, patients who have low platelet counts resulting from GPIIb-IIIa receptor antagonists can develop acute, often profound thrombocytopenia within a few hours after drug administration. In patients receiving abciximab, thrombocytopenia occurs in about 1% after the first exposure. After a second exposure, the incidence of thrombocytopenia rises to 4%.[46] The incidence of drug-induced thrombocytopenia associated with eptifibatide and tirofiban is probably also about 1% after first exposure.[47]

The abrupt development of severe thrombocytopenia in patients who have never been exposed to these drugs initially suggested that platelets were being destroyed by a nonimmune mechanism. However, accumulating evidence indicates that drug-dependent antibodies, which occur naturally, are the underlying cause. Preexisting anti–GPIIb-IIIa autoantibodies are present in these patients, and after the administration of the anti–GPIIb-IIIa antagonist, the binding of the drug to GPIIb-IIIa induces conformational changes in GPIIb-IIIa such that new epitopes are exposed that are recognized by the autoantibodies. These actions would explain the acute onset of profound thrombocytopenia.[47]

When thrombocytopenia develops (i.e., when platelet counts drop below 100,000/μl), the GPIIb-IIIa antagonist and any other potentially offending medications (e.g., heparin) should be discontinued immediately. Depending on the platelet count, it may not be advisable to discontinue antiplatelet agents such as aspirin or clopidogrel, because in such cases, patients are at high risk for acute coronary artery or stent thrombosis. If the platelet count drops below 10,000/μl, strong consideration should be given to platelet transfusion. In general, only one single-platelet transfusion is sufficient. There are anecdotal reports of acute coronary thrombosis associated with platelet transfusion in this setting when the platelet count climbs over 50,000/μl and the patient is off all antiplatelet agents. Thus, antiplatelet agents may need to be reinstituted. Because eptifibatide and tirofiban have very short half-lives and are cleared from the circulation within hours, the duration of thrombocytopenia is short, once the offending drugs have been discontinued. However, because abciximab has a much longer half-life—with inhibition of platelet function reported up to 1 week after drug discontinuance—thrombocytopenia can persist for 5 to 7 days. Platelet counts should be obtained in all patients before, as well as within 2 to 4 hours after, the initiation of an intravenous GPIIb-IIIa antagonist. It should be noted that a subgroup of patients develop delayed thrombocytopenia 5 to 8 days after abciximab administration. On the basis of limited published experience, it appears to be safe to administer eptifibatide or tirofiban to patients who are sensitive to abciximab, and vice versa.[47]

Thrombocytopenia caused by metabolites of naproxen and acetaminophen Five patients have experienced thrombocytopenia after taking naproxen and acetaminophen. In each case, antibodies that reacted with normal platelets in the presence of a known drug metabolite of naproxen or acetaminophen were identified.[48] Therefore, the sensitizing agents are drug metabolites that formed in vivo.

ACCELERATED REMOVAL OF PLATELETS BY NONIMMUNOLOGIC MECHANISMS

There are several nonimmunologic causes for thrombocytopenia. Blood vessel wall injury with increased thrombin generation and increased platelet activation and consumption occurs in several of these conditions.

Thrombotic Thrombocytopenic Purpura and Adult Hemolytic-Uremic Syndrome

TTP and HUS encompass a group of clinical syndromes characterized by widespread platelet-fibrin thrombi deposition in the small arteries and arterioles and capillaries. Thrombotic microangiopathy is a distinct feature of both TTP and HUS; however, the underlying pathogenetic processes in TTP and HUS may differ [*see* Pathogenesis, *below*]. Familial TTP/HUS is rare and usually occurs in the immediate postnatal period or infancy, although there are reported cases of delayed onset until the second to third decade of life. More frequently, TTP is either idiopathic or secondary to a variety of conditions [*see* Etiology, *below*].

Etiology TTP/HUS occurs spontaneously and is also associated with pregnancy, cancer, bone marrow transplantation, autoimmune diseases, and various drugs. In pregnancy, it resembles severe preeclampsia. In the postpartum period, the CNS manifestations may initially be confused with postpartum depression, with tragic results. Cases have been reported after a normal delivery and with abruptio placentae and preeclampsia.

Several drugs appear to cause TTP/HUS. These include chemotherapeutic drugs (e.g., mitomycin C, bleomycin, and cisplatin), immunosuppressive agents (e.g., cyclosporine and FK506), the antiplatelet agent ticlopidine, oral contraceptives, and quinine. Anecdotal cases of TTP/HUS associated with clopidogrel, which is related to ticlopidine, have also been reported.[49]

Pathogenesis There have been significant recent advances in the understanding of TTP, showing that the proper processing of von Willebrand factor (vWF) multimers plays a key role in its pathogenesis. vWF is an abundant plasma protein that mediates platelet adhesion to the subendothelium and serves as a carrier molecule for factor VIII [*see 5:XII Hemostasis and Its Regulation*]. vWF is synthesized by both megakaryocytes and endothelial cells. Monomers of vWF (280,000 daltons) are cross-linked by disulfide bonds to form vWF multimers, which are released into the circulation by endothelial cells and are stored within platelet α-granules and the Weibel-Palade bodies in endothelial cells. The stored vWF multimers can be released upon platelet or endothelial stimulation. These released vWF multimers are larger than plasma vWF multimers and are referred to as ultra-large vWF (ULvWF) multimers, with a molecular size up to 20 million daltons. Functionally, these are the most reactive vWF multimers. In 1982, ULvWF multimers were found in the plasma of patients with chronic relapsing TTP, giving rise to the hypothesis that TTP may result from the deficiency of a vWF-cleaving protease (depolymerase), which causes ULvWF multimers to circulate, contributing to the development of thrombosis.[50] This hypothesis has been proved largely correct with the recent identification of the vWF-cleaving protease and the demonstration that deficiency of the vWF-cleaving protease activity is associated with TTP.

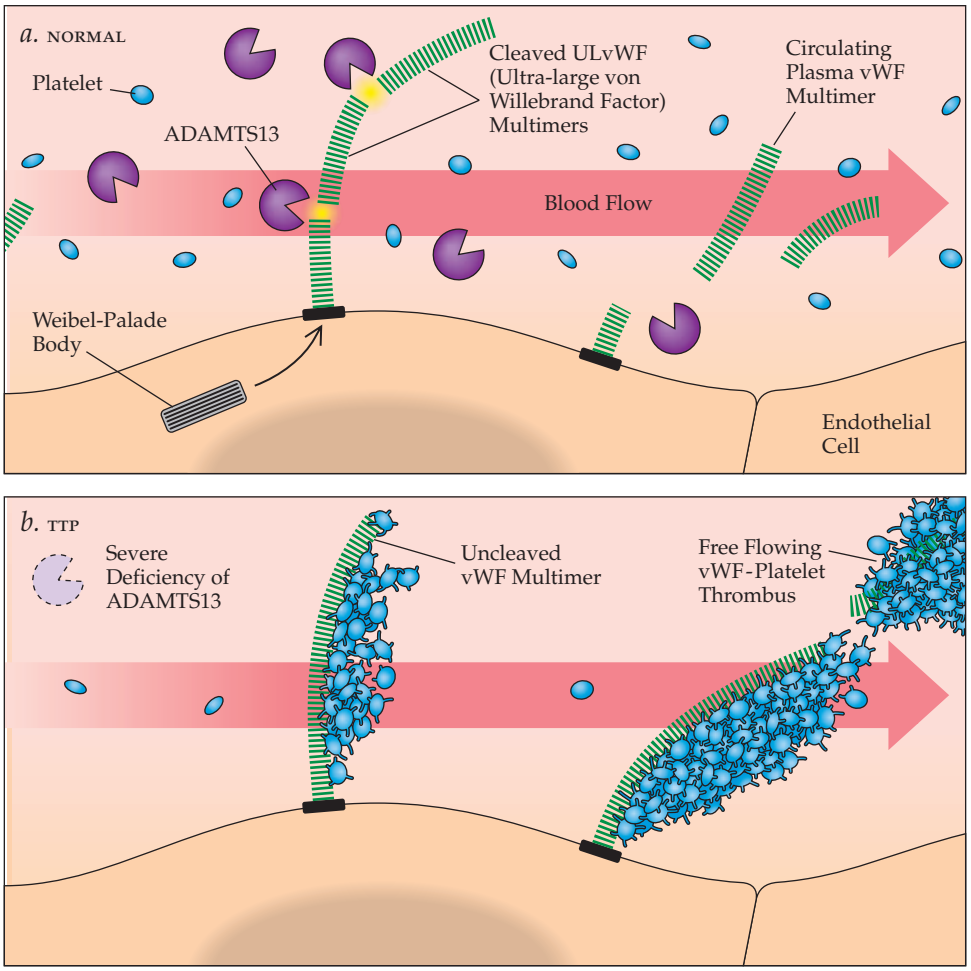

Figure 1 **ADAMTS13 activity in normal and thrombotic thrombocytopenia purpura plasma. (*a*) In normal persons, ADAMTS13 enzyme molecules from the plasma attach to and then cleave the unusually large von Willebrand factor (ULvWF) multimers that are secreted in long strings from stimulated endothelial cells. (*b*) In patients with thrombotic thrombocytopenic purpura (TTP), a deficiency of ADAMTS13 prevents the cleavage of ULvWF multimers secreted by endothelial cells. Platelets carried by flowing blood adhere to the uncleaved ULvWF multimers, resulting in the development of platelet thrombi.**

The vWF-cleaving protease has been identified as ADAMTS13 (a disintegrin-like and metalloprotease with thrombospondin type 1 motif 13).[51] It is a novel metalloprotease that cleaves vWF monomer at a specific site (842Tyr-843Met) in the A2 domain. Current data indicate that ULvWF multimers are secreted from stimulated endothelial cells as a long "string" anchored on the endothelial cell surface. Plasma ADAMTS13 may attach, under flowing conditions within the blood, to the cell surface–bound ULvWF multimers (via the A3 domain in the vWF monomer) and cleave them into the vWF multimers that are normally found in plasma.[52] Partial unfolding of the ULvWF multimers by shear stress forces in the blood presumably enhances the enzymatic cleavage process. Patients with familial TTP have hereditary deficiency of ADAMTS13,[53] whereas patients with acquired idiopathic TTP have antibodies that inhibit the ADAMTS13 activity.[54,55] In either case, the persistence of ULvWF multimers on the stimulated surface of the endothelial cell leads to the adhesion and subsequent aggregation of platelets, which in turn lead to the formation of platelet thrombi [*see Figure 1*]. (Presumably, platelets do not bind to the smaller plasma vWF multimers, because the platelet binding sites are not exposed in these vWF multimers). In addition to causing ischemic injury at the site of thrombi formation, it is likely that platelet thrombi resulting from aggregation of ULvWF multimers will break up and embolize downstream, resulting in further ischemic tissue damage.

The gene encoding ADAMTS13 is located on chromosome 9q34. More than 50 mutations in this gene have been identified in patients with familial TTP, most of which result in greatly reduced ADAMTS13 secretion in vitro.[51] In many cases of acquired idiopathic TTP, an IgG autoantibody against ADAMTS13 is produced transiently, leading to severe deficiency of ADAMTS13 activity. ULvWF multimers are detectable in the plasma in some patients during the acute episodes but not after recovery.[50]

Although the role of ADAMTS13 in the pathogenesis of TTP has been established, it appears that the majority of patients with HUS do not have severe ADAMTS13 deficiency, strongly suggesting that the pathogenesis of HUS is different.

ADAMTS13 as a screening assay The clinical utility of measuring ADAMTS13 is not established. In part, this is be-

cause there is no gold standard for its measurement; most of the current assays have long turnaround times and are not readily available. Furthermore, the sensitivity and specificity of ADAMTS13 deficiency for the diagnosis of TTP remains unclear. Decreased vWF-cleaving activity is found in many clinical conditions that are not associated with TTP, including cirrhosis, chronic renal insufficiency, ITP, DIC, SLE, leukemia, pregnancy, and the postoperative state; it is also associated with advancing age.[56,57] In a prospective study involving 37 patients, severe deficiency in the ADAMTS13 level (< 5%) was found in 80% of patients with idiopathic TTP but in none of the patients with TTP associated with hematopoietic stem cell transplantation, cancer, drugs, or pregnancy.[58] Thus, acquired TTP may be considered as either idiopathic or secondary; the former is generally associated with severe ADAMTS13 deficiency, whereas the latter is not. Among the patients with idiopathic TTP and severe ADAMTS13 deficiency, 44% had inhibitors. Other studies found an incidence of inhibitors in idiopathic TTP of 65% to 95%; however, part of the variation in study results may have to do with patient selection.[59,60]

The reason why an inhibitor is not detectable in a substantial number of the idiopathic TTP patients is unclear. It is possible that the current assay is not sufficiently sensitive; alternatively, the assay may involve a nonneutralizing antibody that binds to ADAMTS13 and accelerates its clearance. New assays using a recombinant vWF fragment as the substrate for the ADAMTS13 protease are in development and should help clarify some of these issues.[61,62]

Clinical features and diagnosis The five major manifestations (pentad) of TTP are (1) severe microangiopathic hemolytic anemia associated with a very high serum lactic dehydrogenase (LDH) level and a blood smear showing the characteristic schistocytes and helmet cells; (2) moderate to severe thrombocytopenia with increased marrow megakaryocytes, which indicates intravascular platelet activation and consumption; (3) fever, which is occasionally quite high; (4) CNS signs and symptoms that can be quite mild initially with transient agitation, headache, and disorientation but that can sometimes progress explosively to hemiparesis, aphasia, seizures, focal deficits, coma, and death; and (5) renal disease, which is usually mild and produces moderate elevations of serum creatinine and urinary protein levels. It should be emphasized that many patients do not present with all these signs and symptoms. Patients with familial TTP/HUS typically exhibit a chronic relapsing course.

The adult form of HUS has features similar to those of TTP, although the pathophysiology may not be identical [*see* Pathogenesis, *above*]. Common features of TTP and HUS include microangiopathic hemolytic anemia, thrombocytopenia, and the presence of platelet fibrin thrombi in the small vessels. Renal involvement is uniformly severe in HUS, whereas CNS disease is less prominent than in TTP. There is a distinct form of HUS that occurs in children after gastrointestinal infection with *Escherichia coli*, usually serotype 0157:H7. These patients present with bloody diarrhea and hemorrhagic colitis. *E. coli* 0157:H7 or other strains elaborate verotoxins (also called Shiga toxins) that bind to specific receptors on the endothelial surface, causing cell damage and even cell death.[63] Verotoxin-1 (VT-1) can induce the upregulation of various prothrombotic and proinflammatory adhesive molecules on endothelial cells.[64] The microvascular endothelial cells are particularly susceptible because they have a high expression of VT-1 receptors, which may explain the propensity for thrombosis in the microcirculation. Antibiotic treatment of children with *E. coli* 0157:H7 infection increases rather than decreases the risk of HUS, presumably because it causes the release of verotoxins from injured bacteria in the intestine, making the toxins more available for absorption. Thus, routine treatment with antibiotics is not recommended.[65]

Whereas a severe deficiency of ADAMTS13 (< 5%) may be specific for TTP,[66] patients with severe ADAMTS13 deficiency may have prolonged asymptomatic periods. It is becoming clear that loss of ADAMTS13 activity, with an associated increase in circulating ULvWF multimers, is necessary but insufficient to cause an acute clinical TTP episode. The current data support the hypothesis that severe ADAMTS13 deficiency, be it from familial or acquired cause, predisposes the patient to thrombosis, and a second vascular inflammatory stimulus, such as infection, surgery, or pregnancy, causes the endothelium to increase its release of the stored UlvWF multimers, which, in the setting of grossly impaired processing, gives rise to ULvWF platelet thrombi in the microcirculation and clinical thrombosis.

Differential diagnosis Both TTP and HUS must be differentiated from SLE and from Evans syndrome. Microangiopathic hemolysis, neutrophilic leukocytosis, and a negative direct Coombs test (direct antiglobulin test) strongly suggest TTP or HUS. Coagulation tests usually reveal no significant abnormalities (i.e., no evidence of DIC); serum LDH is usually elevated. A marrow biopsy is generally not required but may show the characteristic, but not pathognomonic, platelet-fibrin hyaline thrombi in small arteries and arterioles.

Treatment Prompt institution of plasma exchange with fresh frozen plasma is the treatment of choice for TTP/HUS. In a large randomized trial by the Canadian Apheresis Group, intensive plasma exchange was more effective than plasma infusion in terms of patient survival (78% versus 63%).[67] In that study, 1.5 times the calculated plasma volume was removed and replaced with fresh frozen plasma during each of the first 3 days of therapy; subsequently, one single-volume exchange a day was performed for a minimum of 7 days. Some investigators obtained good results with a daily single-volume exchange instead of a 1.5-volume exchange.[68] It is reasonable to start with a daily single-volume exchange if the patient is clinically relatively stable, with moderate thrombocytopenia and no significant neurologic impairment. However, if the clinical situation worsens, more intensive double-volume plasma exchange (5,000 to 6,000 ml/day, or approximately 80 ml/kg/day) is indicated. Because vWF multimers are present in cryoprecipitate, cryosupernatant (i.e., fresh frozen plasma from which cryoprecipitate has been removed) can be substituted as replacement fluid when a patient is not responding to routine plasma exchange. One uncontrolled study showed increased benefit from this preparation as compared with fresh frozen plasma.[69] Once therapeutic benefit has been achieved (as measured by restoration of normal CNS function, by rising platelet counts, and by falling LDH levels), the intensity and frequency of plasma exchange can be reduced to single-volume exchanges, first three times weekly and then twice weekly.

Although the importance of prompt plasma exchange has been established, the use of corticosteroids,[70] aspirin, and dipyridamole has not been tested in prospective clinical trials. With the observation of autoantibody against ADAMTS13 as a significant cause of acquired idiopathic TTP, rituximab (375 mg/m^2

I.V. once weekly for 4 weeks) has been tried and reported to be effective, although the overall experience is still limited.[71-73] Because pheresis tends to lower the platelet count in a patient who is already thrombocytopenic, the problem of platelet transfusion arises. Some investigators have observed that platelet infusion may lead to exacerbation of TTP,[74] whereas others use platelet transfusions as required.

In the previously described prospective study of patients with severe deficiency in ADAMTS13 activity (see above), plasma exchange proved to be a useful therapy; among the patients with idiopathic TTP and severe ADAMTS13 deficiency without detectable inhibitors, the majority responded to plasma exchange with complete remission and a rise in the ADAMTS13 level.[58] However, in patients with mild ADAMTS13 deficiency and high inhibitor levels, plasma exchange was not effective in reducing the inhibitor titer or in increasing the ADAMTS13 activity. Nevertheless, some of these patients had a favorable clinical response, including resolution of thrombocytopenia and cessation of hemodialysis. Among the patients whose TTP was not idiopathic, response to plasma exchange was variable. Of note, mortality in patients with idiopathic TTP with severe ADAMTS13 deficiency has been shown to be 15% to 20%, whereas mortality in patients with nonidiopathic TTP has been much higher, at 55% to 60%.[58,60] Many of the patients in the latter group have had serious underlying disease and comorbidities, such as hematopoietic stem cell transplantation, which likely has contributed to the high mortality.

Management of acute TTP should therefore depend on the clinical manifestations and course of the disease.[75] In all cases, plasma exchange is first-line therapy. Patients who respond promptly and completely to plasma exchange—which most likely will be those patients with idiopathic TTP and very low or nondetectable levels of inhibitors—may not need any further treatment. For patients who show a suboptimal response—such as an initial rise in platelet counts or a recurrence in thrombocytopenia when the plasma exchange treatments are decreased—glucocorticoid is indicated. For patients who experience a more aggressive course (e.g., those with severe neurologic abnormalities or those who do not respond to the initial plasma exchange with or without steroid therapy), more intensive immunosuppressive therapies, such as rituximab, should be considered.

Microangiopathy may persist for weeks or months after all other evidence of disease has subsided. In a large follow-up study of TTP patients, about one third of patients who entered remission had a relapse over a 10-year period.[76] The risk of recurrence is largely restricted to patients with severe ADAMTS13 deficiency—primarily, patients with idiopathic TTP. Relapse seldom occurs in patients who have TTP in association with hematopoietic stem cell transplantation or drugs. Conflicting data have been reported regarding patients who have had relapses after TTP associated with pregnancy.

Most experts treat adult HUS in a manner similar to that for TTP. However, the response to plasma exchange appears to be less favorable in HUS than in TTP, which may be consistent with the recent finding that the ADAMTS13 level is generally not diminished in HUS.

Thrombocytopenia Induced by Infection

Severe viral, bacterial, fungal, and parasitic infections can produce DIC and, consequently, thrombocytopenia [*see 5:XIV Thrombotic Disorders*]; however, mechanisms other than DIC may also cause infection-associated thrombocytopenia.

Viral infections Viral infections such as dengue fever and congenital rubella can directly damage the megakaryocytes. Varicella can cause a form of thrombocytopenia that has the characteristics of an immune reaction: increased numbers of megakaryocytes, no evidence of DIC, and the presence of PA-IgG. Usually, no therapy is required. The acute thrombocytopenia in infectious mononucleosis is probably immune mediated, as shown by the increase in marrow megakaryocytes and the favorable response to corticosteroids.

Bacterial septicemia Patients who have severe gram-negative septicemia and platelet counts lower than 50,000/μl usually have evidence of DIC. However, many patients who have both gram-negative and gram-positive septicemia and platelet counts between 50,000 and 150,000/μl have no signs of DIC. The PA-IgG levels are often elevated, which may represent immune complexes deposited on the platelet surface rather than antiplatelet autoantibodies. The key to controlling the thrombocytopenia is establishing appropriate therapy for the infection. If DIC is present, it should be managed with careful control of hypotension and blood volume.

Protozoan infection Thrombocytopenia is common in malaria, although DIC is rare. Platelet survival is short, and elevated PA-IgG has been found to be elevated. The IgG antibody appears to bind to malarial antigens adsorbed to the platelet surface.[77]

Thrombocytopenia during Pregnancy and Peripartum Period

Mild thrombocytopenia, with platelet counts generally in the range of 110,000 to 150,000/μl and seldom below 70,000/μl, occurs in 5% to 8% of pregnant women (gestational thrombocytopenia). It has no clinical significance, but it must be distinguished from ITP, pregnancy-associated TTP, and preeclampsia.

In addition to having hypertension, proteinuria, and evidence of pathologic changes in the kidneys, liver, CNS, and placenta, approximately 15% of patients with preeclampsia have moderate thrombocytopenia. Only a minority of patients with preeclampsia and thrombocytopenia demonstrate laboratory evidence of DIC. The megakaryocyte number is increased, and platelet survival is somewhat shortened. Some patients with preeclampsia and thrombocytopenia also have microangiopathic hemolysis, which suggests that damaged vessels containing fibrin strands are destroying red blood cells and platelets. Intense vasospasm that causes endothelial damage and leads to platelet activation, adherence, and destruction may also play a role. The clinical picture may be indistinguishable from TTP, in which case it should be managed as TTP. Otherwise, management consists of prenatal care for preeclampsia and efforts to detect thrombocytopenia as early as possible.

HELLP syndrome The HELLP syndrome refers to a disorder that occurs during pregnancy and is characterized by hemolysis, elevated levels of liver enzymes, and a low platelet count. It probably represents an extremely severe form of preeclampsia. At some point between the 23rd and 39th week of pregnancy, affected patients present with thrombocytopenia marked by a platelet count of less than 100,000/μl, microangiopathic hemolysis, abnormal liver function test results, and, occasionally, hypertension.[78] The results of the standard coagulation tests for DIC are normal, although there may be some elevation in the level of

fibrin degradation products. Patients with the HELLP syndrome are often severely ill, with circulatory, respiratory, and renal failure; postpartum hemorrhage; intrahepatic hemorrhage; and seizures.

The differential diagnosis includes acute fatty liver of pregnancy and TTP/HUS. In acute liver of pregnancy, patients have a prolonged PT and aPTT and low fibrinogen levels; hypertension and proteinuria are usually absent. In TTP/HUS, the liver enzymes are normal or only mildly elevated.

HELLP is treated by terminating the pregnancy, usually by delivery, and by providing meticulous supportive care. In a large series of patients with HELLP, the nadir of thrombocytopenia occurred 1 to 2 days after delivery.[79] It may also develop for the first time within 24 to 48 hours post partum.[80] Treatment of HELLP remains controversial, but corticosteroids appear to be beneficial.[81] Persistent thrombocytopenia with microangiopathy or the presence of organ failure suggests postpartum TTP/HUS; in such patients, plasma exchange therapy should be considered.

Platelet Washout and Vascular Bed Abnormalities

Patients who have brisk bleeding during surgery and who require massive transfusions (e.g., 10 units of packed red cells and multiple units of fresh frozen plasma) frequently develop nonimmune thrombocytopenia. If the platelet level falls below 100,000/μl and the patient is undergoing surgery or another hemostatic challenge, platelets should be administered. Platelets may also be removed by an abnormal vascular bed. In giant hemangiomas, there is sluggish blood flow through improperly endothelialized channels. These surfaces may produce low-grade DIC.

Platelet Sequestration

Another major mechanism of thrombocytopenia is platelet sequestration. Platelet counts of 40,000 to 80,000/μl are common in patients with marked splenomegaly. Clinically significant hemorrhage rarely occurs unless a coexistent hemorrhagic disorder is present. Management is directed toward the primary disease. Splenectomy is rarely necessary.

Platelet Function Disorders

The clue to the existence of a platelet function defect is the finding of clinical hemorrhage in the presence of a prolonged bleeding time and a platelet count higher than 100,000/μl. Petechiae are rare. Platelet morphology and tests of platelet function may be abnormal [*see Table 4*].

HEREDITARY ABNORMALITIES OF PLATELET FUNCTION

Platelet Membrane Disorders

Bernard-Soulier syndrome is a rare autosomal recessive disease that is characterized by giant platelets, a prolonged bleeding time, moderate thrombocytopenia, and risk of fatal hemorrhage. The defect, which is an absence of the platelet GPIb-IX-V complex (the major vWF binding site of the platelet), causes impaired platelet adhesion to wound surfaces. Ristocetin-induced platelet agglutination is abnormal and is not corrected by the addition of normal plasma containing vWF. Acute hemorrhage is treated by platelet transfusions.

Glanzmann thrombasthenia is a rare autosomal recessive disorder in which platelet morphology and the platelet count are normal but the bleeding time is prolonged. Because the critically important GPIIb-IIIa complex that forms the platelet binding site for fibrinogen is absent, the platelets do not undergo aggregation after stimulation by ADP, thrombin, or collagen. Ristocetin-induced agglutination, however, is normal. Treatment consists of platelet transfusions when necessary.

Platelet Granule Disorders

Patients with the gray platelet syndrome, a rare disorder, have mucosal bleeding, ecchymoses, and petechiae. Moderate thrombocytopenia is present, and the bleeding time is prolonged. The platelets are larger than normal and appear agranular because of the absence of α-granules. Because the α-granule contents are severely reduced, platelet adhesion and platelet-supported coagulation are deficient. Platelet aggregation with collagen is abnormal. Bleeding episodes should be treated by infusion of normal platelets.

Another rare disorder, the dense granule deficiency syndrome, is characterized by mucosal bleeding associated with a normal platelet count, normal platelet morphology, and variable prolongation of the bleeding time. Platelet aggregation with ADP and collagen are abnormal. The decrease in the dense granular contents of ADP impairs ADP-mediated events. Hemorrhage is treated by platelet transfusion.

1-Desamino-8-D-arginine vasopressin (DDAVP, or desmopressin) is an alternative therapy for patients with primary platelet disorders that require surgery.

ACQUIRED ABNORMALITIES OF PLATELET FUNCTION

Myeloproliferative Diseases and Associated Platelet Abnormalities

Platelet function abnormalities occur in the myeloproliferative diseases: chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, and acute leukemia. The platelet count in chronic myeloproliferative disorders is often very high, but the bleeding time may be prolonged, and clinical bleeding may appear as mucosal hemorrhage and hematomas. The abnormality resembles an acquired storage-pool defect. Megakaryocytes often are abnormal with separated nuclei; the peripheral blood platelets are large and may be degranulated. Management of acute hemorrhage consists of transfusion of normal platelets to bring the level of normal platelets up to 50,000/μl. Aspirin and other NSAIDs should be avoided.

Uremia and Associated Platelet Abnormalities

A prolonged bleeding time associated with clinical bleeding despite a normal platelet count has been well documented in uremia. Uremic platelet dysfunction is presumably caused, in part, by several dialyzable uremic toxins, including phenolic acids and guanidinosuccinic acid.[82] DDAVP (0.3 μg/kg in 50 ml of saline over a 30-minute period) is effective in controlling uremic bleeding for about 4 to 6 hours. DDAVP infusion produces an increase in plasma vWF activity, particularly among the larger multimers of vWF, which may enhance platelet adhesion.

The hematocrit should be maintained above 30% in bleeding uremic patients because the bleeding time is prolonged when the hematocrit falls below 26%.[83] Bleeding may also be controlled by the use of conjugated estrogens. Conjugated estrogen (Premarin) given orally (50 mg/day) or intravenously (0.6 mg/kg/day) for 4 to 5 days shortens the bleeding time by approximately 50% for about 2 weeks.[84] The advantage of conjugated estrogens over DDAVP is the longer duration of their benefi-

Table 4 Classification of Platelet Function Disorders

Type	*Characteristic*	*Cause*
Congenital	Membrane abnormalities	Bernard-Soulier disease (GPIb-IX-V defect, impaired adhesion); Glanzmann thrombasthenia (GPIIb-IIIa defect, impaired aggregation)
	Granule abnormalities	Gray platelet syndrome (absent or impaired α-granule release, impaired aggregation); dense granule deficiency (absent or impaired dense granule release, impaired aggregation)
	Deficiency of a plasma factor	von Willebrand disease (deficiency or abnormality of von Willebrand factor, impaired adhesion); afibrinogenemia (deficiency of fibrinogen, impaired aggregation)
Acquired	Production of abnormal platelets	Myeloproliferative disease (essential thrombocytopenia, chronic myelogenous leukemia, polycythemia vera, myelofibrosis, acute myelogenous leukemia); myelodysplasia
	Dysfunction of normal platelets	Systemic disease (uremia, liver disease, paraproteinemias, disseminated intravascular coagulation); drugs (aspirin and other nonsteroidal anti-inflammatory drugs, ticlopidine, clopidogrel, GPIIb-IIIa antagonists, dextran, antibiotics [penicillin, carbenicillin, moxalactam], psychotropic drugs)

cial effect on platelet function, but they have a more delayed onset of action. The two drugs can be used concomitantly.

Patients with end-stage renal disease have complex hemostatic disorders. Despite decreased platelet function (caused by uremic toxins present in the circulating blood), thrombosis of vascular access shunt commonly occurs in patients with end-stage renal failure who are on hemodialysis. Hemostatic parameters suggestive of a hypercoagulable state, such as increased plasma fibrinogen and factor VIII levels, have been described.[82]

Effects of Macroglobulinemia and Other Dysproteinemias on Platelet Function

The presence of high concentrations of viscous proteins produces complicated effects on the entire hemostatic mechanism. The proteins appear to coat platelets and interfere with adhesion and perhaps with aggregation. Management is directed at the primary disease, but if hyperviscosity and bleeding are significant, prompt plasmapheresis may be required to lower the level of abnormal protein and to correct the bleeding disorder.

Drug-Induced Platelet Disorders

Aspirin and other nonsteroidal anti-inflammatory drugs In normal persons, ingestion of 0.6 g of aspirin prolongs the template bleeding time by 2 to 3 minutes. The platelets are irreversibly affected. Thromboxane A_2 (TXA_2) is a potent inducer of platelet release and aggregation [*see 5:XII Hemostasis and Its Regulation*]. Aspirin acetylates and irreversibly inhibits cyclooxygenase-1 (COX-1) and blocks the subsequent generation of thromboxane. Some apparently normal persons display marked sensitivity to the action of aspirin, so that their bleeding times are very much prolonged and they have clinically significant bleeding, particularly during or after surgery or trauma. These patients may have a mild form of von Willebrand disease or storage-pool disease, and their mild bleeding diathesis becomes exacerbated by aspirin's antiplatelet effect.

Uremic patients are especially sensitive to bleeding induced by aspirin. A small dose of aspirin does not prolong the bleeding time of normal persons, but in uremic patients, it produces a significant prolongation, often as much as 15 minutes. The combination of alcohol and aspirin is also dangerous because of aspirin's ability to prolong the bleeding time.

Aspirin-induced bleeding is diagnosed by determining the existence of an acquired platelet function defect (a platelet count above 100,000/μl, abnormal platelet aggregation test results, and no prior bleeding history) and finding evidence of aspirin ingestion. Because approximately 300 compounds on the market contain aspirin, a negative history should be supplemented either by determining a serum salicylate level or by detecting an abnormal collagen aggregation pattern that reverts to normal in 7 days (the typical pattern of aspirin ingestion).

If bleeding is significant, it can be managed by platelet transfusion. Because inhibition of platelet COX-1 by aspirin is irreversible, the hemostatic compromise may last for 4 to 5 days after the aspirin has been discontinued. If the patient needs analgesia, acetaminophen or codeine can be used because neither affects platelet function.

Alcohol In addition to producing thrombocytopenia by suppressing platelet production, alcohol consumption can cause platelet function defects.[85] In vitro studies have shown that alcohol impairs platelet aggregation and TXA_2 release. Platelet function returns to normal after 2 to 3 weeks of abstinence.

Antibiotics Carbenicillin and ticarcillin can inhibit platelet aggregation and contribute to a bleeding disorder, as can massive doses of penicillin. Massive doses of penicillin impair collagen-induced and ristocetin-induced platelet aggregation. Moxalactam, a third-generation cephalosporin, also causes a platelet function disorder. The clinical situation is most important when an acquired platelet function defect develops in a pancytopenic patient being treated for septicemia. Changing the antibiotics usually corrects this problem.

Miscellaneous agents A wide variety of other agents can modify platelet function [*see Table 5*].[86]

Thrombocytosis and Thrombocythemia

DIAGNOSIS

A platelet count higher than 500,000/μl is referred to as reactive thrombocytosis. In reactive thrombocytosis, tests of platelet function (including platelet aggregation studies) are generally normal, and patients do not experience an increased incidence of hemorrhage or thromboembolism even when the platelet count exceeds 1 million/μl.

Elevated platelet counts (often, 1 million to 3 million/μl or more) also occur in chronic myeloid leukemia, agnogenic myeloid metaplasia with myelofibrosis, polycythemia vera, and essential thrombocythemia. In the diagnosis of essential

thrombocythemia, the platelet count is higher than 600,000/μl and other causes of thrombocytosis (e.g., another myeloproliferative disorder or reactive thrombocytosis) have been excluded. A gain-of-function mutation in tyrosine Janus kinase–2 (JAK2) has been found in many patients with myeloproliferative disorders; it is found in about 80% of patients with polycythemia vera and in about 25% to 50% of patients with essential thrombocythemia.[87-89] In myeloproliferative disorders, test results of platelet function are frequently abnormal [*see* Platelet Function Disorders, *above*]. Some patients with myeloproliferative disorders seem to show an enhanced propensity for hemorrhage and thromboembolism. Neither platelet number nor measurements of platelet function predict the degree of thrombosis or hemorrhage.

Clinically, the hemorrhagic signs include mucosal, particularly gastrointestinal, bleeding; hematomas; and ecchymoses. There may be splenic vein thrombosis, portal or mesenteric vein thrombosis, and recurrent deep vein thrombosis with or without pulmonary embolism. Arterial thrombosis is less common.

TREATMENT

Patients with essential thrombocythemia and polycythemia vera may have debilitating erythromelalgia (burning and itching of the fingers and toes) that can progress to ischemic acrocyanosis.[90] This symptom complex appears to be caused by occlusion and inflammation of arterioles by platelet aggregates. Aspirin or indomethacin produces relief within hours. Aspirin given at a dosage of 325 mg daily can produce lasting benefit.

Hemorrhage and thrombosis are uncommon events even with platelet counts of 1 million/μl. In a patient with essential thrombocythemia who has clinically significant hemorrhage or thrombosis, good control of the platelet count can be achieved with oral hydroxyurea (15 mg/kg/day), with adjustments in the dosage as needed to lower the platelet count. Hydroxyurea therapy requires careful monitoring of the blood count; thus far, hydroxyurea therapy does not appear to increase the risk of a second malignant disorder. Newer therapies for thrombocythemia include the use of anagrelide, a powerful platelet-lowering agent.[91] A recent prospective, randomized trial comparing hydroxyurea with anagrelide showed that although the two agents were equally efficacious in long-term control of the platelet count, anagrelide was associated with an increased risk of arterial thrombosis (mostly transient ischemic attacks) and serious hemorrhage.[92] Thus, hydroxyurea (0.5 to 2.0 g daily to maintain the platelet count at less than 400,000/μl) plus low-dose aspirin (81 mg daily) should be the first-line therapy for patients with essential thrombocythemia who are considered at high risk for vascular events.

Vascular Purpuras

Vascular purpuras are a heterogeneous group of disorders [*see Table 6*] that are characterized by cutaneous hemorrhage and are occasionally associated with mucosal bleeding. The leakage occurs from terminal arterioles, capillaries, and postcapillary venules. The results of tests of platelet number and function and tests of procoagulant function are normal.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia (HHT) is transmitted as an autosomal dominant disease and has an estimated incidence of one in 5,000 to 8,000 persons.[93] Recent linkage analyses have identified at least three HHT loci, including the genes for endoglin and activinlike receptor kinase. Both proteins are expressed on vascular endothelial cells and may function as receptors for transforming growth factor–β (TGF-β). TGF-β plays a complex role in coordinating responses between endothelial cells and the extracellular matrix. A mutation in the gene for either endoglin or activinlike receptor kinase results in a 50% reduction in the normal quantity of protein on endothelial cells (haploinsufficiency) and leads to the development of abnormal blood vessels and arteriovenous malformations (AVMs).[94]

HHT generally does not present at birth but manifests itself with age. Recurrent epistaxis is typically the earliest sign of disease, commonly occurring in childhood. Pulmonary AVMs, occurring in about 30% of HHT patients, become apparent after puberty and may present as dyspnea, chest pain, and hemoptysis. Physical examination may reveal chest bruits and digital clubbing. Mucocutaneous telangiectasias, which occur in the majority of patients and at characteristic sites (e.g., lips, oral cavity, fingers, and nose), typically become noticeable by the third decade of life and increase in size and number as the patient ages. The diagnosis of HHT should be based on four criteria: (1) spontaneous and recurrent epistaxis, (2) multiple mucocutaneous telangiectasias, (3) evidence of visceral telangiectasias and AVMs (e.g., gastrointestinal tract, pulmonary, hepatic, or cerebral AVMs), and (4) a positive family history of HHT.

Coagulation test results are generally normal. The pulmonary AVMs may be associated with hypoxemia and secondary polycythemia. The diagnosis can be confirmed by pulmonary angiography. If the shunts are large and clinically significant, they can be treated by balloon embolotherapy.[95] Paradoxical embolus with stroke can occur in patients with HHT who have pulmonary arteriovenous shunts and malformations. It has been advocated that asymptomatic HHT patients be screened for AVMs and be treated prophylactically with embolotherapy if AVMs are found.[96] Management of recurrent epistaxis should be conservative and often involves devising methods for obtaining nasal tamponade. Cauterization should be avoided because damage to nasal mucosa may result in vascular regrowth. Gastrointestinal bleeding is managed by the use of iron preparations when possible.

Table 6 Vascular Purpuras

Congenital disorders	Hereditary hemorrhagic telangiectasia Hereditary connective tissue disorders Ehlers-Danlos syndrome Marfan syndrome Pseudoxanthoma elasticum
Acquired disorders	Scurvy Amyloidosis Glucocorticoid excess Immunoglobulin disorders Waldenström macroglobulinemia Cryoglobulinemia Hepatitis B Henoch-Schönlein purpura Embolism (i.e., microvascular damage from septic and bland emboli from heart valves, fat embolism, and cholesterol embolism) Senile purpura

ACQUIRED DISORDERS OF BLOOD VESSELS THAT CAUSE BLEEDING

Scurvy

Vitamin C is required for the normal metabolism of collagen, folate, and perhaps iron. The patient with scurvy suffers primarily from impaired collagen synthesis. The lack of proper collagen support for the microvasculature leads to perifollicular hemorrhages, bleeding gums, and even deep tissue hematomas. Presumably, similar collagen defects lead to the so-called corkscrew hair and hyperkeratosis associated with this disorder.[97] The characteristic clinical picture in a malnourished person suggests the diagnosis. Plasma or buffy coat levels of ascorbic acid are low, and other vitamin deficiencies are usually present. Effective therapy consists of 1 g of ascorbic acid daily in divided doses.

Glucocorticoid Excess

Glucocorticoid excess, whether from endogenous or exogenous causes, produces cutaneous hemorrhages, probably because of glucocorticoid-induced catabolism of protein in vascular supportive tissues.

Amyloidosis

Amyloidosis can present as subcutaneous ecchymoses that have a predilection for the neck and upper chest. Biopsy of the site shows the amyloid, which by its infiltration may weaken the vessel walls or interfere with surface activation of platelets, procoagulants, or both. In patients with primary systemic amyloidosis, especially when accompanied by a huge amyloid spleen, the amyloid can in some instances adsorb enough factor X to cause profound factor X deficiency and clinical bleeding. Infusions of fresh frozen plasma are usually ineffective. Recombinant factor VIIa is effective, but it is extremely expensive and provides only temporary benefit. Splenectomy may provide long-term benefit and should be considered in a patient with recurrent serious clinical bleeding.

Immunoglobulin Disorders

The purpuric lesions in patients with immunoglubulin disorders (e.g., cryoglobulinemia, Waldenström macroglobulinemia, Henoch-Schönlein purpura, and multiple myeloma) may be raised (palpable purpura). On biopsy, these lesions may show mast cell degranulation and, when stained appropriately, immune complex deposition. Presumably, the immune complexes provide the chemotactic stimulation that leads to the congregation of neutrophils. Damage to the microvasculature is caused by the complement attack complex and by the release of the contents of the neutrophil granules. This inflammatory component produces the palpable purpura.

Damage to the Microvasculature Due to Emboli

DIC and TTP can cause localized vaso-occlusions leading to microvascular damage and leakage of red blood cells. Similar damage can be caused by emboli that arise from infected heart valves. Fat embolism may complicate fractures of the long bones and pelvis. The syndrome consists of fever; confusion; and petechiae, purpura, or both over the neck, chest, face, and axillae. Cholesterol embolism can also cause petechiae, usually over the lower extremities. It typically occurs in a patient with severe ath-

erosclerosis who has recently undergone an invasive procedure involving the abdominal aorta or renal arteries. Biopsy of the purpura shows cholesterol crystals when an appropriate stain is used.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XIV THROMBOTIC DISORDERS

Lawrence L. K. Leung, m.d.

Thrombosis is more than excessive blood clotting; it also involves vascular inflammation. The classic triad of Virchow identifies three major elements in the pathophysiology of thrombosis: endothelial injury, a decrease in blood flow, and an imbalance between procoagulant and anticoagulant factors.

Endothelial cells can be activated or injured by a variety of stimuli, including mechanical trauma, endotoxins and cytokines, proteases, inflammatory mediators, immune complex deposition, oxygen radicals, and hypoxia. Each of these stimuli affects multiple facets of endothelial cell function, ultimately changing the cell from its natural antithrombotic state to a prothrombotic one.

The vascular endothelium, in its unique location in the vessel wall, is capable of sensing and responding to the different mechanical forces in the blood circulation. The shear stress caused by the friction from blood flow seems to be particularly important in modulating endothelial functions. In areas of linear flow, the blood moves in ordered laminar patterns in a regular pulsatile fashion. Such a steady, laminar blood flow apparently promotes an antithrombotic endothelial phenotype. In areas of disrupted flow, such as at vascular bifurcations or stenoses, the endothelium may be exposed to significant changes in shear gradients, and the cells may become activated and prothrombotic.

Imbalance between procoagulant and anticoagulant factors can be hereditary or acquired [*see Table 1*]. Some clotting factors, such as factor VIII and fibrinogen, are acute-phase reactants: their plasma levels increase significantly with acute inflammation, possibly conferring a transient prothrombotic state. Some hereditary deficiencies of anticoagulant proteins, such as factor V Leiden and antithrombin (AT), are associated with recurrent thrombosis; these are among the best understood clinical hypercoagulable states.

Although the hypercoagulable state is systemic, thrombosis occurs locally (e.g., in the lower extremities). The clinical outcome likely reflects a complex interaction between the systemic prothrombotic predisposition and local hemostatic control mechanisms specific to the vascular bed. Specific and distinctive gene transcript expression patterns in different vascular beds have now been demonstrated.[1]

Assessment of Patients with Thrombotic Disorders

PRIMARY CLINICAL ISSUES IN THROMBOTIC DISORDERS

Important questions in the assessment of thrombosis include the following: (1) How likely is it that the thrombosis is caused by an underlying hypercoagulable state? (2) How extensive a workup is indicated? (3) When should the workup be done? Answers to these questions come from a consideration of the patient's age at the time of the first thrombosis; presence or absence of a provoking factor; family history and past medical history of response to situations associated with high risk of thrombosis; and the site, type, and severity of the thrombosis.

Age of Onset of First Thrombosis

In a retrospective study involving 150 families with an inherited predisposition to recurrent thrombosis (thrombophilia), the mean age at the time of the first thrombosis was 35 to 40 years. However, the first episode of thrombosis can occur as early as the second decade of life if the patient has more than one hereditary risk factor.[2]

Presence or Absence of a Provoking Factor

Common triggers of thrombosis are surgery, trauma, pregnancy, malignancy, prolonged immobilization, and infection. Malignancy or infection can be clinically overt or subclinical. Those circumstances can provoke thrombosis even in persons with a normal coagulation system, and they often uncover a thrombophilia that had been clinically silent.[2] However, sometimes no provoking factors can be identified. Such a spontaneous, idiopathic thrombosis, especially when it occurs in a young person, strongly suggests an underlying hereditary hypercoagulable state.

If thrombosis develops in a patient who has had previous pregnancies or surgeries (especially orthopedic procedures)

Table 1 Inherited and Acquired Hypercoagulable States

- *Inherited*
  - Resistance to activated protein C/factor V Leiden
  - Prothrombin gene mutation 20210A
  - Antithrombin III deficiency
  - Protein C deficiency
  - Protein S deficiency
  - Hyperhomocysteinemia
- *Acquired*
  - Antiphospholipid antibody syndrome
  - Hypercoagulable state associated with physiologic or thrombogenic stimuli:
    - Advancing age
    - Oral contraceptives
    - Pregnancy
    - Surgery
    - Trauma
  - Hypercoagulable state associated with other clinical conditions:
    - Malignancy—Trousseau syndrome
    - Heparin-induced thrombocytopenia with thrombosis
    - Nephrotic syndrome
    - Hyperviscosity (polycythemia vera, Waldenström macroglobinemia, multiple myeloma)
    - Myeloproliferative disorders (polycythemia vera, essential thrombocythemia)
    - Paroxysmal nocturnal hemoglobinuria
    - Sickle cell anemia
- *Rare or not well established*
  - Dysfibrinogenemia
  - Hypoplasminogenemia, dysplasminogenemia
  - Abnormal thrombomodulin
  - Factor XII deficiency
  - Elevated factor VII, factor VIII, fibrinogen, lipoprotein(a), plasminogen activator inhibitor–1

Table 2 Screening Tests for Patients with Suspected Hypercoagulable State

Underlying State	*Laboratory Evaluation*
Venous thrombosis	Resistance to activated protein C Factor V Leiden (genetic test) Clotting assay (unnecessary if the genetic test for factor V Leiden is positive) Prothrombin mutation 20210A (genetic test) Antithrombin III (functional assay) Protein C (functional assay) Protein S Functional assay Antigenic assay for free protein S
Arterial thrombosis	Antibodies associated with heparin-induced thrombocytopenia* Chronic disseminated intravascular coagulation (Trousseau syndrome)* Lipoprotein(a)
Venous thrombosis and/or arterial thrombosis	Plasma homocysteine Fasting level Level after methionine loading (if thrombophilia is strongly suspected) Antiphospholipid antibody Clotting assays for lupuslike anticoagulant ELISA for anticardiolipin antibodies IgG and IgM Dysfibrinogenemia (if thrombophilia is strongly suspected) Functional assay for fibrinogen level Thrombin time, reptilase time

*In appropriate clinical settings.
ELISA—enzyme-linked immunosorbent assay

without any thrombotic complications, an acquired hypercoagulable state should be considered. Likely conditions in such cases are antiphospholipid antibody syndrome or Trousseau syndrome (see below).

Family History

Objectively documented venous thromboembolism before 50 years of age in a first-degree family member strongly suggests a hereditary thrombotic disorder. However, a negative family history does not exclude a hereditary condition. Clinical thrombosis is frequently the culmination of multiple thrombogenic risk factors, only one of which may be hereditary and irreversible. In patients with symptomatic thrombosis and well-documented hereditary hypercoagulable states, it is not uncommon to find other family members with the same deficiency but no clinical thrombosis.

Recurrent Thrombosis

A patient who experiences recurrent thrombosis likely has a hypercoagulable state (hereditary or acquired). However, if a patient who initially presented with deep vein thrombosis (DVT) in a lower extremity returns with symptoms involving the same leg, the problem may be postphlebitic syndrome rather than recurrent thrombosis. Acute exacerbation of the postphlebitic syndrome, with its increased leg edema and pain, can be difficult to distinguish from recurrent acute DVT. As an anticipatory measure, it is sometimes useful to obtain a repeat compression ultrasound study of the lower extremity after resolution of an acute episode of DVT; the repeat scan can provide a baseline for future comparison.

Site of Thrombosis

Most commonly, thromboses involve the deep veins of the lower extremities. Thrombosis at an atypical site, such as the hepatic, mesenteric, or cerebral veins (or skin necrosis after warfarin administration), increases the likelihood of an underlying hypercoagulable state. Spontaneous axillary vein thrombosis may also indicate the presence of an underlying hypercoagulable state, but this association is controversial.[2-4]

Recurrent thrombosis at arterial sites has a differential diagnosis—and therefore a workup—that is quite different from that for recurrent venous thrombosis [*see Table 2*]. Most of the common hereditary hypercoagulable states (e.g., AT deficiency or factor V Leiden) are associated with venous thromboses, such as DVT in the lower extremities. They are seldom associated with arterial thromboses, such as transient ischemic attack, stroke, digital ischemia, and myocardial infarction. A few hypercoagulable states, such as the antiphospholipid syndrome and hyperhomocysteinemia, are associated with both types of thrombosis.

The Hypercoagulable Workup

Extent of the workup On the basis of the above clinical considerations, one may estimate the likelihood of an underlying thrombophilia in a given patient with thrombosis [*see Table 3*]. Because studies of cost-effectiveness and outcomes are not available, it is difficult to list strict practice guidelines regarding the extent of the hypercoagulable workup. In general, however, if the likelihood of an underlying hypercoagulable state is high, an extensive workup is warranted.

A limited workup is appropriate for mild to moderate DVT of the lower extremities with an obvious provoking factor. For example, in a young woman who experiences DVT in the superficial femoral vein while on an oral contraceptive, evaluation of factor V Leiden, prothrombin mutation 20210A, AT, protein C, protein S, homocysteine, anticardiolipin antibodies, and lupus anticoagulant may be sufficient. On the other hand, an acquired hypercoagulable state should be considered in an elderly patient with a spontaneous DVT and no history of previous thrombosis. Diagnostic possibilities in such cases would include antiphospholipid antibody syndrome, acquired AT deficiency (if the patient has evidence of nephrotic syndrome), or Trousseau syndrome.

When the clinical history strongly suggests thrombophilia—as in a patient with recurrent thrombosis or thrombosis at atypical sites—one may argue that a workup for an underlying hypercoagulable state is unnecessary because the result will not alter the management of the case. However, the identification of any underlying risk factors will improve the understanding of the disease for both the patient and the treating physician; and it will guide the counseling of the patient, especially regarding the need for screening of related family members. In the case of hyperhomocysteinemia and elevated lipoprotein(a) levels, identifi-

Table 3 Clinical Features That Suggest Thrombophilia

Age at onset of first thrombosis < 50 yr
No identifiable risk factor
Positive family history
Recurrent thrombosis
Atypical site of thrombosis

cation of risk factors will permit the use of specific therapies (see below).

Timing of the workup The clinician needs to know not only what tests to order but when to order them. In acute thrombosis, many inhibitors of the clotting cascade (e.g., AT and protein C) are consumed. Immediately after the episode, their plasma levels may be decreased, even in patients who do not have a hereditary deficiency. Heparin therapy can reduce antithrombin levels up to 20%, whereas warfarin treatment reduces the levels of protein C and protein S. Usually it is best to postpone measurement of these inhibitors until the acute thrombotic episode is completely resolved, preferably 4 weeks after termination of oral anticoagulation therapy. Tests for specific genotypes (e.g., factor V Leiden) can be performed at any time, however.

Frequency and Relative Risk of Venous Thromboembolism

The frequency of various hypercoagulable states in unselected patients who present with venous thrombosis ranges from 1% to 25% [*see Table 4*]. It should be recognized that these thrombophilias do not confer equivalent thrombotic risk. Factor V Leiden and prothrombin mutation 20210A, the two most prevalent risk factors, confer only a modest increase in relative risk of thrombosis, approximately threefold to sevenfold above normal. Moderate hyperhomocysteinemia, another common risk factor, also carries a modest increase in risk. Heterozygous deficiencies of AT, protein C, and protein S are generally considered more significant risk factors than factor V Leiden. AT deficiency and the antiphospholipid antibody syndrome are probably the greatest risk factors. The recurrence rate in patients with antiphospholipid antibody syndrome is as high as 50% to 70% in some studies.

Patients with symptomatic thrombosis frequently have more than one risk factor, which may have a synergistic effect in increasing the thrombosis risk. For example, women with factor V Leiden who use oral contraceptives have a risk of venous thromboembolism that is 35-fold higher than that in the general population.

Table 4 Frequency and Relative Risk of Venous Thrombosis in Selected Hypercoagulable States*

Condition	*Relative Risk†*	*Frequency‡*
Antithrombin III deficiency	High	1%–2%
Protein C deficiency	High	3%–4%
Protein S deficiency	High	2%–3%
Factor V Leiden	Modest	20%–25%
Prothrombin mutation 20210A	Modest	10%
Hyperhomocysteinemia	Modest	10%
Oral contraceptive use	Modest	NA

*The incidence of venous thromboembolism in the normal population is estimated to be 0.008% a year (0.03% a year in patients who take oral contraceptives).
†Modest risk is defined as an approximate 2.5-fold to fivefold increase in thromboembolism, on the basis of data from the Leiden Thrombophilia Study[146]; high risk is defined as an approximate threefold to fourfold increase over that for factor V Leiden.[2]
‡In unselected patients with venous thromboembolism.

Hereditary Hypercoagulable States

ANTITHROMBIN DEFICIENCY

Epidemiology and Etiology

The frequency of symptomatic inherited AT deficiency in the general population has been estimated to be approximately 1 per 2,000 people.[5] The deficiency is transmitted in an autosomal dominant pattern. Homozygous AT deficiency has not been reported, presumably because the condition is incompatible with normal fetal development.

There are two types of inherited AT deficiency. Type I is quantitative, as measured by antigenic and functional assays. A large number of molecular mutations have been characterized in type I AT deficiency, including partial gene deletions and single-nucleotide substitutions that cause nonsense or missense mutations leading to premature stop signals in the protein-translation process.

Type II deficiency is qualitative; plasma levels of AT antigen are normal. The underlying defect is generally a single nucleotide change that causes missense mutations, giving rise to a dysfunctional protein. Many of these proteins have decreased affinity for heparin binding.

In rare cases, AT deficiency is acquired. This condition may occur after administration of intravenous heparin for more than 3 days or after asparaginase therapy. It may also develop in patients with disseminated intravascular coagulation (DIC), severe liver disease, or the nephrotic syndrome.

Pathophysiology

AT inactivates factor Xa and thrombin by forming a stable stoichiometric complex with each of them. AT is present in sufficient amounts in plasma to inactivate all the thrombin formed in a given plasma volume, but it does so slowly unless it is activated by endothelial cell surface heparan sulfate or by administered heparin [*see 5:XIII Hemorrhagic Disorders*]. Patients with hereditary AT deficiency have evidence of continuous factor X activation and thrombin generation (as supported by elevated plasma levels of prothrombin fragment F1.2) even when they are clinically asymptomatic.

Clinical Presentation

Patients with AT deficiency show an increased incidence of venous thrombosis, usually triggered by a prothrombotic stimulus such as surgery, infection, immobilization, or trauma. This association suggests that the superimposition of a prothrombotic stimulus on an underlying subclinical hypercoagulable state leads to clinical thrombosis.

Typical clinical presentations are DVT of the legs, pulmonary embolism, and occasionally mesenteric vein thrombosis. There is no convincing evidence to suggest that AT deficiency increases the risk of arterial thrombosis.[6]

Affected patients usually have a family history of recurrent thromboses, generally beginning in youth and often associated with surgery or trauma. Pregnancy and the use of oral contraceptives also increase the risk of thromboses in AT-deficient patients. The tendency to thrombosis increases with advancing age: by age 50, only 10% of AT-deficient patients are free of symptoms.

Diagnosis

The AT level should be determined by a functional assay rather than an antigenic assay, so that both type I and type II de-

ficiency can be evaluated. Patients with AT deficiency have a surprisingly modest reduction in the protein: values measured by both bioassay and immunoassay range from 25% to 60% of normal in type I disease.

Treatment

Study of a large AT-deficient kindred indicates that long-term anticoagulant prophylaxis is not warranted in asymptomatic carriers of this deficiency.[7] Asymptomatic carriers should receive prophylactic anticoagulation only in situations known to increase the risk of thrombogenesis, such as abdominal surgery.[7] Once such patients have experienced a thrombotic event, however, they probably require lifelong warfarin therapy. Warfarin is the mainstay of long-term therapy for patients with AT deficiency and recurrent thromboembolism.

Acute episodes of thrombosis must be treated with heparin. Because AT deficiency may render heparin relatively ineffective, the physician should be alert to heparin resistance. In patients receiving unfractionated heparin, resistance is manifested by minimal prolongation of the partial thromboplastin time (PTT) despite the administration of therapeutic doses. If low-molecular-weight heparin (LMWH) is used, as is commonly the case, the level of anti–factor Xa (anti-FXa) should be checked to ensure that a therapeutic anticoagulant effect is achieved [*see 5:XII Hemostasis and Its Regulation*].

If heparin resistance occurs despite increased doses of heparin, heparin plus purified AT concentrates or fresh frozen plasma should be given. AT has a half-life of about 60 hours. These preparations can be used to carry an AT–deficient patient through surgery or delivery and should bring the AT level up to nearly 100%, depending on the patient's baseline AT level. The AT level should be checked and the infusion repeated at 24-hour intervals to maintain a normal AT level for 5 to 7 days after delivery or surgery.

Pregnancy in an AT–deficient patient is difficult to manage. Because warfarin may cause fetal malformations and neonatal hemorrhage, patients should be treated with full-dose unfractionated heparin or LMWH; those receiving LMWH should be switched to unfractionated heparin 1 to 2 weeks before delivery so that rapid reversal of anticoagulation, if necessary, can be more easily attained. If a therapeutic effect cannot be achieved (as measured by the PTT with unfractionated heparin or the anti-FXa level with LMWH), an AT infusion can be given.[8] Generally, this is not necessary. Anticoagulation should be promptly reinstituted after delivery.

PROTEIN C AND PROTEIN S DEFICIENCY

Pathophysiology and Clinical Presentation

Deficiency or defect in protein C or protein S results in a loss of ability to inactivate excess factor VIIIa and factor Va, the two major cofactors that regulate amplification of the clotting cascade. Protein C levels are low in patients with DIC and liver disease, probably because the activation of hemostasis consumes this factor [*see 5:XIII Hemorrhagic Disorders*].

Homozygous protein C deficiency causes lethal thrombosis in infants. Heterozygous protein C deficiency probably occurs with a prevalence of 1 per 200 to 300 in the general population. Clinical expression of heterozygous protein C deficiency varies: many persons with heterozygous deficiency, as well as persons with low-normal protein C levels from other causes, do not experience thrombosis,[9] whereas other patients with heterozygous deficiency exhibit a definite tendency toward venous thrombosis even though their protein C levels are 40% to 50% of normal. This phenotypic variability suggests multiple gene interactions and supports the hypothesis that clinical thrombosis in such patients may result from a combination of protein C deficiency and one or more other prothrombotic mutations.[10] Cerebral venous thrombosis presumably accounts for cases of cerebral hemorrhagic infarction that occur in young adults with protein C deficiency.

Deficiency of protein S also leads to venous thrombosis, including mesenteric vein thrombosis. Pregnancy and the use of oral contraceptives lower the protein S level, which may account for some cases of thromboembolism that occur under such circumstances.[11] Acquired protein S deficiency also occurs in patients with the nephrotic syndrome, who lose protein S in urine.[12] Case reports have associated protein S deficiency with warfarin-induced skin necrosis.[13]

Diagnosis

Functional and antigenic assays for protein C and protein S are now available in most coagulation laboratories. Functional assays are preferable for diagnosis. It is important to measure free protein S because some patients who have low free protein S levels have normal or borderline total protein S levels. Coagulation assays for protein C and protein S can give falsely low values in patients with factor V Leiden.[14]

Treatment

Warfarin is the treatment of choice for preventing thrombosis, even though it lowers protein C levels still further. Because the half-life of protein C is only 6 to 7 hours, much shorter than that of prothrombin and factor X, a period of enhanced hypercoagulability follows initiation of warfarin therapy in patients with protein C deficiency. Heparin should be given along with warfarin during the initiation of anticoagulation; it can be withdrawn afterward. Warfarin-induced skin necrosis is a rare complication of anticoagulation therapy.

FACTOR V LEIDEN

Epidemiology and Etiology

Factor V Leiden is a mutated form of factor V (first identified by researchers in Leiden, The Netherlands) that, once activated, is relatively resistant to the anticoagulant effects of activated protein C (APC). The defect is transmitted as an autosomal dominant trait. Approximately 5% of the general white population is heterozygous for factor V Leiden; the defect is almost absent in other ethnic groups.[15] Factor V Leiden is now considered to be the most common hereditary hypercoagulable state. Its prevalence in patients with thrombophilia is as high as 20% to 50%.[16] In a large cohort study of unselected patients with a first episode of symptomatic DVT, factor V Leiden was found in 16% of patients.[17] In women who have thrombosis while taking oral contraceptives, the frequency of factor V Leiden is about 23%.[18] The relative risk of DVT in a factor V Leiden homozygote (estimated incidence, 0.5% to 1% a year) is approximately 80-fold higher than in a normal person.[19] The risk of thrombosis in persons who are heterozygous for factor V Leiden is estimated to be fourfold to eightfold higher than that in normal persons; the relative risk increases to more than 30-fold when factor V Leiden is combined with oral contraceptive use. The absolute risk of thrombosis, however, is low.[20] Association of factor V Leiden

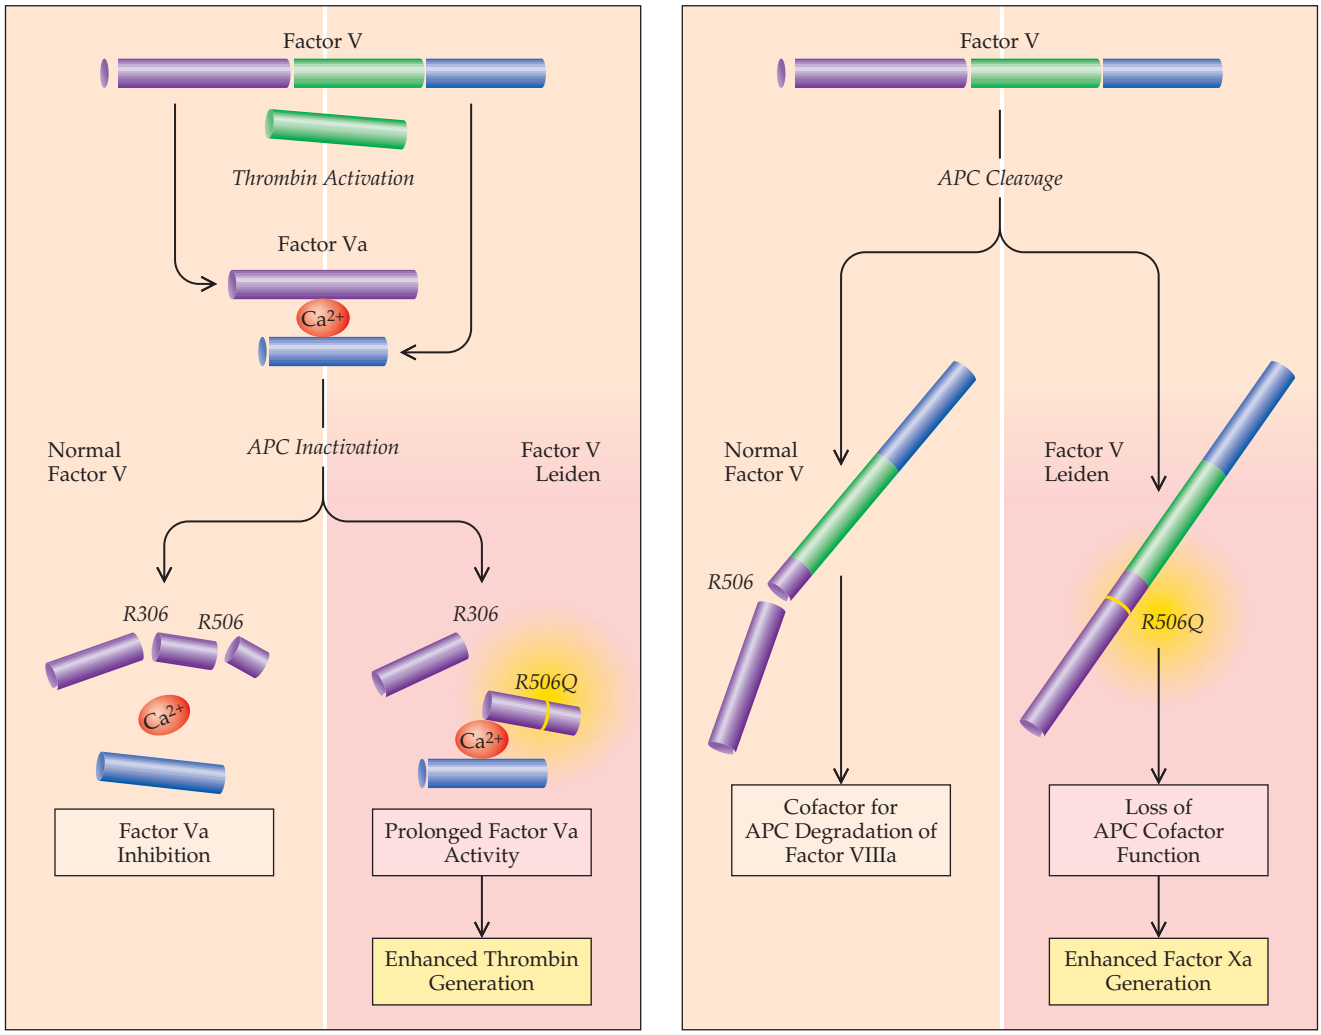

Figure 1 **Degradation of thrombin-activated factor V Leiden by activated protein C (APC) is significantly slower than that of normal activated factor V (factor Va), which leads to enhanced thrombin generation (left). Recent evidence suggests that normal factor V, together with protein S, serves as a cofactor of APC in the inhibition of factor VIIIa (right). This APC cofactor function of factor V requires the cleavage of factor V by APC at arginine 506; therefore, factor V Leiden has a poor cofactor function.**

with deficiencies of protein C, protein S, or AT has been reported in some families.[21-23] Overall, although factor V Leiden is highly prevalent, it is a relatively weak risk factor for thrombosis.

Approximately 5% of cases associated with inherited resistance to APC are attributable to other mutations and defects.[24-26] Conditions such as factor VIII elevation, pregnancy, oral contraceptive use, and lupus anticoagulant may result in APC resistance.[27] APC resistance that is not caused by factor V Leiden may be a risk factor for stroke[28,29] and venous thrombosis.[30,31] The overall risk of venous thrombosis from APC resistance is similar to or less than that posed by factor V Leiden.[32]

Pathophysiology

Resistance to the anticoagulant effects of APC is caused by a specific mutation in factor V (factor V Leiden or factor V R506Q) that results from a single-nucleotide substitution that leads to the replacement of arginine with glutamine at position 506.[32] Arginine 506 is located at one of the two major APC cleavage sites of activated factor V. Activated factor V Leiden expresses normal procoagulant activity, but its degradation by APC is approximately 10 times slower than that of normal activated factor V (factor Va). This slowing leads to increased thrombin generation.[33] In addition, recent evidence suggests that factor V (but not factor Va), together with protein S, serves as a cofactor of APC in the inhibition of the factor VIIIa/factor IXa complex and that factor V Leiden has a poor APC cofactor function [*see Figure 1*].

Clinical Presentation

Clinical manifestations of factor V Leiden are similar to those of deficiencies of AT, protein C, and protein S—mainly, venous thrombosis. However, the first thrombotic manifestation in factor V Leiden often occurs later than in the other hereditary thrombophilic states. Approximately 25% of apparently healthy men older than 60 years who experience a first episode of venous thrombosis have factor V Leiden.[34] There are conflicting data on whether factor V Leiden is associated with an increased risk of recurrent deep vein thrombosis. Several studies reported a slightly enhanced recurrence risk (twofold to fourfold), but more recent studies have shown that the risk of recurrence is similar to that in persons without the mutation.[17,35,36]

Diagnosis

Factor V Leiden can be identified rapidly and precisely with simple DNA-based tests. These tests allow the diagnosis to be made in patients receiving anticoagulation therapy with warfarin and in those who have coexisting antiphospholipid antibodies. Because factor V Leiden is not the sole cause of APC resistance, it may be worthwhile to pursue the diagnosis with an APC-resistance test in selected cases.

Treatment

Management of factor V Leiden is similar to that of AT, protein C, and protein S deficiencies. Patients with a first episode of venous thrombosis should receive anticoagulation therapy for 6 months. Thereafter, they should be given prophylactic anticoagulation therapy in situations known to provoke thrombosis. Long-term anticoagulation should be considered in patients with recurrent thrombosis.[37]

Young women known to be factor V Leiden carriers should avoid the use of oral contraceptives, which increases the relative risk of thrombosis (although the risk remains low in terms of absolute incidence). The optimal treatment of carriers during pregnancy has not been established. The rate of venous thromboembolism is low, about 2% without thrombosis prophylaxis.[20] My practice is not to use thrombosis prophylaxis routinely during pregnancy, but I will consider postpartum prophylaxis for 6 weeks, especially when the family history of thrombosis is strong. Routine screening of family members of patients with factor V Leiden is not cost-effective.[38]

PROTHROMBIN GENE MUTATION 20210A

A G-to-A mutation at nucleotide position 20210 in the 3' untranslated region of the prothrombin gene is associated with an increased incidence of venous thrombosis. The prevalence of the mutation in healthy persons is about 2.3%. Like factor V Leiden, this mutation is very rare in Asians and Africans. Unlike factor V Leiden, it is more common in southern Europeans than in northern Europeans.[39] The relative risk of thrombosis in persons with this mutation is 2.8, which is similar to the relative risk in those with factor V Leiden.[40] The mutation can be found in up to 18% of patients with thrombosis and family histories of thrombosis. The most common presentation is DVT of the lower extremities. Prospective studies have not shown an increased risk of recurrent DVT in patients with this mutation.[41] However, carriers who are heterozygous for both factor V Leiden and the prothrombin mutation have a higher risk of recurrent thrombosis.[35] The combination of oral-contraceptive use and the prothrombin gene mutation is associated with an increased incidence of cerebral vein thrombosis in young women.[42]

HYPERHOMOCYSTEINEMIA

Homocysteine is a highly reactive amino acid that is normally found in blood at levels of 5 to 15 mmol/L. Normally, homocysteine is derived from methionine by a transmethylation process and is remethylated to methionine or converted to cysteine [*see Figure 2*]. Metabolism of homocysteine requires betaine, cobalamin (vitamin B_{12}), folate, and pyridoxine (vitamin B_6).

Homocysteine can promote oxidation of low-density lipoprotein (LDL) cholesterol and presumably is toxic to vascular endothelium.[43,44] It may also inhibit thrombomodulin expression and protein C activation and suppress endothelial heparan sulfate expression; both of these effects lead to hypercoagulability.[45,46] Homocysteine also enhances the binding of lipoprotein(a) (an atherogenic lipoprotein) to fibrin, which may provide a link between hyperhomocysteinemia, thrombosis, and premature atherosclerosis [*see* Lipoprotein(a), *below*].[47] The vascular damage caused by high homocysteine levels leads to arterial and venous thrombosis and, perhaps, accelerated atherosclerosis.

Epidemiology and Etiology

Hyperhomocysteinemia can be divided into three classes: severe (homocysteine plasma concentration > 100 mmol/L), moderate (25 to 100 mmol/L), or mild (16 to 24 mmol/L). Severe hyperhomocysteinemia is usually caused by a homozygous deficiency of the enzyme cystathionine β-synthase. Affected persons have severe mental retardation, ectopic lens, skeletal abnormalities, and severe early-onset arterial and venous thrombotic disease.[48]

Mild or moderate hyperhomocysteinemia results from either hereditary or acquired defects in the homocysteine metabolic pathway. Heterozygous deficiency in cystathionine β-synthase is quite common in the general population, with a frequency of 0.3% to 1.4%.[48] A defect in the remethylation pathway is commonly caused by a thermolabile mutant of the methylenetetrahydrofolate reductase (MTHFR) enzyme whose activity is approximately 50% of normal; the homozygous state has a prevalence of 5% in the general population.[49] However, the homozygous form of the MTHFR thermolabile enzyme isoform is not clinically relevant in patients whose diet includes adequate folate.

Common causes of acquired hyperhomocysteinemia are deficiencies of dietary cobalamin, folate, or pyridoxine. A prospective study found that mild hyperhomocysteinemia is quite common in the elderly, despite normal serum vitamin concentrations.[50] Acquired hyperhomocysteinemia is also common in patients with end-stage renal disease.

Mild to moderate hyperhomocysteinemia is associated with cerebrovascular disease, coronary artery disease, and peripheral vascular disease in persons younger than 55 years and with carotid artery stenosis in the elderly.[51,52] It is found in 10% of patients with a first episode of DVT.[53] In a prospective study, a graded relationship was found between elevated plasma homocysteine levels and mortality in patients with coronary artery disease.[54]

Clinical Presentation

Severe hyperhomocysteinemia should be suspected in patients with the characteristic phenotype (see above). Mild to moderate hyperhomocysteinemia should be suspected in cases of arterial and venous thrombotic disease—including cerebrovascular disease, peripheral arterial disease, and DVT—especially in young persons.

Diagnosis

Plasma homocysteine exists in free and protein-bound forms and is generally measured and reported as total plasma homocysteine (normal range, 5 to 15 mmol/L). Diagnosis of hyperhomocysteinemia is usually made by measuring plasma homocysteine levels after an overnight fast. Because as many as 40% of patients with hyperhomocysteinemia may have a normal fasting level, a methionine-loading test should be considered when indicated.[55] However, methionine is not generally available in most pharmacies. Plasma folate and vitamin B_{12} levels should also be measured to exclude hyperhomocysteinemia caused by folate or B_{12} deficiencies.

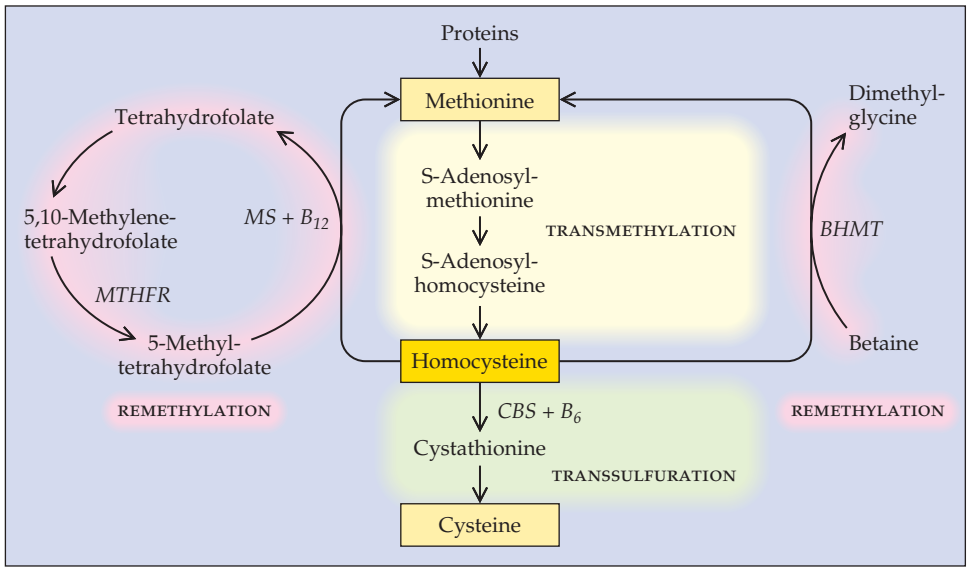

Figure 2 **Homocysteine's intracellular metabolism occurs through remethylation to methionine or transsulfuration to cysteine.[142] Elevation in plasma homocysteine levels can result from hereditary deficiency in cystathionine β-synthase (CBS); a thermolabile mutant of methylene-tetrahydrofolate reductase (MTHFR); or low dietary levels of cobalamin (vitamin B_{12}), folate, or pyridoxine (vitamin B_6), which are essential cofactors in the metabolic process. (BHMT—betaine-homocysteine methyltransferase)**

Treatment

Daily use of oral pyridoxine (250 mg) and folic acid (5 mg) brings elevated homocysteine levels down to normal in most cases.[56] Patients who have vitamin B_{12} deficiency should be given B_{12} supplements. Repeat measurement of plasma homocysteine levels (generally done 1 month after starting supplementation) may be prudent to ensure that the treatment with pyridoxine and folate is working. Betaine (3 g p.o., b.i.d.) is sometimes effective in patients with hyperhomocysteinemia that is resistant to pyridoxine and folate. It is currently unknown whether correction of hyperhomocysteinemia by these measures leads to clinical benefit.

LIPOPROTEIN(A)

Lipoprotein(a) [Lp(a)] is an independent risk factor for coronary artery thrombosis.[57] A prospective case-control study associated elevated plasma Lp(a) levels with an approximately threefold increase in risk of coronary artery disease in men.[58] The association between high Lp(a) and ischemic stroke in young adults is controversial.[59,60] Distributions of Lp(a) are skewed in the general population—especially among whites, in whom the median is 3.7 mg/dl but the mean is 6.9 mg/dl.[61] The 95th percentile for plasma Lp(a) is estimated to be in the 25 to 30 mg/dl range.

The Lp(a) class of lipoproteins is formed by the assembly of LDL particles and apoprotein(a), a protein that has some structural similarities to plasminogen (specifically, in the kringle domains) and competes with plasminogen for the endothelial cell binding site, thereby displacing plasminogen and downregulating plasmin generation at the endothelial cell surface.[62] High plasma concentrations of Lp(a) may therefore suppress the endothelial fibrinolytic response. Lp(a) is found in the intima of human atherosclerotic vessels, and transgenic mice expressing human Lp(a) develop extensive atherosclerosis.[63] Measurement of Lp(a) levels can be done in commercial laboratories and should be considered in young patients with arterial thrombosis. Elevated LDL cholesterol levels appear to elicit or exacerbate the risk factors associated with high Lp(a), and therefore, diet, exercise, and standard pharmacologic approaches should be used in patients with high LDL cholesterol levels.[64] In small studies, niacin at high doses (2 to 4 g p.o. daily) and tamoxifen (20 mg daily) have lowered elevated Lp(a) levels by 30% to 40%.[65,66] High doses of niacin are frequently associated with facial flushing and headaches. These unpleasant side effects can be ameliorated by starting niacin at a low dose (e.g., 300 mg daily) and then increasing the dose incrementally over time or through the use of extended-release niacin. Liver function should be checked periodically.

DYSFIBRINOGENEMIA

Approximately 300 abnormal fibrinogens (dysfibrinogens) have been reported, and about 85 structural defects have been identified in dysfibrinogenemia. These are most commonly characterized by functional defects of fibrinopeptide A release and fibrin polymerization and less commonly by defective plasminogen binding and activation. About half of the fibrinogen mutations are not associated with any clinical symptoms. Mild bleeding or recurrent thrombosis occurs in about equal numbers in the remaining mutations.[67] In rare cases, patients experience both bleeding and thrombosis. Acquired dysfibrinogenemia may complicate hepatocellular carcinoma or chronic liver disease. Evaluation in a general laboratory usually shows a discrepancy between antigenic and functional levels of fibrinogen, because most patients with dysfibrinogens have suboptimal clotting function, with prolonged thrombin time (TT) and reptilase time (RT). The abnormal fibrinogens form fibrin clots that are resistant to clot lysis. Precise identification of the structural defect requires substantial effort in a research laboratory. Management of recurrent thrombosis caused by dysfibrinogenemia is the same as that in other patients with thrombophilia.

DYSPLASMINOGEN AND ABNORMAL FIBRINOLYSIS

In rare cases, abnormal plasminogens (dysplasminogens), which are defective in their activation to plasmin, are associated

with thrombosis. Patients with such a disorder have a low plasma plasminogen level on functional assays.[68] Increased levels of plasminogen activator inhibitor–1 (PAI-1) and decreased plasma fibrinolytic activity have been reported in patients with preeclampsia.[69] Acquired impairment of fibrinolytic activity may be associated with postoperative thrombosis.[70] However, more studies are required to establish the role of abnormal fibrinolysis in recurrent clinical thrombosis.[71] Antigenic assays for tissue plasminogen activator (t-PA) and PAI-1 are available in some commercial laboratories, but specific functional assays are available only in research laboratories.

ELEVATED FIBRINOGEN, FACTOR VII, AND FACTOR VIII LEVELS

A high plasma fibrinogen level is an independent risk factor for coronary artery disease.[72] An elevated factor VII level has also been associated with the development of heart disease.[73] A factor VIII level above the 90th percentile of normal is associated with an approximately fivefold increased risk of a first episode of DVT[74,75]; it also increases the risk of recurrence.[76] Additional studies are required to establish the clinical utility of measuring these parameters in patients with thrombosis.

Acquired Hypercoagulable States

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome is caused by autoantibodies to proteins associated with negatively charged phospholipids. The terms antiphospholipid and anticardiolipin are used synonymously. Antiphospholipid antibodies also include lupus anticoagulant, which is an inhibitor that was first identified in patients with systemic lupus erythematosus. Many patients who have this inhibitor do not have lupus, and it is sometimes called lupuslike anticoagulant.

Epidemiology

Antiphospholipid antibody syndrome occurs secondary to systemic lupus erythematosus and, less commonly, to rheumatoid arthritis, temporal arteritis, and other connective tissue disorders. It is also associated with HIV-1 and hepatitis C infections, lymphoproliferative diseases, and certain drugs (e.g., phenothiazine and procainamide). When no risk factor can be identified, the syndrome is regarded as primary. In a large cohort study of 1,000 patients with antiphospholipid antibody syndrome, 53% of patients were classified as having primary antiphospholipid antibody syndrome, and 47% had secondary antiphospholipid antibody syndrome.[77]

Pathophysiology

The two most common protein targets for the antiphospholipid antibodies appear to be β_2-glycoprotein I (β_2-GPI) and prothrombin. β_2-GPI is a plasma protein that binds anionic phospholipids with high affinity. It has weak anticoagulant function in vitro. β_2-GPI can induce cardiolipin from its usual bilaminar form to a hexagonal form that is highly immunogenic.[78] The anticardiolipin antibody enzyme-linked immunosorbent assay (ELISA) usually detects antibodies directed against the cardiolipin/β_2-GPI complex. Lupus anticoagulant antibodies have been purified that specifically react with prothrombin but not thrombin. These purified antibodies can enhance the binding of prothrombin to the cultured endothelial cell surface.[79] Other protein-phospholipid targets may also be involved. Antiphosphatidylethanolamine antibodies are found in many patients with antiphospholipid antibody syndrome, and some of these antibodies inhibit activated protein C function.[80] Antibodies to heparin and heparan sulfate, which inhibit the heparin-dependent neutralization of thrombin by AT, have been found.[81] On the basis of this heterogeneity of antiphospholipid antibodies, it seems likely that multiple mechanisms are involved in the pathogenesis of thrombosis in this syndrome.

Clinical Presentation

Thrombotic events occur in approximately 30% of patients with antiphospholipid antibodies (overall incidence, 2.5 events per 100 patient-years).[82] In the cohort study cited above, 37% of patients presented with venous thrombosis, 27% with arterial thrombosis, 15% with both venous and arterial thrombosis, and 12% with fetal loss only[77] [*see 15:IV Systemic Lupus Erythematosus*].

Diagnosis

The diagnosis of antiphospholipid antibody syndrome should be considered in any patient who presents with an idiopathic arterial or venous thrombosis or in a woman with a history of recurrent miscarriages. The diagnosis is confirmed by the presence of anticardiolipin antibodies on ELISA (see above) or lupus anticoagulant on clotting assays.

The general criteria for the diagnosis of lupus anticoagulant are (1) prolongation of at least one phospholipid-dependent clotting assay; (2) proof, by mixing studies, that the prolongation is caused by an inhibitor and not a clotting factor deficiency; and (3) confirmation that the inhibitor is phospholipid dependent [*see Table 5*]. The clotting tests commonly used are activated PTT (aPTT) and dilute Russell viper venom time (RVVT). The reagents in aPTT are variably sensitive to the lupus anticoagulant and are influenced by concentrations of some plasma clotting factors (e.g., factor VIII). Therefore, an aPTT reagent that is

Table 5 Proposed Clinical and Laboratory Criteria for the Antiphospholipid Antibody Syndrome[93]

Clinical features	Pregnancy morbidity (any of the following): More than one unexplained fetal death at greater than 10 wk Delivery at less than 34 wk, with severe pregnancy-induced hypertension Three or more pregnancy losses at less than 10 wk Thrombosis: Venous (superficial thrombophlebitis; deep vein thrombosis; pulmonary embolism; cerebral and retinal vein thrombosis; renal, splanchnic, and mesenteric vein thrombosis) Arterial (ischemic cerebral infarction, transient cerebral ischemia, amaurosis fugax, migraine, carotid and vertebrobasilar artery thrombosis, aortic arch syndrome, peripheral arterial thrombosis and embolism, renal and mesenteric artery thrombosis, livedo reticularis)
Laboratory features	Lupuslike anticoagulant: Activated partial thromboplastin time, dilute Russell viper venom time, kaolin clotting time, tissue thromboplastin inhibition test Anticardiolipin antibodies (either of the following): IgG anticardiolipin antibodies (> 20 GPL) IgM anticardiolipin antibodies (> 20 MPL) Thrombocytopenia (platelet count < 100,000/μl)

GPL—IgG phospholipid units MPL—IgM phospholipid units

Table 6 Classification of Antiphospholipid Antibodies[147]

Autoimmune causes
- Primary (do not fulfill criteria for systemic lupus erythematosus)
- Secondary (fulfill criteria for systemic lupus erythematosus or other connective tissue diseases)
- Drug-induced (e.g., phenothiazines, quinidine, quinine, synthetic penicillins, hydralazine)

Alloimmune causes
- Infections (viral, bacterial, fungal)
- Malignancies (e.g., hairy-cell leukemia, lymphoproliferative disease)

sensitive to the lupus anticoagulant should be used in the screening test. Dilute RVVT is much more sensitive than aPTT but is a manual test and not as well standardized. Other tests, such as kaolin clotting time and the tissue thromboplastin inhibition test, are useful when available. The presence of an inhibitor necessitates a mixing study to demonstrate lack of correction with normal plasma. Correction of the prolongation by addition of phospholipid in the form of platelet lysates or as hexagonal-phase phospholipid will confirm the diagnosis. Clotting factor assays can be carried out in equivocal cases. A lupus anticoagulant will cause functional deficiency of several phospholipid-dependent clotting factors, not just one particular factor.

Anticardiolipin antibodies are reported as IgG (in IgG phospholipid [GPL] units) and IgM (in IgM phospholipid [MPL] units). The prevalence of elevated anticardiolipin IgG and IgM antibodies in normal populations is approximately 5%; with repeated testing, the prevalence is less than 2%.[83] High titers of anticardiolipin IgG antibodies (> 33 GPL) are associated with an approximately fivefold increase in overall thrombotic risk.[82,84] The importance of low titers of IgG antibodies (< 20 GPL), isolated IgM antibodies, and IgA antibodies has not been established.[85,86] Both functional and antigenic assays should be ordered in the evaluation of a patient, because these two assays do not completely overlap. In one study of antiphospholipid antibody syndrome, 88% of patients had anticardiolipin antibodies (IgG, IgM, or both) and 54% of patients had lupus anticoagulant. Lupus anticoagulant was typically found in association with anticardiolipin antibodies, but it occurred in isolation in about 12% of patients.[77] Certain infections and drug exposures may lead to a transient appearance of antiphospholipid antibodies, which disappear after the resolution of infection or discontinuance of the drug [*see Table 6*]. Therefore, laboratory tests should be repeated at least once (6 weeks after the first tests) to confirm the diagnosis. Conversely, approximately 20% of patients with low titers of anticardiolipin IgG antibodies will have higher titers upon repeat testing. Retesting is also warranted in patients with new or recurrent thrombosis.[85]

Treatment

The current therapeutic recommendations for antiphospholipid antibody syndrome are mostly based on observational studies that support an association between antiphospholipid antibodies and thrombosis, particularly recurrent thrombosis.[82-86] In the acute treatment of DVT in patients with antiphospholipid antibody syndrome, monitoring the effect of unfractionated heparin can be problematic because lupus anticoagulant prolongs the aPTT. The use of LMWH circumvents this problem because LMWH does not require dose titration and monitoring. The patient should be treated with LMWH and warfarin in the usual fashion, with an overlap of at least 5 days before discontinuing LMWH.

Retrospective analysis shows that patients with the antiphospholipid antibody syndrome and a history of thrombosis have a high rate of recurrent thrombosis (in the range of 50% to 70%) if they are not given prolonged warfarin therapy.[87,88] The site of the first thrombotic event (i.e., arterial or venous) tends to predict the site of the recurrent event.[88] High-intensity warfarin therapy, to an international normalized ratio (INR) of 3.0 to 3.5, had been advocated for these patients. This recommendation was based primarily on a retrospective analysis,[87] however, and two prospective clinical trials have now demonstrated that most of these patients can be adequately treated with conventional levels of anticoagulation (i.e., an INR of 2.0 to 3.0).[89] On the other hand, there are clearly some patients with antiphospholipid antibody syndrome who experience recurrent thrombosis with conventional anticoagulation and hence require a higher level of treatment.

The optimal duration of oral anticoagulation therapy for antiphospholipid antibody syndrome has not been fully established. Recurrent venous thrombosis or ischemic stroke usually justifies long-term warfarin. In a patient with a first episode of DVT who is found to have antiphospholipid antibodies, warfarin therapy is indicated for at least 6 months and perhaps for life.[90] The severity of the specific thrombotic episode, the coexistence of any reversible thrombotic risk factors, and the risks of long-term oral anticoagulation therapy should also be considered. It should be noted that the lupus anticoagulant may occasionally increase the prothrombin time (PT) and, in turn, the INR, thus posing a problem for the monitoring of warfarin therapy.[91] When PT and INR increase, use of a lupus anticoagulant–insensitive thromboplastin reagent is helpful.

In asymptomatic patients with anticardiolipin antibodies or lupus anticoagulant but no history of thrombosis, anticoagulation is not required.

Pregnancy Loss in Antiphospholipid Antibody Syndrome

Several prospective studies confirm an association between recurrent miscarriages and antiphospholipid antibodies. The antibodies presumably cause pregnancy loss by promoting placental thrombosis.[92] Antiphospholipid antibodies should be measured in patients with a history of unexplained second- or third-trimester loss, fetal demise, early-onset severe preeclampsia, and intrauterine growth retardation.[93] In contrast, antiphospholipid antibodies are not associated with sporadic early pregnancy loss,[94] which is frequently the result of genetic abnormalities in the fetus. The relationship of antiphospholipid antibodies with infertility is uncertain at present.

The management of pregnant women with antiphospholipid antibody syndrome is difficult because of the syndrome's association with thrombosis and the increased risk of bleeding with antithrombotic therapy. In a prospective, randomized, placebo-controlled trial, a combination of prednisone and aspirin was demonstrated to be ineffective in promoting live birth; in fact, it increased the risk of prematurity.[95] On the other hand, two prospective trials have demonstrated that heparin and low-dose aspirin (81 mg a day) provide a significantly better pregnancy outcome than low-dose aspirin alone, with viable infants being delivered in 70% to 80% of cases.[96,97] Furthermore, low-dose heparin (given initially as 5,000 units subcutaneously twice daily

and adjusted to maintain the aPTT within the upper limits of the normal range) seems to be as effective as higher-dose heparin combined with low-dose aspirin.[98] Treatment should begin as soon as pregnancy is confirmed. LMWH is preferable to unfractionated heparin for long-term use because LMWH can be given once or twice daily and may reduce the risk of osteopenia and heparin-induced thrombocytopenia (see below). Enoxaparin (40 mg once daily) and aspirin (100 mg daily) has been given from week 12 of gestation until 6 weeks postpartum with good results.[99]

HEPARIN-INDUCED THROMBOCYTOPENIA AND THROMBOSIS

Epidemiology

Heparin-induced thrombocytopenia (HIT) is a relatively common antibody-mediated drug reaction, occurring in about 1% of patients receiving porcine heparin and 5% of patients receiving bovine heparin.[100] The incidence of HIT is much lower in patients treated with LMWH. In a subset of patients, HIT progresses to a potentially fatal disorder characterized by venous and arterial thrombosis. Interestingly, both the frequency of HIT antibody formation and the clinical manifestations of HIT vary considerably in different patient populations. The incidence of HIT antibody formation is much higher after cardiac surgery than after orthopedic surgery (50% versus 15%); however, the incidence of clinically significant postoperative HIT appears to be lower in cardiac surgical patients than in orthopedic patients, in whom the incidence is 5%.[101,102]

Pathophysiology

The pathogenesis of HIT is attributable to the presence of an IgG antibody that recognizes a complex of heparin and platelet factor 4 (PF4) [*see Figure 3*].[103] PF4 is a cationic protein found in platelet α-granules; when released from the granules, PF4 binds to the negatively charged heparin molecule with high affinity. The IgG antibody binds to the PF4-heparin complex on platelet membranes, forming a ternary complex that in turn binds to the platelet membrane FcγRII receptor. This binding activates the platelets, leading to further release of PF4 and formation of PF4-heparin complex. The immune complex–coated platelets are cleared rapidly by the reticuloendothelial system, giving rise to thrombocytopenia. The thrombotic complications in HIT are caused by activation of platelets by the immune complex, which leads to the formation of platelet microparticles and enhanced thrombin generation.[104] PF4 also binds to heparinlike sulfated glycosaminoglycans (e.g., heparan sulfate) on the endothelial cell surface. In vitro evidence indicates that the antibody in HIT is able to bind to endothelial cells. The cells may then become activated, giving rise to thrombosis.[105] Given that only a subset of patients who form HIT antibodies experience clinical HIT,[102] the induction of HIT antibodies and the development of thrombocytopenia and subsequent thrombosis should be regarded as a continuum. Concomitant thrombotic risk factors probably play a major role in determining the clinical progression and manifestations of HIT.

Clinical Presentation

HIT typically develops 5 to 10 days after the initiation of heparin therapy. However, in patients who received heparin within the previous 100 days and are being retreated, the onset can be rapid—within hours after starting heparin.[106] Conversely, onset of HIT may not occur until as long as 19 days after heparin therapy is stopped.[107] This delayed-onset HIT appears to be associated with a higher titer of IgG antibodies against the PF4-heparin complex.

HIT is generally defined as a platelet count below 150×10^9/L or a drop in the platelet count by more than 50% from the postoperative peak at 5 to 14 days after heparin is started. The mean platelet count in HIT is about 60×10^9/L. Severe thrombocytopenia, with platelet counts below 20×10^9/L, occurs in fewer than 10% of patients; in 10% to 15% of patients, despite the 50% drop from peak levels, the platelet count nadir is above 150×10^9/L.[102]

The risk of HIT-associated thrombosis was once thought to be quite small; however, it is now recognized that thrombosis occurs in about one third to one half of patients with HIT, with venous thrombosis occurring more frequently than arterial thrombosis.[104] Thrombosis can occur at any platelet count, even at a very low one.

DVT, with or without pulmonary embolism, is the most common event leading to the diagnosis of HIT. The disorder may be further complicated by limb gangrene, especially in the setting of warfarin treatment without concomitant alternative anticoagulant coverage (see below). Cerebral vein thrombosis and adrenal hemorrhagic necrosis are uncommon but well-documented complications of HIT, and early diagnosis and urgent therapy can be lifesaving. Arterial thrombosis may present as limb ischemia, stroke, myocardial infarction, or, less commonly, mesenteric thrombosis and renal arterial thrombosis. Some patients have laboratory findings that support a diagnosis of DIC. Heparin-induced skin lesions may occur at heparin injection sites and range from painful erythematous papules to extensive dermal necrosis.[108]

Unlike antibodies induced by quinine, quinidine, or sulfonamides, which can persist for years, heparin-induced antibodies appear to be quite transient. They fall to undetectable levels at a median of 50 to 85 days, depending on the assay performed.[106]

Diagnosis

The diagnosis of HIT is supported by the finding of heparin-induced platelet aggregation in the presence of the patient's serum. However, the sensitivity of this test can be as low as 50%.[109] Sometimes, the patient's serum can cause spontaneous aggregation of donor platelets in the absence of heparin, most likely caused by the presence of immune complexes unrelated to HIT, which makes proper interpretation of the test result impossible. Heparin-induced platelet serotonin release using washed platelets has high sensitivity and specificity for HIT but is available only in a few specialized laboratories. ELISAs to detect antibodies that are reactive to the PF4-heparin complex are commercially available and have become the most commonly used test for HIT. These ELISAs have a higher sensitivity than the platelet aggregation assay and can be more easily performed in a general clinical diagnostic laboratory. However, false positive results (i.e., positive tests in the absence of HIT or thrombocytopenia) occur in 10% to 15% of medical patients and in more than 20% of patients receiving heparin for peripheral vascular surgery. A seroconversion rate as high as 50% has been reported in patients undergoing cardiopulmonary bypass surgery, limiting its usefulness in that situation.[110] Because HIT can be complicated by serious thrombotic problems, however, diagnosis of HIT should be based primarily on appropriate clinical findings, and management should be started while laboratory confirmation is awaited.

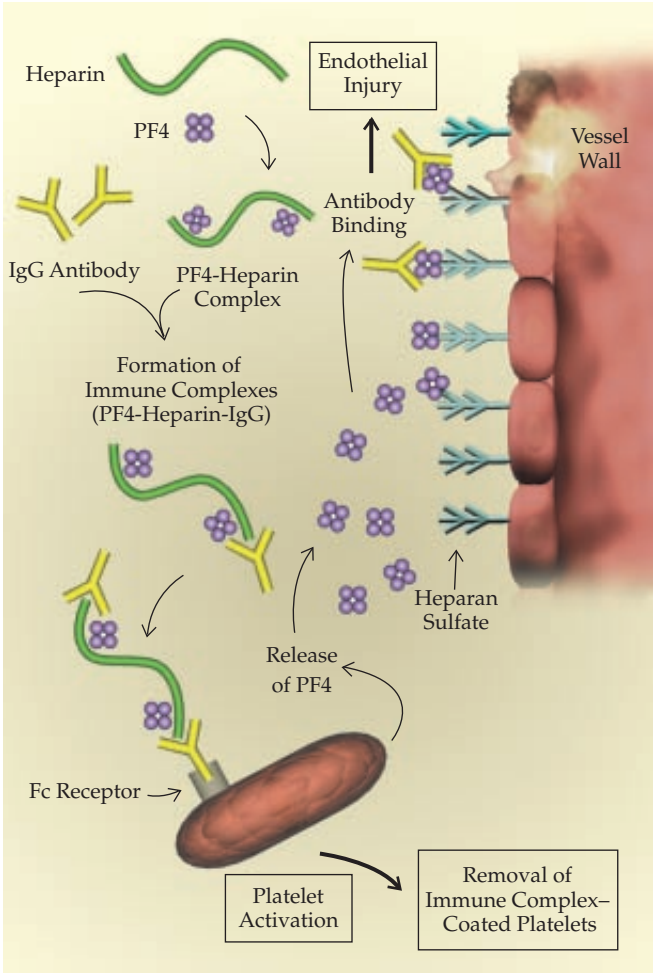

Figure 3 **In a proposed explanation for heparin-induced thrombocytopenia, IgG antibodies recognize platelet factor 4 (PF4)–heparin complexes. The resulting PF4-heparin-IgG immune complexes bind to Fc receptors on circulating platelets. Fc-mediated platelet activation releases PF4 from α-granules in platelets, establishing a cycle of platelet activation and formation of prothrombotic platelet microparticles. Removal of immune complex–coated platelets by the reticuloendothelial system results in thrombocytopenia. PF4 also binds to heparan sulfate on the surface of endothelial cells, leading to immune-mediated injury, thrombosis, and disseminated intravascular coagulation.[145]**

Treatment

Management of HIT consists of stopping heparin immediately and starting alternative anticoagulation therapy. It is important to discontinue all types of heparin: there are anecdotal reports of HIT caused by trace amounts of heparin used in heparin flushes of intravascular lines. Even if the patient has mild thrombocytopenia alone without any evidence of thrombosis, it is advisable to discontinue heparin and treat the underlying hypercoagulable state with an alternative anticoagulant. This aggressive approach is supported by a retrospective cohort study in which thrombosis developed within 30 days of heparin cessation in approximately half of patients who initially had no clinical symptoms from their HIT.[100]

HIT may develop in patients who were receiving heparin for preexisting thrombosis and are in the process of being switched over to warfarin. If the patient has been on warfarin for 4 or 5 days and the INR has reached an adequate therapeutic range, the clinician may rely on warfarin alone and monitor the patient carefully. However, if the patient has been on warfarin for less than 4 days or has evidence of a thrombotic complication from the HIT, an alternative anticoagulant should be used in addition to warfarin.

Alternative anticoagulant agents include lepirudin, argatroban, and fondaparinux. Although LMWH is much less immunogenic than unfractionated heparin in causing HIT,[104] it cannot be used as a safe substitute when a patient develops HIT caused by unfractionated heparin. LMWH and unfractionated heparin have extensive cross-reactivity (> 90%) in terms of antibody recognition. LMWH is not an appropriate choice in patients with HIT.

Hirudin, a 65-amino-acid protein originally extracted from the salivary gland of the medicinal leech (*Hirudo medicinalis*), is a potent direct thrombin inhibitor. Hirudin binds directly to thrombin's active site, independently of AT. It is not neutralized by PF4. Hirudin's anticoagulant function is monitored by aPTT.

Lepirudin is a recombinant form of hirudin that is approved for treatment of HIT. In two prospective clinical trials, use of lepirudin reduced serious thrombotic complications to about 20% (compared with a rate of about 40% in historical control subjects).[111,112] Lepirudin was given by intravenous bolus (0.4 mg/kg), followed by continuous infusion at 0.15 mg/kg/hr for 2 to 10 days as indicated. The dose was adjusted to maintain a target aPTT of 1.5 to 3 times normal. Patients experienced an increase of minor bleeding (from puncture sites, epistaxis, and hematuria) but no intracranial bleeding. Of note, 40% of patients developed antihirudin antibodies. These are not neutralizing antibodies and may actually enhance the drug's potency, perhaps by delaying its clearance—another reason to monitor aPTT levels. Judging from cardiology intervention trials, bleeding risk would be substantially increased with concomitant use of thrombolytics; therefore, it is not advisable to use the agents in combination. There is no effective antidote for lepirudin. It has a half-life of approximately 1.3 hours and is cleared by the kidneys. Thus, in patients with renal insufficiency, the dose of lepirudin needs to be adjusted carefully on the basis of creatinine clearance values.

Argatroban, a synthetic direct thrombin inhibitor, is approved for prophylaxis or treatment of thrombosis in patients with HIT. It is given by continuous intravenous infusion of 2 mg/kg/min to maintain an aPTT of 1.5 to 3 times baseline (not to exceed 100 seconds or 10 mg/kg/min). In one study, argatroban reduced the serious thrombotic complications of HIT by about 50%, as compared with historical controls, with a major bleeding rate of about 7%.[113] Its half-life is only 40 to 50 minutes. In contrast to lepirudin, argatroban is cleared by the liver and therefore can be used more easily in patients with renal insufficiency. Like lepirudin, argatroban does not have a specific antidote, and bleeding complications need to be watched for carefully.

A third alternative anticoagulant is fondaparinux, a synthetic pentasaccharide that activates AT, leading to thrombin inhibition. Fondaparinux has been approved for prophylaxis against DVT in orthopedic surgery. Because of its small size and reduced negative charge, fondaparinux does not form a complex with PF4 and therefore does not react with the antibody directed against the heparin-PF4 complex in HIT. Case reports describe the successful use of fondaparinux in HIT at a fixed dose of 7.5 mg administered subcutaneously once daily.

Patients who have HIT without associated thrombotic com-

plications should be treated with one of the alternative anticoagulants until the platelet count has returned to normal, which generally takes 5 to 7 days. It is my practice to discontinue the alternative anticoagulant at that time. However, some experienced clinicians choose to continue empirical anticoagulation for up to 1 month, on the rationale that HIT represents an intensive hypercoagulable state. In patients who require prolonged anticoagulation—whether because they have other indications for anticoagulation or because they have had thrombotic complications from HIT—warfarin is used for long-term treatment. Warfarin should be started only after the patient has received adequate anticoagulation therapy with one of the alternative anticoagulants. The two agents should be used concurrently for at least 5 days before the alternative anticoagulant is discontinued. Both lepirudin and argatroban may increase the PT and INR, thus interfering with warfarin dose adjustments. The PT should be rechecked 6 hours after the discontinuance of lepirudin or argatroban to ensure that an INR of 2 to 3 has been achieved. For patients who have had HIT-associated thrombosis, warfarin therapy for 3 months should be adequate.

Some patients with serologically confirmed HIT may, at some point in the future, require surgery that involves cardiopulmonary bypass. The use of recombinant hirudin or argatroban in that situation has been described anecdotally.[112,114,115] Given the transient nature of the heparin-induced antibodies, subsequent reuse of heparin is theoretically reasonable, and indeed, a limited number of patients have been given heparin again after the disappearance of heparin-induced antibodies without any significant clinical sequelae.[106,116] Nevertheless, the use of heparin in this situation should be restricted to patients with a compelling indication for it, such as cardiac or vascular surgery, and only after the absence of detectable heparin-dependent antibodies has been confirmed by a sensitive assay, such as a PF4-heparin ELISA. Also, because reexposure to heparin may elicit a recurrence of heparin-dependent antibodies, heparin should be used only during the procedure itself, and an alternative anticoagulant should be started postoperatively for prophylaxis against recurrence of HIT. The anti–heparin-PF4 antibody should be checked postoperatively.

TROUSSEAU SYNDROME

Epidemiology

Some patients with cancer—especially those with occult solid tumors of the pancreas, ovary, liver, brain, colon, lung, or breast—may experience spontaneous venous thrombosis of the upper and lower extremities, or Trousseau syndrome. These patients also have an increased propensity toward recurrent arterial thrombosis and thromboembolism.[117] In a prospective study of patients who presented with idiopathic symptomatic DVT, cancer was diagnosed in approximately 8% of the patients during a 2-year follow-up (odds ratio, 2.3). In patients with recurrent thrombosis, the incidence of cancer was even higher (17%; odds ratio, 4.3).[118]

Pathophysiology

The underlying cause of Trousseau syndrome is a chronic, compensated form of DIC [*see 5:XIII Hemorrhagic Disorders*]. The activated procoagulants generated in DIC enhance thrombosis. Immunochemical staining of sections from tumors commonly associated with Trousseau syndrome often reveals tissue factor on the tumor surface.[119,120] A cancer procoagulant has been purified from some adenocarcinomas and leukemic cells; this procoagulant, identified as a cysteine protease, can activate the clotting cascade by directly activating factor X.[121,122] Interaction of the tumor cells with monocytes, platelets, and endothelial cells may also generate inflammatory cytokines and induce endothelial and monocytic procoagulant activities, further exacerbating the thrombosis. Tumor cells may secrete soluble mucins—complex polysaccharides that can activate leukocytes, leading to platelet-leukocyte microthrombi and thrombin generation.[123] Heparin blocks the tumor mucin activation of leukocytes, which may partially explain heparin's efficacy over warfarin in the treatment of this condition.

Clinical Presentation

Venous thrombosis in Trousseau syndrome usually manifests as migratory superficial thrombophlebitis or DVT of the lower extremities. The recurrent arterial thrombosis in these patients arises from a nonbacterial thrombotic endocarditis in which sterile fibrin is deposited in the mitral valve. The fibrin clot may embolize to cause digital ischemia, transient ischemic attacks, and stroke.

Diagnosis

Coagulation studies in Trousseau syndrome show evidence of chronic, low-grade DIC (i.e., slightly low or even high fibrinogen and platelet levels and high levels of D-dimer). The PT and PTT are generally not prolonged. Overt DIC in such patients is uncommon.

How aggressively should one pursue the diagnosis of an underlying cancer in patients with idiopathic DVT? Research has not yet demonstrated the benefit and cost-effectiveness of an extensive screening approach.[124] In a large cohort study, cancer diagnoses after a primary thrombotic event were highest during the first 6 months of follow-up and declined rapidly to normal levels after the first year. Moreover, 40% of the patients who were diagnosed with cancer in the first year had distant metastases at the time of the diagnosis. It is unclear whether an earlier diagnosis after the thrombotic event would have changed the outcome in these patients. The researchers concluded that an aggressive search for a hidden underlying cancer in such patients is not warranted.[125]

At present, it is prudent to perform a careful history, physical examination, chest x-ray, routine blood counts, and chemistries. Some experts have also recommended multiple tests for fecal occult blood, prostate-specific antigen tests in men, and mammography and pelvic ultrasonography in women.[126,127] Careful follow-up examination and tests should be done as indicated by the initial evaluation.[128]

Treatment

The key to management of Trousseau syndrome is diagnosis and treatment of the underlying tumor. Unfortunately, tumors often present explosively in patients with Trousseau syndrome and may not respond to the usual therapies. In a prospective study, cancer patients had an approximately threefold increase in the rate of recurrent thrombosis and twofold increase in the rate of major bleeding during warfarin treatment of DVT. These complications occurred mostly during the first few months of anticoagulation and did not reflect underanticoagulation or over-anticoagulation but correlated with the extent and severity of the underlying cancer.[129] The likely explanation for the increased thrombosis recurrence in these patients is relative warfarin resistance, whereas the

increased bleeding may be related to bleeding at the primary tumor site. A prospective trial found that the risk of recurrent venous thromboembolism was 50% lower in cancer patients who received long-term treatment with the LMWH dalteparin than in those who received oral anticoagulation; there was no significant difference in the risk of major bleeding.[130] If a patient is receiving chemotherapy for the underlying cancer, an exacerbation of the DIC associated with tumor lysis should be anticipated. An increase in the dose of heparin may be required.

THROMBOTIC REACTIONS TO ESTROGENS

Oral contraceptives increase the risk of thromboembolic disease approximately fourfold.[131] Epidemiologic studies indicate that contraceptives containing a third-generation progestin (e.g., desogestrel) carry a twofold greater risk of thrombosis than those with a second-generation drug (levonorgestrel).[132] For that reason, the preferred choice for first-time users of oral contraceptives is a compound containing a second-generation drug (e.g., Alesse, Levlite, Levora, Nordette, Triphasil, Trivora). The risk of venous thromboembolism disappears when the drugs are discontinued.

In postmenopausal women, estrogen replacement increases the risk of venous thromboembolism about threefold. The absolute risk is low, however—it is estimated to be approximately 3.2 per 10,000 patient-years. Therefore, estrogen replacement is not contraindicated in patients who require hormonal treatment to control severe postmenopausal symptoms. However, patients with a previous history of DVT or pulmonary embolism are at increased risk for recurrence and therefore should avoid hormone replacement therapy if possible.[133]

The association between estrogen use and thromboembolic disease remains unexplained.[134] Estrogen treatment is known to produce changes in the plasma levels of many proteins involved in coagulation and fibrinolysis, including decreases in protein S and AT and increases in plasminogen. The changes are generally quite modest, however, and are not thought to account for the increased risk of thrombosis. On the other hand, in women who are heterozygous for factor V Leiden, oral contraceptive use increases the thrombotic risk synergistically to about 50 times normal.[18] There is also a moderate synergistic increase in thrombotic risk (15-fold) with the combination of factor V Leiden and hormone replacement therapy.[135]

Table 7 General Guidelines for Management of Patients with Venous Thromboembolism

Recurrence Risk	*Management*
High Recurrent idiopathic thrombosis One life-threatening thrombosis One spontaneous thrombosis at an unusual site (e.g., mesenteric or cerebral thrombosis) One spontaneous thrombosis associated with antiphospholipid antibody syndrome One thrombosis with two permanent risk factors One thrombosis with Trousseau syndrome	Lifelong oral anticoagulation therapy: INR 2.0 to 3.0
Medium One thrombosis with one permanent risk factor (except Trousseau syndrome) Idiopathic thrombosis with no identifiable risk factor	6 mo of oral anticoagulation therapy after first episode of thrombosis; vigorous prophylaxis in high-risk situations
Low One thrombosis with reversible risk factor	6 wk–3 mo of oral anticoagulation therapy after first episode of thrombosis; vigorous prophylaxis in high-risk situations

INR—international normalized ratio

Management of Venous Thromboembolism

The acute management of an initial episode of DVT or pulmonary embolism in patients with proven or presumed underlying risk factors for thrombosis is the same as that in other patients: heparin and then warfarin [*see 1:XVIII Venous Thromboembolism*].

The optimal intensity and duration of warfarin treatment in DVT have been the subject of many large clinical trials over the past decade. As regards the intensity of oral anticoagulation, an INR of 2 to 3 has proved optimal, with a low rate of thrombosis recurrence and a rate of major bleeding of about 3% a year.[136,137] In comparison, treatment to an INR of 1.5 to 1.9 is less effective in reducing recurrent thrombosis (although it is better than placebo) and provides no significant reduction in bleeding risk.[136,137]

Warfarin therapy usually should be continued for 3 to 6 months. In a prospective study of oral anticoagulation therapy in patients with a first episode of venous thromboembolism, 6 weeks of therapy was adequate for patients with temporary, reversible risk factors for thrombosis (e.g., surgery, trauma, temporary immobilization, or use of oral contraceptives). On the other hand, 6 months of oral anticoagulation therapy was clearly superior for patients with idiopathic venous thromboembolism (who are presumed to have intrinsic risk factors).[138] The recurrence rate was quite high, however—approximately 12% at 2 years. On the basis of this evidence, at least 6 months of oral anticoagulation therapy is indicated in a patient with a first episode of idiopathic DVT or pulmonary embolism.

Further management should depend on results of the hypercoagulable workup (see above). A risk assessment for other predisposing factors will also be relevant.

Unfortunately, even when warfarin treatment is continued for 12 months after a first episode of idiopathic DVT, this does not reduce the risk of recurrent thrombosis once warfarin treatment is discontinued.[139] Generally, there is a rapid rebound phase of recurrent DVT of about 10% during the first 6 to 12 months after warfarin therapy. This suggests that there is a subset of patients (10% to 20%) who have a stronger tendency toward thrombosis and thus experience recurrences fairly soon after discontinuance of oral anticoagulation.

Persistent elevation of D-dimer levels may help identify patients who are more likely to have recurrent thrombosis. In a prospective study, D-dimer levels that remained elevated 1 month after the discontinuance of warfarin were associated with a higher recurrence risk (approximately threefold to eightfold), whereas normal D-dimer levels had a high negative predictive value for recurrence.[140] Thus, patients with elevated D-dimer levels merit more vigilant monitoring and consideration of long-term anticoagulation.

Because the optimal duration of long-term oral anticoagulation therapy for patients with thromboembolism remains undefined, this question is best addressed individually, on the basis of an estimation of the risk of recurrence [*see Table 7*].[141,142] Before undertaking long-term anticoagulation therapy in a high-risk

patient, the clinician must take the patient's risk of bleeding into account.

Of note, none of the published studies shows a significant difference in mortality between patients who receive long-term therapy and those who receive short-term therapy. There is also no evidence to suggest that prophylactic anticoagulation therapy improves overall survival. In historical studies, families with deficiencies of AT and protein C show no higher mortality than the general population displays.[143,144] Current clinical trials are studying the use of full-dose oral anticoagulation therapy for an extended period of time followed by an indefinite period of low-dose anticoagulation therapy. The results of these studies will help define the optimal long-term treatment for patients who are at high risk for recurrence of thromboembolism.

XV COAGULATION DISORDERS

Lawrence L. K. Leung, m.d.

Bleeding or bruising that is spontaneous or excessive after tissue injury may be caused by coagulation defects, fibrinolysis, abnormal platelet number or function, abnormal vascular integrity, or a combination of these abnormalities. This chapter addresses hemorrhagic disorders associated with abnormalities in coagulation. Hemorrhagic disorders associated with quantitative or qualitative platelet abnormalities and disorders associated with blood vessels are discussed elsewhere [*see 5:XIII Platelet and Vascular Disorders*].

Disorders of coagulation may be inherited or acquired. Congenital coagulation disorders are rare and are most frequently caused by defects in single coagulation proteins, with the two X-linked disorders—factor VIII and factor IX deficiencies—accounting for the majority of defects. Acquired coagulation disorders are more common than the inherited disorders and are more complex in their pathogenesis. The most common acquired hemorrhagic disorders are vitamin K deficiency, drug-induced hemorrhage, and disseminated intravascular coagulation (DIC).

Hereditary Coagulation Disorders

The coagulation disorders appear clinically as either spontaneous hemorrhage or excessive hemorrhage after trauma or surgery. The patient history usually indicates whether the disorder is congenital or acquired. The hereditary disorders are characterized by their appearance early in life and by the presence of a single abnormality that can account for the entire clinical picture.

von Willebrand disease

Pathophysiology

von Willebrand disease (vWD), the most common hereditary bleeding disorder, is caused by a deficient or defective plasma von Willebrand factor (vWF). The gene encoding vWF is on chromosome 12. vWF has specific domains for binding clotting factor VIII, heparin, collagen, platelet GPIb, and platelet GPIIb-IIIa. These domains relate directly to the following functions of vWF: (1) its action as a carrier molecule for factor VIII:C, in which it protects the clotting factor from proteolysis and substantially prolongs its plasma half-life; (2) its promotion of primary platelet adhesion at high wall shear rates by linking platelets via their GPIb-IX-V receptor to subendothelial tissues at the wound site; and (3) its support of platelet aggregation by linking platelets via their GPIIb-IIIa receptors.[1] The vWF circulates as multimers that range in size from 0.5 million daltons (the dimer) to 20 million daltons. Even larger noncirculating multimers are present in endothelial cells, where they are stored in the Weibel-Palade bodies. The ultralarge vWF multimers are normally processed by the ADAMTS13 metalloprotease into smaller multimers as they are released from the endothelial cells. The vWF is released either into the circulation or abluminally, where it attaches to subendothelial collagen. Platelet α-granules also contain vWF, which is released when platelets are activated. The vWF multimers that are 12 million daltons or larger are the most effective in supporting platelet adhesion.

Laboratory Evaluation

The many variant forms of vWD differ in their clinical manifestations, laboratory abnormalities, and required therapies. Because vWF is a carrier protein for factor VIII, the activated partial thromboplastin time (aPTT) is prolonged when the vWF level is low. The platelet count is usually, but not invariably, normal. Bleeding time is generally prolonged but not sufficiently reliable to be used for diagnosis. An automated platelet function test utilizing a platelet function analyzer (PFA-100) has been shown to be a better screening test for vWD than the bleeding time.[2,3] In this assay, citrated whole blood is aspirated through a capillary tube under high shear rates onto a membrane coated with collagen in which a central aperture is made. Platelets are activated by either adenosine diphosphate (ADP) or epinephrine. The closure time is a measure of platelet-vWF interaction.

The diagnosis of vWD requires the determination of factor VIII and vWF levels. There are two caveats: (1) laboratory testing is notoriously variable and (2) the patient's blood group affects the vWF level—that is, patients with blood group O have lower vWF levels than those with blood group A, B, or AB, by as much as 30%.[4] The vWF level is measured by either immunologic or functional methods. The former is reported as a percentage of normal vWF antigen. Because vWF circulates in physiologically important multimeric forms, it is sometimes helpful to determine the multimeric composition of the vWF in the patient's plasma. This is especially useful in identifying type 2 vWD (see below). The functional level of vWF is tested by the ristocetin-induced platelet aggregation test. Ristocetin is added to a patient's platelet-rich plasma, where it causes vWF to bind to platelets via the GPIb-IX-V receptor, leading to platelet activation and aggregation. In some laboratories, formalin-fixed platelets are used and, after the addition of ristocetin, agglutination of fixed platelets is measured.

Clinical Variants

The classification scheme for variants of vWD comprises three major groups: type 1 is a partial quantitative deficiency of vWF, type 2 is a qualitative abnormality of vWF, and type 3 is a severe and virtually total quantitative deficiency of vWF [*see Table 1*].[5]

Type 1 Type 1 vWD is the most common form of vWD, accounting for 75% of cases. It is generally an autosomal dominant trait that usually appears in the heterozygous form. In many cases, a mutation in the vWF protein occurs such that the mutant provWF monomers form dimers normally with the wild-type provWF monomers, but the resulting dimers are trapped in the endoplasmic reticulum and cannot be secreted.[6] Patients with classic type 1 vWD have a lifelong history of mild to moderate bleeding, typically from mucosal surfaces. They may be unaware of a bleeding disorder until they undergo surgery or experience trauma, when bleeding may be severe. vWF antigen, factor VIII, and the ristocetin cofactor levels are all decreased.

Type 2 Type 2 vWD is characterized by qualitative abnormalities of vWF and a variable decrease in vWF antigen, factor VIII, and ristocetin cofactor. In type 2A, the largest multimers are absent; in type 2B, multimers bind excessively to platelets be-

Table 1 Classification and Differentiation of von Willebrand Disease

	Type 1	*Type 2A*	*Type 2B*	*Type 2M*	*Type 2N*	*Type 3*	*Pseudo–von Willebrand Disease*
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive	Autosomal dominant
Incidence	~75%	~20%	~5%	Rare	Rare	Uncommon	Uncommon
Cause	Deficiency of normal vWF	Abnormal vWF	Abnormal vWF	Abnormal vWF	Abnormal vWF	Severe deficiency of vWF	Abnormal platelet membrane
Template bleeding time	N or ↑	↑	↑	↑	N or ↑	↑↑	N or ↑
Factor VIII assay	↓	N or ↓	N or ↓	N or ↓	↓↓	↓↓	N or ↓
vWF antigen	↓	Variable	Variable	Variable	N	↓↓	Variable
Ristocetin cofactor (RIPA)	↓	↓	↑	↓	N	↓↓	↑
Plasma vWF multimer analysis	N	Only low-molecular-weight forms present	Only low- and intermediate-molecular-weight forms present	N	N	Variable	Only low- and intermediate-molecular-weight forms present

N—normal ↓—decreased ↑—increased vWF—von Willebrand factor

cause of a gain-of-function mutation; in type 2M, the abnormal vWF does not bind to GPIb-IX-V; and in type 2N, the binding site of vWF for factor VIII is mutated. All type 2 vWD variants, except for the rare type 2M, are characterized by a loss of the high-molecular-weight vWF multimers in the VWF polymer analysis.

Type 3 The rare homozygous or double heterozygous form (type 3 vWD) is characterized by severe hemorrhage, a long aPTT, and factor VIII levels of less than 5%.

Pseudo–von Willebrand disease A platelet form of vWD, which is termed pseudo–von Willebrand disease (pseudo–vWD), has been described in which an abnormal GPIb is present on platelets, causing excessive binding of normal plasma vWF to unstimulated platelets.

The mean level of vWF antigen is 100 IU/dl, but the population distribution of vWF levels is very broad, with the 95% values encompassing 50 IU/dl to 200 IU/dl. The reasons for this broad distribution in vWF levels are not completely understood, but it makes the commonly used threshold (vWF level at 2 SD [standard deviation] below the mean) inadequate for diagnosis of type 1 vWD. This problem with diagnosis is compounded by the fact that mild bleeding symptoms are extremely common in the general population. A recent survey estimates that 25% of men and 46% of women would give a positive history of bleeding symptoms, such as frequent epistaxis, easy bruising, and postpartum bleeding.[7] This suggests that type 1 vWD may be overdiagnosed, and it has been proposed that a more stringent diagnostic criterion be used—namely, limiting the diagnosis of type 1 vWD to patients with a vWF antigen level of less than 20 IU/dl.[6] Patients with modestly reduced vWF antigen levels (i.e., between 30 and 50 IU/dl) usually do not have identifiable vWF gene mutations and rarely cosegregate with a family history of bleeding. Patients with modestly reduced vWF levels (and no history of family bleeding) may have a modestly increased risk of bleeding.

Treatment

Mild or moderate types 1 and 2 1-Desamino-8-D-arginine vasopressin (DDAVP or desmopressin) is effective in the management of traumatic bleeding and before surgery in some patients with mild or moderate type 1 and type 2A vWD. The intravenous administration of DDAVP at a dosage of 0.3 mg/kg over a 15- to 30-minute period causes the release of large amounts of vWF from endothelial cell stores. The peak response usually occurs in 30 to 60 minutes and persists for up to 4 to 6 hours. Repeated DDAVP administrations over a 24-hour period are ineffective; tachyphylaxis follows depletion of the endothelial vWF stores. A DDAVP nasal spray (300 μg) can be used in the ambulatory treatment of patients with vWD, both for the management of bleeding episodes and as preparation for minor surgery.[8] The side effects of intravenous DDAVP are generally mild, including significant water retention and, rarely, thrombosis. Myocardial infarction has been reported. Because of the variability of response to DDAVP, a patient should be given a trial infusion of DDAVP before undergoing a planned procedure to determine whether the patient has an adequate response. Fibrinolysis inhibitor ε-aminocaproic acid (EACA), 3 g four times daily orally for 3 to 7 days, is also useful for dental procedures and minor bleeding events. Aspirin must be avoided.

Moderate and severe types 2 and 3 Patients with severe types 2A and 2B and with type 3 vWD generally require replacement therapy with Humate-P—a pasteurized intermediate-purity factor VIII concentrate that has a substantial amount of large vWF multimers—or with cryoprecipitate infusion containing vWF, factor VIII, and fibrinogen. Cryoprecipitate is generally not recommended. Transfusion of normal platelets can also be attempted on the grounds that platelet vWF can be hemostatically effective.[9]

Treatment during pregnancy Treatment is generally not needed during pregnancy in women with vWD. The plasma vWF level rises during the second and third trimesters but falls

rapidly after delivery. Late hemorrhage may occur 2 to 3 weeks post partum.[10] DDAVP is not used before delivery because of the concern that it may initiate contractions. Patients with type 2B vWD may have worsening thrombocytopenia during pregnancy because of the increase of abnormal vWF in plasma.[11]

HEMOPHILIA A

Hemophilia A affects one in 10,000 males and is characterized by a deficient or defective clotting factor VIII. The factor VIII gene, which is located on chromosome X at Xq28, is among the largest known human genes, spanning 186 kb and containing 26 exons. It encodes a protein of about 300,000 daltons, which circulates in plasma at very low concentrations and is normally bound to and protected by vWF. The primary source of factor VIII production is likely the liver, because hemophilia A can be corrected by liver transplantation.

Because the gene for factor VIII coagulant activity is carried on the X chromosome, the disease is manifested in hemizygous males. All of the daughters of a hemophiliac male will be carriers, whereas half of the sons of a mother who carries the hemophilia trait will be hemophiliacs and half of her daughters will be carriers. Families appear to be affected to varying degrees, depending on the specific nature of the genetic defect.

The clinical severity of hemophilia A correlates well with the measured levels of factor VIII coagulant activity. In general, factor VIII levels below 1% are associated with severe hemorrhagic symptoms; levels between 1% and 5%, with moderate hemophilia; and levels between 5% and 25%, with mild hemophilia [*see Table 2*].

Approximately one third of hemophilia A cases represent new mutations and have a negative family history. More than 300 abnormal factor VIII genes have been found. The abnormalities, which include point mutations, gene insertions, and gene deletions, result in either deficient factor VIII production or the generation of a functionally defective factor VIII. An inversion within intron 22 of the factor VIII gene, which results in a truncated and unstable factor VIII protein, is found in approximately 45% of all severely affected hemophilia A patients (factor VIII levels below 1%).[12]

Diagnosis

Diagnosis is made on the basis of the clinical picture, family history (positive in two thirds of cases), and the factor VIII coagulant activity level. In most cases, the type of bleeding history and a classic family history rule out vWD (which, unlike hemophilia A, is autosomally transmitted). Accurate DNA analysis for the common intron 22 inversion is now available in DNA testing laboratories. This test provides molecular diagnosis in approximately 45% of patients with severe hemophilia. However, it should not be ordered in patients with mild or moderate hemophilia.

Table 2 Correlation of Factor VIII Coagulant Activity Level with Bleeding Patterns in Hemophilia

Plasma Factor VIII Level	*Bleeding Pattern*
< 1%	Severe, presentation in first year of life, bleeding with circumcision, spontaneous hemarthrosis and deep-tissue bleeding
1%–5%	Moderate, presentation in childhood, bleeding after trauma, spontaneous hemarthrosis rare
5%–25%	Mild; may be present in childhood; bleeding after trauma, surgery, or dental extraction
25%–50%	May be undetected, may present in adulthood with bleeding after major trauma or surgery

Treatment

General principles The psychosocial aspects of hemophilia are complex. A child is often absent from school, is prone to crippling deformities, and runs a risk of drug addiction because of severe pain. Parents are understandably deeply concerned and sometimes troubled by guilt. Treatment should address these issues as well as the specific coagulation problem.

Factor VIII replacement Factor VIII concentrates are effective in controlling spontaneous and traumatic hemorrhage. Currently available factor VIII products derived from plasma have been purified to varying degrees (e.g., Humate-P [intermediate purity], Koate-HP [high purity], and Monoclate [ultrapurity]) and have undergone viral inactivation. There are two forms of full-length recombinant factor VIII (Recombinate and Kogenate), and they are safe and efficacious.[13,14] A second-generation, B-domain–deleted recombinant factor VIII (ReFacto) has also been developed and has been found to be effective and well tolerated.[15] The new recombinant factor VIII has the advantage of considerably higher specific activity, and the final formulation is stable without added human serum albumin, thus further reducing the potential risk of transmission of human infectious agents.

Dental prophylaxis is critically important to reduce the need for dental surgery. Aspirin must be avoided. Revaccination against hepatitis B virus also should be considered.

Genetic counseling should be part of the management program. Because of the difficult life severe hemophiliacs lead, a woman may opt to terminate pregnancy if she is certain of her carrier status or if she knows that her fetus is affected. There are several strategies for detecting carriers. In women who are carriers, factor VIII levels are typically about half of normal, whereas vWF levels are normal. The ratio of factor VIII to vWF for carriers is thus 0.5[16]; however, the error rate for this test is 10% to 17%. A more accurate genetic diagnosis for carriers can be made by a linkage approach. This approach is based on restriction fragment length polymorphisms (RFLPs) within the factor VIII gene. Analysis of the affected male will establish the pattern for the X chromosome carrying the hemophilia allele, without knowledge of the precise mutation. There are a large number of intragenic polymorphisms that allow the two copies of factor VIII genes in a female potential carrier to be distinguished, identifying her carrier state with high accuracy.

These molecular probes for RFLPs are now being used to determine the status of the fetus. Tissue can be obtained by amniocentesis or chorionic villus sampling.

Management of acute hemorrhage Deep tissue bleeding, hemarthrosis, and hematuria are the common forms of clinical bleeding in hemophilia A. Acute threats to life are posed by retroperitoneal hemorrhage; bleeding of the mouth, tongue, or neck that impairs the airway; and intracranial hemorrhage. Both ultrasonography and computed tomography can be used to identify retroperitoneal and intramuscular hematomas.

Principles of replacement therapy A plasma procoagulant level of 100% means that there is one unit of procoagulant per milliliter of plasma. Most persons have 40 ml of plasma per kilogram of body weight. Thus, from a determination of a patient's plasma volume and procoagulant level, the required amount of factor VIII replacement can be calculated. For example, in the case of a 60 kg boy who has an uncomplicated hemarthrosis of the knee and a baseline factor VIII of less than 1%, raising the factor VIII level to about 25% (0.25 U/ml) for 2 to 3 days should suffice. This patient has a plasma volume of 60 kg × 40 ml/kg, or 2,400 ml; he will need 0.25 U/ml × 2,400 ml, or 600 U of factor VIII, as an initial bolus. Another method of estimation is based on the following effect: the infusion of 1 U of factor VIII per kilogram increases factor VIII levels by 2%. Thus, dividing the desired level of factor VIII increase by 2 will give the number of U/kg required. In the example cited, 25% of factor VIII will require 12.5 U/kg, or 750 U, of factor VIII replacement.

The biologic half-life of factor VIII is approximately 12 hours; the dose can be repeated every 12 to 24 hours as long as needed to control the hemorrhage. In patients with hemarthrosis, the factor VIII level should be maintained for 2 to 3 days.

Elective surgery and dental extraction Dental work should be performed by a dentist who is experienced in the treatment of hemophiliacs. Before dental extraction, factor VIII is administered to raise the level to approximately 50%. The fibrinolytic inhibitor EACA is started the night before surgery at a loading dose of 3 g orally and continued at 2 to 3 g three or four times daily for 7 to 10 days after the dental work has been completed. Usually, further administration of factor VIII is not required.

Before elective surgery, the factor VIII level should be raised to 50% to 100% (0.5 to 1.0 U/ml) and then maintained above 50% for the next 10 to 14 days. Maintaining a higher concentration of factor VIII does not reduce the frequency of hemorrhage.[17]

DDAVP can be used to treat acute traumatic hemorrhage in patients with mild to moderate hemophilia and even to prepare such patients for minor surgery. DDAVP, which causes the release of vWF from endothelial cell stores, cannot be used repeatedly over many days, because such stores become depleted. DDAVP is infused at a dosage of 0.3 μg/kg in 50 ml of saline over 15 to 30 minutes and produces a prompt increase in factor VIII. The biologic half-life of the released factor VIII is 11 to 12 hours.

Management of an inhibitor Inhibitors tend to occur in more severely affected patients, who tend to receive the greatest number of factor VIII concentrates. In a recent single-center study of 431 patients over 3 decades, approximately 10% of patients with severe hemophilia A had an inhibitor (about a third were children younger than 10 years).[18] Not all inhibitors produce clinical problems. Assays for factor VIII inhibitors should be performed at regular intervals in all patients who have severe hemophilia.

Hemorrhage in a patient with an inhibitor can be life threatening. In a patient who has an inhibitor titer of less than 5 Bethesda units and who is not a vigorous antibody responder, a large amount of factor VIII concentrate should be administered in an attempt to overwhelm the antibody. Alternative therapies are porcine factor VIII (Hyate:C), prothrombin complex concentrates (e.g., Konyne and Proplex) to circumvent the factor VIII deficiency,[19,20] and activated prothrombin complex concentrates, such as Autoplex-T and FEIBA.

Recombinant activated factor VII (rFVIIa) has been found to be safe and efficacious in 70% to 85% of more than 1,500 bleeding episodes in hemophilia patients with inhibitors.[21,22] Recombinant factor VIIa may compete against the normal plasma unactivated factor VII for tissue factor binding and thus enhance thrombin generation at the bleeding site.[23] In addition, high-dose rFVIIa may bind to activated platelets and activate factors IX and X on the platelet surface in the absence of tissue factor.[24]

High-dose intravenous IgG has been used to treat nonhemophiliacs with acquired factor VIII inhibitors, but it is usually not efficacious in hemophiliacs with inhibitors (alloantibodies).

OTHER HEREDITARY HEMORRHAGIC DISORDERS

Factor IX Deficiency (Hemophilia B)

Factor IX deficiency (hemophilia B, or Christmas disease) is an X-linked disorder that is clinically indistinguishable from hemophilia A. The factor IX gene is on the X chromosome and produces a clotting factor that, like other vitamin K–dependent factors, has a region rich in γ-carboxylated glutamic acids. Calcium ion bridges link this region to the activated platelet cell surface, where factor IXa interacts with factor VIIIa to form a membrane-associated complex that efficiently converts factor X to factor Xa (intrinsic tenase) [*see 5:XII Hemostasis and Its Regulation*]. A large number of insertions, rearrangements, and deletions have been detected in the factor IX gene, and the hemophilia B syndrome is very heterogeneous.[25]

Diagnosis Diagnosis of hemophilia B requires a factor IX assay. The management principles are the same as those for hemophilia A. A plasma-derived pasteurized factor IX concentrate preparation (Mononine) displays excellent specific activity and a desirable biologic half-life of 18 to 34 hours. Recombinant factor IX is also commercially available.

Treatment The level of factor IX that is needed to control hemostasis in patients with hemophilia B is somewhat lower than the level of factor VIII required for the treatment of hemophilia A—about 15% to 20% for the former and 30% to 50% for the latter. Factor IX is a smaller molecule than factor VIII and is distributed in the albumin space. In making replacement calculations, it is assumed that administration of 1 U/kg of factor IX will increase the plasma level by 1%. Factor IX has a biphasic half-life, and plasma levels of this factor can be maintained by infusing the concentrate every 24 hours. Molecular biology techniques can now detect the factor IX deficiency carrier state and permit accurate genetic counseling. Sustained correction of a bleeding disorder in hemophilia B mice has been demonstrated by the gene therapy approach,[26] and clinical trials of factor IX in hemophilia B patients have been initiated.[27]

Factor XI Deficiency

Patients with factor XI deficiency frequently come to medical attention when a prolonged aPTT is detected in preoperative screening. It is most frequently observed in Ashkenazi Jews, although sporadic cases have been described in people of different ethnic origins. Factor XI deficiency is inherited as an autosomal recessive trait, and heterozygous deficiency is not associated with any clinical bleeding. Homozygous or compound heterozygous deficient patients generally have factor XI levels of less than 15%, and most bleeding manifestations in these patients are related to trauma or surgery, especially at sites of high

fibrinolytic activity (e.g., the urinary tract, tonsils, and tooth sockets).[28] Factor XI plays a supportive role in the clotting cascade. It is activated by thrombin and then functions in a positive feedback manner to augment thrombin generation and clot stabilization [*see 5:XII Hemostasis and Its Regulation*]. Thus, factor XI is primarily required in situations in which there is a significant hemostatic challenge; this explains the mild bleeding diathesis in factor XI deficiency.

For patients with severe factor XI deficiency (< 15%) who require surgery, fresh frozen plasma should be used to replenish the plasma level to more than 50%. EACA given orally at a dosage of 3 g three or four times daily is also effective for minor surgical or dental procedures. In a recent retrospective study of 62 women with severe factor XI deficiency, about 70% of the women did not have any postpartum hemorrhage. Of the 30% who did have postpartum hemorrhage, some had a history of recurrent clinical bleeding. Postpartum hemorrhage had no relationship with the particular abnormal factor XI genotype or with the level of factor XI.[29]

Fibrinolytic Abnormalities

Two uncommon congenital hemorrhagic disorders have been ascribed to abnormalities of fibrinolysis. Deficiency of α_2-antiplasmin, the major plasmin inhibitor, has led to uncontrolled plasmin activity with consequent hemorrhage. Enhanced fibrinolytic activity with occasional clinical bleeding has also been linked to deficiency of plasminogen activator inhibitor–1 (PAI-1), the physiologic inhibitor of tissue plasminogen activator (t-PA) and urokinase.[30] Treatment of both types of fibrinolytic abnormalities consists of the antifibrinolytic agents, tranexamic acid, or EACA, all of which block the binding of plasminogen and plasmin to fibrin.

Acquired Hemorrhagic Disorders

In addition to the hereditary coagulation disorders, several acquired disorders have been identified that can lead to generalized hemorrhage.

VITAMIN K DEFICIENCY

A vitamin K–dependent carboxylase in the liver synthesizes γ-carboxyglutamic acid, which is required for the biologic function of prothrombin and factors VII, IX, and X. In the absence of vitamin K, an abnormal prothrombin that lacks γ-carboxyglutamic residues is synthesized. Specific immunoassays performed in patients with vitamin K deficiency reveal a sharp decrease in normal prothrombin levels and a concomitant increased level of the abnormal des-γ-carboxyprothrombin. The same molecular derangement occurs with factors VII, IX, and X.[31]

Clinical Features and Diagnosis

Deficiency of vitamin K, which decreases levels of prothrombin and factors VII, IX, and X, occurs in cases of severe malnutrition, intestinal malabsorption, and obstructive jaundice. In patients with obstructive jaundice, bile salts, which are necessary for the emulsification and absorption of the fat-soluble vitamins (vitamins A, D, E, and K), cannot enter the intestine. Long-term ingestion of oral antibiotics suppresses vitamin K production by intestinal organisms. The effect is especially marked in patients who, because of their illness, are unable to consume a full, nourishing diet. Mucosal bleeding and ecchymoses occur if the procoagulant levels fall below 10% to 15% of normal.

Treatment

Therapy with vitamin K_1 (phytonadione), 10 to 25 mg/day orally for 2 or 3 days—or parenteral vitamin K_1 in cases of obstructive jaundice—usually reverses the abnormality in about 6 to 24 hours. If there is severe bleeding, fresh frozen plasma (approximately 3 units) restores procoagulant levels rapidly [*see* Principles of Replacement Therapy, *above*].

DRUG-INDUCED HEMORRHAGE

Warfarin-Induced Hemorrhage

Warfarin overdose or potentiation of its action by other drugs can cause very severe bleeding. The prothrombin time (PT) is prolonged, and mucosal bleeding, gastrointestinal bleeding, or ecchymosis is the usual pattern. If hemorrhage is significant, treatment to restore procoagulant levels to 30% of normal must be started with fresh frozen plasma. If there is no urgency, oral vitamin K_1 may be given. Generally, 1 to 2.5 mg of vitamin K_1 will be sufficient to return anticoagulation (defined as the international normalized ratio [INR]) to therapeutic levels after 16 hours. High doses of vitamin K_1 (10 mg or more) should be avoided because they may cause warfarin resistance for up to a week. Surreptitious warfarin use can be identified by a serum warfarin assay, which is available at special laboratories. Factitious or accidental ingestion of some of the long-acting vitamin K antagonists that are used as rodenticides (superwarfarins) may lead to prolonged bleeding symptoms. The synthesis of vitamin K–dependent clotting factors can be impaired for months after the initial exposure. Repeated administration of fresh frozen plasma, supplemented by massive doses of oral vitamin K_1 (100 to 150 mg/day), may be required to control bleeding symptoms.

Heparin-Induced Hemorrhage

Heparin overdose may not be obvious. It causes subcutaneous hemorrhages and deep tissue hematomas. The aPTT, PT, and thrombin time (TT) are vastly prolonged, but the reptilase time (RT) is normal. Intravenous protamine administration at a dosage of 1 mg/100 U of administered heparin terminates the overdose response. Because the half-life of protamine is shorter than that of heparin, a heparin rebound may occur, necessitating a second administration of protamine. Low-molecular-weight heparin (LMWH) preparations cause as much bleeding as standard unfractionated heparin. The ability of protamine to reverse the actions of LMWH is incomplete. Protamine (1 mg/100 U of anti–factor Xa) can be tried; if protamine treatment is unsuccessful, recombinant factor VIIa should be considered.

Hemorrhage Caused by Thrombolytic Therapy

Thrombolytic therapy is now used for acute myocardial infarction and for some cases of pulmonary embolism. The complications of thrombolytic therapy are essentially all hemorrhagic. In general, bleeding has been confined to relatively trivial oozing at vascular invasion sites, but subdural hematomas, cerebral infarction, and intracranial bleeding have also occurred. The thrombolytic agents, even those designed to be relatively fibrin specific, occasionally cause a significant systemic lytic state, with low levels of fibrinogen, factor V, and factor VIII. Furthermore, the generation of fibrinogen degradation products in turn interferes with the formation of a firm clot and with platelet function.

If thrombolytic therapy is suspected as the cause of bleeding in a particular patient, blood should be drawn quickly for an aPTT, a TT, an RT, and a fibrinogen level. If thrombolytic thera-

Table 3 Causes of Disseminated Intravascular Coagulation (DIC)

Events that initiate DIC
Septicemia
Cancer procoagulants (Trousseau syndrome)
Acute promyelocytic leukemia
Crush injury, complicated surgery
Severe intracranial hemorrhage
Retained conception products, abruptio placentae, amniotic fluid embolism
Eclampsia, preeclampsia
Major ABO blood mismatch, hemolytic transfusion reaction
Burn injuries
Heatstroke
Malignant hypertension
Extensive pump-oxygenation (repair of aortic aneurysm)
Giant hemangioma (Kasabach-Merritt syndrome)
Severe vasculitis
Events that complicate and propagate DIC
Shock
Complement pathway activation

py is the cause, the aPTT is prolonged, the fibrinogen level is usually below 50 mg/dl, and the TT and RT are both prolonged (as a result of the fibrin degradation products and decreased plasma fibrinogen).

The disorder is treated with cryoprecipitate (to raise the fibrinogen level to approximately 100 mg/dl), fresh frozen plasma, and platelet concentrates. If these measures do not stop the bleeding, the use of a specific antifibrinolytic agent such as EACA should be considered. EACA is given as a 5 g bolus I.V. over 30 to 60 minutes and then in a dosage of 1 g/hr by continuous I.V. infusion.[32]

DYSPROTEINEMIAS

The abnormal proteins associated with myeloma and macroglobulinemia can interfere with platelet function and cause clinical bleeding. These proteins can cause abnormalities in the coagulation tests as well. Both IgG and IgA myeloma proteins can cause prolonged TTs by interfering with the fibrin polymerization process. Less commonly, they may interact with specific clotting factors. Management is directed at the primary disease. Generally, these paraproteins do not cause clinically significant bleeding. If bleeding occurs, plasmapheresis rapidly corrects the defects by abruptly lowering the level of abnormal protein.

DISSEMINATED INTRAVASCULAR COAGULATION

Pathophysiology

Many different circumstances can cause DIC [*see Table 3*]. In each case, massive activation of the clotting cascade overwhelms the natural antithrombotic mechanisms, giving rise to uncontrolled thrombin generation. This condition results in thromboses in the arterial and venous beds, leading to ischemic infarction and necrosis that intensify the damage, release tissue factor, and further activate the clotting cascade. Massive coagulation depletes clotting factors and platelets, giving rise to consumption coagulopathy and bleeding. Tissue damage and the deposition of fibrin result in the release and activation of plasminogen activators and the generation of plasmin in amounts that overwhelm its inhibitor, α_2-antiplasmin. Plasmin degrades fibrinogen, prothrombin, and factors V and VIII and produces fibrin-fibrinogen degradation products. These substances interfere with normal fibrin polymerization and impair platelet function by binding to the platelet surface GPIIb-IIIa fibrinogen receptor. These fibrin-fibrinogen degradation products thus function as circulating anticoagulant and antiplatelet agents, exacerbating the consumption coagulopathy, and play a significant role in the bleeding diathesis [*see Figure 1*].

Endotoxin released during gram-negative septicemia enhances the expression of tissue factor, thereby accelerating procoagulant activation while suppressing thrombomodulin expression. These actions downregulate the protein C/protein S system, further promoting the tendency to DIC.[33] Experimental-endotoxemia models also showed marked suppression of fibrinolysis activity caused by a sustained increase in plasma PAI-1.[34] In patients with solitary or multiple hemangiomas associated with thrombocytopenia (Kasabach-Merritt syndrome), DIC is presumably initiated by prolonged contact of abnormal endothelial surface with blood in areas of vascular stasis. Platelets and fibrinogen are consumed in these hemangiomas, where fibrinolysis appears to be enhanced,[35] and such consumption can lead to hemorrhage. Certain snakebites can also produce DIC; several mechanisms have been identified. For example, Russell viper venom contains a protease that directly activates factor X and can produce almost instantaneous defibrination.

Clinical Consequences

The consequences of DIC depend on its cause and the rapidity with which the initiating event is propagated. If the activation occurs slowly, an excess of procoagulants is produced, predisposing to thrombosis. At the same time, as long as the liver can compensate for the consumption of clotting factors and the

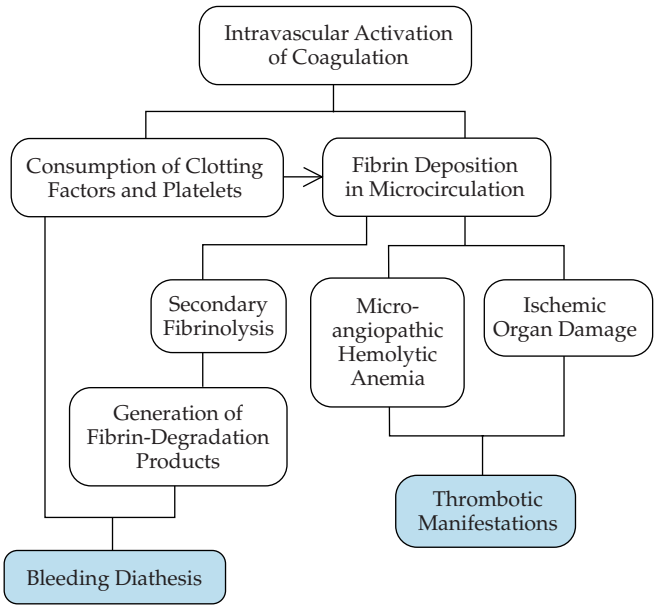

Figure 1 **In compensated disseminated intravascular coagulation (DIC), such as that which occurs in Trousseau syndrome, thrombotic manifestations predominate in the clinical presentation. In decompensated DIC, however, fibrin-fibrinogen degradation products exacerbate the consumption coagulopathy and play a significant role in the bleeding diathesis.**

bone marrow maintains an adequate platelet output, the bleeding diathesis will not be clinically apparent. The clinical situation consists of primarily thrombotic manifestations, which can be both venous thrombosis and arterial thrombosis [*see 5:XIV Thrombotic Disorders*]. Venous thromboses commonly involve deep vein thrombosis in the extremities or superficial migratory thrombophlebitis. Patients can also experience arterial thrombosis, leading to digital ischemia, renal infarction, or stroke. Arterial ischemia can in part be the result of emboli that originate from fibrin clots in the mitral valve, a condition termed nonbacterial thrombotic endocarditis, or marantic endocarditis. This condition is sometimes known as compensated, or chronic, DIC and accounts for Trousseau syndrome[36] (a chronic DIC caused by an underlying malignancy, most frequently pancreatic or other gastrointestinal cancer). The cancer cells may produce either tissue factor or another procoagulant that activates the clotting system.

If the reaction is brisk and explosive, the clinical picture is dominated by intravascular coagulation; depletion of platelets, fibrinogen, prothrombin, and factors V and VIII; and the production, by plasmin action, of fibrin degradation products, which further interfere with hemostasis. The clinical consequence is a profound systemic bleeding diathesis, with blood oozing from wound sites, intravenous lines, and catheters, as well as bleeding into deep tissues. The intravascular fibrin strands produce microangiopathic hemolytic anemia.

Diagnosis

Microangiopathic red blood cells on smear and a moderate to severe thrombocytopenia suggest the diagnosis. A number of laboratory abnormalities are present in DIC, depending on the stage of the DIC. Because of clotting factor depletion, the aPTT and PT are prolonged and the fibrinogen level is low. Because fibrin degradation products interfere with fibrin polymerization, the TT and RT are also prolonged. The level of fibrin degradation products, as measured by the D-dimer level, is elevated. Plasma plasminogen, protein C, and α_2-antiplasmin levels are also low because of consumption; however, these measurements are generally not required. In the case of compensated DIC, most of these parameters can be normal except for the elevation of the D-dimer level, which indicates the presence of intravascular cross-linked fibrin deposition and fibrinolysis. Sometimes, the fibrinogen level can even be high because fibrinogen is an acute-phase reactant. When the DIC becomes decompensated, consumption coagulation predominates and the other laboratory abnormalities listed are present (see above). Repetition at regular intervals of specific coagulation tests (see above), especially the platelet count, fibrinogen level, and D-dimer level, is critical. These tests provide a kinetic parameter that greatly aids in the assessment of the severity of the DIC and the choice of appropriate management.

Treatment

Currently, management must be directed at the primary disease to switch off the initiating event. This approach may involve chemotherapeutic treatment of an underlying tumor, administration of antibiotics and surgical drainage of an abscess, or emptying the uterus when complications of pregnancy have been the inciting cause. Hemodynamic support is essential. The use of antifibrinolytic agents such as EACA or aprotinin is contraindicated. Despite its bleeding complications, DIC is a severe hypercoagulable state, and these agents block the fibrinolytic system and may exacerbate its thrombotic complications. The administration of blood products, such as platelets, fresh frozen plasma, or cryoprecipitate, may add fuel to the fire and worsen the consumption coagulopathy. However, if clinical bleeding becomes significant, it is prudent to give vigorous blood product support.

The use of heparin in cases of acute DIC has not been established. Although heparin, by activating antithrombin (AT), is effective in inhibiting thrombin and therefore should be efficacious in the treatment of DIC, its use is generally limited to situations of chronic or compensated DIC. Heparin, given subcutaneously, is effective in the treatment of venous thrombosis in patients with Trousseau syndrome. In the case of decompensated DIC, in which bleeding is the major clinical manifestation, heparin may significantly exacerbate the bleeding and is therefore generally not indicated. The use of high-dose AT infusion has been advocated in this situation, but its efficacy has not been established by randomized studies.[37,38]

Recombinant human activated protein C (APC, or drotrecogin alfa [activated]) has been shown to significantly reduce mortality in patients with severe sepsis (mortality was 24.7% in patients given APC versus 30.8% in patients given placebo).[39] Although it is associated with a slightly increased risk of bleeding, APC appears to be an effective agent in the treatment of severe DIC in patients with sepsis, even for patients with normal protein C levels.[40] In large randomized trials, neither recombinant tissue factor pathway inhibitor (TFPI) nor AT concentrate reduced mortality in septic patients.[41,42] In cases of DIC associated with solitary or multiple hemangiomas, the hemangiomas can be excised when they are localized, and they occasionally show a good response to local irradiation. Attempts to control DIC associated with hemangiomas by the administration of heparin, corticosteroids, aspirin, and estrogens have not been successful. The key to successful management of DIC associated with certain snakebites is identification of the type of snake and prompt administration of appropriate antivenin.

ACQUIRED HEMOPHILIA AND OTHER DISORDERS OF CIRCULATING INHIBITORS

In addition to the hemorrhage caused by the circulating alloantibody inhibitors in severe hemophilias A and B, clinical hemorrhage is occasionally caused by circulating inhibitors directed against specific clotting factors, which seem to appear spontaneously. Because acquired autoantibody to factor VIII, which gives rise to the clinical picture of acquired hemophilia, is the most common of these circulating inhibitors, it will be described here in some detail, but many of the same principles apply to other inhibitors.

Autoantibodies to factor VIII are usually IgGa and, frequently, IgG4 and thus do not fix complement. They are usually directed against the functionally important A2 and C2 domains[43] on factor VIII. About half of the patients with an acquired factor VIII inhibitor have no identifiable associated disorder, but many disease states have been identified in the other patients, including autoimmune disorders such as systemic lupus erythematosus, lymphoproliferative disorders, plasma cell malignancies, drug reactions (e.g., reaction to penicillin), the postpartum state, and skin disorders.[44]

Diagnosis

Patients with an acquired factor VIII inhibitor commonly present with new-onset mucosal hemorrhages, hematomas, and ecchymoses but have a negative bleeding history. Typically, the

clinical picture of acquired hemophilia caused by factor VIII inhibitor occurs in an elderly patient or in a young woman during pregnancy or in the postpartum period. The laboratory hallmark of an acquired inhibitor to a clotting factor is a prolonged clotting time that is not corrected by mixing equal parts of the patient's plasma with normal plasma. In the case of factor VIII inhibitor, the PTT is prolonged and the PT and TT are normal. The antibody binds to factor VIII with complex kinetics such that the inhibitory effect becomes apparent only after prolonged incubation. Therefore, if an acquired factor VIII inhibitor is suspected, mixing studies should be performed after 5-minute and 60-minute incubations. The diagnosis can be confirmed by demonstration of a very low factor VIII level when other clotting factor levels are normal. Determination of the titer of the factor VIII inhibitor (expressed in Bethesda units [BU] per milliliter, with 1 BU/ml indicating a sufficient number of inhibitors to cause the complete inhibition of factor VIII in 1 ml of blood) is useful in choosing the appropriate therapy.

Treatment

The hemorrhage caused by circulating inhibitors may be clinically life threatening. Attempts at factor replacement are usually not successful, because the inhibitor inactivates the exogenous factor VIII. Occasionally, if the inhibitor has a low titer (e.g., < 2 to 3 BU/ml), massive factor VIII replacement can overwhelm the inhibitor. However, this treatment may trigger a significant anamnestic response resulting in increased levels of antibody, which complicates further management. Immunosuppressive therapy with a combination of cyclophosphamide (given either as a monthly intravenous pulse therapy or orally on a daily basis) and prednisone has been successful in most cases.[45,46] The inhibitor usually becomes undetectable after three or four monthly cycles of chemotherapy. In the case of severe or life-threatening hemorrhage in which there is insufficient time to reduce the level of inhibitor, porcine factor VIII can be administered, because the antibody usually displays low cross-reactivity.

Another alternative therapy for acute bleeding is the administration of procoagulant complexes, which may bypass the inhibitor block by providing large amounts of factor X and factor VII.[47] Still other therapeutic options include plasmapheresis and high-dose intravenous IgG, although the response rate for intravenous immune globulin (IVIg) appears to be quite low.[48] Recombinant activated factor VII (90 μg/kg given as an I.V. bolus every 2 to 3 hours) has been used successfully in patients with this condition. There is growing evidence that rituximab, given intravenously at 375 mg/m^2 once weekly for 4 weeks, is effective.[49,50] In patients with a very high titer inhibitor (>100 BU/ml), a combination of rituximab and cyclophosphamide may be required.

ACQUIRED VON WILLEBRAND DISEASE

Diagnosis

Patients with acquired von Willebrand disease, who are generally in their 50s and 60s and do not have a personal or family history of a bleeding disorder, present with mucocutaneous-type bleeding.[51] The workup is the same as that for vWD. The acquired form of the disease frequently occurs in the setting of underlying lymphoproliferative, myeloproliferative, or cardiovascular disease. A study showed that acquired vWD is quite common in patients with severe aortic stenosis. vWF abnormalities are directly related to the severity of aortic stenosis and improve after valve replacement.[52] Acquired vWD is also occasionally associated with angiodysplasia in patients with recurrent gastrointestinal bleeding. Frequently, a small monoclonal gammopathy is found on serum protein electrophoresis. The plasma antibody to vWF is functional in a minority of cases, as demonstrated by inhibition of vWF in a functional assay by mixing studies.[53] However, most cases involve nonneutralizing antibodies to vWF, which can be demonstrated by enzyme-linked immunosorbent assay (ELISA). Presumably, the antibody binds to vWF and causes its rapid clearance, leading to a low plasma vWF level. Nonimmune mechanisms (e.g., adsorption of vWF onto tumor cells) have also been described. Multimeric analysis of plasma vWF typically shows a decrease in the high-molecular-weight multimers, resembling type 2A vWD.

Treatment

DDAVP is useful in correcting the bleeding diathesis in about one third of cases of acquired vWD. High-dose intravenous IgG (1 g/kg I.V. daily for 1 to 2 days) generally garners a good temporary response, with an increase in the vWF level and a shortening of the aPTT, lasting from a few days to 2 weeks. If the patient has a defined lymphoproliferative, myeloproliferative, or autoimmune disease, the underlying disease should be treated. However, the response of acquired vWD to immunosuppressive therapy with cyclophosphamide and prednisone is generally not as favorable as the response in the case of acquired factor VIII inhibitor.

HEMORRHAGE CAUSED BY SEVERE LIVER DISEASE

Patients with severe liver disease may suffer life-threatening hemorrhages. The most frequent types are esophageal and gastrointestinal hemorrhages related to varices, gastritis, or peptic ulcer. There may also be bleeding from biopsy sites and during and after surgery. Mucosal and soft tissue bleeding may occur, but generally, this is not the dominant bleeding problem.

The coagulopathy of severe liver disease is complex and not well delineated. Because the liver is the major site of synthesis for all the clotting factors, decreased levels of multiple clotting factors are observed, including fibrinogen, prothrombin, factor V, and factor VII; factor VIII is excepted, presumably because it is an acute-phase reactant. An increased level of abnormal fibrinogen with reduced clotting capability is also observed in patients with cirrhosis.[54] In addition, there is reduced clearance of activated clotting factors by the liver. DIC appears to occur commonly in patients with cirrhosis[55] (presumably because of triggering of the clotting cascade by hepatic tissue damage), but its precise role in both acute fulminant hepatitis and chronic liver disease has not been firmly established. Moderate thrombocytopenia is common, resulting from a combination of decreased platelet production (from relative deficiency of thrombopoietin [TPO], because the liver is the major site of TPO synthesis) and increased platelet destruction from hypersplenism. Platelet function is generally maintained. There is also evidence of hyperfibrinolysis, but its contribution to the overall hemostatic defect is uncertain. The liver also synthesizes most of the natural anticoagulant proteins. AT, protein C, and protein S levels are decreased. The best screening tests for this disorder include the PT, aPTT, platelet count, fibrinogen level, and D-dimer level. Specific assays that may guide therapy include factor V, factor VII, and AT. Replacement for active bleeding is accomplished by administering fresh frozen plasma, cryoprecipitates, and platelets as required. Prothrombin-complex concentrates are not recommend-

ed, because they do not replenish all the deficient clotting factors and may exacerbate the DIC. In general, although the multiple hemostatic defects contribute to the bleeding diathesis in severe liver disease, hemodynamic and anatomic factors are the primary determinants in this situation.

PRIMARY FIBRINOLYSIS

Cases of generalized primary fibrinolysis are rare. Many of the early reports of primary fibrinolysis probably represented secondary fibrinolysis associated with DIC. Postprostatectomy hematuria may constitute a true example of hemorrhage caused by localized fibrinolysis. The high concentration of urokinase in the urine in this condition causes plasminogen to be converted to plasmin with resulting clot lysis. If other causes of persistent postoperative hematuria can be ruled out, the condition can be treated with oral or intravenous EACA. Local instillation of EACA by urethral catheter is also effective.

BLEEDING AFTER CARDIOPULMONARY BYPASS

A mild thrombocytopenia (approximately 100,000/μl) commonly occurs in patients after cardiopulmonary bypass surgery.[56] A significant acquired platelet function disorder develops in some patients, probably caused by contact between the platelets and the oxygenator apparatus, which in turn leads to partial platelet degranulation.[57] In addition to the release of platelet granule contents, activation of fibrinolysis may occur together with modest clotting factor depletion.[58] The hemorrhage in such cases generally responds to platelet transfusions. The use of DDAVP in this setting has been reported to reduce postoperative blood loss; however, a meta-analysis of 17 clinical trials showed only a modest beneficial effect.[59]

The bovine protease inhibitor aprotinin has been shown to reduce bleeding and transfusion requirements in patients undergoing cardiopulmonary bypass.[60] Aprotinin inhibits plasmin and may also attenuate the systemic inflammatory response by inhibition of the proinflammatory mediator kallikrein.[61] It reduces plasmin-mediated proteolysis of platelet membrane proteins and preserves platelet function.[62] Randomized clinical trials showed that the two antifibrinolytic agents EACA and tranexamic acid are equally efficacious as aprotinin in this setting.[63,64] Aprotonin should be reserved for patients who are likely to require blood transfusion, especially those undergoing second operations and those with preexisting hemostatic defects. Preoperative testing of hemostasis appears not to be useful.

During bypass surgery, patients are sometimes exposed to topical thrombin (fibrin glue), which is used for local hemostasis control. Generally, bovine thrombin and trace amounts of other clotting factors to which patients may develop antibodies are used in these preparations. The antibodies against bovine thrombin cause a prolongation of the TT but are innocuous in themselves. However, potentially serious complications arise when the antibodies cross-react with human thrombin. Some patients develop antibodies against bovine factor V that cross-react with human factor V and may lead to clinical bleeding.[65,66] A review of reported cases found that bovine thrombin-associated factor V antibodies developed in 40% to 66% of cardiac surgery patients and in 20% of neurosurgery patients, and clinical bleeding complications occurred in about one third of these cases.[67] Mixing studies utilizing the patient's plasma and normal plasma will reveal the presence of the inhibitors, and the measurement of the appropriate factor levels will allow the correct diagnosis to be made. Sometimes, plasmapheresis is required to control the acute bleeding.

EVALUATION OF POSTOPERATIVE BLEEDING

Serious hemorrhage during or after surgery is a complicated clinical problem requiring rapid diagnosis and prompt intervention. The first question is whether the bleeding has a local anatomic cause (e.g., unligated vessel) or is the result of a systemic hemostatic failure. If the patient is bleeding only in the operative area, it would suggest a local anatomic cause, such as an unligated bleeding vessel. The patient's bleeding history, especially with the results of prior surgical procedures, is extremely useful, but the available history may be inadequate or incomplete. A revealing clue to a systemic malfunction is bleeding at multiple sites, particularly areas other than that of the surgical wound. Bleeding around a catheter, from venipuncture sites, and from venous cutdowns is highly indicative of a hemorrhagic disorder.

Rapid assessment of the total clinical setting is imperative. The following questions should be addressed:

- Does the patient have underlying renal, hepatic, or malignant disease?
- Has the surgery required pump bypass techniques or the induction of hypothermia, or has the patient been in shock or been hypothermic?
- How many units of blood and blood products have been given and over what period of time?
- Were baseline screening procoagulant tests obtained before surgery, and is the patient's frozen plasma still available?

The differential diagnosis of postoperative hemorrhage should include a number of bleeding disorders [*see Table 4*].

Prompt resolution of postoperative bleeding requires a panel of coagulation tests—including aPTT, PT, TT, fibrinogen assay, and D-dimer—a platelet count, and a well-stained blood smear for evaluation of platelet and red cell morphology. This battery of tests should be performed immediately. More specialized studies can be obtained if there is evidence of a specific disorder.

Table 4 Differential Diagnosis of Postoperative Hemorrhage

Dilutional thrombocytopenia caused by massive transfusion
Acquired platelet function defect after cardiopulmonary bypass
Inadequate heparin neutralization
Disseminated intravascular coagulation
Coagulopathy caused by shock liver
Acquired antithrombin and anti–factor V inhibitors after exposure to fibrin glue
Heparin-induced thrombocytopenia
Thrombocytopenia caused by GPIIb-IIIa inhibitors (e.g., abciximab)
Hyperfibrinolysis after prostate surgery
Undiagnosed von Willebrand disease or hemophilia
Thrombocytopenia caused by posttransfusion purpura
False abnormalities in coagulation test results

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Recombinant factor VIIa has not been approved by the FDA for uses described in this chapter.

I ORGANS AND CELLS OF THE IMMUNE SYSTEM

John R. David, m.d.
Cox Terhorst, ph.d.

The Characteristics of the Immune System

The immune system mediates the individual's relationship with the microbial environment. Immunity involves innate, or natural, responses and highly specific acquired, or adaptive, responses. The essential difference between the two types of immunity lies in the means by which microorganisms are recognized. In innate immunity, glycolipids and macromolecules with repeat patterns that are unique to infectious organisms are recognized by cell surface receptors on macrophages, dendritic cells, natural killer (NK) and NK T (NKT) cells, as well as by the complement system. In acquired immunity, lymphocytes use very specific antigen receptors to recognize infectious agents and other antigens, either directly or when processed by antigen-presenting cells (APCs), such as dendritic cells. Thus, an interplay exists between innate and acquired immunity at the level of the APC. Once an otherwise healthy person has had an infection with bacteria or with a virus, the immune system recognizes that pathogen and prevents its recurrence. In addition, the immune system has the remarkable capacity to discriminate between antigens, even if their structures are closely related. Lymphocytes can also react to self-antigens, causing autoimmunity.

The immune response needs to be able to distinguish between self and nonself. Otherwise, T cells and antibodies would constantly be attacking autologous cells, tissue components, or even commensal bacteria. In the 1950s, Sir Frank Macfarlane Burnet first proposed that in the prenatal state, the interaction of self-antigens with antigen-specific lymphocytes leads to the elimination of self-reactive lymphocytes and hence to immunologic tolerance.[1] When immunologic tolerance breaks down, the antibodies and sensitized (antigen-reactive) cells that are directed against self-antigens cause autoimmune diseases [*see 6:IX Immunologic Tolerance and Autoimmunity*].

Lymphocytes

There are two major groups of lymphocytes, the T cells (also called thymus-derived lymphocytes, or T lymphocytes) and the B cells (also called bone marrow–derived lymphocytes, or B lymphocytes). T cells and B cells make up 80% to 95% of the peripheral blood lymphocytes.

T cells and B cells have a vast power of antigen recognition. Two unique features underlie this power: (1) a B cell family of variable genes, which combined can recognize an almost infinite number of antigens; and (2) a T cell family of variable genes with only a slightly more limited capacity. Neither T cells nor B cells constitute a homogeneous population of cells; each group comprises a number of subgroups that can be differentiated by the constant region of their receptors, by specific sets of developmentally expressed surface markers, by their location in lymphoid organs, and by their function. The binding of combinations of monoclonal antibodies to surface receptors is currently the most specific technique used to identify the major subsets of these cells.

T cells

Mature T cells express either αβ T cell receptors (TCR-αβ) or γδ TCR (TCR-γδ) in a complex with the CD3 proteins. CD4 is expressed on 50% to 65% of peripheral T αβ cells, and CD8 is expressed on 25% to 35% of peripheral T αβ cells. Usually, T γδ have no CD4 or CD8. Although CD4 and CD8 are expressed together on cortical thymocytes, only one or the other is expressed on the complementary subsets of mature thymocytes and peripheral T αβ cells ($CD4^+$ and $CD8^+$ T cells) [*see Figure 1*]. $CD4^+$ T cells recognize antigen when the antigen is presented in association with major histocompatibility complex (MHC) class II molecules (HLA-D and HLA-DR) or in association with CD1d, the latter being NKT cells. $CD8^+$ T cells recognize antigen in the context of MHC class I molecules (HLA-A, HLA-B, and HLA-C) [*see 6:III Immune Response Mechanisms*]. The context of antigen recognition by T γδ is unknown.

$CD4^+$ helper T (T_H) cells can be further differentiated into T_{H1} and T_{H2} cells on the basis of the cytokines they produce.[2] T_{H1} cells secrete interleukin-2 (IL-2) and interferon gamma (IFN-γ), which are important for cell-mediated immunity. T_{H2} cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13, which are critical for antibody production. The cytokines that are produced by each of these cell types also influence the other cell type. For example, the IFN-γ produced by T_{H1} cells can inhibit the function of T_{H2} cells, whereas IL-10, which is secreted by T_{H2} cells, monocytes, macrophages, and B cells, can inhibit the function of T_{H1} cells. In addition to having a helper function, T_{H1} cells can induce inflammatory cascades leading to autoimmunity, as occurs in inflammatory bowel diseases and rheumatoid arthritis.

CD4 on the surface of helper T cells plays an important role in HIV infection. In early infection, the virus uses CD4 as a coreceptor, together with CCR5, which itself is a receptor for several chemokines, including RANTES (regulated on action, normal T cell expressed and secreted), macrophage inflammatory protein–1α (MIP-1α), and MIP-1β. One percent of whites are homozygous for a defect in the CCR5 receptor and are resistant to HIV infection. The chemokine receptor CCR4, which is a receptor for stromal cell–derived factor–1 (SDF-1), is involved in late HIV infection.[3-5]

B cells and plasma cells

B cells are precursors of the immunoglobulin-producing cells (plasma cells) of the immune system and are identified by the presence of immunoglobulin on their surface. These surface membrane immunoglobulin–positive ($SmIg^+$) cells constitute 5% to 15% of the peripheral blood lymphocytes. The majority of B cells have both IgM and IgD on their surface; about one quarter of all B cells have only IgM or IgD on their surface. One percent of B cells exhibit IgG or IgA.

On the surface of B cells is the complement receptor 2 (CR2 or CD21), which binds C3d/C3dg and Epstein-Barr virus. FcγRIIb (CD32) is the main Fc receptor on B cells, which is involved in B

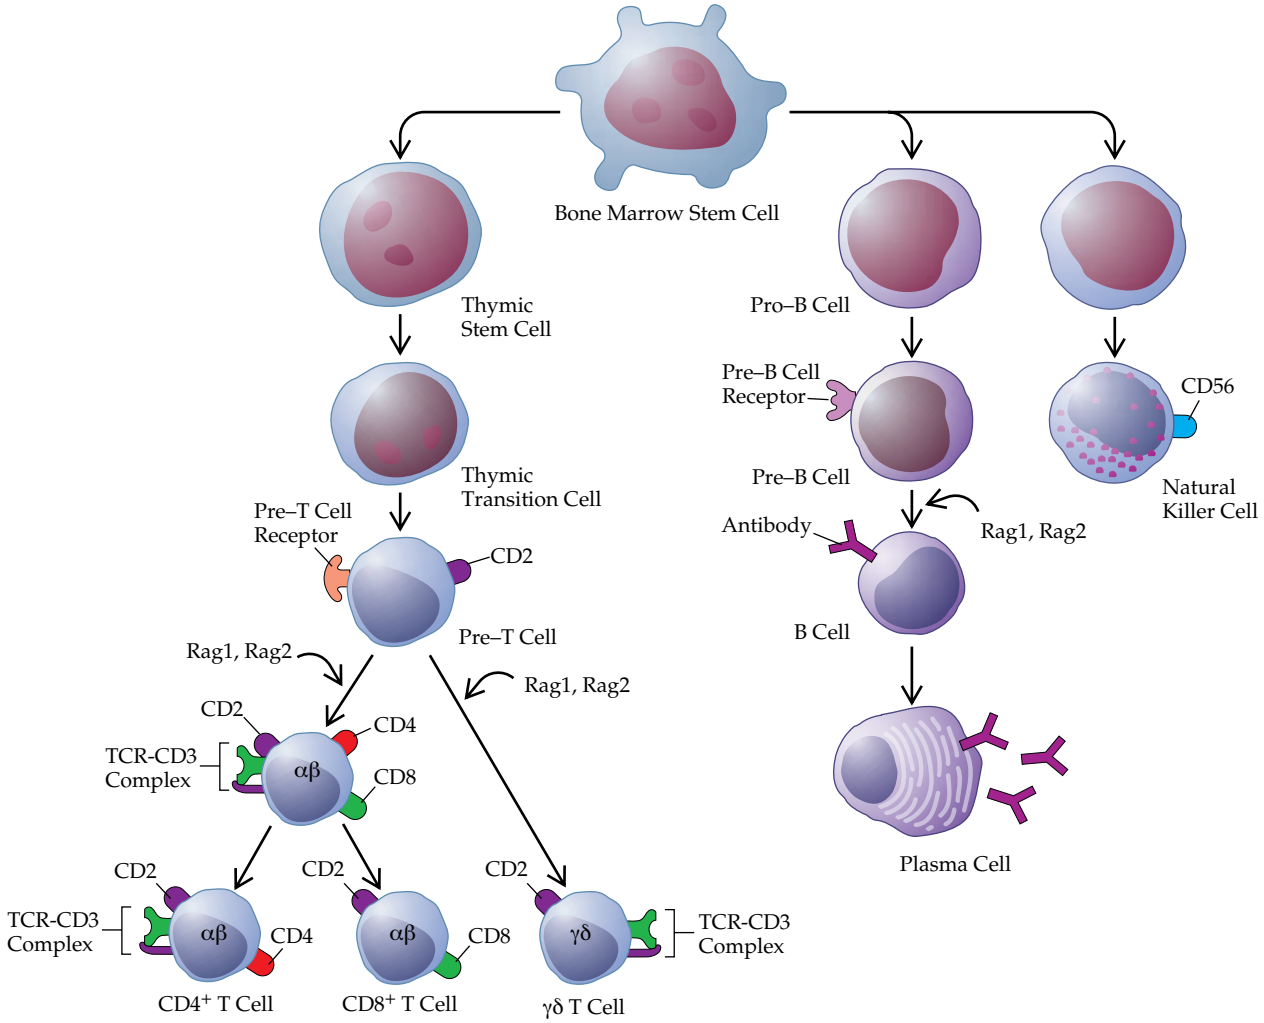

Figure 1 **Lineages of cells of the immune system and of blood cells all begin with the stem cell. Stem cells that differentiate to generate B cells reside in the bone marrow, and those that produce T cells migrate from the bone marrow to the thymus. T cell maturation involves the progressive expression of selected cell surface markers and the activation of various genes, including α, β, γ, and δ genes that code for the chains that make up the αβ and γδ T cell receptors (TCRs). Individuals lacking the Rag1 or Rag2 enzyme do not progress past the pre–T or pre–B cell stage and therefore have no lymphocytes. Positive and negative selection of T cells occurs at the so-called double-positive ($CD4^+$,$CD8^+$) stage. Natural killer cells develop both in the bone marrow and in the thymus.**

lymphocyte activation. A common marker that is used to identify B cells is CD19, which forms a larger complex with CD21 and CD81 (target for antiproliferative antigen–1 [TAPA-1]).[6]

B1 cells, a subset of B cells, develop early and have a very long life. B1 cell progenitors are found in fetal liver and in embryonic omentum but not in adult bone marrow. B1 cells that express CD5 on their surface are referred to as B1a, and B1 cells that lack CD5 are called B1b. B1 cells are frequently associated with autoantibody production. They also produce substantial amounts of IL-10.[7]

Under the influence of antigen, T cells, and accessory cells, B cells differentiate into plasma cells, the mature antibody-producing cells [*see Figure 1*]. Plasma cells are larger than lymphocytes and are characterized by an eccentric round nucleus with coarse heterochromatin arranged in a cartwheel pattern. Plasma cells have a highly basophilic cytoplasm and a well-developed endoplasmic reticulum, often organized in parallel concentric layers. Plasma cells may be distended with granular material, which consists of the antibody they are producing [*see Figure 2*]. Sometimes, one or more of the endoplasmic cisterns are distended by large inclusions called Russell bodies. These bodies are aggregates of incompletely formed immunoglobulin molecules. Plasma cells no longer bear surface immunoglobulin. They are also end cells, which means they do not divide. The immature precursors of plasma cells, the plasmablasts, are difficult to distinguish from lymphoblasts and large lymphocytes. Plasma cells are not normally found in the peripheral blood.

NATURAL KILLER CELLS

Natural killer cells are large granular lymphocytes that lack the TCR-CD3 complex characteristic of T cells or the SmIg characteristic of B cells. A bone marrow–derived stem cell is the precursor of T, B, and NK cells [*see Figure 1*]. In vitro, NK cells can kill a variety of tumor cells and virus-infected cells in a nonspecific manner; that is, they do not require previous sensitization or the presence of antibody to be cytotoxic. The granules contain pore-forming proteins that can mediate cell lysis. NK cells express killing inhibitory receptors (KIR) that recognize class 1 MHC molecules. Thus, NK cell functions are inhibited by cells that express MHC class 1 but are activated by cells lacking MHC class 1. Human NK cells express a second group of inhibitory re-

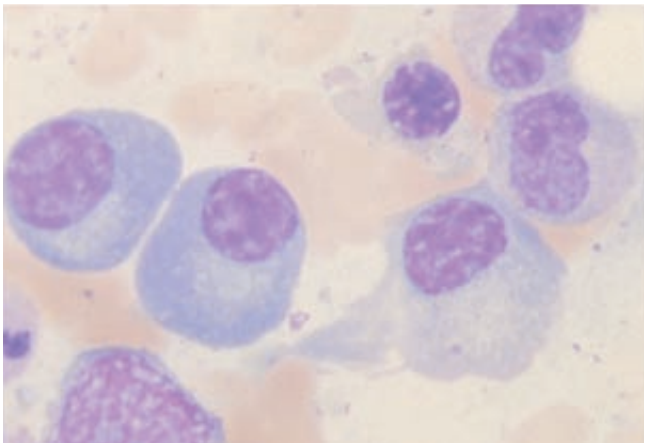

Figure 2 **Plasma cells are the antibody-producing cells of the immune system. They differentiate from B cells; are 6 to 20 μm in diameter; and have an eccentric nucleus, a highly basophilic cytoplasm, and a prominent, clear juxtanuclear area that contains the Golgi apparatus and the diplosome.**

ceptors, which comprises two subunits: a variable subunit NKG and the invariant cell surface structure CD94. Its ligand is unknown. IL-12 stimulates NK cells to proliferate and to produce IFN-γ, which is important for a number of immune reactions.[8,9]

Monocytes, Macrophages, and Dendritic Cells

Monocytes belong to the mononuclear phagocytic system, previously called the reticuloendothelial system. They are large mononuclear cells that constitute 3% to 8% of the peripheral blood leukocytes. Their cytoplasm is much more abundant than that of the lymphocytes. Usually, their nucleus is eccentric and either oval or kidney shaped [*see Figure 3*]. Lysosomes filled with degradative enzymes appear as small vacuoles in the cytoplasm. Monocytes originate from promonocytes, which are rapidly dividing precursors in the bone marrow. When the mature cells enter the peripheral blood, they are called monocytes; when they leave the blood and infiltrate tissues, they undergo additional changes and are then known as macrophages. Other cells derived from this lineage include Kupffer cells, alveolar macrophages, microglia, and osteoclasts.

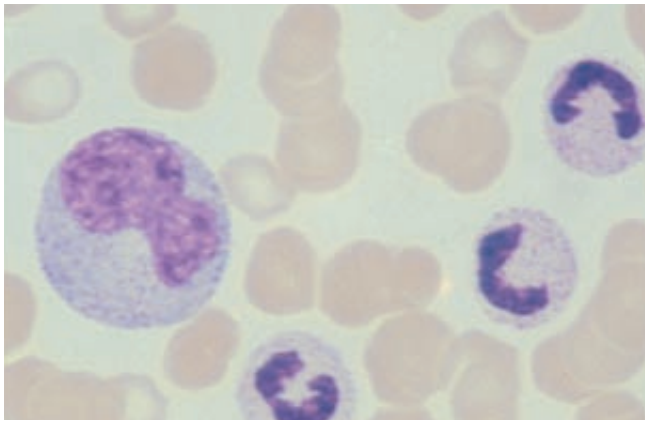

Figure 3 **A monocyte (large cell at left), which can reach 17 μm in diameter, has abundant basophilic cytoplasm and a large eccentric nucleus.**

Macrophages contain pattern recognition receptors (Toll-like receptors [TLRs] 1 through 10)[10] and scavenger receptors. Furthermore, receptors for antibody and complement enhance their ability to phagocytose organisms that are coated with these substances. The antibody receptors recognize the Fc portion of IgG1, IgG3, and IgE. There are two complement receptors, CR1 and CR3. CR1 has a high affinity for the complement component C3b and a lower affinity for iC3b and C4b. CR3, also called macrophage antigen–1 (MAC-1), interacts with iC3b as well as with certain carbohydrate molecules, including carbohydrate-containing antigens of the protozoan *Leishmania*. Through these receptors, macrophages act as effector cells, attacking microorganisms and neoplastic cells and removing foreign material.

Of equal importance, macrophages present processed antigen to lymphocytes and thus play a major role in the induction of acquired immune responses. A small amount of MHC class II antigen is present on monocytes, and its expression is greatly increased when macrophages are activated. Macrophages can be activated by a number of cytokines, including IFN-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage-activating factor (MAF), and migration inhibitory factor (MIF) [*see 6:III Immune Response Mechanisms*]. Cytokines such as IL-4 and transforming growth factor–β (TGF-β) antagonize this activation.

Macrophages themselves produce a large number of soluble substances that are important in the immune response and in the process of inflammation. These substances include enzymes such as plasminogen activating factor and elastase; growth factors such as GM-CSF; cytokines such as IL-1, IL-6, IL-10, IL-12, and tumor necrosis factor–α (TNF-α); factors that are critical for combating microorganisms, such as oxygen metabolites and nitric oxide; complement components for the classical and the alternative pathway; MIPs; and factors that promote tissue repair, such as fibroblast growth factor (FGF).

Dendritic cells are the professional APCs that engage specific responses by T cells.[11-13] They are present where antigens and microorganisms have first contact with the body—for example, in the skin (Langerhans cells) and the gastrointestinal and respiratory tracts. The function of the dendritic cells is discussed [*see* Lymph Nodes and Spleen, *below*].

Lymphoid Organs and Lymphocyte Traffic

The immune system consists of a number of lymphoid organs, including the thymus, lymph nodes, spleen, and tonsils; aggregates of lymphoid tissue in nonlymphoid organs, such as Peyer patches in the gut; clusters of lymphoid cells dispersed throughout the connective and epithelial tissues of the body, as well as throughout the bone marrow and blood; and a variety of individual cells that travel from the various lymphoid organs to the rest of the body. The lymphocytes are derived from precursors in the bone marrow: the T cells develop in the thymus and are then exported to the periphery, whereas the B and NK cells develop in the bone marrow and then go out to the periphery. Of the nonlymphoid hematopoietic cells, the monocytes, macrophages, and dendritic cells are key elements of innate and acquired immunity, whereas granulocytes (e.g., neutrophils, eosinophils, basophils, and mast cells) and platelets play important accessory roles in the immune system.

THE THYMUS

The thymus, which originates from the third and fourth pharyngeal pouches of the embryo, lies in the anterior mediastinum

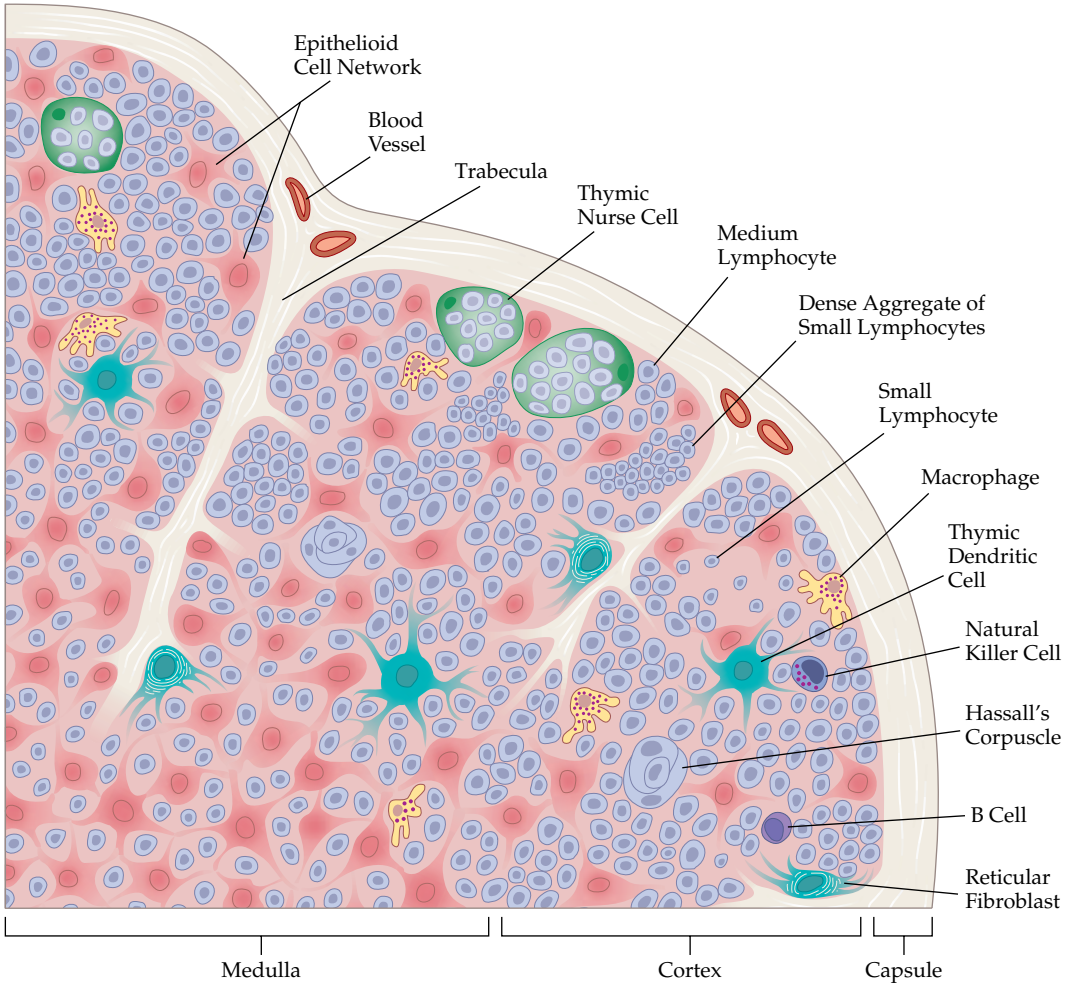

Figure 4 **Many lobules make up the thymus gland. Most of the lymphocytes in the cortex are immature, rapidly dividing cells that can readily be destroyed by cortisone. During maturation, they move to the medulla, where they become immunocompetent and resistant to cortisone. From there, they migrate to the secondary lymphoid organs, including the lymph nodes and the spleen. Cell division and maturation are influenced by the epithelial cells; dense aggregates of these cells form bodies known as Hassall corpuscles.**

and consists of many lobules, each containing a cortex and a medulla [*see Figure 4*]. Bone marrow–derived T cell precursors enter the thymus, congregating first in the subcapsular area. They develop into cells expressing the TCR-αβ–CD3 complex and subsequently acquire the potential to react with different peptides bound to MHC. These cortical $CD4^+$,$CD8^+$ thymocytes undergo either negative or positive selection, which involves complex mechanisms [*see* Development of the T Cell Repertoire, *below*]. Only a small percentage of positively selected thymocytes, $CD4^+$ (MCH class II recognizing) or $CD8^+$ (MHC class 1 recognizing), migrate to the medulla and then move into the peripheral lymphoid system. It is unclear whether all γδ T cells differentiate in the thymus.

Mature T cells emigrate through the wall of the postcapillary venules of the medulla to enter the bloodstream and subsequently home to the lymphoid system's peripheral organs. Once there, the lymphocytes leave the bloodstream, again through the postcapillary venules, and travel further into the T cell regions of the peripheral lymphoid organs. These include the inner cortex of the lymph nodes; the periarterial sheaths of the spleen; and the intranodular areas in Peyer patches, the tonsils, and the appendix. Some of the T cells in the intestinal mucosa (intraepithelial lymphocytes) are thought to differentiate outside the thymus.

Persons who are born without a thymus have lymphocytopenia, with a marked depletion or an absence of T cells. The T cell zones of the peripheral lymphoid system are also devoid of lymphocytes. There is marked impairment of cell-mediated immunity, and antibody responses that require cooperation from T cells (except the IgM response) are severely impaired [*see 6:VIII Deficiencies in Immunoglobulins and Cell-Mediated Immunity*]. The thymus involutes with age, which may explain the development of immune system deficiencies in elderly persons.

LYMPH NODES AND SPLEEN

The major sites of initial T cell activation are in the lymph nodes and in the spleen, where blood-borne lymphocytes and lymph-borne antigen, soluble mediators, and cells converge [*see Figure 5*]. Lymph and cells enter the node in the subcapsular region, through the afferent lymphatics; percolate into the subcapsular sinus; and leave through the efferent lymphatics in the hilum. In the spleen, the lymphocytes are concentrated in the

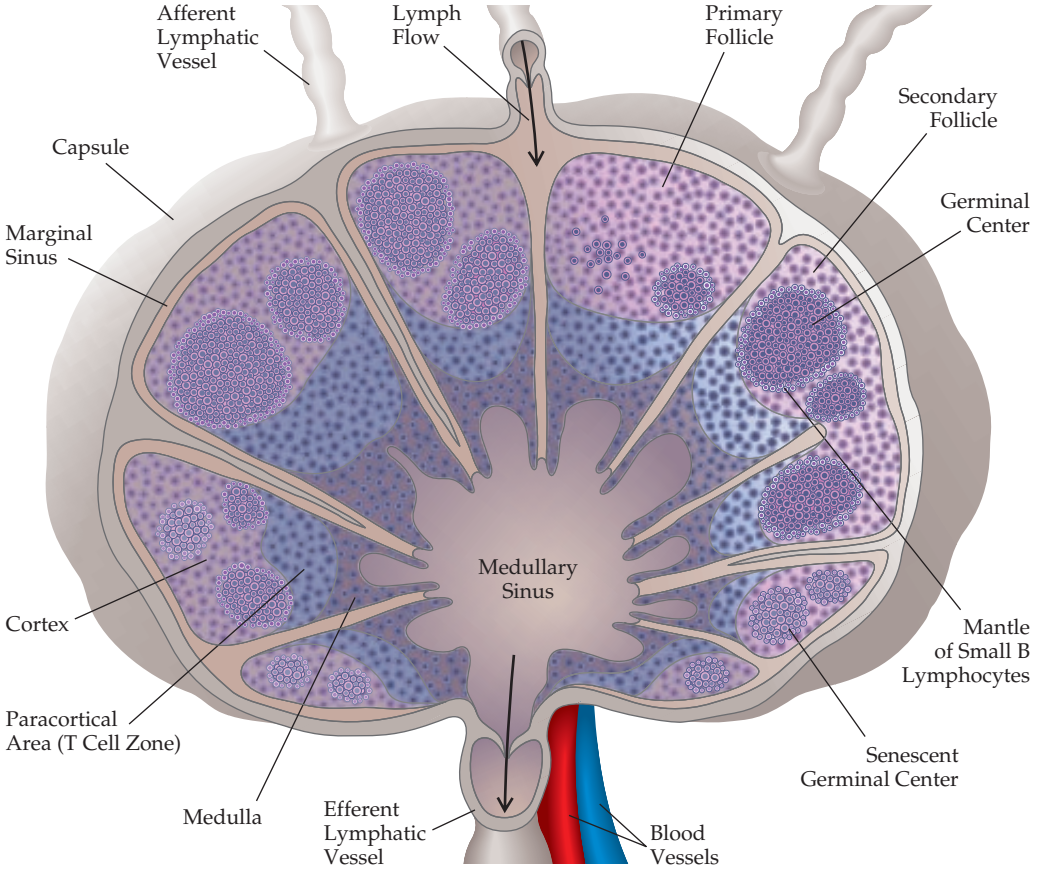

Figure 5 **Lymph containing lymphocytes, antigen, and soluble mediators drains from surrounding tissues and enters the lymph nodes via afferent lymphatic vessels. The lymph node consists of a cortex and a medulla. The outermost area of the cortex has B cells organized into lymphoid follicles, and its deep, or paracortical, area consists mainly of T cells and dendritic cells. After B cells encounter antigens for which they have receptors, along with the appropriate T cells, central areas of marked B cell proliferation called germinal centers develop in the lymphoid follicles. As these reactions die out, the germinal centers become senescent. In the medulla are medullary cords, which are strings of macrophages and plasma cells.**

white pulp, which consists of follicles with germinal centers that surround the central arterioles [*see Figure 6*].

Lymph Nodes

The infrastructure of the lymph node is an extensive reticular network where APCs and T cells meet and interact. For example, bone marrow–derived dendritic cells in the skin pick up antigen and travel through the lymphatics to the draining lymph node. The cells then migrate through the floor of the subcapsular sinus of the lymph node to the interfollicular regions, where they settle in the reticular network of the paracortex as interdigitating dendritic cells (IDCs). T cells from the blood migrate through specialized postcapillary venules, known as high endothelial venules (HEVs), and migrate along the same reticular network, where they come in contact with the numerous antigen-presenting IDCs.[14]

The germinal centers contain B cells, which are derived from stem cells and differentiate in the bone marrow [*see Figure 1*]. The lymphoid follicles contain follicular dendritic cells (FDCs), which are not derived from the bone marrow. FDCs, which are found only in lymphoid follicles, express complement receptors CR1, CR2, CR3, and Fc receptors. These receptors enable the FDCs to present antigen to activated B cells in the form of antigen-antibody-complement complexes. FDCs can retain these complexes for a long time.

Active germinal centers are surrounded by a mantle of B cells (follicular mantle cells) that express IgD on their surface and can mature into plasma cells that produce IgM antibodies only. The B cells in the germinal center (centrocytes) undergo class switching to produce the other isotypes, such as IgG, IgA, and IgE. The B cells with high-affinity antibody on their surfaces are thought to be selected by binding to the antigen-retaining FDCs. The B cells that are not selected die by apoptosis (programmed cell death). The most mature B cell, the memory cell, is also found in the germinal center and can develop into plasma cells producing all the antibody isotypes.

Bone marrow–derived dendritic cells, found in the paracortical areas of the lymph node, are professional APCs that play a crucial role in initiating T cell–dependent immune responses.[12-14] These cells are also found as immature cells in nonlymphoid organs, especially in the epidermis, where they are called Langerhans cells. Through their many receptors, particularly TLR1 through TLR10 and scavenger receptors, immature dendritic cells efficiently internalize and process antigens and present antigen through their MHC. There are two subsets of dendritic cells, myeloid and plasmacytoid, which produce distinct cytokines. Some cytokines (e.g.,

IL-1β and TNF-α), promote the migration of the dendritic cells via afferent lymphatics to the lymph nodes. At this location, they mature, lose their ability to phagocytose, and express critical costimulatory molecules CD80 (B7-1) and CD86 (B7-2); these costimulatory molecules enhance their ability to present antigen to T cells. Immature dendritic cells are also found in lymph nodes, where these cells can phagocytize antigen entering via the afferent lymphatics and then mature into APCs.

MUCOSAL AND SKIN IMMUNE RESPONSES

Lymphocytes are also found in various other locations. Gut-associated lymphoid tissue includes Peyer patches and the appendix. These gut-associated lymphoid tissues contain regions with concentrations of T cells or B cells similar to those found in germinal centers. Specialized epithelial cells termed M cells are thought to have a unique ability to take up and present antigen to the adjacent lymphocytes.[15] M cells are found close to Peyer patches. Other lymphocytes in the intestine are the lamina propria lymphocytes (LPLs), found in the villi, and the intraepithelial lymphocytes (IELs), found between epithelial cells. Migration and adherence of LPLs are in part dictated by integrins and selectins, which are surface molecules on tissues and cells that mediate cell interactions and homing. Mucosa-associated lymphoid cells are also found in the respiratory tract and genitourinary tract. The specialized immune system of the skin contains Langerhans cells in the epidermis (specialized myeloid dendritic cells) and a higher concentration of γδ T cells than elsewhere.[16]

LYMPHOCYTE CIRCULATION

There are three major types of lymphocyte circulation: (1) the seeding of the stem cells from the fetal liver or bone marrow to the primary lymphoid organs and the subsequent differentiation and distribution of these cells to the peripheral lymphoid system, (2) the recirculation of lymphocytes from blood to lymph to blood, and (3) the distribution of effector cells to particular parts of the body. Lymphocytes circulate continuously from blood to tissues and back to the blood. However, the trafficking of naive T cells (CD45RA) is different from that of activated effector or memory cells (CD45RO). Naive T cells recirculate through the secondary lymphoid tissues, such as the lymph nodes, spleen,

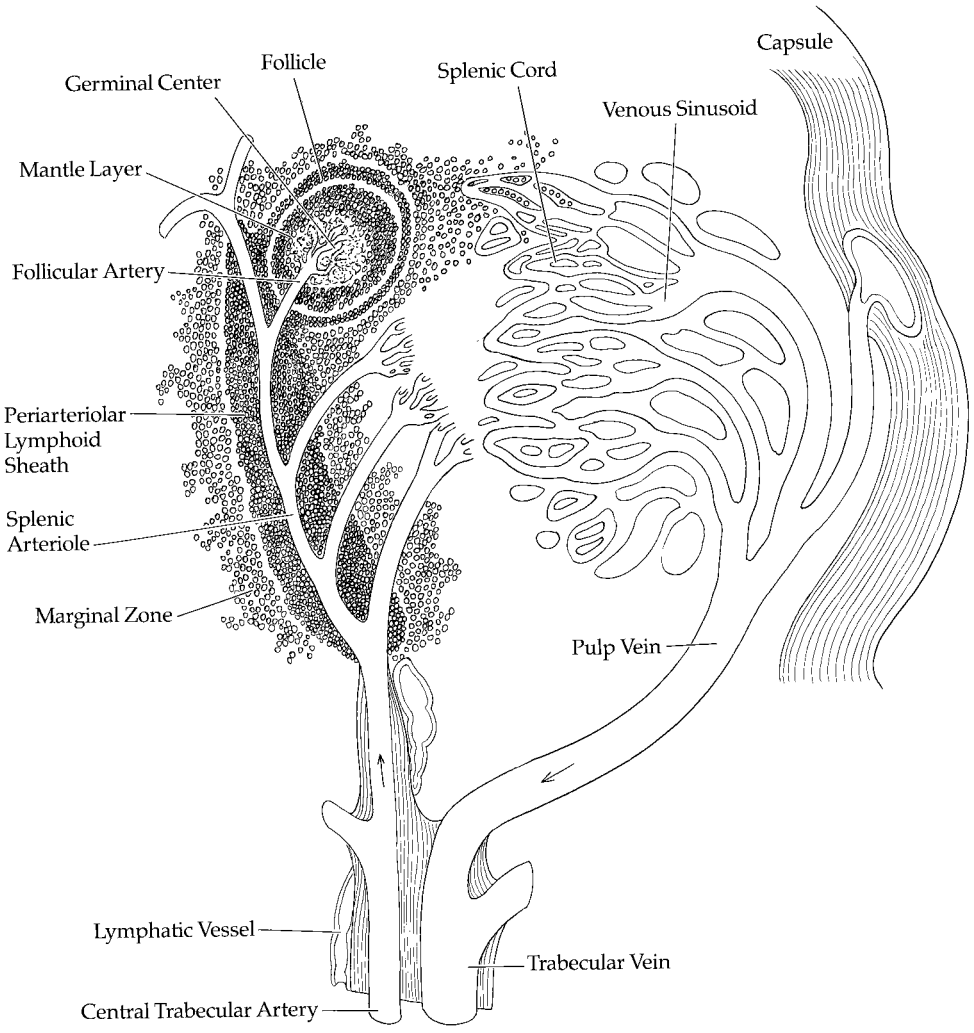

Figure 6 **In the spleen, the lymphoid cells around the splenic arteriole form the periarteriolar lymphoid sheath, which is predominantly a thymus-dependent area. The follicle with a germinal center contains B cells. The T cells are found mainly in the central region of the periarteriolar lymphoid sheaths, whereas the B cells in the germinal centers concentrate more toward the periphery of the sheaths. Lymphocytes enter and leave the periarteriolar lymphoid sheaths via the capillaries of the central arterioles in the marginal zone.**

tonsils, and Peyer patches, to special microenvironments where they encounter antigen, cytokines, and other cells leading to their activation. In contrast, activated effector or memory cells can also traffic to extralymphoid sites in various tissues, such as skin and intestinal lamina propria.[17]

The homing of lymphocytes to the vascular endothelium and their passage through it are controlled by the expression of various receptors on the lymphocyte surface and counterreceptors on the vascular endothelium. To stop the flow of cells in the blood and lymph vessels, initial primary adhesion occurs between lymphocyte receptors on the cells' microvilli, such as L-selectin, and the counterreceptor on the endothelium, such as peripheral lymph node addressin (PNAd). Other cell receptors allow attachment to endothelial E-selectin and P-selectin. Subsequently, the cells can attach and roll using integrin-Ig surface receptors such as α4β7 and α4β1, which bind to endothelial mucosal addressin cell adhesion molecule–1 (MAdCAM-1) and vascular cell adhesion molecule–1 (VCAM-1), respectively. These interactions can lead to stable arrest involving a receptor that triggers adhesion through intracellular signaling by a guanosine triphosphate (GTP) binding protein. Cooperation between receptor interactions is essential because the initial interaction with L-selectin may be too weak to induce the LFA-1/ICAM-1 (leukocyte-function–associated antigen–1/intercellular adhesion molecule–1) stable interaction and therefore requires the α4β7/MAdCAM-1 interaction. In contrast, when tissues display high levels of receptor L-selectin, contact and rolling mediated by L-selectin may be sufficient to allow LFA-1–mediated stable arrest. The lymphocytes can then pass through the vascular endothelium, a process called diapedesis. A similar process is involved with the diapedesis of other leukocytes.[17]

Variations on these mechanisms are thought to channel subsets of lymphocytes to the various microenvironments in the lymph nodes, such as the germinal centers, the paracortical areas, and the T zone, where cells, antigen, and soluble factors lead to particular immunologic responses. These microenvironments are further regulated by various cytokines, such as TGF-β1, which can upregulate integrins and mediate B cell binding to APCs. Cytokines such as TNF-α regulate lymphocyte adhesion receptors, and other cytokines influence lymphocyte activity as they traverse the tissues. Some chemokines, such as RANTES, also activate the expression of adhesion molecules on the surface of effector T cells. Other chemokines, such as thymus-expressed chemokine (TECK), recruit T cells bearing the TECK receptors (CCR9) to their homing organ, in this case the gut.[18,19]

The Hallmarks of the Immune System: Specificity and Memory

The immune responses are controlled by three large gene families: (1) the genes coding for the variable elements of the immunoglobulins, (2) the genes coding for the TCRs, and (3) the genes coding for the MHC antigens [*see 6:II Antigens, Antibodies, and T Cell Receptors*]. In each person, there are an enormous number of genes coding for the variable elements of the immunoglobulins and TCRs, allowing specific recognition of millions of antigens. However, the extreme variability of the MHC applies to the population as a whole; any individual will have only a few variations.

The ability of T cells and antibodies produced by B cells to discriminate between antigens is governed by two independent sets of variable region genes for T and B cells, each composed of rearranging V (variable), D (diversity), and J (joining) DNA segments. Rearrangement of the DNA sequences of these genes occurs as T cells and B cells mature, giving rise to TCRs and immunoglobulins. Additional somatic mutation occurs in B cells during further maturation, which expands the repertoire. This system can discriminate between billions of antigens [*see 6:II Antigens, Antibodies, and T Cell Receptors*].

Each lymphocyte has a surface receptor that recognizes a single antigenic determinant, or epitope. B cell receptors recognize native antigens. After B cells interact with an antigen, they proliferate and differentiate into plasma cells for the production of antibodies, and some become memory cells.

Before being recognized by T cells, an antigen is taken up by an APC (e.g., a dendritic cell or a macrophage), which breaks up the antigen into small peptide fragments. In the APC, certain peptide fragments or epitopes are taken up by MHC class II molecules and carried to the surface of the APC. Thus, TCRs do not recognize native antigen, only processed parts of it [*see 6:II Antigens, Antibodies, and T Cell Receptors*].

The requirement that the antigen be presented in association with an MHC class I or II molecule is referred to as MHC restriction. The nature of the MHC explains why some individuals may not respond to certain antigens. For example, although TCRs recognize epitopes that are bound to MHC molecules, some antigen peptides may not fit into the groove of the particular MHC molecule of an individual. Thus, the appropriate T cell type will not react to that epitope, and the individual will not be able to mount an immune response against it.

DEVELOPMENT OF THE T CELL REPERTOIRE

Of the two types of T cells, αβ and γδ, only the development of the cells that express TCR-αβ is well understood. After gene rearrangement occurs, the TCR-αβ is expressed on the surface of the immature cortical thymocyte together with the CD3 proteins [*see Figure 1*]. At about the same time as gene rearrangement occurs, CD4, CD8, and CD2 are expressed.[6] Single-positive (either $CD4^+$ or $CD8^+$) mature thymocytes bearing high levels of TCR-αβ are selected from the pool of $CD4^+$,$CD8^+$ thymocytes by processes termed positive selection and negative selection.

Positive Selection

Positive selection is controlled by epithelial cells of the thymic cortex and dedicated APCs, such as macrophages, dendritic cells, and interdigitating cells. Many of these stromal cells are located in the corticomedullary junction. Because T cells can react to antigens only in association with self-MHC, only T cells with a TCR that can bind to self-MHC are selected. When these cells react with self-MHC on thymic stromal cells, $CD4^+$,$CD8^+$ TCR-αβ cells that bind to MHC class II molecules become $CD4^+$ and $CD8^-$, downregulating the CD8 and upregulating the TCR-CD3 complex. Conversely, the $CD4^+$,$CD8^+$ cells that bind to MHC class I molecules downregulate the CD4 and become $CD4^-$,$CD8^+$ TCR-αβ cells. In this manner, self-MHC–restricted $CD4^+$ TCR-αβ cells and $CD8^+$ TCR-αβ cells are selected. Only thymocytes whose TCR has a moderate affinity for MHC-peptide are positively selected. CD4 or CD8 cells contribute to the avidity of the interaction as they themselves bind to MHC class II and class I, respectively.

Negative Selection

Most T cells do not interact with self-MHC and therefore undergo apoptosis because of the lack of any interaction. The active process of negative selection eliminates T cells that have a TCR with a high avidity for MHC-peptide. If they were not removed, such T cells could cause serious autoimmune disease. There are

many self-antigens on thymic epithelial cells, and studies show that certain self-antigens can be presented by various APCs in the thymus, such as macrophages and dendritic cells. It is possible that negative selection for some self-antigens occurs when the T cells move to the peripheral lymphoid system after leaving the thymus. This high-affinity interaction between the self-antigen presented by the MHC and the TCR on immature T cells triggers several processes leading to cell death (e.g., apoptosis) (see below).

POSITIVE AND NEGATIVE SELECTION OF B CELLS

Positive selection of precursor B cells takes place in the bone marrow. The pre–B cells bear on their surface the IgM heavy chain (μ) in association with the so-called surrogate light chain (lambda 5 or λ5). If the latter receptor is not on the surface, the cell is eliminated by apoptosis. Pre–B cells develop into immature B cells, which carry IgM on their surface. Those cells develop into mature B cells unless they are eliminated by antigen recognition and negative selection in the lymph nodes. If the affinity is high, elimination involves apoptosis, whereas if the affinity is low, it involves anergy (the cell is present but does not develop).

APOPTOSIS

Removal of autoreactive T and B cells in the periphery also uses apoptosis. Apoptotic signals acting on the cell membrane lead to programmed cell death with nuclear chromatin condensation and cleaving, and within minutes to hours, the cell is destroyed and cleared by macrophages. The main receptors on lymphoid cells that trigger apoptosis are members of the 18-member family of TNF receptors.[20] Examples include the Fas receptor (CD95/APO-1), which is triggered by Fas ligand; and the TNF receptor–1 (TNFR-1), triggered by TNF-α and lymphotoxin-α. Of note, the TNFRs also trigger pathways that lead to activation of nuclear factor κB (NF-κB), which protects against apoptosis.[21] The signals for apoptosis eventually act on a family of cysteine proteases similar to the IL-1b converting enzyme (ICE), the prototype that acts on the cytokine precursor IL-1b, converting it to the active cytokine. ICE-related proteases activate other proteases, which then act on a number of substrates; this, in turn, leads to apoptosis.

AMPLIFICATION AND THE AMNESTIC RESPONSE

Characteristic of the immune response is its ability to increase the number of antigen-specific lymphocytes after an antigenic stimulus occurs; because of memory T and B cells, subsequent exposure to the same antigen results in a faster and a greater response (i.e., the anamnestic response). The basis for this enhanced response is the proliferation of antigen-specific lymphocytes and the production of memory cells after lymphocytes interact with an antigen. These responses are mediated through production of cytokines by lymphocytes and other cells [*see 6:III Immune Response Mechanisms*]. Immune response mechanisms are also amplified through the release of mediator substances from antibody-coated mast cells and basophils, the activation of complement proteins, and the expression of integrin molecules on cells. Altered vascular permeability, the expression of receptors for leukocytes on endothelial cells, and the release of chemotactic factors through these secondary mechanisms attract a host of other cell types to the reaction. These cells greatly contribute to the resulting inflammation by aiding the phagocytic process and the disposal of foreign antigens.

After T cells interact with an antigen, they proliferate and differentiate into effector cells, some helper T cells, and other cytotoxic T cells (CTLs); all of these have a memory cell component. An independent lineage of $CD4^+$ T cells are regulatory T cells (Treg), which control immune responses by producing inhibitory cytokines and by direct cell-to-cell contact.[22,23] Antigen-specific Treg cells may also develop as an independent lineage in the thymus.[24] The memory aspects of Treg cells are not known.

The memory B cells enhance the immune response to previously encountered antigen as part of the anamnestic response. These memory B cells undergo somatic mutation in the variable regions of their immunoglobulin genes. When this somatic mutation occurs in the lymph node germinal centers that contain antigens bound to follicular dendritic cells, it leads to the selection of memory B cells that have high-affinity receptors for the antigens.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

II INNATE IMMUNITY

M. Kathryn Liszewski, b.a.
Wayne M. Yokoyama, m.d.
John P. Atkinson, m.d., f.a.c.p.

The body uses two forms of immunity to recognize and respond to infectious microorganisms: innate immunity, which is nonspecific, and adaptive immunity, which is highly specific. The innate immune system is ancient, being present in all multicellular organisms. Adaptive immunity developed from the innate system, beginning about 400 million years ago in primitive fishes such as the lamprey. In vertebrates, the two systems cooperate to produce an immune response. Genetically, the innate system is hardwired and inflexible. In contrast, the adaptive system splices DNA to make new genes that can code for an almost infinite array of immunoglobulin and T cell receptors.

The innate immune system is particularly active at the interface between the environment and those surfaces of the body that are lined with epithelial cells—namely, the skin and the gastrointestinal, genitourinary, and sinopulmonary tracts. Intact physical barriers are, of course, critically important for preventing infections.

The epithelial cells' innate immune response to disturbance by a pathogen has only recently begun to be deciphered. For example, Toll-like receptors—the mammalian counterpart of Toll receptors in fruit flies—were not discovered until 1997. Engagement of these epithelial cell receptors results in the activation of genes that encode inflammatory cytokines, such as tumor necrosis factor (TNF), interferons, and interleukin-1 (IL-1) and IL-12, as well as genes that encode antimicrobial peptides ("Nature's antibiotics").

In addition to the epithelial barrier itself, the fluids in these tracts contain mucus, natural antibodies (IgG and IgA), a complement system, and lectins. Mucus itself is a protective film that traps organisms and debris and also contains antibacterial substances. The complement system in secretions is present at about 10% to 20% of the concentration found in plasma. The lectins in these secretions bind sugars on pathogens and thereby activate the lectin pathway of complement activation. It is probably safe to say that for every major human pathogen, there is a lectin that recognizes a sugar structure on the pathogen's surface. Granulocytes undergo margination in small blood vessels throughout much of these barrier tissues and are available for rapid recruitment to a site of possible infection. Monocytes/macrophages are also present in secretions and in most tissues, where they phagocytose unwanted microbes.

From an evolutionary standpoint, the goal of the immune system is for the individual to survive to reproductive age. This concept suggests that a so-called hyperreactive immune system in early life may provide a survival advantage, even if it subsequently predisposes to allergies or autoimmunity. A second concept is that innate immunity provides guidance to the adaptive immune system regarding which infectious disease antigens it should respond to and what strategy to employ for the most efficient destruction of pathogens. In other words, it tells the adaptive immune system when and how to respond to a pathogen. A third point is that, in contrast to normally sterile areas of the body, such as the bloodstream or spinal fluid, epithelial surfaces are inhabited by large numbers of commensal organisms, against which an immune response would be unnecessary and even potentially harmful. Consequently, at these barriers, the immune system must not only discriminate between self and nonself but, faced with a sea of nonself microorganisms, must single out the dangerous ones. Failure to meet this substantial challenge is not uncommon and results in allergies (reaction to a foreign but benign substance) and autoimmunity (reaction to self).

The innate immune system also accounts for many aspects of the sepsis syndrome. Most house officers vividly remember their first patient with bacteremia or septicemia.[1] Neither textbooks nor attending physicians could provide sound explanations for the signs and symptoms in these patients. Instead, the explanation offered would usually involve "too many bugs in the blood." Of course, microbes in the bloodstream are the primary cause, but the innate immune system's reaction to those organisms is what produces the clinical syndrome. The simplified paradigm is that the bacteria and their products become bound—either directly or through soluble proteins (i.e., lectins, natural antibodies, complement proteins)—to receptors on endothelial and epithelial cells, and this binding signals cytokine and chemokine release (creating a so-called cytokine storm). Most of the clinical signs and symptoms of sepsis result from the effects of excessive quantities of these mediators on vascular endothelium and epithelial cells.

Epithelial Cell Receptors and Their Signaling Pathways

Toll and pattern-recognition receptors

The breakthrough in the field of epithelial cell receptors took place when Janeway and colleagues recognized that the Toll (German slang for "way out" or "crazy") receptor of the fruit fly had intracytoplasmic signaling motifs with homology to those found in mammalian IL-1 and TNF receptors.[2-6] Sequencing of the fruit fly genome led to the discovery of 10 to 20 of these receptors, as well as related soluble binding proteins. These proteins directly recognize key structural components on microbial pathogens—for example, lipopolysaccharides in the outer membrane of gram-negative organisms or peptidoglycans in the cell wall of gram-positive organisms [*see Table 1*]. These structural components are not easily modified in a substantial fashion by the organism. In many cases, soluble binding proteins make first

Table 1 Toll-like Receptors and Their Ligands [4]

Receptor	*Ligands*
TLR2	Lipoproteins, lipoarabinomannan, LPS from *Leptospira* and *Porphyromonas gingivalis*, peptidoglycan from gram-positive bacteria, zymosan from yeast, GPI anchor from *Treponema cruzi*
TLR4	LPS from gram-negative bacteria (except *Leptospira* and *P. gingivalis*), plant products (Taxol), viral products (RSV), host-derived products (HSP60, fibronectin fragments)
TLR5	Flagellin
TLR9	CpG DNA

GPI—glycosylphosphatidylinositol HSP60—heat shock protein 60 LPS—lipopolysaccharide RSV—respiratory syncytial virus TLR—Toll-like receptor

Table 2 Pattern-Recognition Receptors[36]

Pattern-Recognition Receptor (PRR) Type	*PRR*	*Protein/Domain Family*	*Ligands*	*Function*
Secreted PRRs	MBL	C-type lectin	Terminal mannose residents	Activation of the lectin pathway of complement
	CRP, SAP	Pentraxins	Phosphorylcholine on microbial membranes	Opsonization; activation of classical complement pathway
	LBP	Lipid-transfer protein family	LPS	LPS recognition
Cell-surface PRRs	CD14	Leucine-rich repeats, C-type lectin	LPS, peptidoglycan	Coreceptor for TLRs
	Macrophage mannose receptor	C-type lectin	Terminal mannose residues	Phagocytosis
	Macrophage scavenger receptor	Scavenger receptor, cysteine-rich domain	LDL, anionic polymers	Phagocytosis, LPS clearance, and lipid homeostasis
	MARCO	Scavenger receptor, cysteine-rich domain	Bacterial cell walls	Phagocytosis
Intracellular PRRs	PKR	dsRNA-binding domain, protein kinase domain	dsRNA	Activation of NF-κB and MAP kinases; inhibition of translation and induction of apoptosis in virally infected and stressed cells
	Nod	Leucine-rich repeats, nucleotide-binding domain, CARD domain	Ligands for most Nod proteins are unknown; Nodl and Nod2 recognize LPS	Activation of NF-κB and MAP kinases; some family members may be involved in the induction of apoptosis; the exact function is unknown

CARD—caspase-recruitment domain CRP—C-reactive protein dsRNA—double-stranded RNA LBP—lipopolysaccharide-binding protein LDL—low-density lipoprotein LPS—lipopolysaccharide MAP—mitogen-activated protein MARCO—macrophage receptor with collagenous structure MBL—mannan-binding lectin NF-kB—nuclear factor-kB Nod—nucleotide-binding oligomerization domain PKR—dsRNA-activated protein kinase SAP—serum amyloid protein TLRs—Toll-like receptors

contact with the organism, which then facilitates engagement of the receptor. The subsequent cellular signaling involves nuclear factor–κB (NF-κB) and its intracellular signaling cohorts; these cohorts are analogous to those that mammalian cells use to set off an inflammatory response. Once activated, NF-κB travels to the nucleus, where it triggers the transcription of genes that prepare the host cell to do battle with the infecting organism. There is specificity to the response in the sense that the cytokines and the defensins elaborated are tailored to the class of microbe. For example, the cell elaborates different antibacterial defensins for a gram-negative organism than for a gram-positive organism, and it elaborates antifungal peptides distinct from those liberated in an antibacterial response.

Toll-like receptors and pattern recognition receptors (PRRs) [*see Table 2*] were eventually found on human epithelial cells and monocytes/macrophages. Amazingly, this same general scheme (i.e., the Toll-like receptor and its signaling pathway) is used by tomato plants to ward off the mosaic virus.[7]

Innate Immune Cells

NATURAL KILLER CELLS

Natural killer (NK) cells constitute the third major population of lymphocytes, after T cells and B cells.[8] They were initially identified because they spontaneously (i.e., naturally) kill certain tumor cells, a process that does not require prior exposure to the target. Like T cells and B cells, NK cells are involved in host immune defense. They are more closely related to T cells than to B cells in that they share effector functions, including the same killing mechanism and the capacity to produce cytokines. Unlike other lymphocytes, NK cells are components of innate immunity—they respond early against infections (and possibly tumors) and do not require gene rearrangement for maturation and function. Much remains to be clarified regarding the nature of NK cell receptors and their ligands. NK cells are negative for the T cell receptor (CD3) and B cell receptor (membrane immunoglobulin). Most NK cells in human peripheral blood are $CD56^+$; this feature can be used for their identification, because expression of this adhesion-promoting molecule is restricted to NK cells and a small population of T cells. NK cells also express the transmembrane form of the low-affinity receptor for IgG (CD16 or FcγRIIIA) that is absent on mature T cells. When CD16 on the NK cell binds the Fc portion of IgG that is coating a target, this receptor activates release of cytoplasmic granules containing molecules that form pores in the target cell membrane and others that mediate apoptosis, resulting in antibody-dependent cellular cytotoxicity. Natural killing is mediated by the same mechanism, although CD16 is not required. Identification of the receptors that initiate natural killing is a topic of active research.

Of note, NK cells are better able to kill cells that lack major histocompatibility complex (MHC) or human leukocyte antigen (HLA) class I molecules, such as may result from tumorigenesis or viral infection. Although decreased expression of MHC class I molecules may allow targets to evade destruction by MHC class I–restricted cytotoxic T cells, it makes the targets more susceptible to killing by NK cells. This finding led to the so-called missing-self hypothesis, which holds that NK cells survey tissues for

MHC class I molecules, which are normally expressed on most nucleated cells in the body.[9] If MHC class I expression is decreased or absent, the NK cells are released from the negative influence of MHC class I and kill the target. This process may provide a fail-safe mechanism to protect the body from disease processes that evade acquired, specific T cell immunity.

Ongoing studies indicate that NK cells express a multitude of inhibitory receptors that guide their capacity to kill tumor and virus-infected cells.[10] These receptors, termed killer immunoglobulin-like receptors and CD94/NKG2 heterodimers, bind to HLA molecules on their targets. Subsequently, specific tyrosine residues are phosphorylated within immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in the cytoplasmic domains. This results in the recruitment and activation of cytoplasmic phosphatases that dephosphorylate molecules in the activation cascade, hence inhibiting NK cell stimulation. NK cells also express related molecules lacking ITIMs. These molecules are prime candidates for activation receptors that bind as yet uncharacterized molecules on the surface of the target cell.

Early studies of NK cells focused on their role in tumor surveillance (i.e., the eradication of cancers before they become clinically apparent). NK cells can be expanded in tissue culture by exposure to high concentrations of the lymphokine IL-2, which results in production of lymphokine-activated killer (LAK) cells. Adoptive transfer of LAK cells into patients with radiation- and chemotherapy-resistant tumors can lead to remissions.[11] However, high concentrations of IL-2 have to be simultaneously administered, increasing the risk of potentially serious complications such as pulmonary edema and capillary leak syndromes.

Subsequent studies have shown that NK cells also play a critical role in early innate immune responses to viral infections. Persons who lack NK cells suffer recurrent, severe systemic viral infections, particularly from herpesviruses.[12] Depletion of NK cells has also been described in patients with advanced HIV infection and AIDS. This depletion, which apparently results from infection of the NK cell itself by herpesvirus 6 and HIV,[13] may partially account for these patients' susceptibility to opportunistic infections such as those from herpesvirus and cytomegalovirus.

NK cell lymphomas and leukemias are rarely found in Western populations[14] but are more common in Asian populations. NK cell lymphomas often present as nasal tumors, are associated with Epstein-Barr virus infections, and may occur in conjunction with autoimmune syndromes.

Natural killing by peripheral blood NK cells is altered in a variety of conditions. However, the significance of such findings is unclear. On the other hand, as more reagents become available to definitively detect NK cells in clinical specimens, the apparent role of NK cells in disease pathogenesis will become clearer, as suggested by studies indicating marked expansion of NK cells in synovial fluid of patients with early rheumatoid arthritis.[14]

γδ T CELLS AND CD1–RESTRICTED T CELLS

T cells were traditionally thought to respond only to peptide antigens presented in the context of self-MHC. However, CD1-restricted T cells respond to a variety of nonpeptide antigens, especially glycolipids. These cells appear to be more closely related to NK cells than to traditional T cells, because they have a very restricted T cell receptor repertoire and often express molecules usually found on NK cells; hence their designation as NKT cells. NKT cells may have arisen to combat pathogens that feature lipid antigens, such as mycobacteria. Increasing evidence points to populations of T cells as being specifically designed to present complex lipids and related antigens for an immune response.

γδ T cells are found in large numbers in the mucous membranes of many tissues, including the skin, small intestine, female reproductive tract, and lung. These locations suggest that they are a first line of defense against invading microorganisms. These cells appear to mediate cellular immune functions without requiring antigen processing. Thus, these cells are probably important in triggering and controlling the local immune response to pathogens such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*. In so doing, they shape the local inflammatory reaction to the invading pathogen, which includes playing a role in maintaining host tissue integrity. There is still much to learn about how these NKT cell and γδ T cell populations function in the immune response. One hypothesis is that they are the T cell equivalents of natural antibodies and lectins, insofar as they are programmed to provide an innate immune response to certain organisms.

MACROPHAGES

Macrophages are present in body secretions and in tissue sites bordering epithelial tissues. In these locations, they respond to pathogens with phagocytosis and the release of cytokines. They accomplish this by expressing many types of receptors, including PRR, Toll, lectin, scavenger, Fcγ, and complement.[15] In general, these receptors can be divided into two groups. Opsonic receptors recognize microbes coated with immunoglobulins and complement. In contrast, the nonopsonic receptors directly recognize a structure on the surface of the infecting organism. Most of the PRR, Toll, and lectin receptors are nonopsonic. The principles that govern the function of the Toll receptors and PRR (see above) also apply to macrophages, including the signaling pathways and cellular response of cytokine production. Of course, a major difference is that macrophages can phagocytose and kill an organism through oxidative and other microbicidal means not available to epithelial cells. The secreted cytokines, like those from epithelial cells, are designed to activate nearby cells for an inflammatory/immune response. The macrophage lectin receptors recognize sugar moieties (e.g., mannose, galactose, β-glucan, galactose, *N*-acetylglucosamine, and other oligosaccharides). The fine structure of these moieties differs sufficiently from that of host sugars that receptors recognize them but not host sugars. One complement receptor, CR3, like several of the lectin receptors, has multiple specificities: it recognizes C3bi (an opsonic receptor), as well as β-D-glucose, some mannoses, and *N*-acetylglucosamine–containing sugars. In most cases, the recognition of microbes by macrophages leads to phagocytosis and an immune response. However, some organisms use these receptors to gain entrance to intracellular compartments, which can be favorable locations.

DENDRITIC CELLS

The immune system has developed a system for capturing, processing, and then displaying antigens to lymphocytes. Macrophages can phagocytose and present antigens, but they do so much less efficiently than the so-called professional antigen-presenting cells (APCs, or dendritic cells). Most antigens enter via epithelial barriers, where they encounter a cell type bearing long dendritic processes. In the skin, these dendritic cells are called Langerhans cells. The capture of antigens by receptors on APCs (most such receptors are similar to those on macrophages, as described above) occurs by phagocytosis and pinocytosis. The APCs are relatively inefficient (i.e., immature)

in their baseline state, but in an environment rich in inflammatory cytokines from epithelial cells or macrophages (as part of the innate immune response), these immature dendritic cells gradually turn into exceptionally efficient APCs. After antigen capture, the immature or maturing APCs migrate to regional lymph nodes, where they encounter T cells; this encounter initiates an adaptive immune response.

Cytokines of the Innate Immune System

In response to invading microbes, epithelial cells and macrophages secrete cytokines that mediate immune and inflammatory reactions. Cytokines communicate to the cells that produce these signals (autocrine action) and to nearby cells (paracrine action) through cytokine receptors. Through this process, cytokines prepare the local environment to engage microbes and to prepare immunocompetent cells for an immune response. Cytokines commonly released by macrophages and epithelial cells include TNF, IL-1, IL-6, IL-12, IL-15, interferon alfa, and interferon beta. Some of these cytokines of innate immunity also provide second signals for activation of B and T cells [*see 6:III Adaptive Immunity: Antigens, Antibodies, and T Cell and B Cell Receptors*].

The Complement System

The complement system lies at the interface between innate and acquired immunity. As a key component of innate immunity, it promotes the inflammatory response and attacks and destroys foreign substances.[16-19] In this process, it is a facilitator and instructor of the adaptive immune response against the foreign antigen. Further, it provides one of the main effector mechanisms for antibody-mediated host defense [*see Table 3*].

Table 3 Roles of the Complement System in Immunity

First line of defense (innate immunity)
Mediates an inflammatory response
Modifies membranes of invading microbes
Instructor of adaptive immunity
Antigen identification, processing, transportation, and retention
Cellular activation and induction of costimulatory molecules, cytokines, and other mediators of immune response (lowers threshold for B cell signaling)
Effector arm of humoral immunity
Promotes microbial killing via opsonization and lysis
Removes antigens by immune complex formation

From its initial description more than 100 years ago as a heat-labile lytic substance that "complemented" antibodies in destroying bacteria, we now know that the complement system consists of three initiating arms, as well as many regulators and receptors [*see Figure 1*]. The early-reaction sequences behave as biologic cascades in which, by limited proteolysis, one component activates the next. This produces a rapid and robust amplification of the activation process. The primary goal is to attach clusters of C3b on a target (opsonization) so that phagocytes bearing C3 receptors can adhere to and then ingest the material. To counteract the potential for self-injury, almost half of the complement proteins serve as regulators or inhibitors. Despite this tight control, complement is an important contributor to tissue injury in ischemia-reperfusion injury and disease states, especially those featuring autoantibodies and immune complexes. Inherited deficiencies of components in the activating cascade predispose to infectious diseases, primarily of a pyogenic type; surprisingly, such deficiencies also predispose to autoimmunity, especially systemic lupus erythematosus (SLE). Deficiencies of regulators lead to excessive activation and tissue injury. Complement determinations facilitate the diagnosis and management of a number of illnesses. Although no agents for inhibiting complement activation are as yet commercially available, two promising candidates are in clinical trials, and more are in the pipeline.

COMPLEMENT NOMENCLATURE

The early part of the complement system is divided into three branches: the antibody-initiated classical pathway (CP), the antibody-independent (i.e., innate) alternative pathway (AP), and the more recently described lectin pathway (LP). Although each branch is triggered differently, all share the common goal of depositing clusters of C3b on a target. This deposition results in the assembly of a common lytic mechanism, called the membrane attack complex (MAC) or C5b-9.

The CP proteins are identified by numbers (C1, C4, C2, and C3), and the AP proteins are designated by capital letters (factors B, D, and P) [*see Table 4*]. Each MAC consists of one each of C5b, C6, C7, and C8, and many C9s. In the early steps of the cascades, activated proteases cleave the next component in line to liberate a small fragment (these fragments are designated by a lower case "a" [e.g., C3a]), while the large fragment attaches to the target, after which it is designated "b" (e.g., C3b). Limited proteolytic cleavage produces further degradative fragments that are designated by lowercase letters; for example, C3b is cleaved to C3bi, and C3bi is in turn cleaved to C3c and C3dg [*see Figure 2*]. Complement proteins expressed on cell membranes are regulators or receptors for activated components. They may be identified according to so-called cluster of differentiation (CD) designations or according to function. For example, complement receptor 1 (CR1) is also called CD35 and the C3b/C4b or immune adherence receptor.

THE ALTERNATIVE PATHWAY

The AP is an ancient pathway of innate immunity. Unlike the CP, the AP does not require antibody for initiation. Rather, the natural breakdown (i.e., low-grade turnover) of plasma C3 via spontaneous cleavage of a highly reactive thioester bond allows C3 to attach to any nearby host or foreign surface. Regulatory proteins on host cells protect cells by inactivating such fragments. However, foreign membranes usually do not possess such inhibitors, so amplification (the feedback loop of AP) becomes engaged. Target-bound C3b binds to plasma component factor B. The latter undergoes proteolytic cleavage, mediated by plasma protein serine protease factor D, to produce Bb + Ba. The AP C3 convertase thus formed, C3bBb, is stabilized by properdin, which increases the half-life of the enzyme complex. As the stabilized convertase cleaves more C3 to C3b, a feedback loop becomes engaged for autoamplification. Through this mechanism, the AP can deposit several million C3bs on a bacterial surface in a few minutes.[20]

Membrane Attack Complex

As a further assault against a pathogen, the AP assembles the MAC. In this case, the C5 convertase (C3bBbC3bP) cleaves C5 to C5b. This promotes assembly of C6 + C7 + C8 and multiple C9s

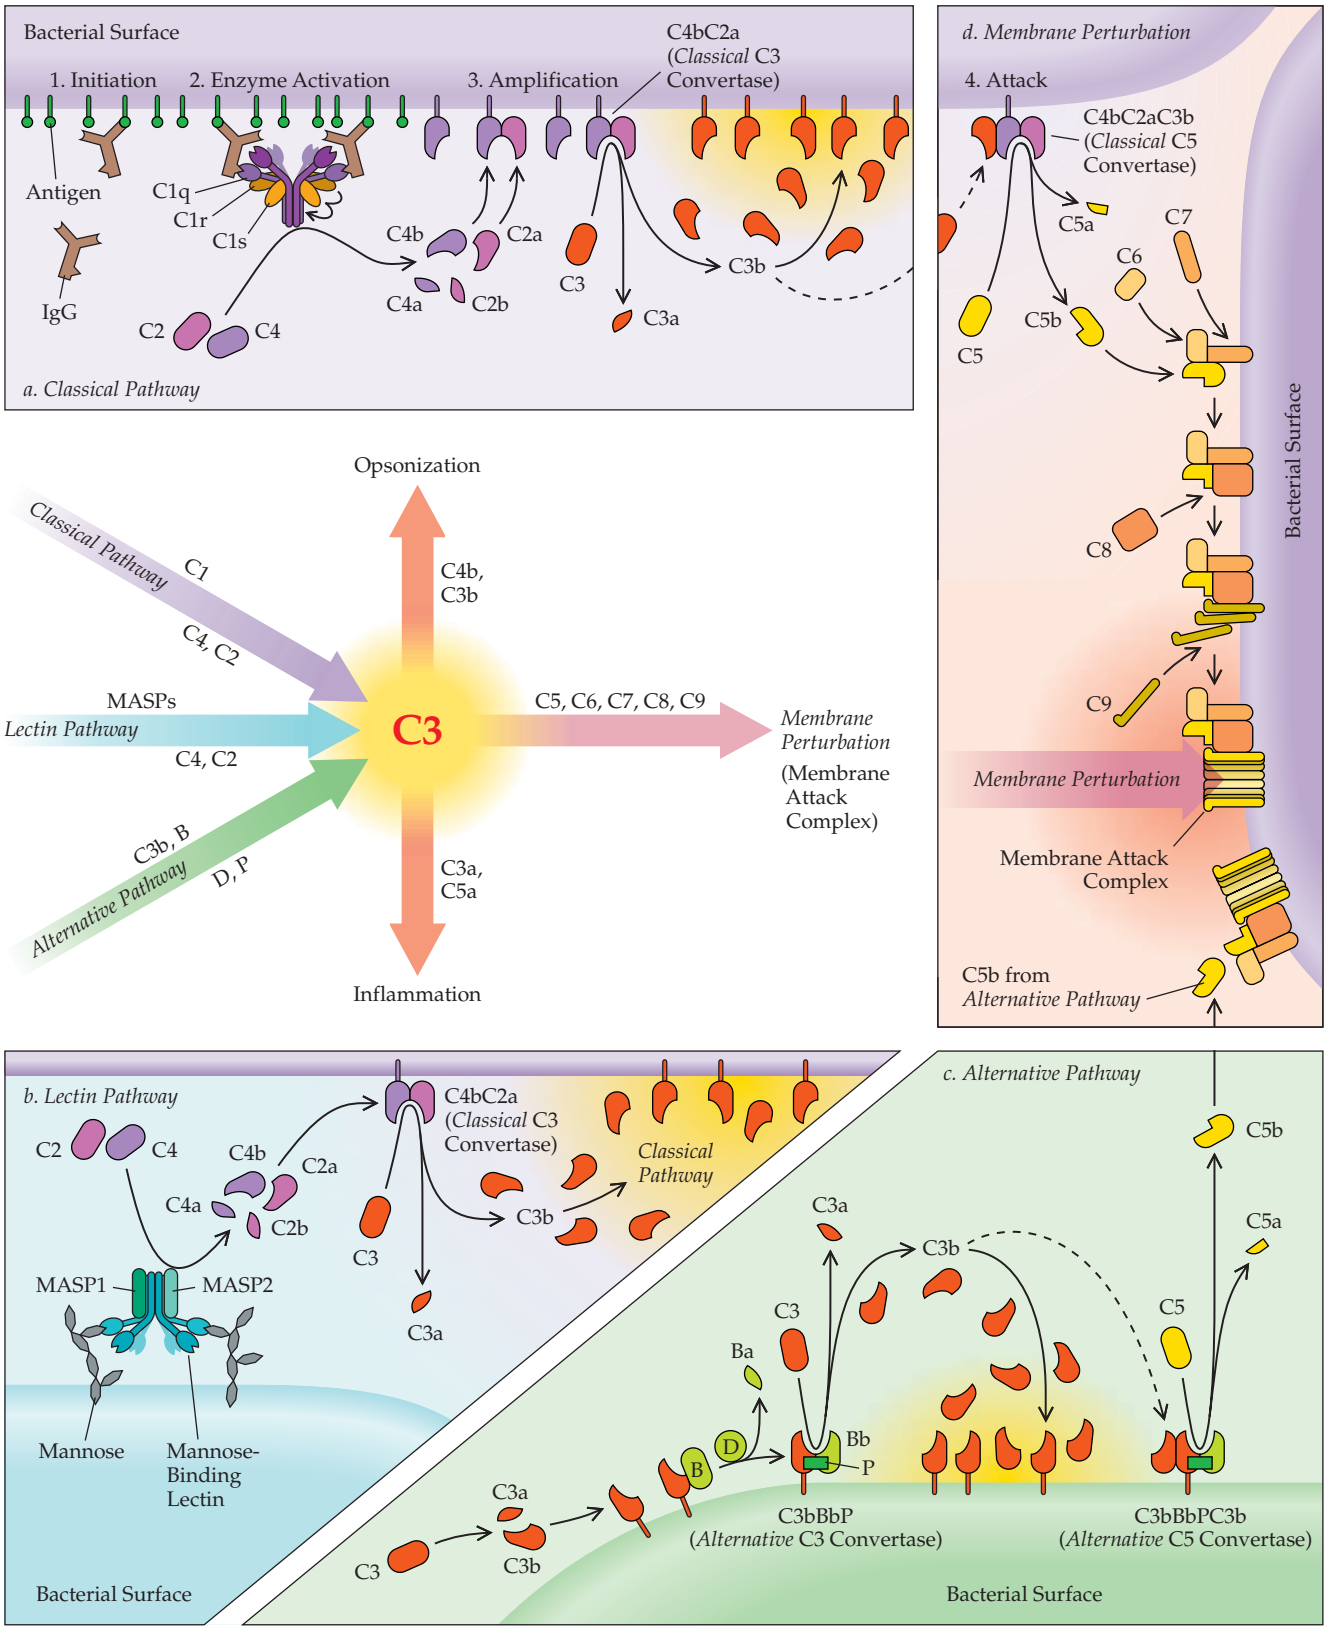

Figure 1 **Function of the complement system. The early part of the complement system comprises three branches: the classical pathway (*a*), the lectin pathway (*b*), and the alternative pathway (*c*). These pathways converge to produce membrane pertubation (*d*) on bacterial surfaces. The most important function of complement is opsonization—the coating of a pathogen with clusters of complement activation fragments. These fragments, in turn, facilitate interactions with complement receptors and in some cases (e.g., certain gram-negative bacteria and viruses) lead to lysis. The second critical function of complement is to activate cells so as to promote inflammatory and immune responses. Through opsonization and cell activation, complement serves as nature's adjuvant to prepare, facilitate, and instruct the host for an adaptive immune response.[34] (MASPs—mannan-binding lectin–associated serine proteases)**

Table 4 Plasma Components of the Complement Cascades

Pathway	*Component*	*Serum Concentration (μg/ml)*	*Function*
Classical pathway (CP)	C1	50	Triggers CP
	C1q	Part of C1 complex	Binds Fc portion of IgG/IgM
	C1r	Part of C1 complex	Protease; cleaves C1s
	C1s	Part of C1 complex	Protease; cleaves C4 and C2
	C4	200–500	Opsonin,* C4a release
	C2	20	Protease; cleaves C3/C5
Alternative pathway (AP)	MBL	150 (wide range)	Binds sugars to trigger LP
	MASP-1	5	Protease
	MASP-2	5	Protease; cleaves C4 and C2
	Factor B	150–250	Protease; cleaves C3/C5
	Factor D	1-2	Protease; cleaves factor B
	Properdin	25	Stabilizes AP convertases
Central protein	C3	550–1,200	Opsonin,* C3a release
Terminal pathway	C5	70	MAC component (C5b), C5a release
	C6	60	MAC component
	C7	60	MAC component
	C8	60	MAC component for pore formation
	C9	60	MAC component for pore formation

*C4b and C3b; also forms part of the C3 and C5 convertases.
LP—lectin pathway MAC—membrane attack complex MASP—MBL-associated serine protease MBL—mannan-binding lectin

to allow perforation (i.e., channel or pore formation) of the foreign membrane. MAC assembly occurs through protein-protein interactions (i.e., no proteolysis is involved after C5 cleavage) to form the lytic complex. Cleavage of C5 also releases the anaphylatoxin C5a, which has potent inflammatory and chemotactic properties.

CLASSICAL PATHWAY

Four concepts underlie the function of the CP: initiation, enzyme activation, amplification, and attack.

Initiation

The CP is triggered by an interaction between the C1q subcomponent [*see Figure 3*] of the C1 complex after it attaches to the Fc portion of antibody (an immune complex). IgM and IgG subclasses 1, 2, and 3 activate the CP, whereas IgA, IgD, IgE, and IgG4 do not. Additionally, C-reactive protein is an acute-phase reactant that activates the CP.[21]

Enzyme Activation

After C1 binds to antibody, the C1r subcomponent undergoes an autoactivation process, activating C1s by cleavage. C4 and C2 are then cleaved by C1s. Large proteolytic fragments derived from C4 (C4b) and C2 (C2a) (an exception to the nomenclature whereby smaller fragments are designated with an "a") attach to the target surface, as well as to antibodies, to assemble the C3 convertase, C4b2a. This enzyme complex rapidly converts C3 to C3b. C4, a structural cousin of C3, also possesses the remarkable post-translational thioester modification. Activated C4b (produced by cleavage of the parent protein) has the transient ability to "glue" covalently onto a nearby surface via a hydroxyl group (i.e., to form an ester linkage).

Amplification

Each activated C1 produces large numbers of C4b and C2a. Most of the C4b serve as opsonins to coat nearby surfaces, whereas others form convertases that rapidly and robustly amplify the system via C3b. Clusters of C3b deposited on a surface serve as ligands for complement receptors.

Attack

Whereas some C3bs serve as ligands for complement receptors, others form C5 convertases (i.e., C4b2a3b). These convertases cleave C5 to initiate the MAC.

LECTIN PATHWAY

Lectins are carbohydrate-binding proteins that were initially identified by their capability of agglutinating red blood cells. They are now recognized as important players in innate immu-

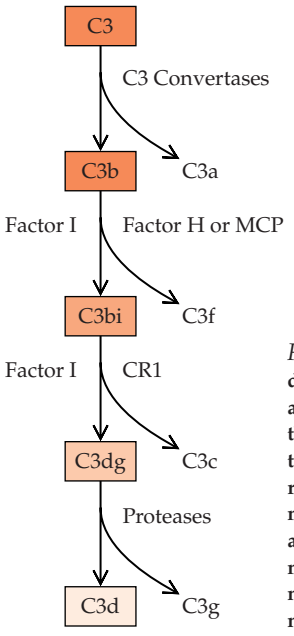

Figure 2 **C3 activation and degradation. The boxed activation fragments are those that are covalently attached to the target. The other fragments are released into the surrounding milieu. C3a is a potent anaphylatoxin. C3f may be a marrow-mobilizing factor for neutrophils. C3c and C3g have no known function.**

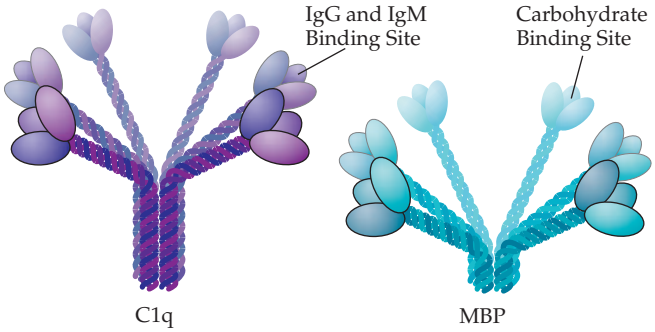

Figure 3 **Similarity of structure between C1q and mannan-binding lectin (MBL, also called mannose-binding protein [MBP]).[19] Ficins, surfactins, and other members of the collectin family of proteins share this general structure. Many activate the lectin pathway upon interaction with their ligands.**

nity. The activation scheme of the lectin pathway is similar to that of the CP, except that lectins substitute for antibodies, and associated proteases replace the C1r/C1s subcomponent of C1. In particular, mannan-binding lectin (MBL, also called mannose-binding protein [MBP]) is a plasma protein that preferentially binds to repeating mannoses and other sugars on pathogens [*see Figure 3*]. The resulting MBL-associated serine proteases (MASPs) cleave C4 and C2. MBL levels are elevated as part of the acute-phase response.[22,23]

RECEPTORS AND REGULATORS OF COMPLEMENT

Many of the effects of the complement system (e.g., immune adherence, phagocytosis, cell signaling) result from the interaction of receptors and activation fragments [*see Tables 5 and 6*].[24] For example, complement receptors mediate clearance of immune complexes bearing complement proteins.[25] Complement receptor 1 (CR1; CD35) on erythrocytes binds C3b/C4b-coated immune complexes for processing and transport to the liver and spleen. In these organs, immune complexes are transferred from erythrocytes to tissue macrophages, and the erythrocytes then return to the circulation. CR1 on granulocytes and monocytes promotes immune complex adherence and phagocytosis, whereas CR1 on B cells, tissue macrophages, and follicular-dendritic cells (FDCs) facilitates trapping and processing of immune complexes in lymphoid organs. Other receptors for C3b fragments help to localize immune complexes to FDC-rich and B cell–rich areas of the spleen and lymph nodes, where they guide the adaptive immune response. Receptors for anaphylatoxins exert vasomodulatory and chemotactic effects after the binding of C3a and C5a. Finally, receptors in the lectin group enhance phagocytosis.

Complement regulatory proteins [*see Table 7*] provide the checks and balances to the system.[24] Unregulated, the system would fire to exhaustion, a point well illustrated by inborn errors of several regulatory proteins. The system is designed so that the initial activation is unencumbered on foreign surfaces, yet rapidly inhibited on self-tissue.

Regulation of the early phase of the CP is provided by C1 inhibitor (C1-Inh), which prevents excessive plasma C1 activation. The C3/C5 convertases are regulated by a family of proteins that include two membrane proteins, decay accelerating factor (DAF; CD55) and membrane cofactor protein (MCP; CD46), as well as the serum inhibitors C4b-binding protein and factor H. These proteins function by disassembling the convertases (decay-accelerating activity), by facilitating proteolytic inactivation of C4b or C3b, or by both processes [*see Figure 4*]. Inactivation occurs in collaboration with the plasma serine protease factor I and is called cofactor activity. The MAC also has regulators in plasma and on cells. Vitronectin (S-protein) binds and inactivates MAC liberated into the fluid phase. On host cells, the glycolipid-anchored CD59 binds C8 and C9 to prevent proper MAC insertion.

COMPLEMENT PARTICIPATION IN ADAPTIVE IMMUNITY

In addition to complement's long-appreciated role as a mediator of antibody-directed events, complement activation is instrumental for generating a humoral immune response.[26] More than 25 years ago, it was found that mice depleted of C3 by cobra venom factor had markedly impaired primary antibody responses. Similar results were associated with deficiencies or defects in C4, C2, C3, CR1, or CR2. The major findings of these studies were variable but often included a low primary IgM response; a failure to class switch; and, on a second antigenic challenge, a lack of recall (memory). The defective response could be overcome with larger doses of antigen.

These results have given rise to two hypotheses, which are not mutually exclusive.[26] One hypothesis suggests that the binding of C3b to an antigen enhances the immune response by promoting transmittal of the antigen to a local lymph node or spleen for uptake, processing, and retention by APCs (especially FDCs). The second hypothesis suggests that the binding of CR2 with C3d complexed on antigen enhances signaling through the B cell antigen receptor. Reconstitution studies are helping to define mechanisms and determine the contributions of CR2 of B cells, relative to the contributions of FDCs. In such studies, B cell deficiency of CD21 (CR2) most closely resembled the knockout, although a contribution of FDCs to long-term memory was apparent.[26]

Table 5 Complement Receptors for C3 and C4

Name (CD Number)	*Primary Ligand*	*Location*	*Function*
CR1 (CD35)	C3b/C4b	Peripheral blood cells (except for platelets), FDC, B cells, podocytes	Immune adherence, phagocytosis, antigen localization
CR2 (CD21)	C3dg/C3d	B cells, FDC	Coreceptor for B cell signaling, antigen localization
CR3 (CD11b/CD18), CR4 (CD11c/CD18)	C3bi	Myeloid lineage	Phagocytosis, adherence

FDC—follicular dendritic cells

Table 6 Complement Receptors for Anaphylatoxins

Receptor	*Ligand*	*Distribution*	*Function*
C3aR	C3a	Myeloid lineage, including mast cells, smooth muscle, epithelial/endothelial cells	Cell activation including granule exocytosis, upregulation of adhesins, chemotaxis, cytoskeletal effects
C5aR	C5a	Similar to C3aR	Similar to C3a but with more chemotactic effects

COMPLEMENT AND DISEASE

The complement system is a double-edged sword. Once unsheathed, it can attack in a robotic fashion. The pathophysiology of many inflammatory diseases involves the synthesis of autoantibodies and the presence of excessive quantities of immune complexes. If the host produces an antibody that reacts to a self-antigen (e.g., on an erythrocyte), the complement cascade becomes activated. Thus, just as complement can destroy a microbe, it may lyse an erythrocyte, opsonize a platelet, or disrupt a basement membrane. If immune complexes lodge in blood vessel walls in a particular tissue, they may activate complement to produce synovitis, vasculitis, dermatitis, or glomerulonephritis. Similarly, a powerful complement barrage may result from ischemia-reperfusion injury as the alternative pathway elicits C3b deposition on the damaged tissue, which is regarded as foreign.

Complement component deficiencies, although rare, predispose to autoimmune diseases (e.g., SLE) and bacterial infections [*see Table 8*].[17,18,27,28] Deficiencies of complement regulatory proteins allow excessive activation of complement cascades [*see Table 7*]. These conditions are usually inherited as autosomal recessive traits, with the exception of deficiencies of C1-Inh (which is an autosomal dominant trait) and properdin (which is X-linked). The effects of these conditions are predictable, because the affected person experiences a loss of function of the deficient protein and of all the proteins that would ordinarily follow in the cascade. Deficiencies of early components (e.g., C1q, C1r/C1s, C4, and C2) predispose to SLE, whereas deficiency of C3, MBL, or MAC components leads to recurrent bacterial infections.

C1-Inh deficiency causes hereditary angioedema, whose symptoms range in severity from a minor inconvenience to life-threatening laryngeal edema [*see 6:XIII Urticaria, Angioedema, and Anaphylaxis*].[29] Deficiency of factor H may lead to uncontrolled AP activation on, and damage to, endothelial cells, resulting in hemolytic uremic syndrome or glomerulonephritis.[30]

Acquired deficiencies of complement also predispose to illness. C1-Inh deficiency may occur as a result of excessive utilization of C1-Inh (usually because of a malignancy) or inactivation of C1-Inh by an autoantibody. An acquired deficiency of C3 may occur as a result of production of an autoantibody that binds and stabilizes the C3 convertase. In the AP, this antibody is called the C3 nephritic factor, whereas in the CP it is termed the C4 nephritic factor. Most patients with C3 nephritic factors are chil-

Table 7 Complement Regulatory Proteins

Regulation Site	*Protein*	*Tissue Distribution*	*Function*	*Disease Associated with Deficiency*
Initiation of complement cascade	C1 inhibitor	Plasma	Inactivates C1r, C1s, and MASPs; a SERPIN	Hereditary angioedema
Convertases	Factor I	Plasma	Cleaves C3b and C4b; requires a cofactor protein	Infection (secondary to low C3 levels)
	Membrane cofactor protein	Most cells	Cofactor for cleavage of C4b and C3b	Hemolytic-uremic syndrome
	Decay-accelerating factor	Most cells	Destabilizes C3 and C5 convertases	None*
	C4b-binding protein	Plasma	Cofactor for cleavage of C4b; decays CP C3 and C5 convertases	None*
	Factor H	Plasma	Cofactor for cleavage of C3b; destabilizes AP C3 and C5 convertases	Hemolytic-uremic syndrome; glomerulonephritis
	Complement receptor type 1 (CR1)	Blood cells	Receptor for C3b and C4b; cofactor activity for C3b and C4b and decays C3 and C5 convertases	None†
MAC	S protein	Plasma	Blocks fluid-phase MAC	Unknown
	CD59	Most cells	Blocks MAC on host cells	Paroxysmal nocturnal hemoglobinuria
Other	Anaphylatoxin inactivator	Plasma	Inactivates C3a, C4a, and C5a	Hives

*Too few cases of complete deficiency described to establish an association.
†A complete deficiency has not been reported.
AP—alternative pathway CP—classical pathway MAC—membrane attack complex MASPs—mannan-binding lectin–associated serine proteases SERPIN—serine protease inhibitor

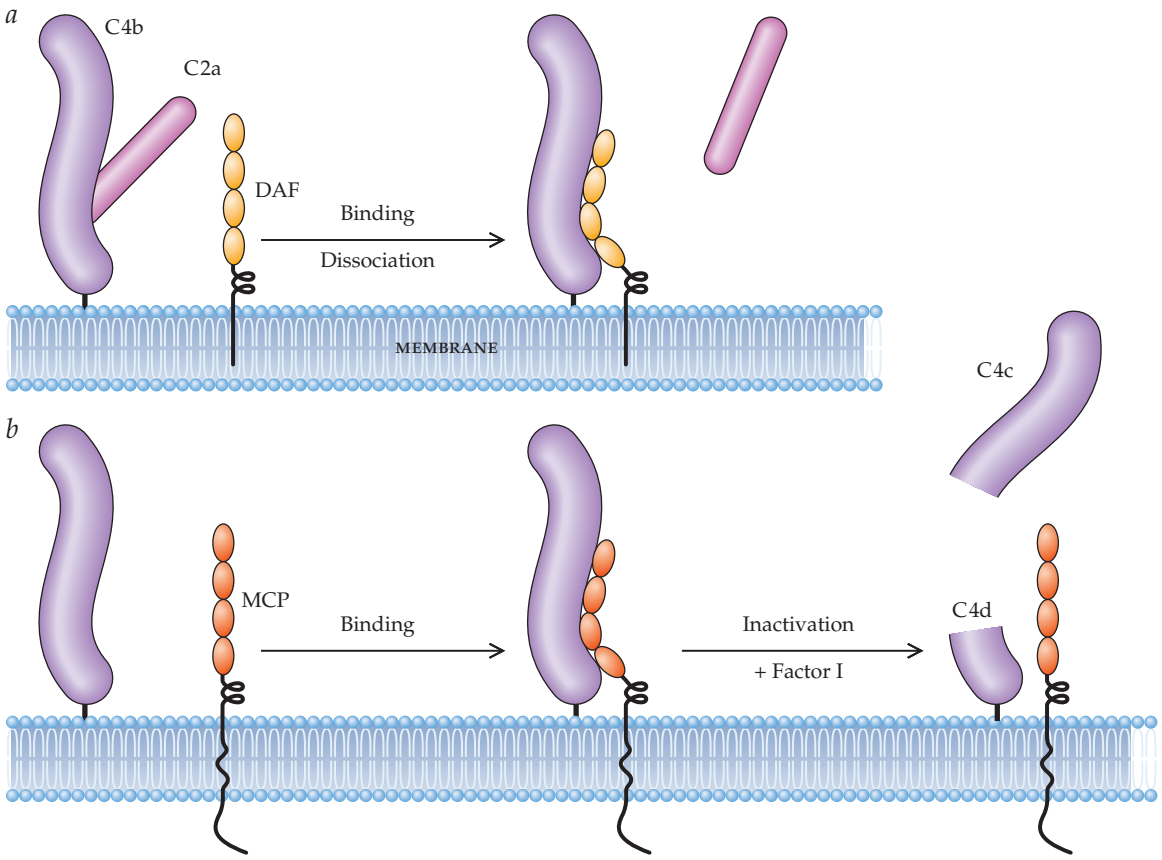

Figure 4 **The membrane proteins decay-accelerating factor (DAF) and membrane cofactor protein (MCP) regulate the C3 and C5 convertases.[35] These proteins function by disassembling the convertases (decay-accelerating activity), by facilitating proteolytic inactivation, or by both processes. In the classical pathway, the components of C3 convertase are the proteases C4b and C2a. Decay-accelerating activity (*a*) occurs when DAF binds C4b, displacing the C2a. Proteolytic inactivation (*b*) occurs when MCP, in concert with the serine protease factor I, cleaves C4b; this prevents C4b from interacting with newly formed C2a. The residual bound C4d has no known biologic activity. In the classical pathway, C5 convertase (which consists of a C4bC2a with an attached C3b) is similarly inactivated by decay-accelerating activity. Although C3 and C5 convertases in the alternative pathway have a different structure, they are disassembled in an identical fashion by DAF and MCP.**

dren; they may present with a combination of glomerulonephritis, partial lipodystrophy, and frequent infections with encapsulated bacteria.

An acquired hematopoietic stem cell disorder produces paroxysmal nocturnal hemoglobinuria [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*]. A mutation in a stem cell prevents expression of an enzyme needed to produce so-called greasy foot (i.e., glycolipid) proteins. As a result, blood cells are deficient in proteins that have this cellular anchor. In particular, deficiencies of CD59 and DAF predispose erythrocytes to complement-mediated hemolytic anemia.

COMPLEMENT MEASUREMENT

Complement levels can be assessed using either antigenic or functional assays [*see Table 9*]. The former are easier to perform and are most commonly employed for measuring C3 and C4 levels. The total hemolytic complement (THC or CH_{50}) assay measures activation of the entire CP by assessing the ability of the test serum to lyse sheep erythrocytes optimally sensitized with rabbit antibody. Interpretation of the results is rather straightforward [*see Table 10*]. Decreased C4 and C3 levels almost always indicate CP activation, whereas AP activation is indicated by normal levels of C4 but low levels of C3 (and factor B, if measured). All nine components of the CP (C1 through C9) are needed to obtain a normal result on the CH_{50} assay. A CH_{50} of 200 means the tested serum lysed 50% of the antibody-coated sheep erythrocytes when assayed at a dilution of 1:200. A similar assay, AH_{50}, measures the total alternative pathway, with the target for lysis being

Table 8 Clinical Manifestations of Complement Deficiency in the Activation Pathways

Pathway Involved	*Deficient Component*	*Clinical Syndrome*
Classical pathway	C1q	SLE, infections*
	C1r/C1s	SLE, infections*
	C4	SLE, infections*
	C2	SLE, infections*
Lectin pathway	MBL	Infections
Central component	C3	Severe infections,* glomerulonephritis, SLE
Membrane perturbation	C5, C6, C7, C8, or C9	*Neisseria* infections
Alternative pathway	Properdin, factor D	*Neisseria* infections

*Typically, with commonly encountered pyogenic organisms.
MBL—mannan-binding lectin SLE—systemic lupus erythematosus

Table 9 Assays for Complement Activation in Human Disease

Method	*Use*	*Comments*
CH_{50} or THC	Screen for a component deficiency or activation of classical pathway	Functional assay; requires appropriate sample handling
AP_{50}	Screen for component deficiency or activation of alternative pathway	Functional assay; requires appropriate sample handling
Antigenic (ELISA, immunodiffusion, nephelometry)	Standard method for C3, C4, factor B, C1-inhibitor, and MBL determinations	Widely available, easy to perform, reliable, inexpensive
Antigenic or hemolytic assay of individual components	To further define a suspected deficiency	Samples usually sent to laboratories specializing in complement assays
Activation fragments C3a, C5a, Bb C1-INH; C1r/C1s C5b-9 (neoantigen)	Additional tests to detect complement turnover	More sensitive than static levels; sample collection technique important; often available through commercial laboratories; expensive
C1-inhibitor function	When clinical picture is consistent with HAE but C1-inhibitor levels by antigenic assay are normal or elevated	15% of HAE patients have normal or elevated levels of a nonfunctional protein
Immunofluorescence	Demonstration of complement activation fragments in tissue	C1q, C4, and C3 are most commonly studied in kidney and skin biopsy specimens
Antiglobulin testing (nongamma Coombs)	Demonstration of C3 fragments on erythrocytes	Usual fragment detected is C3d

AP_{50}—alternative pathway equivalent of THC or CH_{50} ELISA—enzyme-linked immunosorbent assay HAE—hereditary angioedema MBL—mannan-binding lectin THC—total hemolytic assay for classical pathway (also called CH_{50})

unsensitized rabbit red blood cells. Less widely used tests include measurement of the anaphylatoxins C5a and C3a or activation fragments, such as C3d and Bb. Tests showing increased levels of these substances have the advantage of reflecting ongoing activation and are more sensitive. In addition, specialized laboratories can determine the functional and antigenic levels of each of the complement components and regulators.

EVOLVING THERAPEUTIC STRATEGIES

Currently, no therapeutic agent is commercially available to block the deleterious effects of pathologic complement activation.[31-33] Two plasma-based therapies are undergoing clinical trials. A humanized monoclonal antibody to C5 adopts the straightforward strategy of blocking the function of a single component; specifically, it blocks cleavage of C5 by C5 convertases. A significant advantage of this approach is that recombinantly produced humanized monoclonal antibodies are already an established therapy in clinical medicine (e.g., anti-TNF). Recombinant monoclonal antibodies have a relatively long half-life and, if humanized, are usually nonimmunogenic. However, it is unclear how much tissue damage in clinical syndromes results from the activation of C5 as compared with that caused by C3. An advantage of this therapeutic approach is that activation up to and including C3 remains intact.

A second compound in clinical trials is a solubilized version of CR1 (sCR1), which degrades C3b/C4b and decays C3/C5 convertases. Proof of principle has been established in animal models, as it has been for the monoclonal antibody to C5. Poten-

Table 10 Interpretation of Complement Assays

Test Result			*Interpretation*
THC (units/ml)	*C4 (mg/dl)*	*C3 (mg/dl)*	
150–250	16–40	100–180	Normal range
250	40	200	Acute-phase response
100	10	80	CP activation
100	30	50	AP activation
< 10 or 0	30	140	Inherited deficiency or in vitro activation*
50	< 8	100	Partial C4 deficiency or fluid-phase activation†

*In vitro activation is more common than an inherited deficiency state. The lack of activity (< 10 THC) in the setting of normal C4 and C3 antigenic levels suggests (1) an improperly handled sample, (2) cold activation (such as by cryoglobulins) after collection of the sample, or (3) homozygous component deficiency (most commonly C2 with a lupus presentation or, if a *Neisseria* infection is present, of an AP or membrane-attack-complex component).

†Detectable THC excludes a complete deficiency of C4. A partial C4 deficiency, such as of C4A, could give this result. Some types of immune complexes, especially cryoglobulins, and a deficiency of the C1-inhibitor (hereditary angioedema) also give this pattern. In these cases, measurement of C2 is often helpful: a low value suggests activation, whereas a normal value suggests an inherited, partial C4 deficiency. Also, C4A and C4B alleles can be assessed by commercial laboratories.

AP—alternative pathway CP—classical pathway THC—total hemolytic complement (also called CH_{50})

tial barriers to the use of sCR1 in clinical practice include cost, lack of selectivity, the need for intravenous administration, and the potential for infectious complications.

The search for a complement therapeutic has led to two unanticipated observations. First, complement activation contributes to tissue damage in ischemia-reperfusion injury syndromes such as myocardial infarctions and stroke; second, C5b–C9 and C5a bear responsibility for more of the tissue damage during complement activation than predicted.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III ADAPTIVE IMMUNITY: ANTIGENS, ANTIBODIES, AND T CELL AND B CELL RECEPTORS

Cox Terhorst, ph.d.
John R. David, m.d.

Antigens

An antigen is any substance capable of generating an immune response; that is, antigens react with T cells and B cells to induce the formation of antibodies and to sensitize lymphocytes, and those antibodies and sensitized cells then react with the antigens. The first antigens to be studied were microorganisms and foreign proteins, and it remains true that foreign proteins are almost universally antigenic. In addition, polysaccharides can induce antibody formation when coupled to proteins, and certain purified polysaccharides are themselves effective antigens. One such example is purified pneumococcal polysaccharide, which can be used as a vaccine against the particular strain of pneumococcus from which the polysaccharide is obtained. Although most antigens are macromolecules, some small molecules can also be antigenic. Antibodies to DNA or RNA occur in many patients with rheumatic diseases, especially systemic lupus erythematosus.

antigen recognition

Antigens are recognized not only by antibodies but also by antigen-specific B cell receptors (BCRs) [*see* B cell receptors, *below*] and T cell receptors (TCRs) [*see* T Cell Receptors, *below*], which are located on the surfaces of B cells and T cells, respectively. In general, TCRs and antibodies recognize different antigenic determinants.

Two distinct types of TCRs exist: TCR-αβ and TCR-γδ. Each has different mechanisms for recognizing antigens [*see 6:IV Cell-Cell Interactions, Cytokines, and Chemokines in Immune Response Mechanisms*]. For example, T cells bearing TCR-αβ recognize antigens that have been processed by antigen-presenting cells (APCs) to become peptide fragments bound to major histocompatibility complex (MHC) class I or class II molecules on the surface of the APCs. In contrast, T cells bearing TCR-γδ appear not to require antigen presentation by MHC molecules. Helper T cells recognize only peptide fragments bound to MHC class II molecules, whereas cytotoxic T cells recognize processed viral antigens presented by both MHC class I and MHC class II molecules on the surface of virus-infected cells. Pure lipids from mycobacteria can be presented as antigen to TCR-αβ by CD1 molecules rather than by MHC class I or class II molecules.

adjuvants

Adjuvants are substances capable of increasing the immunogenicity of antigens and are critical in the production of vaccines. Many microbial products have been used as adjuvants,[1] including substances from *Mycobacterium tuberculosis,* bacillus Calmette-Guérin (BCG), *Corynebacterium parvum, Brucella abortus,* and *Bordetella pertussis,* as well as toxoids from *Vibrio cholerae* and *Clostridium tetani.* Adjuvants have also been derived from vaccinia virus and other poxviruses, BCG, and *Salmonella* by transfecting the organism with genes for an antigen of interest. Others have come from lipopolysaccharide derivatives, such as monophosphoryl lipid A. Freund complete adjuvant, which consists of dead mycobacteria in oil emulsified with an antigen in aqueous solution, is now infrequently used because it generally causes a strong local inflammatory reaction. Other adjuvants are extracts from the soap bark tree (*Quillaja saponaria*), polymers (e.g., inulin), peptide complexes, and a number of cytokines. The aluminum salt alum is approved for general use as an adjuvant in humans. The complex of antigen and complement fragments, particularly those derived from C3, probably serves as the physiologic adjuvant.

Antibodies

Antibodies are a heterogeneous group of serum proteins called immunoglobulins. Immunoglobulins are secreted by differentiated B cells called plasma cells. According to Sir Francis MacFarlane Burnett's clonal selection theory, a single plasma cell produces only one specific antibody. This theory is aptly illustrated by the disease multiple myeloma, in which malignant proliferation of plasma cells occurs in bone marrow. The multiple myeloma plasma cell produces an abnormal monoclonal immunoglobulin called a myeloma protein. Its homogeneity is clearly visible on electrophoresis as a single dense band. Certain antibodies that are produced in response to highly homogeneous antigens, such as streptococcal polysaccharide, may also be relatively homogeneous.

Immunoglobulin molecules consist of two identical heavy chains and two identical light chains [*see Figure 1a*]. Each light chain is attached to a heavy chain by disulfide (S—S) bonds, and the heavy chains are also attached to each other by one or more S—S bridges. Amino acid sequences in both heavy and light chains are divided into regions that are either constant or variable [*see Figure 1b*]; in addition, each variable region contains sequences that are hypervariable.

classification of immunoglobulins

There are five classes of immunoglobulins, and each class contains a specific heavy chain: IgG contains two γ chains; IgM, two μ chains; IgA, two α chains; IgD, two δ chains; and IgE, two ε chains. There are also two types of light chains, κ and δ, which can be differentiated antigenically. One form of IgM, the secreted form, is a pentamer. The monomeric form of IgM is expressed on the extracellular surface of B cells. IgA exists as a monomer or a dimer. The polymeric forms of IgM and IgA have an additional J (joining) chain that facilitates polymerization.

IgG IgG is the major immunoglobulin in the serum, where it exists as a monomer. IgG has a half-life in the blood of approximately 23 days. It is the main antibody raised after antigenic challenge. There are four subclasses of IgG—IgG1, IgG2, IgG3, and IgG4—each different in structure and biologic properties. For example, only IgG1 and IgG3 bind the first component of

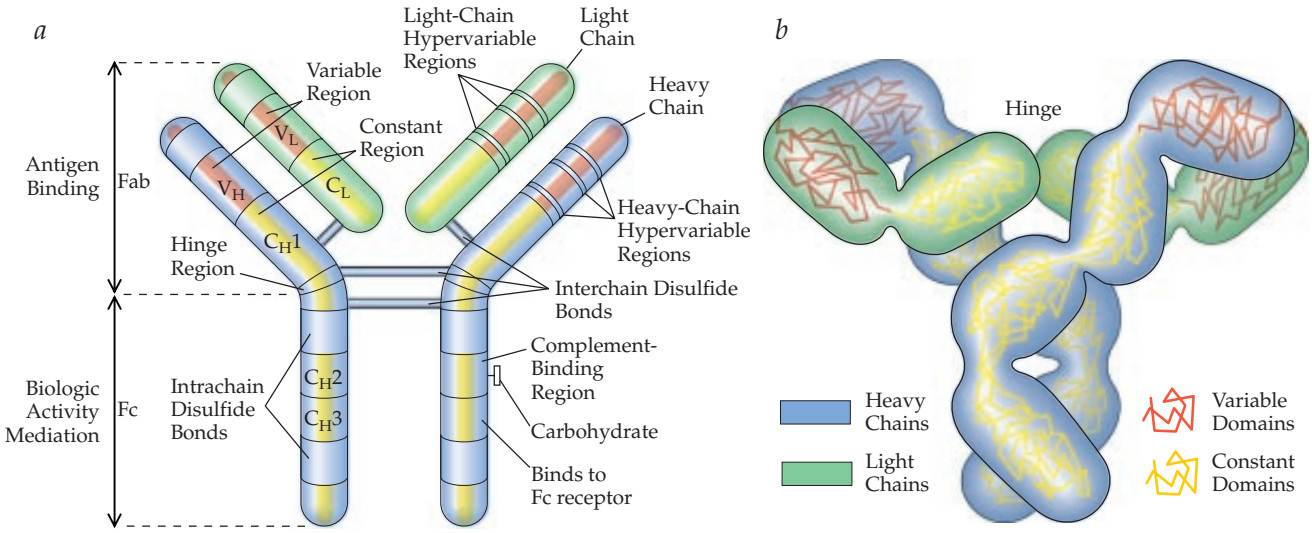

Figure 1 **(*a*) The immunoglobulin molecule is a Y-shaped protein made up of four polypeptide chains. Two heavy chains (blue) are joined to two light chains (green) by disulfide bonds. Blue squares represent intrachain S—S bonds; blue bars indicate interchain S—S bonds. The heavy chains extend from the stem of the Y into the arm; the two light chains are confined to the arms. Each polypeptide has regions whose amino acid sequences are constant (white and yellow) and variable (red). The variable regions also contain hypervariable regions. All antibodies of a given type have the same constant regions, but the variable regions differ from one clone of a B cell to another. The heavy- and light-chain variable regions fold to create an antigen-binding site. (*b*) Schematic model of the domain structure of an antibody molecule. The domains have a characteristic folding pattern, which is also seen in the T cell receptor and proteins of the major histocompatibility complex.[17]**

complement and adhere to monocytes. The antibodies that coat microorganisms and render them more susceptible to phagocytosis (i.e., opsonization) are of the IgG class. IgG antibodies can also neutralize viruses and toxins such as diphtheria toxin. Human antibodies to polysaccharides are mainly of the IgG class, but lesser amounts of IgM and IgA are also produced. Although the fetus does not produce this class of immunoglobulin, IgG readily crosses the placenta; therefore, IgG antibodies found in the newborn are from the mother.

Clinically, IgG has been used successfully for reconstituting the immunity of patients with primary immune deficiencies, such as agammaglobulinemia, and for preventing hemolytic disease in the newborn. Women with Rh-negative blood who bear a fetus with Rh1-positive red blood cells are sensitized at the first delivery by Rh1-positive red blood cells from the fetus. The mother then produces anti-Rh1 IgG antibodies that will cross the placenta during subsequent pregnancies; these antibodies react with fetal red blood cells, causing hemolytic disease. Erythroblastosis fetalis can be prevented by injecting IgG rich in anti–Rh-positive antibodies (RhoGAM) into an Rh1-negative mother at the time of delivery or abortion. These antibodies presumably combine with any fetal Rh1-positive red blood cells present and prevent them from immunizing the mother.

IgG can be split into three fragments by the proteolytic enzyme papain. Two of the fragments are similar and are called Fab; the third is called Fc [*see Figure 1a*]. The Fc portion is responsible for the biologic activity of the various immunoglobulins; among other things, the Fc portion controls the ability of immunoglobulins to bind to cells, fix complement, and traverse the placenta. Another proteolytic enzyme, pepsin, splits the IgG molecule behind the S—S bonds that bridge the heavy chains, leaving one large fragment, $F(ab')_2$, which is able to bind and precipitate antigen because of its bivalency and capacity to form a lattice.

IgA IgA is the predominant immunoglobulin in secretions, where it is usually found as a dimer and is released as such by local plasma cells. Monomeric IgA constitutes 15% of the serum immunoglobulins. In the serum, it has a half-life of 5 to 6 days. There are two subclasses of IgA: IgA1 and IgA2. The IgA dimer combines with the secretory piece, which is a polypeptide chain produced by local epithelial cells. In this form, IgA is quite resistant to proteolytic digestion. Unlike serum IgA, IgA combined with the secretory piece can undergo active transport across the mucosal epithelium by endocytosis [*see Figure 2*].

IgA is present in saliva, tears, and colostrum. It also occurs in the respiratory and gastrointestinal tracts, in the vagina, and in the prostate. The increased levels of antibodies to dietary antigens that are found in persons with IgA deficiency suggest that the IgA class of immunoglobulin normally limits the absorption of such antigens.

IgA may play an important role in local immunity by neutralizing viruses and by combining with viruses and bacteria, thereby preventing their adherence to mucosal surfaces. Although IgA does not bind to the first component of complement, as IgG and IgM do, it can lead to activation of the alternative complement pathway [*see 6:II Innate Immunity*]. One of the complement components generated by this pathway, C3b, aids in the opsonization of bacteria, enhancing their uptake and killing by phagocytes.

IgM Most B cells have monomeric IgM on their surface. However, IgM exists primarily as a pentamer and is found mainly in the serum, where it makes up 10% of the immunoglobulins. In the immune response, IgM is the first immunoglobulin raised in response to antigen stimulation. Cells that produce IgM or their precursors do not become memory cells, so that a second challenge with antigen produces no more IgM antibody than the first stimulus. Because the IgM response to antigen is short-lived, the presence of specific IgM in the serum may be helpful in establishing the diagnosis of acute infection with a particular pathogen. The fetus makes IgM anti-

bodies to certain microorganisms, which can be helpful in the diagnosis of fetal toxoplasmosis, rubella, or syphilis. Not all fetuses infected by these organisms produce such antibodies, however.

As a pentamer, IgM is highly efficient at fixing complement. Molecule for molecule, IgM is 20 times as effective as IgG in agglutinating bacteria and red blood cells and 1,000 times as active in bactericidal reactions. Isohemagglutinins, such as anti-A and anti-B, are of the IgM class. Waldenström macroglobulinemia is a disease characterized by the monoclonal production of IgM.

IgD IgD, which is a monomer, occurs in the serum in trace amounts. It is found in relatively high concentrations in umbilical cord blood. Most of the B cells of umbilical cord blood have IgD on their surface, and most B cells in adults have both IgM and IgD on their surface. Plasma cells that produce IgD have been found in the tonsils and adenoids, although they are very rare in other lymphoid tissues. The function of IgD is unknown.

IgE IgE is present in trace amounts in the serum, constituting only 0.004% of the immunoglobulins. Plasma cells that produce IgE are found in the tonsils and adenoids and on the mucosa of the respiratory and GI tracts.

Distinct receptors for IgE are found on the surface of mast cells, B cells, T cells, macrophages, and eosinophils. IgE binds to its receptor on these cells by its Fc portion; heating the antibody destroys its cell-binding ability. Formerly referred to as reagin, IgE plays a primary role in immediate hypersensitivity—namely, the immune reaction in hay fever, extrinsic asthma, wheal-and-flare reactions, and anaphylaxis. IgE binds tightly to mast cells and basophils. When these IgE-coated cells interact with specific antigens, termed allergens, they release potent mediators of immediate hypersensitivity, including histamine, slow-reacting substance of anaphylaxis (SRS-A), and an eosinophilic chemotactic factor [*see 6:X Allergic Response*]. Levels of IgE are higher than normal in persons with atopic dermatitis, as are the levels of IgE antibody specific for allergens to which the individual is susceptible. In patients with allergies, specific IgE antibodies are detected by means of a radioimmunoassay called the radioallergosorbent test (RAST).

The exact function of IgE is unknown. Certainly, the manifestations of immediate hypersensitivity, such as hay fever and extrinsic asthma, do not appear to serve any useful purpose for the person affected or for the species in general. Therefore, the observation that IgE levels are sometimes elevated in persons living in the tropics, and especially in those afflicted with helminthic parasites, was greeted by immunologists as a possible indication that IgE plays a protective role against parasites. The mediators released could affect the parasite either directly or by producing an increase in vascular permeability and the release of eosinophilic chemotactic factor, which may lead to the accumulation of other necessary antibodies (e.g., IgG) and cells to attack the parasite. In this context, it is of interest that eosinophils can mediate IgG-dependent damage to schistosomula (the larval form of the parasite *Schistosoma mansoni*). In addition, parasite-specific IgE immune complexes can induce a macrophage-mediated cytotoxic response to schistosomulum organisms.

Antigenic Differences of Immunoglobulins

Immunoglobulins have three types of serologic, or antigenic, determinants: isotypic, allotypic, and idiotypic.

Isotypic determinants Isotypic determinants distinguish between the constant regions of the various classes and subclasses of heavy chains and light chains; they represent the different constant-region genes. For example, there are four IgG heavy-chain isotypes: γ_1, γ_2, γ_3, and γ_4, representing the subclasses IgG1, IgG2, IgG3, and IgG4, respectively. There is only one κ light-chain isotype and one λ light-chain isotype.

Allotypic determinants Allotypic determinants distinguish between immunoglobulins of a particular isotype; they represent different alleles of immunoglobulin genes and therefore are genetically determined according to mendelian laws in a man-

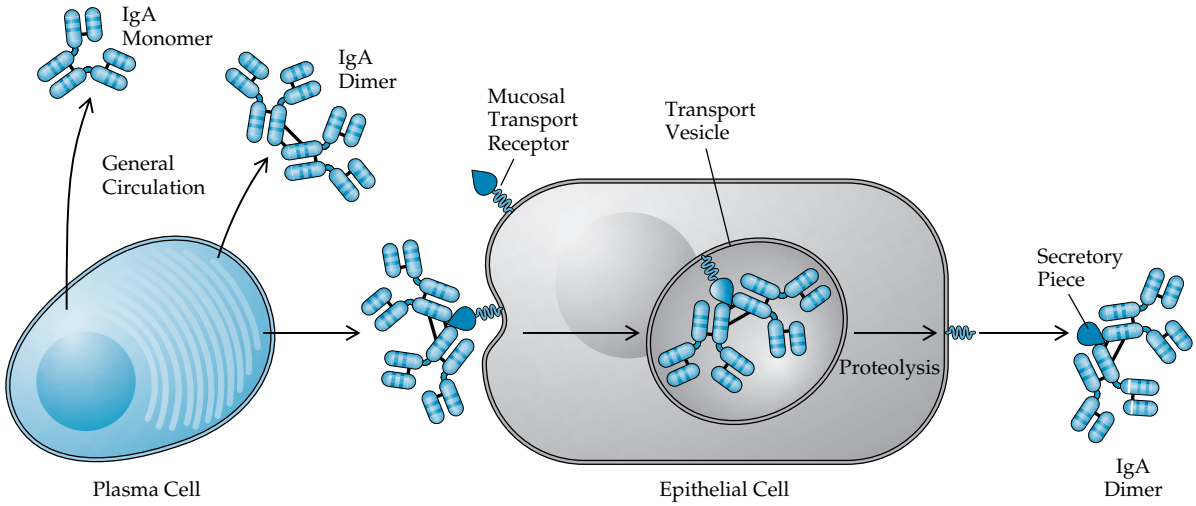

Figure 2 **Plasma cells secrete IgA molecules into the general circulation as either monomers or dimers. The circulating dimer can combine with a mucosal transport receptor on the surface of an epithelial cell. As the antibody-receptor complex is transported through the cell, the receptor is cleaved. The portion of the receptor that remains attached to the antibody dimer is called the secretory piece. The secretory piece is joined to the constant region of IgA by disulfide bonds. The mucosal transport receptor contains five immunoglobulin-like domains and is anchored in the membrane by a proteolytically labile segment.[18]**

ner similar to the way that the ABO blood groups are determined. The γ heavy chains have more than 20 different allotypic markers, which are collectively termed Gm. In addition, κ light chains contain a set of at least three allotypic markers, collectively called Km. There are no known allotypic markers for the μ, δ, and ε heavy chains or for the λ light chain.

Idiotypic determinants An idiotope is defined as a single antigenic determinant on the hypervariable region of an antibody. An idiotype is the antigenic character of the variable region of an antibody. Idiotypic determinants distinguish one immunoglobulin from another of the same allotype.

Genetic Source of Antibody Diversity

The carboxyl-terminal halves of all κ light chains have almost identical amino acid sequences; this portion of the molecule is therefore called the constant, or C, domain. The amino-terminal half has a variable sequence of amino acids and is known as the variable, or V, domain [*see Figure 1*]. The first 110 amino acids of the amino-terminal portion of the λ light chain and the heavy chain are also variable. The remaining 75% of the heavy chain is constant and contains three homologous regions.

Within the variable regions, three areas—referred to as the hypervariable, or complementarity-determining, regions—show great variation; these areas correspond to the antigen-binding site of the antibody. X-ray analysis has shown that immunoglobulin molecules are built up from compact globular units connected by short segments of more or less linear polypeptide chains [*see Figure 1*]. As expected, the hypervariable regions are located at the interface between immunoglobulin and antigen.

The most intriguing aspect of the genetic control of immunoglobulin synthesis is the diversity of the product: plasma cells can make antibodies that react with an indefinite number of different antigenic sites. How can DNA code for such a large number of antigens, many of which have only recently (on the evolutionary time scale) come into existence?

VDJ RECOMBINATION

In all cells, DNA for the κ light chain codes for more than 300 variable (V) regions, five joining (J) regions, and one constant (C) region. The V and J regions are separated from the C region by an intervening stretch of DNA. Thus, in the so-called germline configuration, DNA encodes the information for at least 1,500 different combinations of V and J regions; in other words, at least 1,500 different κ light chains are possible.

The emergence of individual plasma cell lines is the result of somatic recombination in the DNA and RNA splicing [*see Figure 3*]. As the pre–B cell differentiates into a plasma cell, rearrangements and deletions in the DNA bring one of the V genes, chosen at random, adjacent to one of the J genes. This V-J unit and the remaining J regions are separated from the C gene by a short length of DNA. In the next step, the DNA is transcribed to nuclear RNA, and the stage is set for a second event.

This event begins when an enzyme cleaves the nuclear RNA to produce messenger RNA (mRNA). In a process called RNA splicing, the segment that separates the V-J unit from the C region is removed, along with any superfluous J segments. The remaining V-J-C segment is now translated into one of the 1,500 κ light-chain proteins. Actually, the number of possible proteins is higher because the joining of any V region to a J region can involve one of a variety of base pairs at the recombination site.

Variability in the heavy chain makes an important contribution to the specificity of an antibody and also results from somatic recombination and RNA splicing. The germline configuration of the DNA carries instructions for several hundred different heavy-chain V genes, six J genes, 10 to 20 diversity (D) genes, and nine C genes (these C genes code for the heavy-chain classes: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE). DNA deletion, transcription to nuclear RNA, and RNA splicing produce the final V-D-J-C sequence in the mRNA that is translated by ribosomes to a heavy-chain protein. This assembly process produces more than 18,000 possible varieties of heavy-chain proteins (antibody specificity does not vary with class, so the nine C genes do not enter into the calculation).

The combination of more than 1,500 light-chain varieties with the 18,000 heavy-chain varieties yields more than 27 million different kinds of antibodies with different antigen-binding sites. In addition, somatic hypermutation occurs, particularly during affinity maturation, and the rate of somatic hypermutation is relatively high (one base pair per 1,000 cell divisions). Therefore, the potential number of specific antibodies in a single person is indefinite.

Although some of the mechanisms of V-D-J rearrangement are unique to B cells (and T cells, as synthesis of TCRs occurs by a similar mechanism [*see* T Cell Receptors, *below*]), the general mechanisms of DNA repair are also engaged.[2] Two genes involved in V-D-J rearrangement in B cells are the recombination-activating genes *rag1* and *rag2*.[3-5] Disruption of the *rag1* or *rag2* gene causes a block in B cell development before the transition from pro–B cell to pre–B cell, as found in patients with severe combined immunodeficiency syndrome or Omenn syndrome.[6] Disruption of the surface IgM gene, the J region of the heavy chain, or the J region of the κ light chain leads to a similar block in B cell development.

ALLELIC EXCLUSION

In an individual B cell, only one of the chromosomes undergoes complete V-D-J recombination leading to expression of heavy and light chains. A mechanism exists that prevents the other chromosome from being rearranged and therefore expressed in the same cell. This is called allelic exclusion. It prevents a B cell from expressing two entirely different immunoglobulins or BCRs. A similar mechanism operates during synthesis of TCRs in T cells [*see* T Cell Receptors, *below*].

Primary and Secondary Antibody Responses

When antigen is first introduced into the body, a primary response occurs that is characterized by a lag phase that lasts several days, during which no antibody is detected. Increasing amounts of IgM antibody appear in the serum, usually reaching a peak level after 7 days. After 6 to 7 days, IgG antibody is also detected. The IgM titer begins to wane before the maximal IgG titer is reached, about 10 to 14 days after the antigen is introduced. Antibody titers then decrease, and very little antibody is detected 4 to 5 weeks after a single dose of antigen.

If the antigen is encountered a second time, a secondary response (also called an anamnestic or booster response) occurs because of the existence of memory B cells. Both IgM and IgG titers rise exponentially, without the lag phase seen in the primary response. Whereas the peak IgM level during the secondary response may be the same as, or slightly higher than, the peak IgM level during the primary response, the IgG peak level dur-

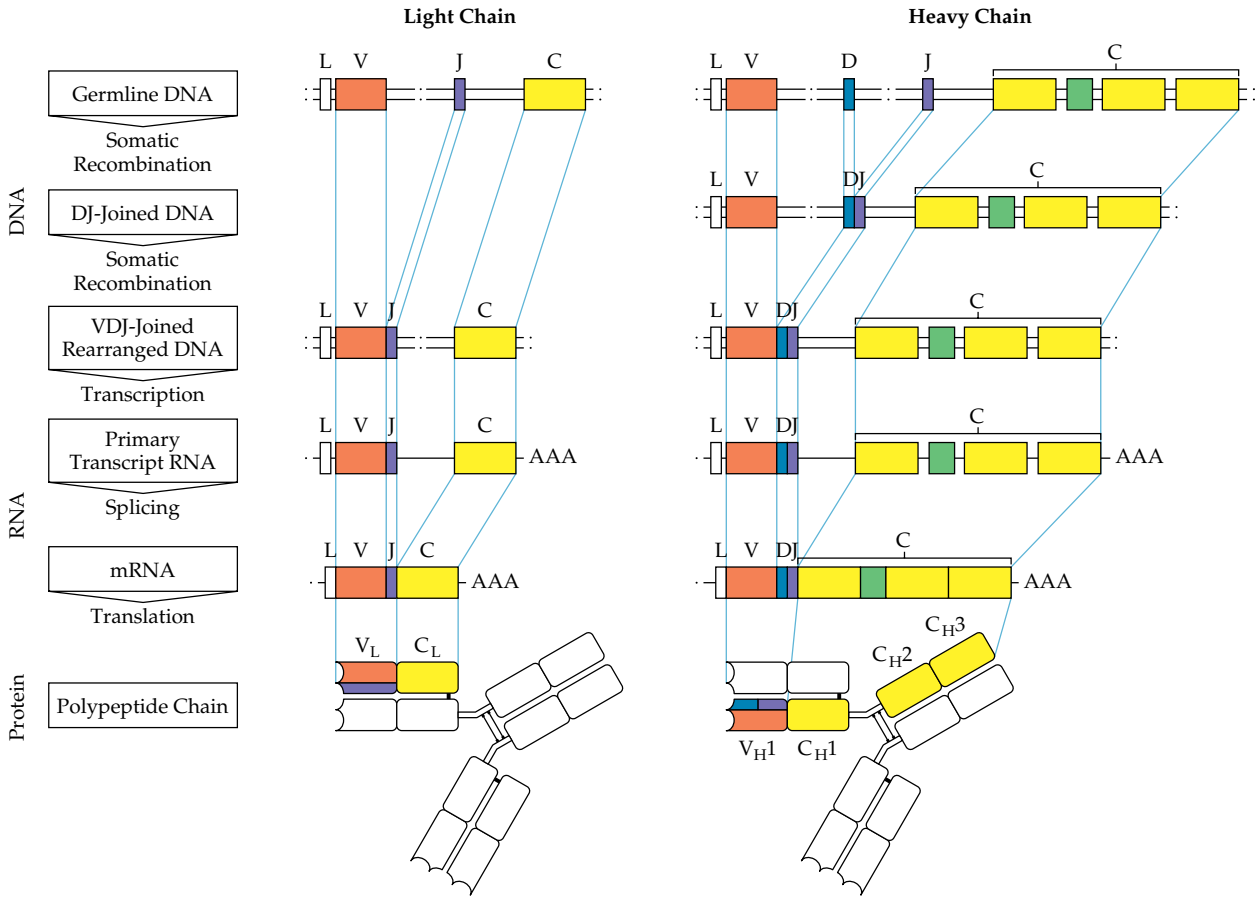

Figure 3 **Variable-region genes are constructed from gene segments. Light-chain variable genes are constructed from two segments (center panel). A variable (V) and a joining (J) gene segment in the genomic DNA are joined to form a complete light-chain variable-gene–region gene. The constant region is encoded in a separate exon and is joined to the variable-region gene by RNA splicing of the light-chain message to remove the L to V and the J to C introns. Immunoglobulin chains are extracellular proteins, and the V gene segment is preceded by an exon encoding a leader peptide (L), which directs the protein into the cell's secretory pathways and is then cleaved. Heavy-chain variable regions are constructed from three gene segments (right panel). First the diversity (D) and J gene segments join, then the V gene segment joins to the combined DJ sequence, all at the genomic DNA level. The heavy-chain constant-region sequences are encoded in several exons: note the separate exon encoding the hinge domain (purple). The constant-region exons together with the L sequence are spliced to the variable-domain sequence during processing of the heavy-chain gene RNA transcript. Posttranslational alterations remove the L sequence and attach carbohydrate moieties.[19]**

ing the secondary response is much greater and lasts longer than the peak level during the primary response. This variation in response is an apt illustration of immunologic memory and is caused by a proliferation of antigen-specific B cells and helper T cells during the primary response. The characteristics of the primary and secondary responses explain the need for booster injections in immunization programs.

AFFINITY MATURATION BY HYPERMUTATION

The binding properties of antibodies change with time by a process termed affinity maturation, which involves somatic hypermutation and selection. After the first stimulation, the antibodies have progressively greater affinity for the antigen as antigen exposure progresses, and increasingly stable antigen-antibody complexes are formed. In addition, the antibody becomes less specific, and cross-reactions with related antigens increase. The lessening specificity reflects the fact that cross-reactions were previously too weak to detect; they become apparent as antibody develops greater affinity for antigen.

IMMUNOGLOBULIN CLASS SWITCH RECOMBINATION

The genes that code for the IgM and IgD heavy chains (the μ and δ genes, respectively) play a critical role in the primary immune response. Whereas IgM antibodies are unable to act in many tissues of the human body, IgG, IgA, and IgE serve functions in the peripheral immune system. Class switching means that the same variable region can be transferred from the heavy chain of IgM to one of the other antibody heavy chains. In the switch from IgM to IgG production that constitutes the booster response, constant-region genes are deleted before the DNA is transcribed to RNA.[6,7] If the cell switches to production of IgG3, for example, the genes for μ and δ are deleted [*see Figure 4*]. After transcription, RNA splicing produces an mRNA with the sequence V-D-J-$C_{\gamma 3}$, which is translated into protein.

MECHANISMS INVOLVED IN SOMATIC HYPERMUTATION AND CLASS SWITCH RECOMBINATION

An exciting recent breakthrough explains the mechanism underlying both somatic hypermutation (SHM) and class switch

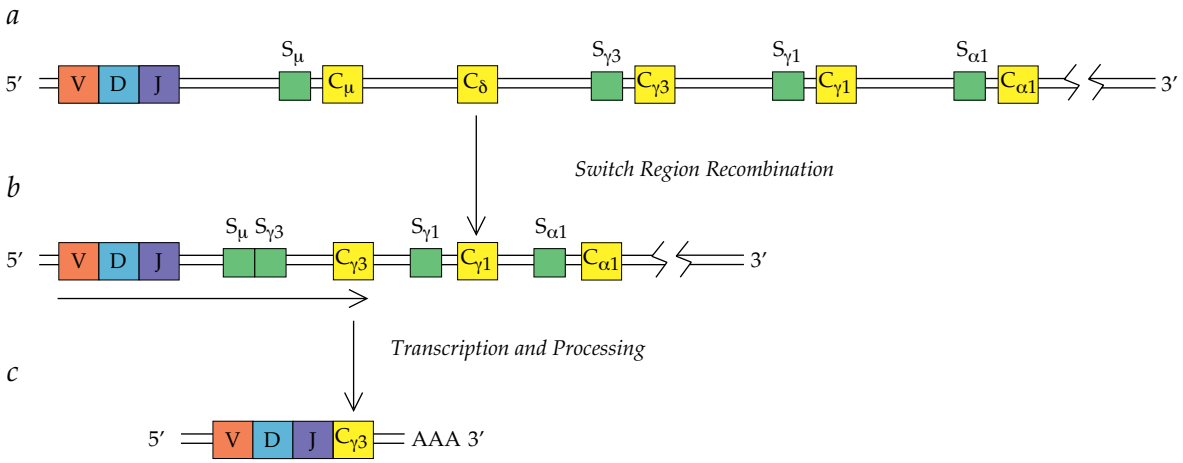

Figure 4 **In the booster response, a plasma cell switches from IgM production to IgG production, a process called class switching. In this hypothetical model of heavy-chain class switching to $C_{\gamma 3}$, the heavy-chain C-region exon clusters (yellow) and the switch regions (green) are indicated (*a*). The switch region is a stretch of DNA that directs the deletion events. In this model, recombination of the switch regions S_{μ} and $S_{\gamma 3}$ and the deletion of the intervening DNA occur first to produce a DNA sequence in which the gene for $C_{\gamma 3}$ has been brought into close proximity to the V-D-J segment (*b*). Further processing and transcription of this DNA yields the messenger RNA (mRNA) encoding IgG3 (*c*).**

recombination (CSR). This was the discovery of activation-induced cytosine deaminase (AID), an enzyme necessary for both processes. SHM and CSR occur only in the B cells in germinal centers of lymph nodes that have been stimulated by antigen. Further, AID is expressed only in antigen-stimulated B cells.

AID converts a cytosine to uracil in the variable region of the antibody gene. The cell regards this as an error, because uracil does not belong in DNA, and the correction process can introduce a variety of mutations. If a glycosylase removes the uracil, then during the subsequent replication or repair process, low-fidelity or error-prone DNA polymerase may fill in the gap with a different base or may fill it in and extend it by strand displacement. If a glycosylase does not remove the uracil, then in the subsequent replication process, a high-fidelity DNA polymerase may recognize the uracil as thymine and pair it with an adenine [*see Figure 5*].

Enhancers in the intron DNA also play a role in determining the location of the hypermutation. The AID enzyme plays a similar role in CSR, determining which heavy chain the VDJ will be switched to from the μ chain. The processes are not exactly parallel, however. For instance, SHM occurs in the G2 phase of the cell cycle and involves homologous recombination and a κ intronic enhancer element, whereas CSR occurs in the G1 phase and involves nonhomologous end joining and a 3′ immunoglobulin heavy (IgH) gene enhancer element. Thus, the same unique mechanism is employed in the development of two quite different properties of antibodies, with their high specificity and their function depending on SHM and CSR, respectively.

Immunoglobulin Receptors

B cell receptors

In addition to being secreted, immunoglobulins are also expressed on the surface of B cells, where they act as antigen receptors.[8] These cell surface membrane immunoglobulins (SmIgs) differ from secreted immunoglobulins in that they have a transmembrane domain and are monomeric. The first SmIg that a B cell expresses is IgM; at a later stage of B cell development, IgD is coexpressed. SmIgs do not travel to the cell surface by themselves; the process requires formation of a complex consisting of the immunoglobulin and two polypeptide chains called Igα and Igβ, which takes place in the endoplasmic reticulum [*see Figure 6a*]. Binding of the resultant BCR with antigen drives the B cell to maturation. Stimulation by the helper T cell activates the B cell, causing it to differentiate into a plasma or memory cell that produces secretory antibody specific for the antigen encountered. Igα and Igβ are not expressed after terminal differentiation. The mature plasma cell ceases to express SmIgs, although it may retain the SmIg mRNA.

BCRs play important roles in regulation of the immune response. B cell responses to antigen can become anergic, thus providing a control mechanism for B cell responses and antibody production. A precursor of the BCR expressed on the surface of pre–B cells is thought to control allelic exclusion. In addition, BCRs interplay with Fc receptors.

Fc receptors

Fc receptors bind the Fc portion of an immunoglobulin; they are expressed on a multitude of cells, including mast cells, macrophages, eosinophils, and tumor cells. Fc receptors are composed of a family of molecules. The Fc receptor for IgE (FcεRI) is the model for all Fc receptors and consists of three polypeptide chains, designated α, β, and γ. FcεRI mediates signal transduction in the mast cell when IgE binds to the receptor. FcεRIα is the binding site for the Fc portion of IgE. FcεRIβ is a transmembrane molecule that connects FcεRIα with FcεRIγ, the chain responsible for recruiting signal transduction molecules.[9,10] FcRIIβ1, another Fc receptor that is expressed on B cells, provides a negative feedback signal to the BCR, which leads to the termination of humoral immune responses.[11]

Engineered Antibodies

Lymphocyte hybridoma

The development of the lymphocyte hybridoma, a product of cell fusion, has had a revolutionary impact on immunology and clinical medicine. B lymphocyte hybridomas are the means by

which extraordinarily high titers of very specific, pure antibodies can be produced for experimental and clinical purposes. The B lymphocyte hybridoma, as developed by Köhler and Milstein,[12] is the product of the fusion of a mouse myeloma cell and a lymphocyte from the spleen of a mouse immunized with a specific antigen. The hybrids can be cloned and selected for specific antibody production.

HUMAN MONOCLONAL ANTIBODIES

Several methods of generating human monoclonal antibodies exist. One method entails taking the complementary DNA coding for a mouse monoclonal antibody and systematically replacing the mouse sequences with human sequences. Another method of humanizing mouse monoclonal antibodies entails making a transgenic mouse containing large segments of human DNA, including several variable regions and all the human constant regions.[13] Because this mouse still has its own immunoglobulin regions, it is bred with a mouse in which there has been a targeted disruption of the mouse J region of the immunoglobulin heavy-chain and κ light-chain genes. The progeny of this breeding can then be injected with any antigen, and they will produce humanized monoclonal antibodies to it. Because the transgenic mouse contains a limited number of human variable regions, the potency of these antibodies relies on the natural somatic mutation and affinity maturation that occurs in the mouse. A third method of generating human monoclonal antibodies entails constructing expression libraries of human variable regions either in bacteria or in bacteriophages. In theory, all the variable regions can be cloned. The antibody can be expressed on the surface of the bacterium or bacteriophage and selected by affinity to the antigen of interest.

Monoclonal antibodies are being used in many therapies. For instance, humanized monoclonal antibodies to tumor necrosis factor–α (TNF-α) have been used successfully in the treatment of Crohn disease and rheumatoid arthritis. In other applications, monoclonal antibodies are used to remove T cells and tumor cells before bone marrow transplantation and during acute transplant rejection. Other potential uses of monoclonal antibodies are the production of anti-IgE antibodies and anti–hormone receptors to prevent allergy and modulate endocrine abnormalities, respectively. A monoclonal anti-IgE, omalizumab, was recently approved by the FDA for treatment of allergic asthma.

T Cell Receptors

Unlike the immunoglobulin receptors on B cells, which recognize free antigens, TCRs recognize antigens only in conjunction with autologous MHC antigens, which are expressed on the surface of professional APCs (e.g., dendritic cells, macrophages, and B cells). The $CD4^+$ helper T cells (as well as the few $CD4^+$ cytotoxic T cells) require MHC class II molecules, and the $CD8^+$ cytotoxic T cells require MHC class I molecules [*see 6:V Adaptive Immunity: Histocompatibility Antigens and Immune Response Genes*]. This phenomenon is referred to as MHC restriction. The ability of T cells to recognize these self-MHC molecules is determined during development in the thymus before the lymphocytes are exposed to antigen [*see 6:I Organs and Cells of the Immune System*].

The molecules that make up the TCR have been identified, and the genes that encode these molecules have been isolated and cloned. The TCR is composed of six distinct polypeptides, known as the TCR-CD3 complex.[14-16] From 85% to 95% of normal peripheral blood lymphocytes carry TCR-αβ; only 5% to 15% carry TCR-γδ. The antigen-recognizing portion of the TCR-αβ complex consists of two glycosylated polypeptide chains, termed TCR-α and TCR-β, that are linked by disulfide bonds to form a heterodimer. The corresponding polypeptide chains in the TCR-γδ complex consist of TCR-γ and TCR-δ. The TCR-α, TCR-β, TCR-γ, and TCR-δ chains each contain variable and constant portions that are analogous to those of immunoglobulin molecules.

TCR-αβ and TCR-γδ heterodimers are closely associated with the CD3 proteins CD3γ, CD3δ, CD3ε, and CD3ζ [*see Figure 6b*]. The CD3 proteins are present on all peripheral blood T cells and on 90% of thymocytes. Expressions of the CD3 and the TCR complexes on the cell surface are mutually dependent: neither complex is observed on the surface of the T cell without the other. Structural and functional data suggest that the activities of the TCR are distributed among the subunits of the TCR-CD3 complex: the TCR polypeptides (α, β, γ, and δ) bind to antigen and

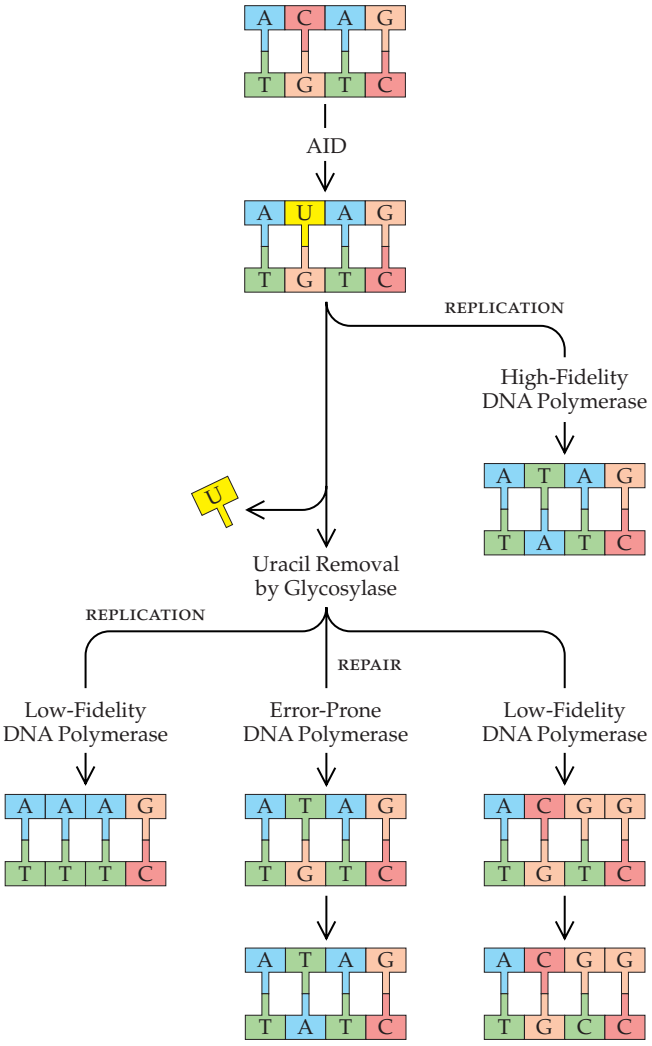

Figure 5 **Antibody diversity is promoted by the enzyme activation-induced cytosine deaminase (AID), which generates mutations by converting cytosine (C) to uracil (U) in the variable region of the antibody gene. During replication, high-fidelity DNA polymerase will recognize the uracil as a thymine (T) and pair it with an adenine (A). Alternatively, the uracil may be removed by a glycosylase. Subsequently, mutations may occur during replication, as a low-fidelity DNA polymerase fills the gap more or less at random, or during repair, as an error-prone DNA polymerase preferentially fills the gap with thymine or as a low-fidelity DNA polymerase fills in the gap and extends it by synthesizing bases by strand displacement, which mostly occurs opposite adenine and thymine.[20]**

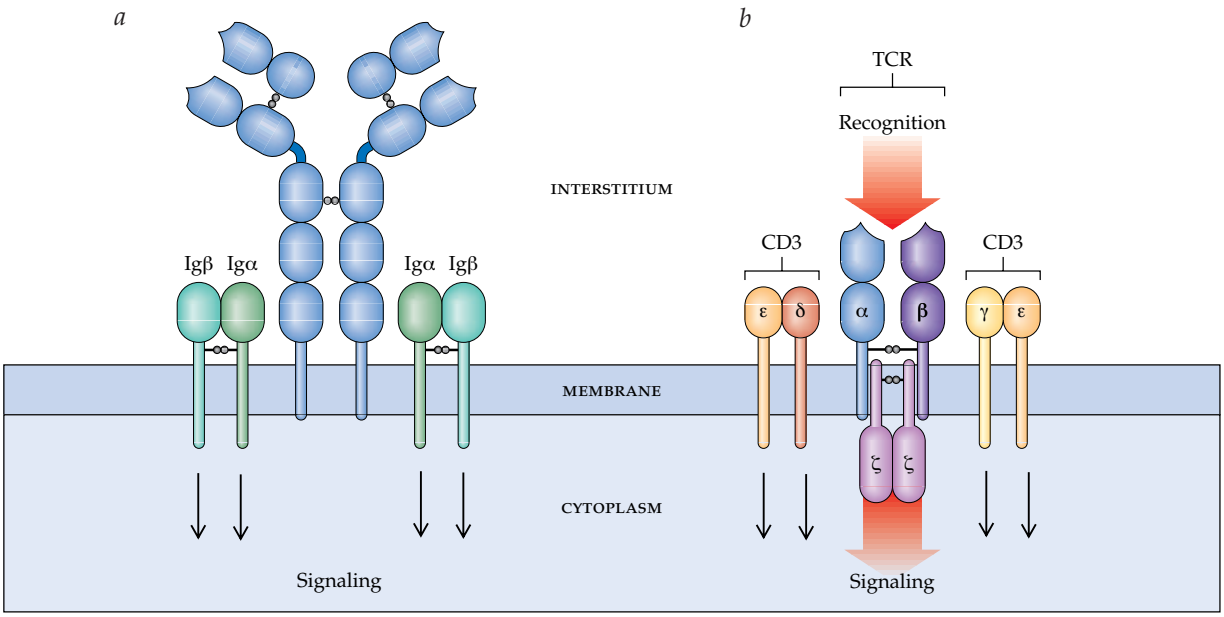

Figure 6 **(*a*) Cell surface membrane immunoglobulins form a complex with the proteins Igα and Igβ. Igα and Igβ are linked by disulfide bonds, but the exact stoichiometry is unknown. The exact ratio of these two proteins to each immunoglobulin molecule is also unknown. (*b*) The TCR-CD3 complex is shown. A T cell receptor for antigens is composed of six distinct polypeptide chains. Two of the chains, α and β, are the disulfide-bonded chains of the heterodimer TCR that binds to antigen. The four other chains—γ, δ, and two ε chains—are collectively called CD3. CD3 associates with TCR and transports it to the T cell surface. When antigen binds to the TCR, CD3, along with a homodimer of ζ chains, sends a signal to the nucleus, via intracellular signaling pathways. Specific genes are then transcribed, and cytokines, chemokines, and other immunodulatory molecules are produced that mediate the antigen-specific immune response.**

MHC gene products, and the CD3 proteins transduce the binding signal to the cytoplasm of the T cell, which results in activation of T cell functions.

By the use of mice containing spontaneous and engineered mutations of various genes of TCRs, the development pathway of the T cell has been confirmed. The organization of the genes that encode the human TCR-α, -β, -γ, and -δ chains is analogous to that of the immunoglobulin heavy-chain genes: there are V, D, and J segments, which are flanked by recognition sequences that mediate site-specific recombination [*see* Antibodies, *above*]. Thus, the diversity of TCRs is generated by many of the same mechanisms that are used by B cells for the production of immunoglobulins. T cells and B cells may in fact use the same recombination enzyme, or recombinase.

The genomic sequences that encode the TCR-β chain contain two very similar constant-region genes, $C\beta_1$ and $C\beta_2$, each of which is associated with a cluster of six or seven J genes and a single D gene. There are at least 70 Vβ genes that are associated with the two Cβ genes. These variable regions are distinct from the immunoglobulin variable regions. Rearrangement of the β-chain gene segments can lead to the production of approximately 3,600 different β chains.

The TCR-α genes are arranged differently. A single Cα gene is preceded by a very large stretch of DNA containing at least 50 distinct J genes. A Dα gene segment has not been demonstrated directly. Some Vα genes are organized as families of related genes. Rearrangement of the α-chain gene segments can account for approximately 2,500 different polypeptides. No somatic hypermutation has been detected in TCRs. Thus, 10^7 TCR-αβs can be formed. The genes for CD3γ, CD3δ, CD3ε, and CD3ζ are transcribed in all T cells; however, these genes do not undergo rearrangement.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

IV CELL-CELL INTERACTIONS, CYTOKINES, AND CHEMOKINES IN IMMUNE RESPONSE MECHANISMS

John R. David, m.d.
Cox Terhorst, ph.d.

The immune response is defined by three principles: discrimination between self and nonself, specificity, and memory [*see 6:I Organs and Cells of the Immune System*]. This chapter will discuss the manifestation of those principles through antigen processing and presentation, the T cell response to antigen, interactions between T cells and B cells, and the actions of cytokines and chemokines. The cellular and humoral mechanisms of innate immunity are described in detail elsewhere [*see 6:II Innate Immunity*].

Two principal arenas of the immune response are sites of pathogenic invasion and the lymph nodes that drain these sites. The immune response begins with exposure of epithelial cells, macrophages, and dendritic cells to a pathogen. In the lymph nodes, these cells (antigen-processing cells [APCs]) concentrate and process antigens and present them to T and B cells.

The critical first step of the T cell immune response to a specific antigen is the recognition and binding of processed antigen on the surface of an APC with a T cell receptor (TCR) on the surface of a helper ($CD4^+$) T cell [*see 6:I Organs and Cells of the Immune System*]. This event is relayed to the helper T cell nucleus by a cascade of cytoplasmic signaling molecules. In the nucleus, activation of specific transcription factors stimulates expression of the genes that encode soluble factors—cytokines and chemokines—that mediate the immune response. This response has two aspects: humoral and cell mediated. In the humoral response, cytokines secreted by a specific form of activated T cells induce antigen-stimulated B cells to differentiate into antibody-secreting plasma cells. In the cell-mediated response, cytokines from $CD4^+$ T cells induce $CD8^+$ T cells to differentiate into cytolytic effectors and also can activate macrophages, another effector cell. B cells recognize nonprocessed antigens in solution or antigens that are attached to the surface of follicular dendritic cells—a cell type that is particularly adept at antigen processing, presentation, and retention. Both T cells and B cells are induced to expand their population and control the initial infection and to produce memory cells for long-term acquired immunity.

Antigen Processing and Presentation

THE MAJOR HISTOCOMPATIBILITY COMPLEX

The major histocompatibility complex (MHC) is a membrane glycoprotein complex that binds antigenic peptide in the cytoplasm of an APC and transports it to the cell surface for interaction with T cells.[1] An extensive polymorphism exists in the MHC gene (i.e., there are many alleles per locus); however, each person expresses only a small number of different MHC molecules. To ensure an adequate immune response against a wide range of nonself antigens, each MHC molecule must be able to bind a large number of different peptides.

Two main classes of MHC have been identified. The two classes of molecules have a similar structure: two immunoglobulin-like domains and a binding site for processed antigens (peptides) [*see 6:V Adaptive Immunity: Histocompatibility Antigens and Immune Response Genes*]. Whereas MHC class I molecules bind only smaller peptides of defined lengths (eight to 11 amino acids), MHC class II molecules bind longer peptides with no apparent restriction on peptide length. An interesting finding is that certain peptides bind only to specific alleles of either MHC class I or MHC class II molecules. Thus, persons who lack one of those alleles would not develop an immune response to its associated peptide.

The differences in peptide binding between MHC class I and MHC class II molecules result from small structural dissimilarities within the relatively fixed framework of the peptide-binding site and probably also from fundamental differences in the mechanism of peptide processing, which takes place in the endoplasmic reticulum (ER) for MHC class I molecules and in the endosomes and lysosomes for MHC class II molecules.

The MHC Class I Pathway

Antigen processing with MHC class I molecules essentially entails three steps: (1) generation of antigenic peptides in the cytosol of the APC, (2) transport of the peptides into the ER, and (3) assembly of the peptide–MHC class I complexes. The completed complexes then migrate through the Golgi apparatus to the cell surface and insert in the plasma membrane for presentation on the extracellular surface [*see Figure 1a*].

The MHC Class II Pathway

Assembly of antigenic peptide–MHC class II molecule complexes in the APC requires four steps: (1) uptake of exogenous antigens by vesicles (endosomes, lysosomes, and, possibly, undefined endosomal subcompartments), (2) proteolytic degradation of proteins in the endosome, (3) assembly of MHC class II molecules in the ER and migration of these molecules through the Golgi apparatus to the endosomes, and (4) assembly of the peptide–MHC class II complexes in the late endosome. After the peptides are bound to MHC class II molecules, the endosome containing these complexes migrates to the cell surface and inserts in the plasma membrane [*see Figure 1b*]. Of note is that partially unfolded antigenic proteins can bind to MHC class II molecules before undergoing proteolytic degradation. This may explain why the length of peptides bound to MHC class II molecules is highly variable.

ALTERNATIVE ANTIGEN-PRESENTING COMPLEXES

A third class of MHC includes CD1 molecules, which are related to MHC class I molecules but which bind lipid and glycolipid antigens for presentation to T cells. For example, CD1

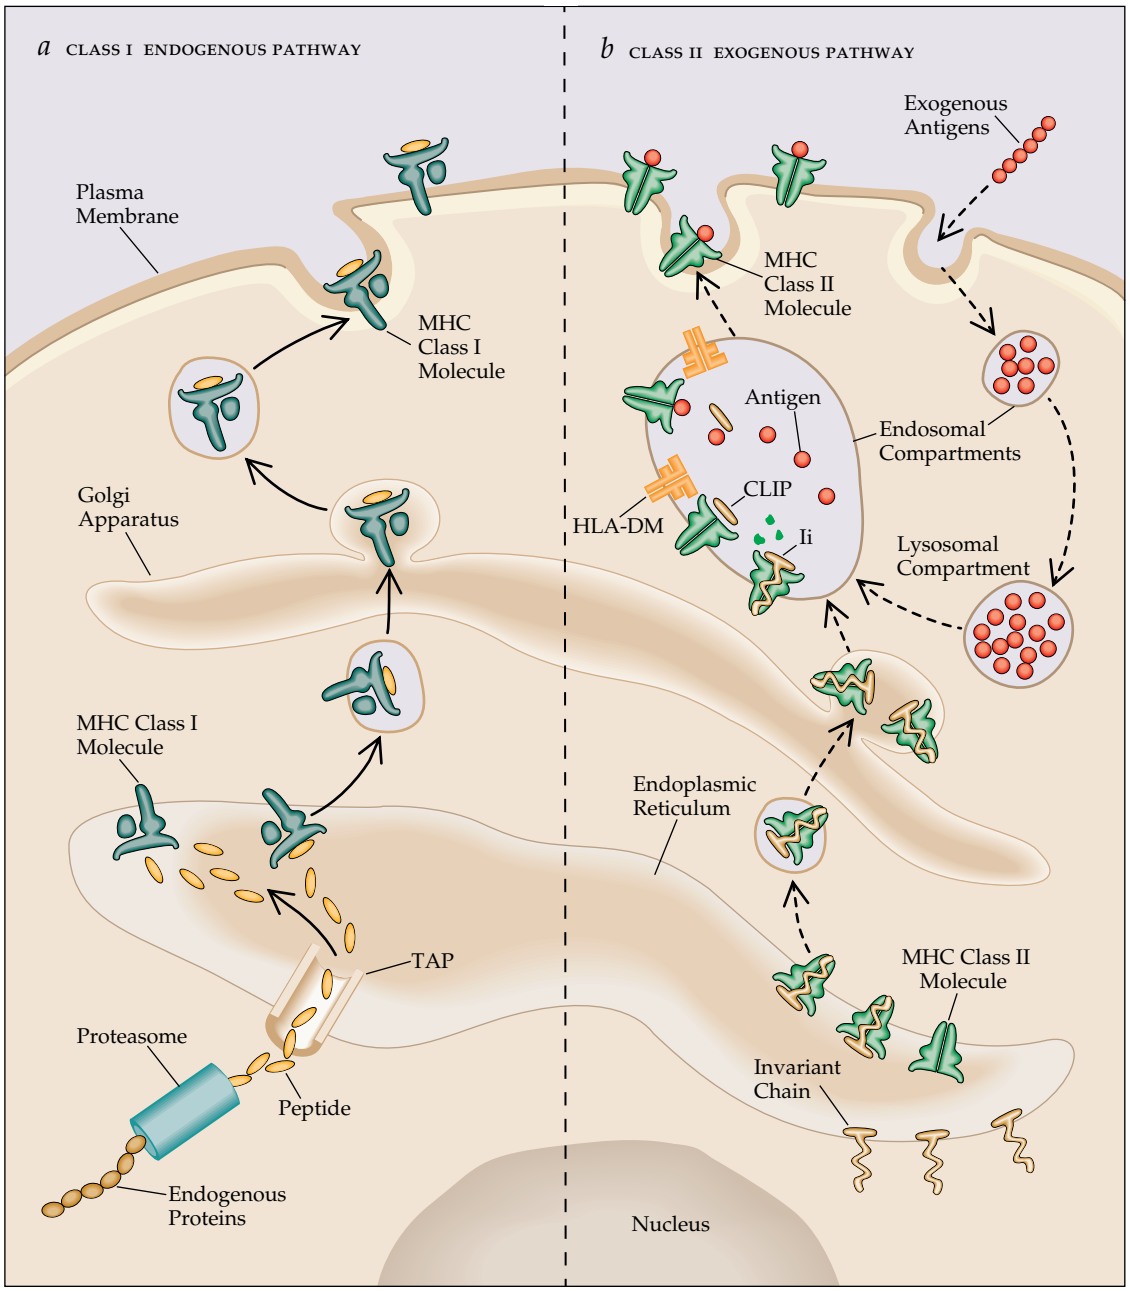

Figure 1 **The pathways for formation of antigenic peptide–MHC molecule complexes on antigen-presenting cells. (*a*) In the MHC class I molecule pathway, endogenous proteins are broken down by proteasomes into smaller peptides. In the endoplasmic reticulum (ER), an antigenic peptide binds to the peptide binding site in an MHC class I molecule. The peptide-MHC complex then migrates through the Golgi apparatus to the cell surface. (*b*) In the MHC class II molecule pathway, the α and β subunits of the MHC class II molecule bind to the invariant chain (Ii) in the ER. Ii is partially degraded in an endosomal compartment. The portion of Ii that occupies the antigenic peptide binding site on the MHC class II molecule (called CLIP) is removed with the help of HLA-DM, freeing the molecule for binding processed antigen. Once antigenic peptide has bound to an MHC class II molecule, the complex migrates to the cell surface.**

molecules present glycolipids from *Mycobacterium tuberculosis* to a restricted group of T cells.[2] This ability to recognize non-protein microbial antigens suggests that T cells recognize a broader range of antigens than was once thought. A subset of $CD1^+$ T cells often reacts to self-antigens; these cells have been implicated in such autoimmune diseases as type 1 diabetes mellitus and systemic lupus erythematosus. It has been suggested that they are involved at the early innate phase of these immune responses.[3] Another molecule related to MHC class I, MR1, is found on a subset of T cells that are preferentially located in the gut lamina propria and are called mucosal-associated invariant T (MAIT) cells. MAIT cells are probably involved in the host response at the site of pathogen entry and may regulate intestinal B cell activity. MAIT cells are absent in humans and mice that have B cell deficiency, which suggests that the selection or expansion of this cell population requires B cells.[4]

Superantigens

Superantigens constitute a class of immunostimulatory proteins derived from microbial agents (e.g., viral proteins and the staphylococcal toxins that cause toxic-shock syndrome and food poisoning). Superantigens bind to MHC class II molecules outside the conventional antigen-binding site and stimulate massive T cell activation[5] [*see 7:XXX Sepsis*]. Different MHC class II alleles have distinct binding constants for superantigens; thus, superantigens can activate distinct segments of the T cell repertoire.

PROFESSIONAL ANTIGEN-PRESENTING CELLS

Whereas MHC class I molecules are expressed on the surface of all eukaryotic cells, MHC class II molecules have a restricted tissue distribution. In fact, certain cells—including B cells, dendritic cells, macrophages, Langerhans cells, and endothelial cells—are termed professional APCs because they present antigenic peptide with MHC class II molecules more efficiently than other APCs.[6] This efficiency is primarily attributed to their ability to process endocytosed antigens. Professional APCs also interact with T cells more efficiently because they have several cell surface markers that bind to costimulatory molecules on the surface of T cells (see below). The most potent APCs are dendritic cells, which present antigen only on maturation and migration to the lymph nodes. This maturation process is triggered by the uptake of antigen.

T Cell Responses to Antigen

T cell recognition of antigen proceeds in two distinct stages. The first step, which is nonspecific, is the adhesion of a T cell to an APC. The second step, which is specific, is an interaction between the TCR and a compatible antigen-MHC complex on the APC. This process highlights two fundamental properties of T cells: their broad scope of action (i.e., their ability to migrate throughout the body and adhere to many types of cells) and their great specificity for particular antigens.

The diversity of the variable regions in TCRs facilitates highly specific responses to antigens [*see 6:III Adaptive Immunity: Antigens, Antibodies, and T Cell and B Cell Receptors*]. The prototypical T cells, αβ T cells, have a TCR made up of α and β chains, which are expressed in association with CD3. A subset of peripheral T cells, γδ T cells—so called because their TCR is made up of γ and δ chains—may recognize antigen that has not been processed.

APCs process many peptide antigens simultaneously and thus express on their cell surfaces a large number of different antigen-MHC complexes. A given αβ T cell clone can recognize only a small number of these complexes. T cells screen APCs for compatible antigen-MHC complexes by adhering to the APC. Adhesion is aborted if the TCRs do not recognize specific antigen; adhesion is intensified when a TCR makes contact with a compatible antigen-MHC complex. On adhesion, TCR-CD3 complexes aggregate on the surface of the T cell and bind to the antigen-MHC complexes that have aggregated on the surface of the APC. In the absence of antigen recognition, TCR-CD3 complexes are unable to cluster and detachment occurs immediately.

Interactions between a helper T cell clone and an APC or between a cytotoxic T cell and its target cell follow the same general pattern. Initially, only a very small number of antigen-MHC complexes engage with specific TCRs in an area of cell-cell contact established by adhesion. Subsequently, TCR-CD3 complexes and MHC molecules bearing the correct antigenic peptide migrate into the contact region. This establishes a high local density of TCRs, which promotes antigen binding and T cell activation. The existence of these clustered TCRs has been demonstrated experimentally, through the use of tagged monoclonal antibodies.[7] In addition, visualization of clusters of TCRs using fluorescence-tagged antigen-MHC complexes has permitted incisive studies of T cell responses to infections with Epstein-Barr virus or HIV.[8,9]

COSTIMULATORY MOLECULES

The recognition of antigen by the TCR and subsequent activation of the T cell is regulated by other T cell surface molecules [*see Figure 2 and Table 1*].[10] Costimulatory molecules are involved in both adhesion and T cell signaling and play a major role in the coordination and kinetic regulation of T cell activation. Clinically, these costimulatory molecules are important because aberrant activation of the TCR can initiate disastrous immune responses, such as those seen in autoimmune diseases.

The costimulatory molecules CD28 and cytotoxic T cell–associated antigen 4 (CTLA-4) initiate a signaling pathway that is different from, and often independent of, the pathway mediated by the TCR-CD3 complex. CD28 is expressed on the surface of essentially all $CD4^+$ and most $CD8^+$ T cells. CD28 binds to B7 on APCs, leading to T cell activation and proliferation. Although CTLA-4 is homologous to CD28, it has opposite effects: binding of CTLA-4 to B7 delivers an inhibitory signal that leads to downregulation of T cell proliferation. Of note is that research entailing manipulation of CD28–CTLA-4 interactions with their natural ligands suggests that these costimulatory molecules have a potential role in the treatment of such diseases as arthritis, multiple sclerosis, and asthma and in protection against HIV infection.[11] For example, a soluble construct of CTLA-4 (called CTLA-4–Ig) is able to inhibit T cell activation when administered early in the immune response. Several new members of the B7 and CD28–CTLA-4 families have recently been discovered, and these may also be important for regulating the responses of previously activated T cells.[12]

The SLAM (signaling lymphocyte activation molecule) family of receptors serves as costimulatory molecules on T cells (and other immune cells). In T cells and natural killer (NK) cells, SLAM-associated protein (SAP) regulates signaling of the SLAM family of receptors. The *SAP* (or *SH2D1A*) gene is defective or absent in patients with X-linked lymphoproliferative syndrome.[13,14]

Fas (also called APO-1 and CD95) has been implicated in both positive and negative signaling events after binding with its ligand (CD95L) on cytolytic effector cells. Fas is a member of the tumor necrosis factor receptor (TNFR) family, and binding of Fas on T cells with its ligand typically causes the programmed death of the target cell (i.e., apoptosis; see below). However, Fas can also function as a costimulatory molecule for TCR-CD3 activation. Thus, a single molecule can have different signaling outcomes at different stages of T cell development.

T Cell Signaling after Antigen Recognition

In response to antigen recognition, resting T cells undergo a complex series of events known as T cell activation.[15,16] The recognition and binding of TCRs to antigen-MHC complexes and of costimulatory molecules to their appropriate ligands—

all of which takes place on the cell surface—is followed by an intracellular cascade of biochemical events (i.e., signal transduction) that ultimately reaches specific genes in the nucleus. The resulting production of cytokines, chemokines, and other immunomodulatory molecules leads to cell proliferation, differentiation, and expression of unique effector functions.

Most of the biochemical events that occur immediately after engagement of the TCR with the antigen-MHC complex have been defined [*see Figure 3*]. Transduction of signals starts with the CD3 elements of the TCR-CD3 complex and proceeds to the nucleus via different pathways. One pathway involves the calcium-dependent enzyme calcineurin; other coupled pathways involve the enzymes Ras and Rac and serine-threonine kinase. These pathways converge on the activation of transcription factors that control the expression of genes mediating T cell effector function (e.g., the gene for the cytokine interleukin-2 [IL-2]) [*see Figure 3*]. Thus, the exquisitely T cell clone–specific TCR connects, via a number of intermediate molecules, with universal signal transduction pathways.

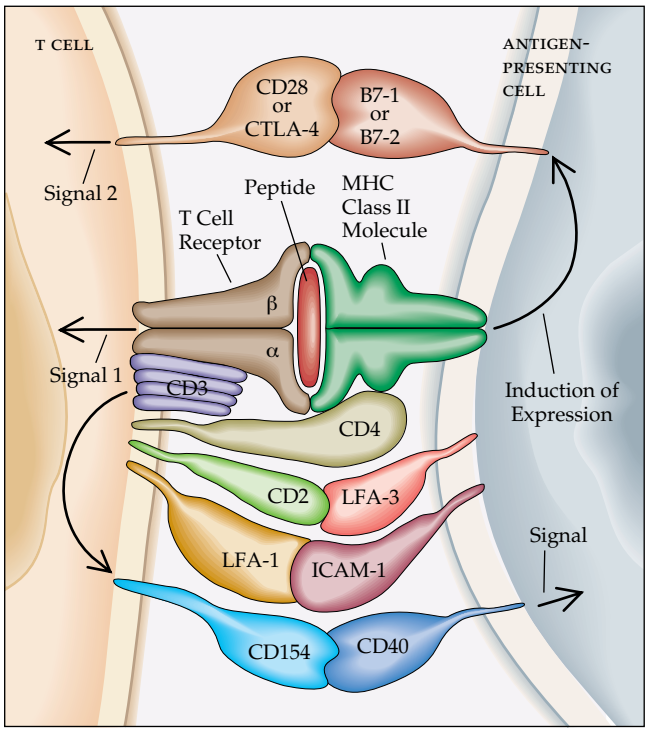
Drugs are being developed to interfere with nodal points of these signal transduction pathways. However, cyclosporine, which interferes with the calcineurin pathway, remains the most successful agent of this type.

B Cell Responses to Antigen

When a B cell receptor (BCR) binds soluble antigen, one of two events takes place: apoptosis or proliferation and further maturation of B cells. The signals for these processes are generated intracellularly by Igα and Igβ. These proteins are associated with BCRs in the way that CD3 proteins are associated with TCRs. Igα and Igβ recruit signal transduction molecules in a manner similar to that for activating T cells and involving some of the same proteins.

Relatively little is known about the signaling that takes place in B cells when they have presented an antigen to a helper T cell that recognizes that antigen. T cell–B cell interaction can also lead to either apoptosis or proliferation of B cells. With T cell help, however, proliferation results in the generation of several different classes of B cells.

a



b

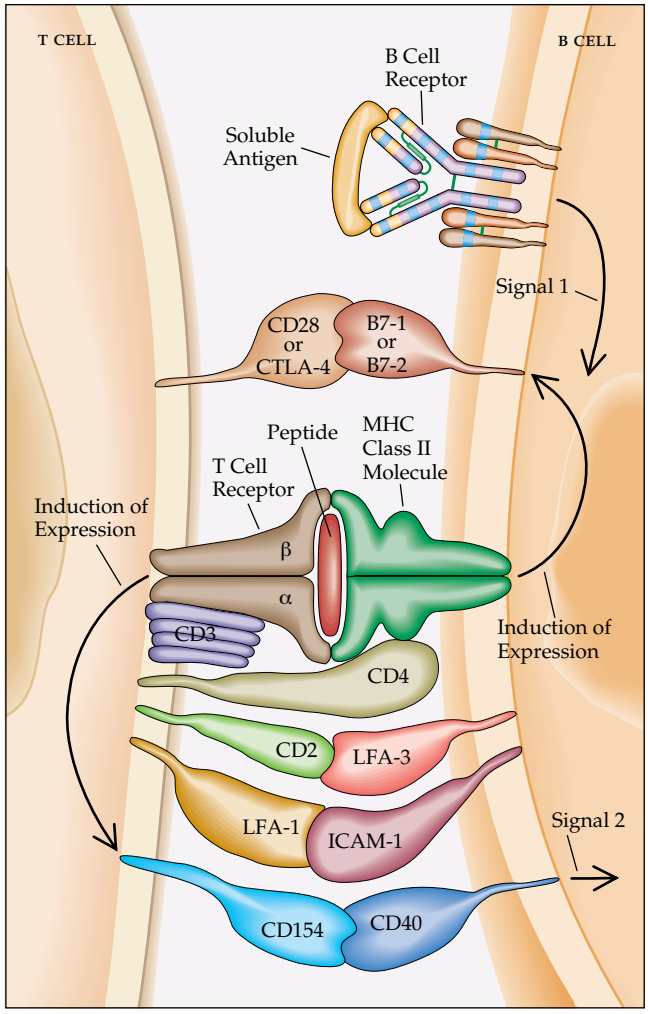


Figure 2 **(*a*) Two signals are necessary for activation of an antigen-specific T cell by an antigen-presenting cell (APC). Signal 1 is initiated by the interaction between the antigen bound to a class II major histocompatibility complex (MHC) and the T cell receptor (TCR) and its coreceptor (in this example, CD4). The costimulatory molecules B7-1 and B7-2 are transiently expressed on the surface of so-called professional APCs and are presumed to be inducible by signaling from the antigen-MHC complex. Thus, signal 2 is initiated by the binding of CD28 on the T cell to B7-1 or B7-2. CTLA-4, which is homologous to CD28, is upregulated after T cell activation. (*b*) Activation of B cells can occur with either helper T cells or soluble antigen. Binding of soluble antigen to the B cell receptor, a cell surface immunoglobulin associated with Igα and Igβ, can lead to B cell proliferation or apoptosis. Alternatively, B cells can process antigen for presentation to TCRs on T cells. Binding of antigen-MHC complex to the TCR induces expression of the CD40 ligand (CD154) on the T cell surface, which in turn induces expression of CD40 on the B cell surface. This results in B cell proliferation and is indispensable for immunoglobulin class switching and probably for somatic mutation. CD154 signaling also plays an important role in the maturation of dendritic cells. (ICAM-1—intercellular adhesion molecule–1; LFA—leukocyte-function–associated antigen)**

B CELL SUBSETS

Follicular Mantle Cells

Follicular mantle cells derive their name from their location, surrounding the active germinal centers in lymph nodes. These cells express IgD but not CD38 on their surface (i.e., they are $IgD^+,CD38^-$) and can mature into plasma cells that produce IgM antibodies only. These cells produce IgM antibodies that display extensive heterogeneity, but the cells do not undergo somatic mutation to generate larger numbers of heterogeneous antibody molecules.

Centrocytes

Centrocytes are found in the germinal center of lymph nodes. The process leading to somatic mutation occurs in the centrocytes, which are $IgD^-,CD38^+$ B cells that have undergone class switching to produce IgG. The maturation step from $IgD^+,CD38^-$ B cells to $IgD^-,CD38^+$ B cells depends on cell-cell contact with antigen-specific T cells and cytokines. IL-4 in particular is of great importance for the events that lead to class switching.

Memory B Cells

The most mature B cell, the memory cell, does not express IgD or CD38 but is distinguished by the presence of other cell surface markers and by its location within the germinal center of lymph nodes. Memory cells can also develop into plasma cells producing IgM, IgG, IgA, and IgE. In general, the generation of plasma cells from memory B cells is independent of T cell help.

T Cell–B Cell Interactions

An important pathway for B cell activation involves CD40, a B cell surface receptor belonging to the TNFR family. The natural ligand for CD40, CD40L (also called CD154), is a glycoprotein related to TNF. Transient CD40L expression on the surface of T cells is induced by the binding of TCR to antigen-MHC complex and by binding of B7 to CD28 or CTLA-4. The binding of CD40 to CD40L stimulates B cell immunoglobulin class switching. This was best demonstrated by elucidation of the molecular defect in a genetic immunodeficiency termed hyper-IgM syndrome [*see 6:VIII Deficiencies in Immunoglobulins and Cell-Mediated Immunity*]. Patients with the X-linked form of this syndrome have a mutation in the gene encoding CD40L that results in defective antibody class switching. T cell–independent B cell responses and responses induced by anti-CD40 are unaffected by this mutation. Thus, T cell help for B cell activation is primarily directed through the CD40-CD40L costimulatory pathway. The observation that persons with hyper-IgM syndrome are susceptible to opportunistic infections such as those seen in AIDS—that is, infections from pathogens normally dealt with by T cells—underscores the role of CD40L costimulation in normal T cell activation. Absence of CD40L has a more dramatic effect on immunoglobulin class switching than does an absence of T cells. Thus, it seems that CD40L may be expressed on cells other than T cells that could induce immunoglobulin class switching in B cells through the ligation of CD40.

Cytokines

CYTOKINES AND T CELL SUBSETS

Cytokines, a diverse group of proteins produced by a number of different cell types, are critical in the regulation of immune responses [*see Table 2*]. They are also important in the differentiation of cell systems. In general, cytokines are synthesized in response to stimulation of cells. In some cases, the active cytokine is released from an inactive precursor by proteolysis. Occasionally, cytokines are stored in cells.

After secretion, cytokines usually act locally by binding to receptors on cell surfaces. Cytokines may act on many different cells, and different cytokines may have similar activities. Cytokine receptors are often composed of the same protein chains. For instance, the cytokine receptors IL-2R, IL-4R, IL-7R, IL-9R, IL-13R, and IL-15R have the γ chain in common. Most cytokines form a network that regulates the activation of cells and the production of other cytokines.[17] The binding of cytokines to receptors on cell surfaces activates intracellular signaling mech-

Table 1 Costimulatory Molecules on T Cells

Molecule	*Ligand*	*Function*
CD4	MHC molecules on the surface of APCs	Helps generate $CD4^+$ T cells in the thymus; directly influences TCR-initiated signaling
CD8	MHC molecules on the surface of APCs	Helps generate $CD8^+$ T cells in the thymus; directly influences TCR-initiated signaling
CD2	CD58 on the surface of APCs	Promotes T cell activation and proliferation
CD11/CD18	ICAM-1 (CD54), the complement component iC3b, extracellular matrix proteins	Promotes T cell activation and proliferation
CD28	B7-1 (CD80), B7-2 (CD86) on the surface of APCs	Promotes T cell activation and proliferation
CTLA-4	B7-1 (CD80), B7-2 (CD86) on the surface of APCs	Inhibits T cell activation and proliferation
SLAM*	SLAM receptors on the surface of APCs	Promotes activation and proliferation of T cells and other immune cells
CD27	CD70 on activated T and B cells	T cell proliferation
Fas (APO-1; CD95)	CD95L on cytolytic effector cells	Causes apoptosis or promotes TCR-CD3 activation

*Also found on natural killer cells.
APC—antigen-presenting cell CTLA-4—cytotoxic T lymphocyte–associated antigen–4 ICAM-1—intercellular adhesion molecule–1 SLAM—signaling lymphocyte activation molecule TCR—T cell receptor

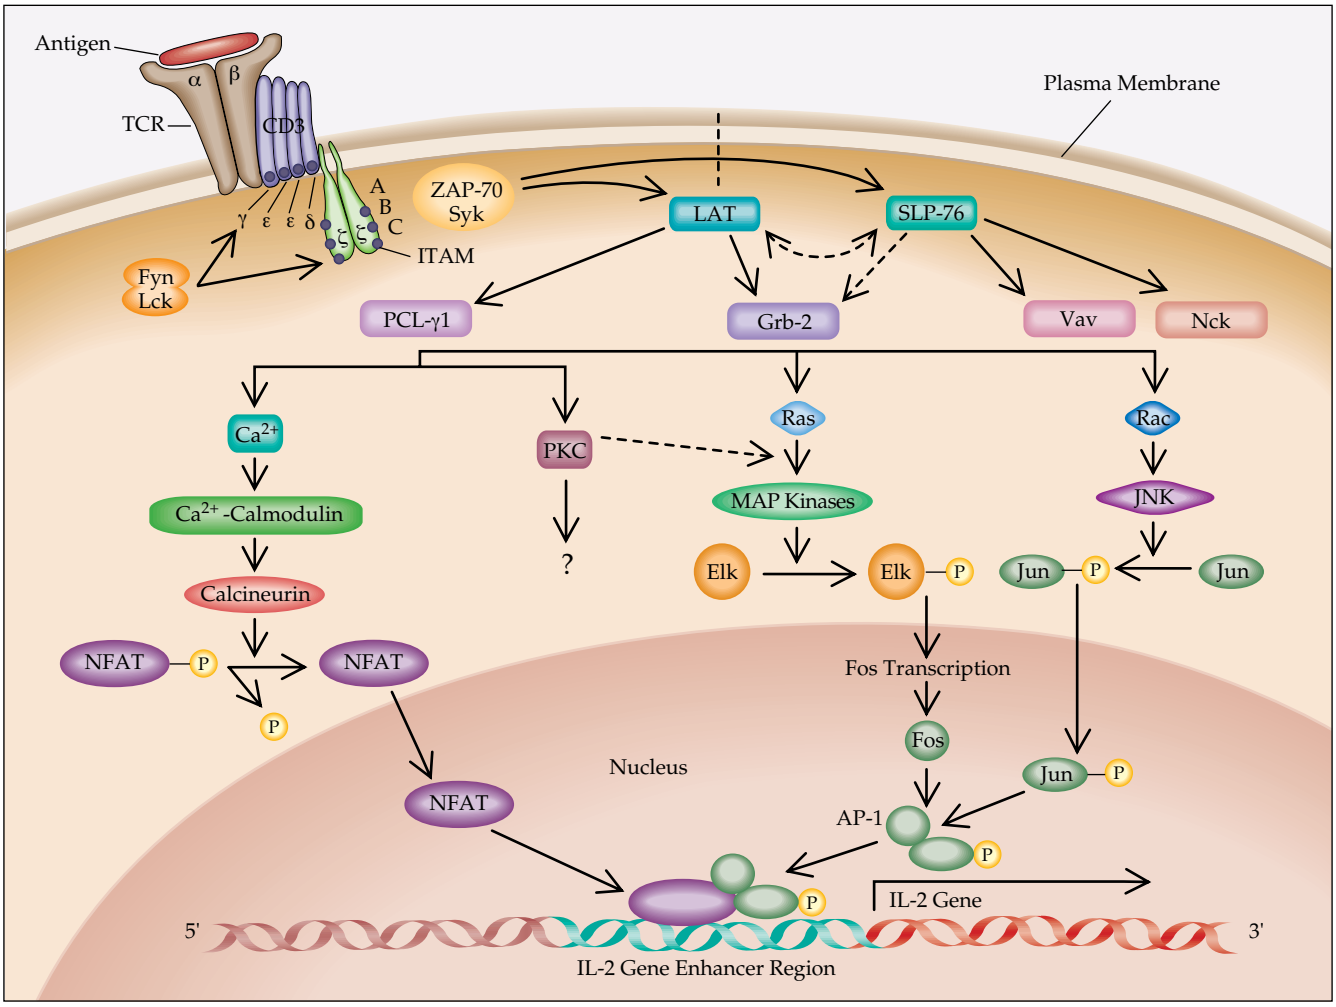

Figure 3 **The downstream signaling pathways induced after TCR stimulation are shown. Phosphorylation of the cytoplasmic tails of the CD3-γ, CD3-δ, CD3-ε, and CD3-ξ by the Src kinase Fyn or Lck recruits the kinase Syk or ZAP-70, which relays the signal of TCR binding through tyrosine phosphorylation of two adapter proteins, LAT and SLP-76. Nck is an adapter protein associated with SLP-76. These adapter proteins act on components of classic signal transduction pathways, including phospholipase C-γ1 (PLC-γ1), growth factor receptor–bound protein–2 (Grb-2, a protein-linking receptor tyrosine kinase), the p85 subunit of phosphatidylinositol-3–kinase (PI-3 kinase), and possibly Vav (a guanosine triphosphate/guanosine diphosphate [GTP/GDP] exchange factor for Rho-family GTPases, including Ras and Rac). Activation of PLC-γ causes the release of diacylglycerol, which in turn activates protein kinase C (PKC). PKC is involved in initiating the cascade of other serine-threonine kinases, including Raf-1, mitogen-activated protein (MAP) kinase, and MAP kinase kinase (MEK). The central signal transduction molecule Ras appears to be involved in late events after PKC activation. The Ras and Rac pathways and the serine-threonine kinase pathways are coupled; they activate early genes, such as *jun* and *fos*. The Ca^{2+} generated by PLC-γ1 activates another downstream cascade, the calcineurin pathway. Calcineurin, a serine-threonine phosphatase, is a calcium- and calmodulin-dependent enzyme involved in induction of transcription factor NFAT (nuclear factor for activated T cells). PI-3 kinase is a ubiquitous enzyme in the mitogenic signaling and apoptotic pathways of both receptor and nonreceptor protein tyrosine kinases. These various signaling pathways converge by delivering a distinct set of transcription factors, including Jun, Elk, NFAT, Fos, and AP-1 (all DNA-binding proteins), to the promoter region of the *IL-2* gene, stimulating expression of the gene and production of IL-2.**

anisms, which lead to expression of particular genes (e.g., genes for the bound cytokine, or other cytokines). The principal intracellular cytokine signal transducers are two families of transcription factors: Jak (Janus kinase) protein tyrosine kinases and STAT (signal transducers and activators of transcription).

Helper T cells

Cytokines play a major role in T cell development and regulation. Indeed, the two helper T cell subsets, Th1 and Th2, are defined by the cytokines they produce [*see 6:X Allergic Response*]. Th1 and Th2 cells play key roles in determining the balance between host resistance and immunopathology.[18] Th1 responses can help eradicate infectious agents, but a Th1-dominated response that is poorly effective or too prolonged can result in host damage. Th2 responses are primarily involved in allergic reactions, antibody production, and antibody class switching. They can limit potentially harmful Th1-mediated responses and may be part of the suppressor mechanism for exaggerated or inappropriate Th1 responses.[19]

Each of the two helper T cell subsets inhibits the development and function of the other. Interferon gamma (IFN-γ) produced by Th1 cells inhibits the development and function of

Table 2 Selected Cytokines

Cytokine	*Sources*	*Principal Functions*	*Comments*
Interferon-γ (IFN-γ)	T cells, NK cells	Primary macrophage-activating factor (MAF)	Used to treat chronic granulomatous disease, drug-resistant leishmaniasis
Interleukin-1	Monocytes, macrophages, other cells	MAF, endogenous pyrogen	IL-1 inhibitors counteract rheumatoid arthritis and other inflammatory processes
Interleukin-2	Th1 cells	Activation of lymphocytes, NK cells; MAF	Used in cancer therapy
Interleukin-4	Th1 cells, other cells	Activation of lymphocytes, monocytes; B cell class switching	—
Interleukin-5	Th2 cells, activated mast cells	Eosinophil recruitment and activation	—
Interleukin-6	Th1 cells, macrophages	Activates T cells and macrophages, promotes inflammation	—
Interleukin-8	T cells, macrophages	Activates neutrophils	—
Interleukin-10	T cells, B cells, macrophages, activated mast cells, keratinocytes	Suppresses lymphocyte responses by downregulating macrophage cytokines	—
Interleukin-12	Macrophages	Stimulates development of Th1 cells, stimulates production of IFN-γ by Th1 and NK cells	Possible use as vaccine adjuvant
Interleukin-18	Macrophages	Stimulates production of IFN-γ	—
Lymphotoxin	Th1 cells	Lyses tumor cells, activates neutrophils, increases vascular adhesion and extravasation of leukocytes	—
Migration inhibitory factor	Macrophages, T cells	Counterregulates glucocorticoid action	—
Transforming growth factor–β	Platelets, lymphocytes, activated macrophages, placenta cells, others	Anti-inflammatory; inhibits activation of macrophages and maturation of cytotoxic T cells	—
Tumor necrosis factor–α	Macrophages, activated T cells, NK cells, mast cells	Enhances protective inflammatory response	Antibodies to TNF-α are used in the treatment of Crohn disease and rheumatoid arthritis

NK—natural killer Th1—type 1 helper T cells Th2—type 2 helper T cells

Th2 cells, whereas IL-4 and IL-10 produced by Th2 cells inhibit the development and function of Th1 cells. IL-4 acts partly by downregulating the expression of the IL-12 receptor, IL-12Rβ, which is upregulated by IFN-γ [*see Figure 4*]. IL-12 enhances cell function because it is a potent growth factor for NK cells, which also produce IFN-γ. Presumably, the reason Th1 and Th2 cells inhibit each other is that both subsets also induce inflammation, which must be regulated [*see* Inflammatory Cytokines *and* Anti-inflammatory Cytokines, *below*].

Certain microorganisms may affect the relative balance of Th1 and Th2. For example, the parasite *Schistosoma* drives a strong Th2 immune response. A carbohydrate found on the surface of *Schistosoma,* lacto-*N*-fucopentaose-III (LNFP-III), induces expansion of B_1 cells and secretion of large amounts of IL-10. Acting through macrophages, IL-10 both blocks development of Th1 cells and favors Th2 responses.[20,21] A related carbohydrate, lacto-*N*-neotetraose (LNnT)—which is found on other helminths, *Helicobacter pylori*, *Neisseria meningitidis,* and other microorganisms—has a mode of action similar to that of LNFP-III.[22] LNFP-III is also found on the surface of cancer cells, and LNnT is found in human milk, which suggests that in these circumstances, as well, the two carbohydrates are being used to shut off the host's protective cell-mediated immune response. Logically, such carbohydrates may have therapeutic value for the inhibition of Th1-initiated autoimmune diseases.

MEMORY T CELLS

On reexposure to an antigen, memory cells mediate a faster and stronger immune response than naive T cells. Memory cells secrete a full range of cytokines and may show the same selection of cytokines as Th1 and Th2 cells.[10] The requirements for proliferation and cytokine production in memory cells are not as strict as those for production in naive T cells, but optimum responses require costimulation.[23] Memory T cells selectively migrate (home) to specific nonlymphoid tissues such as gut, skin, and lung. Those that home to the gut have specialized integrins (adhesion molecules) on their surface that mediate this migration [*see 6:I Organs and Cells of the Immune System*]. In the absence of antigenic stimulation, memory cells appear to persist as nondividing cells. A reencounter with an antigen can expand the population to a stable, higher level; competition from another antigen can decrease the population.[23]

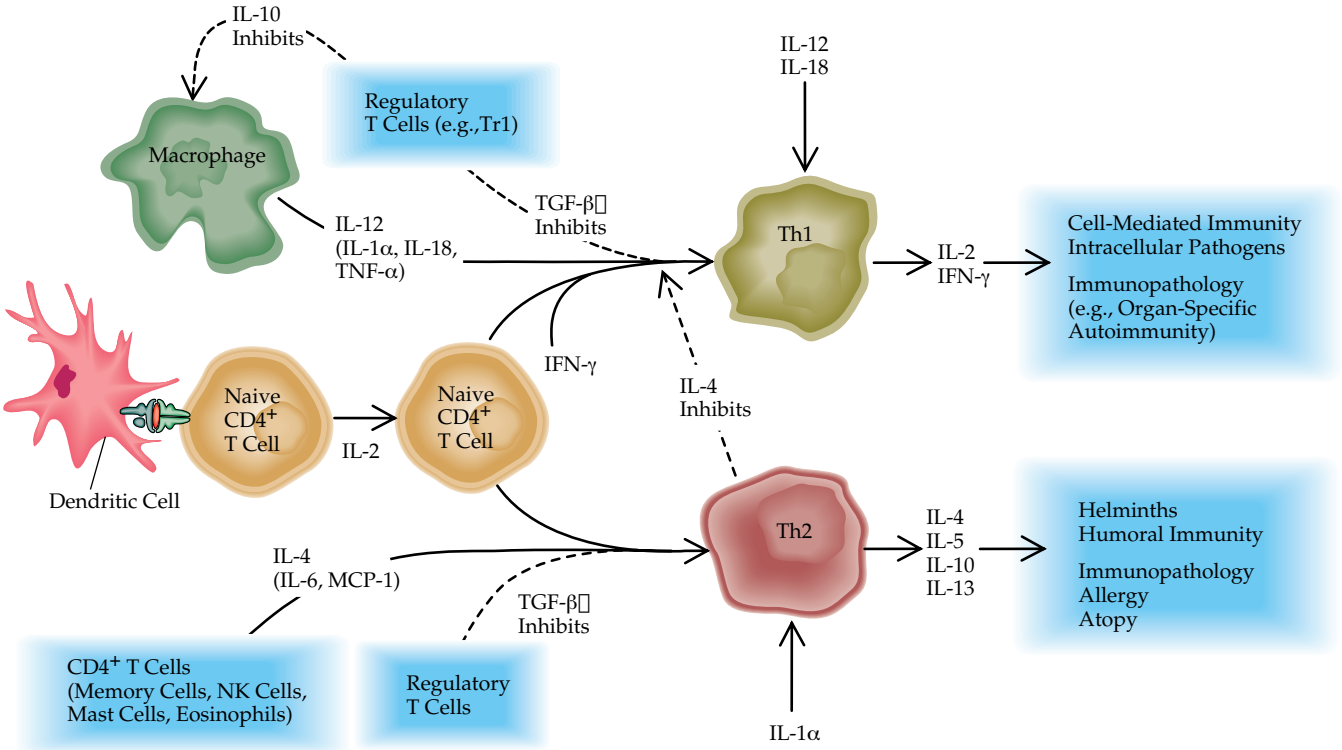

Figure 4 **Regulation of helper T cell responses. In response to IL-12 and cofactors such as IL-18 and IL-1a, naive $CD4^+$ T cells can develop into type 1 helper T (Th1) cells responsible for cell-mediated immunity; differentiation is dependent on interferon gamma (IFN-γ). Th1 cells produce IFN-γ and IL-2. Th1 responses are directly antagonized by IL-4 and indirectly by IL-10, as it inhibits production of IL-12 and IL-18 by macrophages. Th2 cells, which are responsible for inducing antibody production by B cells and allergic responses, depend on IL-4 for differentiation from naive $CD4^+$ T cells. Th2 cells produce IL-4, IL-5, IL-10, and IL-13. TGF-β can inhibit both Th1 and Th2 development. (MCP—monocyte chemoattractant protein; TGF—transforming growth factor)**

REGULATORY T CELLS

Natural regulatory T (Treg) cells are a population of T cells that primarily regulate responses to self antigens by other T cells and, therefore, contribute to the maintenance of self-tolerance. For example, removal of certain Treg cells from the periphery of normal mice leads to spontaneous development of various autoimmune and inflammatory diseases (e.g., autoimmune thyroiditis, gastritis, type 1 diabetes mellitus, and inflammatory bowel disease). Treg cells function via secreted or membrane-bound transforming growth factor–β (TGF-β) and by secretion of IL-10.[24]

Most Treg cells are $CD4^+$ and constitutively express CD25 on their surface. $CD4^+$,$CD25^+$ T cells are produced by the normal thymus as a functionally mature T cell subpopulation with a broad T cell repertoire; they can recognize both self and nonself antigens.[25] The *Foxp*-3 gene serves as a marker of this natural regulatory population. However, induction of Treg cells also takes place in the periphery (adaptive Treg cells).[26] Chronic activation of human $CD4^+$ T cells in the presence of IL-10 gives rise to a subset of antigen-specific $CD4^+$ T cell clones with low proliferative capacity that produce high levels of IL-10, low levels of IL-2, and no IL-4. These T cells, called type 1 regulatory T (Tr1) cells, suppress the proliferation of $CD4^+$ T cells in response to antigen, which suppresses antigen-specific immune responses and actively downregulates a pathologic immune response.[27]

INFLAMMATORY CYTOKINES

Interleukin-12 and Interleukin-18

IL-12 is a critical cytokine that stimulates the differentiation of naive helper T cells into Th1 cells, and it stimulates NK cells and Th1 cells to produce IFN-γ. IL-12 also enhances the cytolytic function of cytolytic T cells and NK cells. IL-12 is produced by activated macrophages and dendritic cells, in response to a variety of microorganisms. It has been used experimentally as an adjuvant in vaccines aimed at stimulating Th1-induced cellular immunity. As with most cytokines, binding of IL-12 with its receptor generates signaling through the Jak and STAT pathways.

IL-18, which is produced by macrophages, also stimulates the production of IFN-γ but appears to be less necessary than IL-12; whereas IL-12–deficient mice are susceptible to *Leishmania major* infection, IL-18–deficient mice combat such infection normally, although their initial immune response is slow.[28] Similarly, IL-12 is critical for immunity to cytomegalovirus, whereas IL-18 is not.[29]

Tumor Necrosis Factor–α

TNF-α, a major inflammatory cytokine, is one of the most abundant substances produced by macrophages after stimulation with IFN-γ, migration inhibitory factor (MIF), or bacterial lipopolysaccharide (LPS). TNF-α is also produced by activated T cells, NK cells, and mast cells.

At low concentrations, TNF-α enhances the protective inflammatory response, activating and enhancing the function of various leukocytes, including neutrophils, macrophages, and eosinophils. This can further stimulate macrophages to produce cytokines, including TNF-α itself, IL-1, IL-6, MIF, and a variety of chemotactic cytokines [*see* Chemokines, *below*]. TNF-α enhances expression of MHC class I molecules, potentiates cytotoxic T cell–induced cell lysis, functions as an endogenous pyrogen (i.e., induces fever, by direct and indirect actions on the brain), activates the clotting system and the production of acute-phase proteins by the liver, and can cause immunodeficiency through suppression of the bone marrow. When present for prolonged periods, TNF-α causes cachexia.

TNF-α plays a primary role in the host response to gram-negative bacteria. The LPS of these bacteria causes the release of MIF, which in turn enhances TNF-α production by macrophages. At low concentrations of LPS, TNF-α mediates a protective response. At high concentrations of LPS, however, TNF-α mediates disseminated intravascular coagulation—part of what is known as the Shwartzman reaction—and can cause death from shock.

Protective immunity to certain intracellular organisms, such as *Leishmania,* is enhanced by TNF-α, and TNF-α also has potent antiviral activity. However, many of the symptoms of malaria, especially of cerebral malaria, and some symptoms of HIV infection may be mediated by TNF-α. Antibodies to TNF-α have been approved for the treatment of Crohn disease and rheumatoid arthritis [*see 4:IV Inflammatory Bowel Diseases and 15:II Rheumatoid Arthritis*].[30]

Lymphotoxin

Produced exclusively by Th1 cells, lymphotoxin has many of the same biologic properties as TNF-α and utilizes the same cell receptor as TNF-α; it is also referred to as TNF-β. Like TNF-α, lymphotoxin lyses tumor cells but not normal cells, activates neutrophils, and increases vascular adhesion and extravasation of leukocytes. In addition, lymphotoxin plays a role in the development of lymphoid tissue.

Interleukin-1 and Interleukin-6

IL-1 is produced mainly by monocytes and macrophages but also by other cells, such as epithelial and endothelial cells. It is an endogenous pyrogen, and many of its functions are similar to those of TNF-α. It induces the production of additional IL-1 and of IL-6 from macrophages and induces glucocorticoid synthesis and the release of prostaglandin, collagenase, and acute-phase proteins. IL-1 increases the expression of surface molecules on endothelial cells, leading to adhesion of leukocytes and coagulation, and stimulates the production of macrophage chemokines that in turn activate neutrophils. IL-1 differs from TNF-α in that it does not produce necrosis of tumors or tissue injury, increase expression of MHC, or, by itself, mediate the Shwartzman reaction.

Macrophages produce an IL-1 receptor antagonist (IL-1ra) that, along with the IL-1 receptors shed from activated cells, inhibits IL-1 and thus acts as a regulator. Such natural inhibitors to IL-1 are now in clinical use to counteract certain inflammatory processes, especially in rheumatoid arthritis.

IL-6 is induced by IL-1 and by TNF-α from macrophages and, in turn, inhibits macrophage production of IL-1 and TNF-α. Like IL-1 and TNF-α, IL-6 is an endogenous pyrogen. IL-6 acts on hepatic cells to produce acute-phase proteins, such as fibrinogen, α_2-macroglobulin, and serum amyloid A protein. This cytokine can also inhibit macrophage activation.

Interferon Gamma and Other Macrophage-Activating Factors

IFN-γ, produced by T cells and NK cells, is the primary macrophage-activating factor (MAF). MAFs play an important role in cell-mediated immunity because activated macrophages produce many cytokines and chemokines intimately involved in inflammation, including TNF-α, IL-1, IL-6, and MIF. Other MAFs include granulocyte-macrophage colony-stimulating factor (GM-CSF) and MIF. IL-1 and TNF-α have weak MAF activity. IL-12 stimulates NK cells to produce greater amounts of IFN-γ, enhancing IFN-γ–dependent reactions. Both on its own and by enhancing the effects of TNF-α, IFN-γ causes the expression of adhesion molecules on the surface of vascular endothelial cells, leading to T cell adhesion and extravasation.

The inflammatory effects of IFN-γ are countered by TGF-β and IL-10, which inhibit macrophage activation. IFN-γ has been used successfully to treat chronic granulomatous disease and drug-resistant visceral leishmaniasis.[31]

Migration Inhibitory Factor

MIF, the first T cell cytokine to be discovered, derives its name from the fact that it inhibits the random migration of macrophages in vitro. MIF acts as an endogenous hormone that counterregulates glucocorticoid action.[32] Macrophages and T cells release MIF in response to glucocorticoids and other inflammatory stimuli. MIF then overrides the immunosuppressive effects of steroids on macrophage and T cell cytokine production.[32,33]

The gene for MIF is expressed in many different tissues.[34] Large quantities of the gene are found in macrophages and pituitary cells. Indeed, LPS stimulates the release of MIF by the pituitary. When given to mice, MIF greatly enhances the lethality of LPS; conversely, anti-MIF antibodies completely reverse the lethality of LPS.[35] MIF upregulates the receptor for LPS on macrophages (Toll-like receptor 4). Recombinant MIF activates macrophages to kill *Leishmania* and stimulates macrophages to produce TNF-α and nitric oxide. Mice lacking the gene for MIF show enhanced resistance to the lethal effects of high doses of LPS and *Staphylococcus aureus* enterotoxin B, as well as to *Pseudomonas aeruginosa* and *Escherichia coli*, but they are susceptible to *Leishmania, Salmonella,* and *Cysticercosis*.[36-39] MIF has been shown to play a pathogenic role in several experimental models of inflammation and autoimmunity, including glomerulonephritis, arthritis, inflammatory bowel disease, atherogenesis, and acute lung injury; it also inhibits p53 and enhances carcinogenesis. Mechanisms of MIF action include the activation of the extracellular signal-regulated kinase–1 and –2 (ERK-1 and -2), leading to activation of phospholipase A_2, cyclooxygenase-2, and prostaglandin E_2; enhancement of Toll-like receptor–4; and inhibition of p53 and apoptosis.

Anti-MIF therapies are under development. The goal is to increase the immunosuppressive and anti-inflammatory properties of endogenously released glucocorticoids, thereby reducing the need for steroid therapy in a variety of autoimmune and inflammatory conditions.[32] Anti-MIF therapy should also have a role in treating some gram-negative infections and preventing septic shock.

Interleukin-5

IL-5 mainly affects eosinophil recruitment and activation. IL-5 is produced by Th2 cells and activated mast cells and stimulates the growth and differentiation of eosinophils. In addition to IL-5, other substances involved in the activation of eosino-

phils are TNF-α and an eosinophil cytotoxicity–enhancing factor derived from monocytes. Activated eosinophils produce tissue damage in allergic states and kill helminthic parasites.

Other Interleukins

DNA sequence information from the Human Genome Project has led to the identification of a number of new cytokines: IL-19 through IL-24. Their role in the immune response needs further exploration. Several of these cytokines appear to have some properties similar to those of IL-10, IL-12, and IL-15. Hematopoietic cytokines and growth factors are discussed elsewhere [*see V:I Approach to Hematologic Disorders*].

ANTI-INFLAMMATORY CYTOKINES

Interleukin-4 and Interleukin-13

IL-4 stimulates the expression of an adhesion molecule on endothelial cells, leading to the binding of eosinophils, lymphocytes, neutrophils, and monocytes and their subsequent extravasation. However, IL-4 also acts as an anti-inflammatory cytokine, inhibiting activated macrophages and diminishing the production of TNF-α and nitric oxide. IL-13 has the ability to take over some of the functions of IL-4. Both IL-4 and IL-13 induce IgE synthesis in B cells and differentiation of T cells to Th2 cells and can suppress inflammatory processes induced by Th1 cells. These cytokines also act on macrophages to suppress the inflammatory response. Activated mast cells and basophils produce additional IL-4. Of interest is that mutated IL-4 can inhibit IgE synthesis by IL-4 and IL-13 and may prove useful in treating some allergic states.

Transforming Growth Factor–β

TGF-β is produced by a variety of cells, including platelets, lymphocytes, activated macrophages, and placenta cells. It is an important anti-inflammatory cytokine because it inhibits the activation of macrophages and the maturation of cytotoxic T cells and thus controls the effects of many cytokines.

Interleukin-10

IL-10 is an important regulatory cytokine. It is produced by $CD4^+$ and $CD8^+$ T cells, B cells, macrophages, activated mast cells, and keratinocytes. Although usually associated with activity of Th2 cells, IL-10 can also be produced by Th1 cells. IL-10 suppresses lymphocyte responses by downregulating macrophage cytokines—including IL-1, TNF-α, IL-6, IL-8, GM-CSF, and granulocyte colony-stimulating factor (G-CSF)—and inhibiting nitric oxide production.

Chemokines

Chemokines are a superfamily of low-molecular-weight chemotactic cytokines that mediate the directional migration of leukocytes during normal and inflammatory processes.[40] They play an important role in attracting granulocytes into sites of inflammation. There are four distinct families of chemokines, distinguished on the basis of the position of their first two conserved cysteine residues: CXC (the first two cysteines are separated by one amino acid), CC, C, and CX3C. The receptors for chemokines are all integral membrane G-protein–coupled receptors, which constitute one of the largest classes of signaling molecules.

CXC chemokines predominantly activate neutrophils.[41] This family includes IL-8; β-thromboglobulin (β-TG); the growth-related gene products gro-α, gro-β, and gro-γ; and platelet factor 4. They are usually produced by monocytes, but some are produced by other cells, including T cells, endothelial cells, and platelets. IL-8 induces expression of neutrophil-binding integrins on endothelial cells, resulting in the rapid accumulation of neutrophils in tissues. The chemokine gro also stimulates neutrophil accumulation, as well as the release of lysosomal enzymes that contribute to the local inflammatory response. Platelet factor 4 and β-TG are released from aggregated platelets and stimulate fibroblasts, which are required for repair at sites of hemorrhage or thrombosis.

The CC chemokines activate T cells, monocytes, and eosinophils. This family includes RANTES (regulated on activation, normal T cell expressed and secreted), macrophage chemotactic and activating factor (MCAF), macrophage inflammatory protein–1α (MIP-1α), and MIP-1β. CC chemokines are produced by activated T cells and monocytes. RANTES is a potent attractant for memory T cells (but not for naive T cells) and also attracts monocytes. MCAF acts exclusively on monocytes, attracting them, activating them, and regulating the expression of integrins on their surface. MIP-1α and MIP-1β attract only monocytes. The CC chemokines eotaxin, eotaxin-2, and monocyte chemoattractant protein–4 (MCP-4) predominantly activate eosinophils.[41]

In addition to their role in inflammation, chemokines are important in the hemostasis of lymphocytes moving through the lymphatic system; in the location of T cells, B cells, and dendritic cells in the lymph node; in Th1 and Th2 cell development; and in angiogenesis, angiostasis, and metastasis of tumor. In fetal mice lacking the CXC chemokine receptor–4, the heart and cerebellum do not develop properly, indicating that chemokines also play a part in nonlymphoid organ development.[42,43]

Chemokine receptors play an important role as coreceptors for HIV. The virus first interacts with CD4 on T cells but requires a coreceptor to penetrate the cell membrane. The CC chemokine receptor–5 (CCR5), which mediates activation of T cells and macrophages, is the major coreceptor for some HIV-1 strains. The natural ligands for CCR5 include RANTES, MIP-1α, and MIP-1β.[44] The CXC chemokine receptor–4 appears to be important in late-stage HIV infection.[45]

Effector Mechanisms in Cell-Mediated Immunity

Cell-mediated immunity encompasses the killing of invading microorganisms, such as bacteria, viruses, fungi, and parasites; the destruction of tumor cells; the rejection of tissue grafts; and injury to tissues in various disease states, including autoimmunity. Cell-mediated immune reactions can also be induced by contact with antigens, such as those found in poison ivy and numerous drugs. Drugs are more likely to provoke cell-mediated reactions when applied topically than when given systemically.

Most cell-mediated immune reactions involve initial interaction between sensitized T cells and antigens on presenting cells. This reaction can trigger several effector pathways, including activation of cytotoxic T cells, stimulation of T cell production of cytokines that activate macrophages and promote the proliferation of NK cells, and production of antibodies involved in antibody-dependent cell-mediated cytotoxicity by NK cells and other cell types. Although cell-mediated immune reactions other than antibody-dependent cell-mediated cytotoxicity do

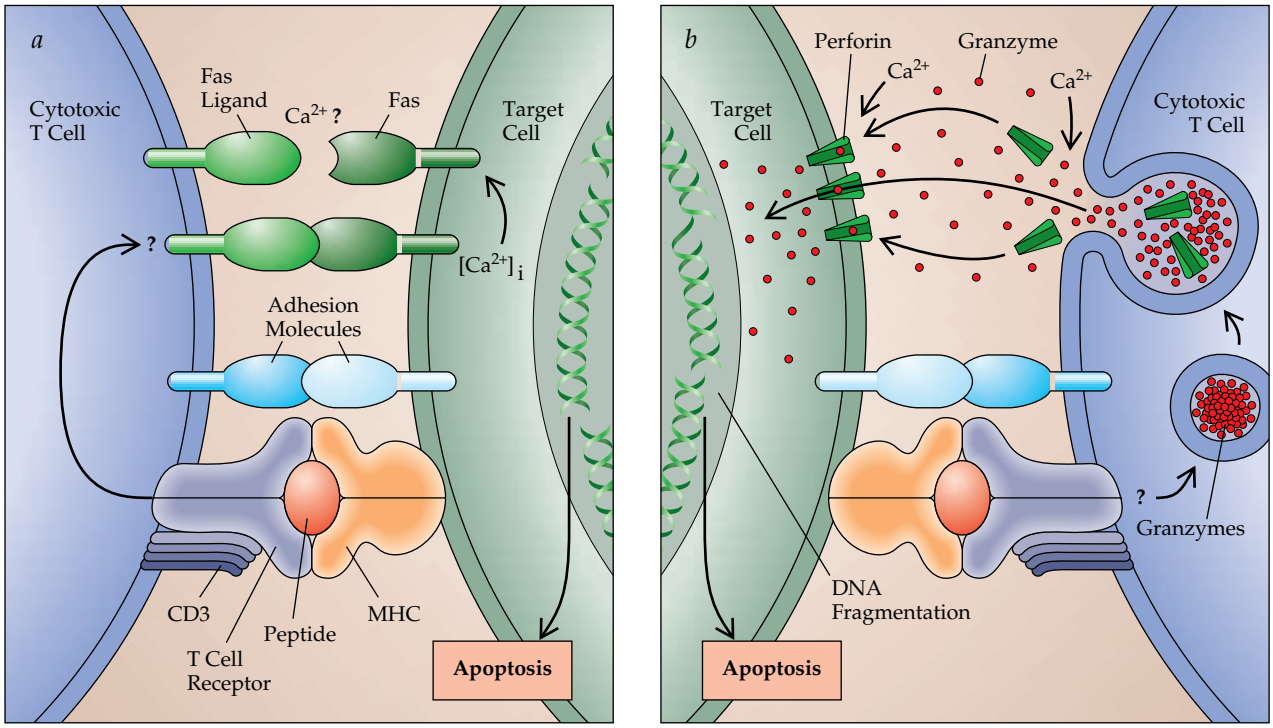

Figure 5 **Cytotoxic cells recognize surface markers on cells that are to be destroyed. (*a*) Apoptosis is triggered by the cytotoxic T cell through nonsecretory Fas–Fas ligand interaction. (*b*) Apoptosis is triggered by the cytotoxic T cell by means of secretory mechanisms initiated by perforin and granzymes.**

not require the presence of antibody or complement, they can be modified by these humoral factors. Subsequent events require cooperation between different subsets of T cells; the reactions involved are controlled by various cytokines.

The mechanisms of cell-mediated immunity involving T cell–macrophage interactions can be both protective (leading to the killing of invading microorganisms) and harmful (leading to inflammation and tissue destruction). Sometimes, the two go hand in hand; in tuberculosis, for example, both the killing of tubercle bacilli and the development of cavities in the lungs are consequences of T cell–macrophage interactions. In addition to the acquired cell-mediated immunity discussed above, innate immunity also involves the mounting of an immune response by cells directly stimulated by microorganisms. Macrophages, other granulocytic cells, and NK cells are involved in innate cell-mediated immune responses [*see 6:II Innate Immunity*].

CYTOTOXIC T CELLS

Cytotoxic T cells are antigen-specific effector cells that are important in resisting infectious agents, especially viruses that are present in cells other than macrophages; in killing tumors; and in allograft rejection. Most cytotoxic T cells are $CD8^+$ T cells that recognize antigen presented by MHC class I molecules, although a considerable number of $CD4^+$ T cells have the capability to kill target cells. Killing by a cytotoxic T cell begins with adhesion to the target cell (which requires magnesium ions), followed by the delivery of cytotoxic chemicals to the target cell (which requires calcium ions). The cytotoxic T cell then dissociates from the target cell; death proceeds in the absence of the cytotoxic T cell, which recycles to attack another target cell. If the cytotoxic T cell adheres to a cell that does not carry the targeted antigenic peptide–MHC molecule combination, no cytotoxic chemicals are released and the cells dissociate more rapidly.

Cytotoxic T cells develop granules that contain cytotoxic molecules, including perforins (proteins that produce holes or pores in a cell's surface membrane), serine proteases (granzyme A and granzyme B), and serine esterases.[46] Of these, perforins are the most important, as has been shown in mice in which the gene encoding perforin has been deleted. A second killing mechanism involves the Fas ligand on the cytotoxic T cell and Fas on the target cell. Binding of these leads to apoptosis of the target cell. This is the only mechanism of killing available to mice that lack perforin, and it is used preferentially—but not exclusively—in $CD4^+$ cytotoxic T cells [*see Figure 5*].

Viral infection results in the production of a large number of virus-specific cytotoxic T cells. This is most dramatically shown during the initial responses to B cells infected with Epstein-Barr virus. Cytotoxic T cell clones specific for some antigen-MHC complexes are extremely abundant, constituting approximately 50% of all cytotoxic T cells.[9] When the cytotoxic T cell response diminishes, these abundant T cell clones are probably removed through apoptotic mechanisms.

ACTIVATED MACROPHAGES

Macrophages are usually activated by Th1 cells that have been stimulated by antigens or microorganisms. Those Th1 cells then express CD40 ligand (CD40L) and produce macrophage-activating cytokines, especially IFN-γ and MIF. These cytokines, in combination with CD40L interacting with the CD40 on the macrophage surfaces, induces intracellular signaling transcription pathways in the macrophage. These pathways result in activation of transcription factors leading to production of various proteins and surface markers that characterize the activated macrophage. Activated macrophages produce reactive oxygen intermediates, including nitric oxide, that are involved in the destruction of microorganisms or foreign cells.

Bacterial killing also involves phagolysosomal fusion, which mobilizes enzymes such as cathepsins.

Activated macrophages produce many of the inflammatory cytokines (e.g., IL-12, TNF-α, IL-1, and MIF) and chemokines (e.g., MIP-1) that are involved in immunity to microorganisms and foreign antigens and in enhancing the process of activation itself. Activated macrophages also express MHC class II and costimulatory molecules, which further amplify the process. In addition, activated macrophages produce the cytokines IL-10 and TGF-β; these counteract the activation, damping down the inflammatory process and acting as feedback regulators [*see 6:I Organs and Cells of the Immune System*].

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

V ADAPTIVE IMMUNITY: HISTOCOMPATIBILITY ANTIGENS AND IMMUNE RESPONSE GENES

Edgar L. Milford, m.d.
Charles B. Carpenter, m.d.

The major histocompatibility complex (MHC) was first appreciated in mice as a set of proteins, encoded by closely linked genes on chromosome 17, that serve as the major targets for rejection of skin grafts. Humans were subsequently shown also to have MHC antigens, which are homologous to those found in the mouse but are encoded in the human leukocyte antigen (*HLA*) region on the short arm of chromosome 6 [*see Figure 1*]. Initially, human MHC antigens could be defined only by use of sera from multiparous women who had mounted humoral immune responses against the paternally derived MHC antigens in their fetuses. The development of DNA-based methods for genotyping of individuals has permitted more extensive study of these extraordinarily polymorphic molecules. This chapter reviews the genetics and structure of the MHC, its function in the immune response, and its association with disease.

Structure and Antigens of the Major Histocompatibility Complex

There are two structural types of MHC molecules, called class I and class II. The molecules of both classes are active in antigen recognition and help focus immune defenses during invasions from the microbial world. They are also engaged in the communication that occurs between cells during the immune response. MHC molecules act by binding peptide fragments of antigens that have been processed in specialized antigen-presenting cells. Clonally determined antigen receptors on T cells then recognize and bind to specific peptide-MHC complexes, setting into motion the appropriate immune response. Segments of MHC molecules show sequence homologies with immunoglobulins, T cell antigen receptors, and T cell interaction molecules such as CD4 and CD8, which suggests that all these molecules share a common evolutionary ancestry.
