of DM are further subdivided into microvascular (retinopathy, neuropathy, nephropathy) and macrovascular complications (coronary artery disease, peripheral arterial disease, cerebrovascular disease). Nonvascular complications include problems such as gastroparesis, infections, and skin changes. The risk of chronic complications increases as a function of the duration of hyperglycemia; they usually become apparent in the second decade of hyperglycemia. Since type 2 DM often has a long asymptomatic period of hyperglycemia, many individuals with type 2 DM have complications at the time of diagnosis.

The microvascular complications of both type 1 and type 2 DM result from chronic hyperglycemia. Large, randomized clinical trials of individuals with type 1 or type 2 DM have conclusively demonstrated that a reduction in chronic hyperglycemia prevents or delays retinopathy, neuropathy, and nephropathy. Other incompletely defined factors may modulate the development of complications. For example, despite long-standing DM, some individuals never develop nephropathy or retinopathy. Many of these patients have glycemic control that is indistinguishable from those who develop microvascular complications, suggesting that there is a genetic susceptibility for developing particular complications.

Evidence implicating a causative role for chronic hyperglycemia in the development of macrovascular complications is less conclusive. However, coronary heart disease events and mortality are two to four times greater in patients with type 2 DM. These events correlate with fasting and postprandial plasma glucose levels as well as with the A1C. Other factors (dyslipidemia and hypertension) also play important roles in macrovascular complications.

MECHANISMS OF COMPLICATIONS Although chronic hyperglycemia is an important etiologic factor leading to complications of DM, the mechanism(s) by which it leads to such diverse cellular and organ dysfunction is unknown. Four prominent theories, which are not mutually exclusive, have been proposed to explain how hyperglycemia might lead to the chronic complications of DM (Fig. 323-7).

One theory is that increased intracellular glucose leads to the formation of advanced glycosylation end products (AGEs) via the nonenzymatic glycosylaton of intra- and extracellular proteins. Nonenzymatic glycosylation results from the interaction of glucose with amino groups on proteins. AGEs have been shown to cross-link proteins (e.g., collagen, extracellular matrix proteins), accelerate atherosclerosis, promote glomerular dysfunction, reduce nitric oxide synthesis, induce endothelial dysfunction, and alter extracellular matrix composition and structure. The serum level of AGEs correlates with the level of glycemia, and these products accumulate as glomerular filtration rate declines.

A second theory is based on the observation that hyperglycemia increases glucose metabolism via the sorbitol pathway. Intracellular glucose is predominantly metabolized by phosphorylation and subsequent glycolysis, but when increased, some glucose is converted to sorbitol by the enzyme aldose reductase. Increased sorbitol concentration alters redox potential, increases cellular osmolality, generates reactive oxygen species, and likely leads to other types of cellular dysfunction. However, testing of this theory in humans, using aldose reductase inhibitors, has not demonstrated significant beneficial effects on clinical endpoints of retinopathy, neuropathy, or nephropathy.

A third hypothesis proposes that hyperglycemia increases the formation of diacylglycerol leading to activation of protein kinase C (PKC). Among other actions, PKC alters the transcription of genes for fibronectin, type IV collagen, contractile proteins, and extracellular matrix proteins in endothelial cells and neurons.

A fourth theory proposes that hyperglycemia increases the flux through the hexosamine pathway, which generates fructose-6-phosphate, a substrate for O-linked glycosylation and proteoglycan production. The hexosamine pathway may alter function by glycosylation of proteins such as endothelial nitric oxide synthase or by changes in gene expression of transforming growth factor β (TGF-β) or plasminogen activator inhibitor-1 (PAI-1).

Growth factors appear to play an important role in DM-related complications, and their production is increased by most of these proposed pathways. Vascular endothelial growth factor (VEGF) is increased locally in diabetic proliferative retinopathy and decreases after laser photocoagulation. TGF-β is increased in diabetic nephropathy and stimulates basement membrane production of collagen and fibronectin by mesangial cells. Other growth factors, such as platelet-derived growth factor, epidermal growth factor, insulin-like growth factor I, growth hormone, basic fibroblast growth factor, and even insulin, have been suggested to play a role in DM-related complications. A possible unifying mechanism is that hyperglycemia leads to increased production of reactive oxygen species or superoxide in the mitochondria; these compounds may activate all for of the pathways described above. Although hyperglycemia serves as the initial trigger for complications of diabetes, it is still unknown whether the same pathophysiologic processes are operative in all complications or whether some pathways predominate in certain organs.

GLYCEMIC CONTROL AND COMPLICATIONS The Diabetes Control and Complications Trial (DCCT) provided definitive proof that reduction in chronic hyperglycemia can prevent many of the early complications of type 1 DM. This large multicenter clinical trial randomized over 1400 individuals with type 1 DM to either intensive or conventional diabetes management, and prospectively evaluated the development of retinopathy, nephropathy, and neuropathy. Individuals in the intensive

diabetes management group received multiple administrations of insulin each day along with extensive educational, psychological, and medical support. Individuals in the conventional diabetes management group received twice-daily insulin injections and quarterly nutritional, educational, and clinical evaluation. The goal in the former group was normoglycemia; the goal in the latter group was prevention of symptoms of diabetes. Individuals in the intensive diabetes management group achieved a substantially lower hemoglobin A1C (A1C; 7.3%) than individuals in the conventional diabetes management group (A1C; 9.1%).

The DCCT demonstrated that improvement of glycemic control reduced nonproliferative and proliferative retinopathy (47% reduction), microalbuminuria (39% reduction), clinical nephropathy (54% reduction), and neuropathy (60% reduction). Improved glycemic control also slowed the progression of early diabetic complications. There was a nonsignificant trend in reduction of macrovascular events. The results of the DCCT predicted that individuals in the intensive diabetes management group would gain 7.7 additional years of vision, 5.8 additional years free from ESRD, and 5.6 years free from lower extremity amputations. If all complications of DM were combined, individuals in the intensive diabetes management group would experience 15.3 more years of life without significant microvascular or neurologic complications of DM, compared to individuals who received standard therapy. This translates into an additional 5.1 years of life expectancy for individuals in the intensive diabetes management group. The benefit of the improved glycemic control during the DCCT persisted even after the study concluded and glycemic control worsened.

The benefits of an improvement in glycemic control occurred over the entire range of A1C values (Fig. 323-8), suggesting that at any A1C level, an improvement in glycemic control is beneficial. Therefore, there is no threshold beneath which the A1C can be reduced and the complications of DM prevented. The clinical implication of this finding is that the goal of therapy is to achieve an A1C level as close to normal as possible, without subjecting the patient to excessive risk of hypoglycemia.

The United Kingdom Prospective Diabetes Study (UKPDS) studied the course of >5000 individuals with type 2 DM for >10 years. This study utilized multiple treatment regimens and monitored the effect of intensive glycemic control and risk factor treatment on the development of diabetic complications. Newly diagnosed individuals with type 2 DM were randomized to (1) intensive management using various combinations of insulin, a sulfonylurea, or metformin; or (2) conventional therapy using dietary modification and pharmacotherapy with the goal of symptom prevention. In addition, individuals were randomly assigned to different antihypertensive regimens. Individuals in the intensive treatment arm achieved an A1C of 7.0%, compared to a 7.9% A1C in the standard treatment group. The UKPDS demonstrated that each percentage point reduction in A1C was associated with a 35% reduction in microvascular complications. As in the DCCT, there was a continuous relationship between glycemic control and development of complications. Improved glycemic control did not conclusively reduce (nor worsen) cardiovascular mortality but was associated with improvement with lipoprotein risk profiles, such as reduced triglycerides and increased HDL.

One of the major findings of the UKPDS was that strict blood pressure control significantly reduced both macro- and microvascular complications. In fact, the beneficial effects of blood pressure control were greater than the beneficial effects of glycemic control. Lowering blood pressure to moderate goals (144/82 mmHg) reduced the risk of DM-related death, stroke, microvascular end points, retinopathy, and heart failure (risk reductions between 32 and 56%). Despite concerns that insulin therapy is associated with weight gain and may worsen underlying insulin resistance and hyperinsulinemia, most available data support strict glycemic control in individuals with type 2 DM.

Similar reductions in the risks of retinopathy and nephropathy were also seen in a small trial of lean Japanese individuals with type 2 DM randomized to either intensive glycemic control or standard therapy with insulin (Kumamoto study). These results demonstrate the effectiveness of improved glycemic control in individuals of different ethnicity, and, presumably a different etiology of DM (i.e., phenotypically different from those in the DCCT and UKPDS).

The findings of the DCCT, UKPDS, and Kumamoto study support the idea that chronic hyperglycemia plays a causative role in the pathogenesis of diabetic microvascular complications. These landmark studies prove the value of metabolic control and emphasize the importance of (1) intensive glycemic control in all forms of DM, and (2) early diagnosis and strict blood pressure control in type 2 DM.

OPHTHALMOLOGIC COMPLICATIONS OF DIABETES MELLITUS DM is the leading cause of blindness between the ages of 20 and 74 in the United States. The gravity of this problem is highlighted by the finding that individuals with DM are 25 times more likely to become legally blind than individuals without DM. Blindness is primarily the result of progressive diabetic retinopathy and clinically significant macular edema. Diabetic retinopathy is classified into two stages: nonproliferative and proliferative. *Nonproliferative diabetic retinopathy* usually appears late in the first decade or early in the second decade of the disease and is marked by retinal vascular microaneurysms, blot hemorrhages, and cotton wool spots (Fig. 323-9). Mild nonproliferative retinopathy progresses to more extensive disease, characterized by changes in venous vessel caliber, intraretinal microvascular abnormalities, and more numerous microaneurysms and hemorrhages. The pathophysiologic mechanisms invoked in nonproliferative retinopathy include loss of retinal pericytes, increased retinal vascular permeability, alterations in retinal blood flow, and abnormal retinal microvasculature, all of which lead to retinal ischemia.

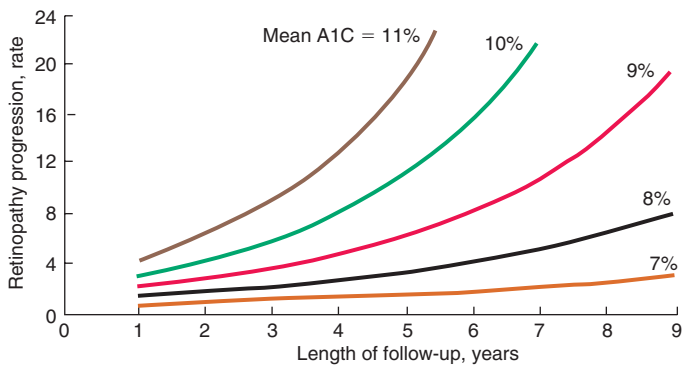

FIGURE 323-8 Relationship of glycemic control and diabetes duration to diabetic retinopathy. The progression of retinopathy in individuals in the Diabetes Control and Complications Trial is graphed as a function of the length of follow-up with different curves for different A1C values. *(Adapted from The Diabetes Control and Complications Trial Research Group, Diabetes 44:968, 1995.)*

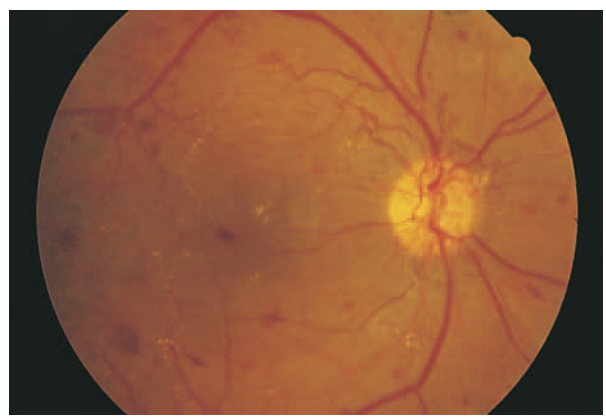

FIGURE 323-9 Diabetic retinopathy results in scattered hemorrhages and yellow exudates. This patient has neovascular vessels proliferating from the optic disc, requiring urgent pan retinal laser photocoagulation.

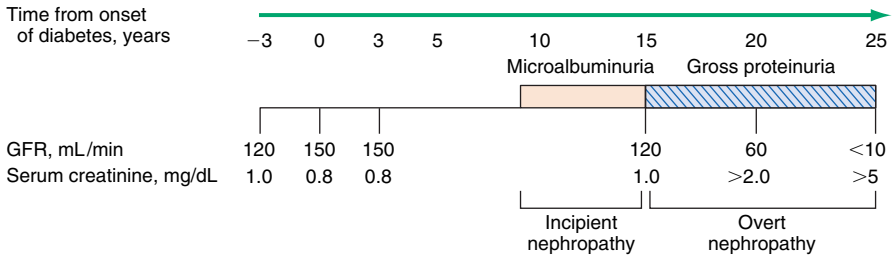

FIGURE 323-10 Time course of development of diabetic nephropathy. The relationship of time from onset of diabetes, the glomerular filtration rate (GFR), and the serum creatinine are shown. *(Adapted from RA DeFronzo, in Therapy for Diabetes Mellitus and Related Disorders, American Diabetes Association, Alexandria, VA, 1998.)*

The appearance of neovascularization in response to retinal hypoxia is the hallmark of *proliferative diabetic retinopathy*. These newly formed vessels appear near the optic nerve and/or macula and rupture easily, leading to vitreous hemorrhage, fibrosis, and ultimately retinal detachment. Not all individuals with nonproliferative retinopathy develop proliferative retinopathy, but the more severe the nonproliferative disease, the greater the chance of evolution to proliferative retinopathy within 5 years. This creates an important opportunity for early detection and treatment of diabetic retinopathy. *Clinically significant macular edema* can occur when only nonproliferative retinopathy is present. Fluorescein angiography is useful to detect macular edema, which is associated with a 25% chance of moderate visual loss over the next 3 years.

Duration of DM and degree of glycemic control are the best predictors of the development of retinopathy; hypertension is also a risk factor. Nonproliferative retinopathy is found in almost all individuals who have had DM for >20 years (25% incidence with 5 years, and 80% incidence with 15 years of type 1 DM). Although there is genetic susceptibility for retinopathy, it confers less influence than either the duration of DM or the degree of glycemic control.

℞ TREATMENT

The most effective therapy for diabetic retinopathy is prevention. Intensive glycemic and blood pressure control will delay the development or slow the progression of retinopathy in individuals with either type 1 or type 2 DM. Paradoxically, during the first 6 to 12 months of improved glycemic control, established diabetic retinopathy may transiently worsen. Fortunately, this progression is temporary, and in the long term, improved glycemic control is associated with less diabetic retinopathy. Individuals with known retinopathy are candidates for prophylactic photocoagulation when initiating intensive therapy. Once advanced retinopathy is present, improved glycemic control imparts less benefit, though adequate ophthalmologic care can prevent most blindness.

Regular, comprehensive eye examinations are essential for all individuals with DM. Most diabetic eye disease can be successfully treated if detected early. Routine, nondilated eye examinations by the primary care provider or diabetes specialist are *inadequate* to detect diabetic eye disease, which requires an ophthalmologist for optimal care of these disorders. Laser photocoagulation is very successful in preserving vision. Proliferative retinopathy is usually treated with panretinal laser photocoagulation, whereas macular edema is treated with focal laser photocoagulation. Although exercise has not been conclusively shown to worsen proliferative diabetic retinopathy, most ophthalmologists advise individuals with advanced diabetic eye disease to limit physical activities associated with repeated Valsalva maneuvers. Aspirin therapy (650 mg/d) does not appear to influence the natural history of diabetic retinopathy, but studies of other antiplatelet agents are under way.

RENAL COMPLICATIONS OF DIABETES MELLITUS Diabetic nephropathy is the leading cause of ESRD in the United States and a leading cause of DM-related morbidity and mortality. Proteinuria in individuals with DM is associated with markedly reduced survival and increased risk of cardiovascular disease. Individuals with diabetic nephropathy almost always have diabetic retinopathy.

Like other microvascular complications, the pathogenesis of diabetic nephropathy is related to chronic hyperglycemia (Fig. 323-7). The mechanisms by which chronic hyperglycemia leads to ESRD, though incompletely defined, involve the effects of soluble factors (growth factors, angiotensin II, endothelin, AGEs), hemodynamic alterations in the renal microcirculation (glomerular hyperfiltration or hyperperfusion, increased glomerular capillary pressure), and structural changes in the glomerulus (increased extracellular matrix, basement membrane thickening, mesangial expansion, fibrosis). Some of these effects may be mediated through angiotensin II receptors. Smoking accelerates the decline in renal function.

The natural history of diabetic nephropathy is characterized by a fairly predictable sequence of events that was initially defined for individuals with type 1 DM but appears to be similar in type 2 DM (Fig. 323-10). Glomerular hyperperfusion and renal hypertrophy occur in the first years after the onset of DM and cause an increase of the glomerular filtration rate (GFR). During the first 5 years of DM, thickening of the glomerular basement membrane, glomerular hypertrophy, and mesangial volume expansion occur as the GFR returns to normal. After 5 to 10 years of type 1 DM, ~40% of individuals begin to excrete small amounts of albumin in the urine. *Microalbuminuria* is defined as 30 to 300 mg/d in a 24-h collection or 30 to 300 μg/mg creatinine in a spot collection (preferred method). The appearance of microalbuminuria (incipient nephropathy) in type 1 DM is an important predictor of progression to overt proteinuria (>300 mg/d) or overt nephropathy. Blood pressure may rise slightly at this point but usually remains in the normal range. Once overt proteinuria is present, there is a steady decline in GFR, and ~50% of individuals reach ESRD in 7 to 10 years. The early pathologic changes and albumin excretion abnormalities are reversible with normalization of plasma glucose. However, once overt nephropathy develops, the pathologic changes are likely irreversible.

The nephropathy that develops in type 2 DM differs from that of type 1 DM in the following respects: (1) microalbuminuria or overt nephropathy may be present when type 2 DM is diagnosed, reflecting its long asymptomatic period; (2) hypertension more commonly accompanies microalbuminuria or overt nephropathy in type 2 DM; and (3) microalbuminuria may be less predictive of diabetic nephropathy and progression to overt nephropathy in type 2 DM. Finally, it should be noted that albuminuria in type 2 DM may be secondary to factors unrelated to DM, such as hypertension, congestive heart failure, prostate disease, or infection. Diabetic nephropathy and ESRD secondary to this develop more commonly in African Americans, Native Americans, and Hispanic individuals than in Caucasians with type 2 DM.

Type IV renal tubular acidosis (hyporeninemic hypoaldosteronism) also occurs in type 1 or 2 DM. These individuals develop a propensity to hyperkalemia, which may be exacerbated by medications [especially angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs)]. Patients with DM are predisposed to radiocontrast-induced nephrotoxicity. Risk factors for radiocontrast-induced nephrotoxicity are preexisting nephropathy and volume depletion. Individuals with DM undergoing radiographic procedures with contrast dye should be well hydrated before and after dye exposure, and the serum creatinine should be monitored for several days following the procedure. Treatment with acetylcysteine (600 mg bid) on the day before and the day of the dye study appears to protect high-risk patients [creatinine, >212 μmol/L (>2.4 mg/dL)] from radiocontrast-induced nephrotoxicity.

℞ TREATMENT

The optimal therapy for diabetic nephropathy is prevention. As part of comprehensive diabetes care, microalbuminuria should be detected

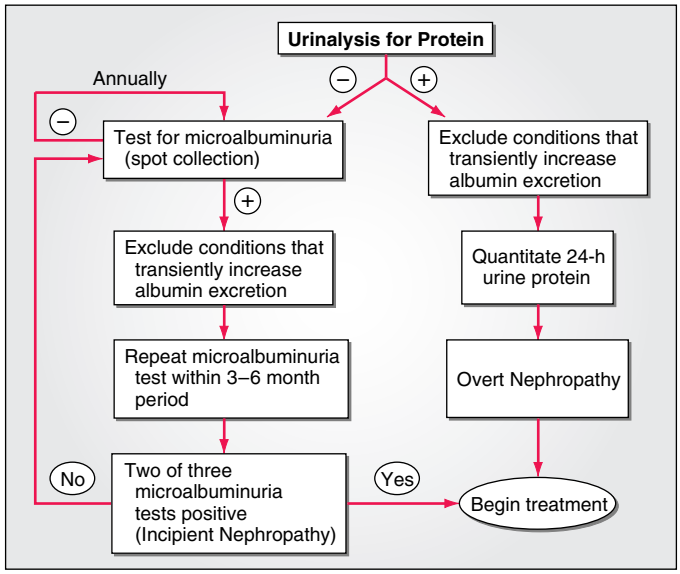

FIGURE 323-11 Screening for microalbuminuria. *(Adapted from RA DeFronzo, in Therapy for Diabetes Mellitus and Related Disorders, American Diabetes Association, Alexandria, VA, 1998.)*

at an early stage when effective therapies can be instituted. The recommended strategy for detecting microalbuminuria is outlined in Fig. 323-11. Interventions effective in slowing progression from microalbuminuria to overt nephropathy include: (1) near normalization of glycemia, (2) strict blood pressure control, and (3) administration of ACE inhibitors or ARBs, and (4) treatment of dyslipidemia.

Improved glycemic control reduces the rate at which microalbuminuria appears and progresses in type 1 and type 2 DM. However, once overt nephropathy exists, it is unclear whether improved glycemic control will slow progression of renal disease. During the phase of declining renal function, insulin requirements may fall as the kidney is a site of insulin degradation. Furthermore, glucose-lowering medications (sulfonylureas and metformin) are contraindicated in advanced renal insufficiency.

Many individuals with type 1 or type 2 DM develop hypertension. Numerous studies in both type 1 and type 2 DM demonstrate the effectiveness of strict blood pressure control in reducing albumin excretion and slowing the decline in renal function. Blood pressure should be maintained at <130/80 mmHg in diabetic individuals without proteinuria. A slightly lower blood pressure (125/75) should be considered for individuals with microalbuminuria or overt nephropathy (see "Hypertension," below).

ACE inhibitors and ARBs reduce the progression of overt nephropathy in individuals with type 1 or type 2 DM and should be prescribed in individuals with type 1 or type 2 DM and microalbuminuria. After 2 to 3 months of therapy, measurement of proteinuria should be repeated and the drug dose increased until either the albuminuria disappears or the maximum dose is reached. ARBs can be used as an alternative in patients who develop ACE inhibitor-associated cough. Both ACE inhibitors and ARBs can induce hyperkalemia or renal insufficiency. If use of either of these types of agents is not possible, then calcium channel blockers (non-dihydropyridine class) can be used. However, their efficacy in slowing the fall in the GFR is not proven. Blood pressure control with any agent is extremely important, but a drug-specific benefit in diabetic nephropathy, independent of blood pressure control, has been shown only for ACE inhibitors in type 1 DM and ARBs in type 2 DM.

A consensus panel of the ADA suggests modest restriction of protein intake in diabetic individuals with microalbuminuria (0.8 g/kg per day) or overt nephropathy (<0.8 g/kg per day, which is the adult Recommended Daily Allowance, or about 10% of the daily caloric intake). Conclusive proof of the efficacy of protein restriction is lacking.

Nephrology consultation should be considered after the diagnosis of early incipient nephropathy. Once overt nephropathy ensues, the likelihood of ESRD is very high. As compared to nondiabetic individuals, hemodialysis in patients with DM is associated with more frequent complications, such as hypotension (due to autonomic neuropathy or loss of reflex tachycardia), more difficult vascular access, and accelerated progression of retinopathy. Survival after the onset of ESRD is shorter in the diabetic population compared to nondiabetics with similar clinical features. Atherosclerosis is the leading cause of death in diabetic individuals on dialysis, and hyperlipidemia should be treated aggressively. Renal transplantation from a living-related donor is the preferred therapy but requires chronic immunosuppression. Combined pancreas-kidney transplant offers the promise of normoglycemia but requires substantial expertise.

NEUROPATHY AND DIABETES MELLITUS Diabetic neuropathy occurs in approximately 50% of individuals with long-standing type 1 and type 2 DM. It may manifest as polyneuropathy, mononeuropathy, and/or autonomic neuropathy. As with other complications of DM, the development of neuropathy correlates with the duration of diabetes and glycemic control; both myelinated and unmyelinated nerve fibers are lost. Because the clinical features of diabetic neuropathy are similar to those of other neuropathies, the diagnosis of *diabetic neuropathy* should be made only after other possible etiologies are excluded (Chap. 363).

Polyneuropathy/Mononeuropathy The most common form of diabetic neuropathy is distal symmetric *polyneuropathy*. It most frequently presents with distal sensory loss. Hyperesthesia, paresthesia, and dysesthesia also occur. Any combination of these symptoms may develop as neuropathy progresses. Symptoms include a sensation of numbness, tingling, sharpness, or burning that begins in the feet and spreads proximally. Neuropathic pain develops in some of these individuals, occasionally preceded by improvement in their glycemic control. Pain typically involves the lower extremities, is usually present at rest, and worsens at night. Both an acute (lasting <12 months) and a chronic form of painful diabetic neuropathy have been described. As diabetic neuropathy progresses, the pain subsides and eventually disappears, but a sensory deficit in the lower extremities persists. Physical examination reveals sensory loss, loss of ankle reflexes, and abnormal position sense.

Diabetic polyradiculopathy is a syndrome characterized by severe disabling pain in the distribution of one or more nerve roots. It may be accompanied by motor weakness. Intercostal or truncal radiculopathy causes pain over the thorax or abdomen. Involvement of the lumbar plexus or femoral nerve may cause pain in the thigh or hip and may be associated with muscle weakness in the hip flexors or extensors (diabetic amyotrophy). Fortunately, diabetic polyradiculopathies are usually self-limited and resolve over 6 to 12 months.

Mononeuropathy (dysfunction of isolated cranial or peripheral nerves) is less common than polyneuropathy in DM and presents with pain and motor weakness in the distribution of a single nerve. A vascular etiology has been suggested, but the pathogenesis is unknown. Involvement of the third cranial nerve is most common and is heralded by diplopia. Physical examination reveals ptosis and opthalmoplegia with normal pupillary constriction to light. Sometimes cranial nerves IV, VI, or VII (Bell's palsy) are affected. Peripheral mononeuropathies or simultaneous involvement of more than one nerve (mononeuropathy multiplex) may also occur.

Autonomic Neuropathy Individuals with long-standing type 1 or 2 DM may develop signs of autonomic dysfunction involving the cholinergic, noradrenergic, and peptidergic (peptides such as pancreatic polypeptide, substance P, etc.) systems. DM-related autonomic neuropathy can involve multiple systems, including the cardiovascular, gastrointestinal, genitourinary, sudomotor, and metabolic systems. Autonomic neuropathies affecting the cardiovascular system cause a resting tachycardia and orthostatic hypotension. Reports of sudden death have also

been attributed to autonomic neuropathy. Gastroparesis and bladder-emptying abnormalities are often caused by the autonomic neuropathy seen in DM (discussed below). Hyperhidrosis of the upper extremities and anhidrosis of the lower extremities result from sympathetic nervous system dysfunction. Anhidrosis of the feet can promote dry skin with cracking, which increases the risk of foot ulcers. Autonomic neuropathy may reduce counterregulatory hormone release, leading to an inability to sense hypoglycemia appropriately (*hypoglycemia unawareness*; Chap. 324), thereby subjecting the patient to the risk of severe hypoglycemia and complicating efforts to improve glycemic control.

℞ TREATMENT

Treatment of diabetic neuropathy is less than satisfactory. Improved glycemic control should be pursued and will improve nerve conduction velocity, but the symptoms of diabetic neuropathy may not necessarily improve. Efforts to improve glycemic control may be confounded by autonomic neuropathy and hypoglycemia unawareness. Avoidance of neurotoxins (alcohol), supplementation with vitamins for possible deficiencies (B_{12}, B_6, folate; Chap. 61), and symptomatic treatment are the mainstays of therapy. Aldose reductase inhibitors do not offer significant symptomatic relief. Loss of sensation in the foot places the patient at risk for ulceration and its sequelae; consequently, prevention of such problems is of paramount importance. Since the pain of acute diabetic neuropathy may resolve over the first year, analgesics may be discontinued as progressive neuronal damage from DM occurs. Chronic, painful diabetic neuropathy is difficult to treat but may respond to tricyclic antidepressants (amitriptyline, desipramine, nortriptyline), gabapentin, nonsteroidal anti-inflammatory agents (avoid in renal dysfunction), and other agents (mexilitine, phenytoin, carbamazepine, capsaicin cream). Referral to a pain management center may be necessary.

Therapy of orthostatic hypotension secondary to autonomic neuropathy is challenging. A variety of agents have limited success (fludrocortisone, midodrine, clonidine, octreotide, and yohimbine) but each has significant side effects. Nonpharmacologic maneuvers (adequate salt intake, avoidance of dehydration and diuretics, and lower extremity support hose) may offer some benefit.

GASTROINTESTINAL/GENITOURINARY DYSFUNCTION Long-standing type 1 and 2 DM may affect the motility and function of gastrointestinal (GI) and genitourinary systems. The most prominent GI symptoms are delayed gastric emptying (gastroparesis) and altered small- and large-bowel motility (constipation or diarrhea). *Gastroparesis* may present with symptoms of anorexia, nausea, vomiting, early satiety, and abdominal bloating. Nuclear medicine scintigraphy after ingestion of a radiolabeled meal is the best study to document delayed gastric emptying, but noninvasive "breath tests" following ingestion of a radiolabeled meal are under development. Though parasympathetic dysfunction secondary to chronic hyperglycemia is important in the development of gastroparesis, hyperglycemia itself also impairs gastric emptying. Nocturnal diarrhea, alternating with constipation, is a common feature of DM-related GI autonomic neuropathy. In type 1 DM, these symptoms should also prompt evaluation for celiac sprue because of its increased frequency. Esophageal dysfunction in long-standing DM is common but usually asymptomatic.

Diabetic autonomic neuropathy may lead to genitourinary dysfunction including cystopathy, erectile dysfunction, and female sexual dysfunction (reduced sexual desire, dyspareunia, reduced vaginal lubrication). Symptoms of diabetic cystopathy begin with an inability to sense a full bladder and a failure to void completely. As bladder contractility worsens, bladder capacity and the post-void residual increase, leading to symptoms of urinary hesitancy, decreased voiding frequency, incontinence, and recurrent urinary tract infections. Diagnostic evaluation includes cystometry and urodynamic studies.

Erectile dysfunction and retrograde ejaculation are very common in DM and may be one of the earliest signs of diabetic neuropathy (Chap. 43). Erectile dysfunction, which increases in frequency with the age of the patient and the duration of diabetes, may occur in the absence of other signs of diabetic autonomic neuropathy.

℞ TREATMENT

Current treatments for these complications of DM are inadequate. Improved glycemic control should be a primary goal, as some aspects (neuropathy, gastric function) may improve. Smaller, more frequent meals that are easier to digest (liquid) and low in fat and fiber may minimize symptoms of gastroparesis. Cisapride (10 to 20 mg before each meal) is probably the most effective medication but has been removed from use in the United States except under special circumstances. Other agents with some efficacy include dopamine agonists (metoclopramide, 5 to 10 mg, and domperidone, 10 to 20 mg, before each meal) and bethanechol (10 to 20 mg before each meal). Erythromycin interacts with the motilin receptor and may promote gastric emptying. Diabetic diarrhea in the absence of bacterial overgrowth is treated symptomatically with loperamide but may respond to clonidine at higher doses (0.6 mg tid) or octreotide (50 to 75 μg tid subcutaneously). Treatment of bacterial overgrowth with antibiotics is sometimes useful (Chap. 275).

Diabetic cystopathy should be treated with timed voiding or self-catherization. Medications (bethanechol) are inconsistently effective. The drug of choice for erectile dysfunction is sildenafil, but the efficacy in individuals with DM is slightly lower than in the nondiabetic population (Chap. 43). Sexual dysfunction in women may be improved with use of vaginal lubricants, treatment of vaginal infections, and systemic or local estrogen replacement.

CARDIOVASCULAR MORBIDITY AND MORTALITY Cardiovascular disease is increased in individuals with type 1 or type 2 DM. The Framingham Heart Study revealed a marked increase in peripheral arterial disease, congestive heart failure, coronary artery disease, myocardial infarction (MI), and sudden death (risk increase from one- to fivefold) in DM. The American Heart Association recently designated DM as a major risk factor for cardiovascular disease (same category as smoking, hypertension, and hyperlipidemia). Type 2 diabetes patients without a prior MI have a similar risk for coronary artery–related events as nondiabetic individuals who have had a prior myocardial infarction. Because of the extremely high prevalence of underlying cardiovascular disease in individuals with diabetes (especially in type 2 DM), evidence of atherosclerotic vascular disease should be sought in an individual with diabetes who has symptoms suggestive of cardiac ischemia, peripheral or carotid arterial disease, a resting electrocardiogram indicative of prior infarction, plans to initiate an exercise program, proteinuria, or two other cardiac risk factors (ADA recommendations). The absence of chest pain ("silent ischemia") is common in individuals with diabetes, and a thorough cardiac evaluation is indicated in individuals undergoing major surgical procedures. The prognosis for individuals with diabetes who have coronary artery disease or myocardial infarction is worse than for nondiabetics. Coronary artery disease is more likely to involve multiple vessels in individuals with DM.

The increase in cardiovascular morbidity and mortality appears to relate to the synergism of hyperglycemia with other cardiovascular risk factors. For example, after controlling for all known cardiovascular risk factors, type 2 DM increases the cardiovascular death rate twofold in men and fourfold in women. Risk factors for macrovascular disease in diabetic individuals include dyslipidemia, hypertension, obesity, reduced physical activity, and cigarette smoking. Additional risk factors specific to the diabetic population include microalbuminuria, gross proteinuria, an elevation of serum creatinine, and abnormal platelet function. Insulin resistance, as reflected by elevated serum insulin levels, is associated with an increased risk of cardiovascular complications in individuals with and without DM. Individuals with insulin resistance and type 2 DM have elevated levels of plasminogen activator inhibitors (especially PAI-1) and fibrinogen, which enhances the coagulation process and impairs fibrinolysis, thus favoring the de-

velopment of thrombosis. Diabetes is also associated with endothelial, vascular smooth muscle, and platelet dysfunction.

Proof that improved glycemic control reduces cardiovascular complications in DM is lacking; in fact, it is possible that macrovascular complications may be unaffected or even worsened by such therapy. Concerns about the atherogenic potential of insulin remain, since in nondiabetic individuals, higher serum insulin levels (indicative of insulin resistance) are associated with a greater risk of cardiovascular morbidity and mortality. In the DCCT, the number of cardiovascular events did not differ between the standard and intensively treated groups. However, the duration of DM in these individuals was relatively short, and the total number of events was very low. An improvement in the lipid profile of individuals in the intensive group [lower total and low-density lipoprotein (LDL) cholesterol, lower triglycerides] suggested that intensive therapy may reduce the risk of cardiovascular morbidity and mortality associated with DM. In the UKPDS, improved glycemic control did not conclusively reduce cardiovascular mortality. Importantly, treatment with insulin and the sulfonylureas did not appear to increase the risk of cardiovascular disease in individuals with type 2 DM, refuting prior claims about the atherogenic potential of these agents.

In addition to coronary artery disease, cerebrovascular disease is increased in individuals with DM (threefold increase in stroke). Individuals with DM have an increased incidence of congestive heart failure (diabetic cardiomyopathy). The etiology of this abnormality is probably multifactorial and includes factors such as myocardial ischemia from atherosclerosis, hypertension, and myocardial cell dysfunction secondary to chronic hyperglycemia.

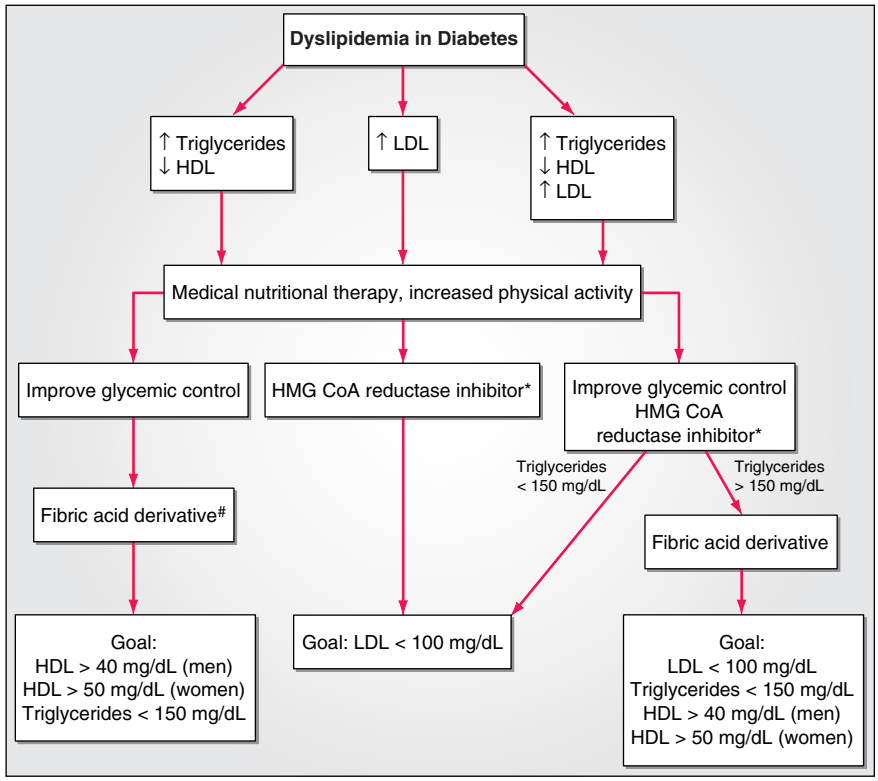

FIGURE 323-12 Dyslipidemia management in diabetes. *Second line treatment: fibric acid derivative or bile acid–binding resin. #Alternative treatment: high dose HMG CoA reductase inhibitor. The level of HDL in women should be 10 mg/dL higher. LDL, low-density lipoprotein; HDL, high-density lipoprotein.

TREATMENT

In general, the treatment of coronary disease is no different in the diabetic individual (Chap. 226). Revascularization procedures for coronary artery disease, including percutaneous coronary interventions (PCI) and coronary artery bypass grafting (CABG), are less efficacious in the diabetic individual. Initial success rates of PCI in diabetic individuals are similar to those in the nondiabetic population, but diabetic patients have higher rates of restenosis and lower long-term patency and survival rates. The use of stents and a GPIIb/IIIa platelet inhibitor has improved the outcome in diabetic patients. Perioperative mortality from CABG is not altered in DM, but both short- and long-term survival are reduced. Recent trials indicate that diabetic individuals with multivessel coronary artery disease or recent Q-wave MI have better long-term survival with CABG than PCI.

The ADA has emphasized the importance of glycemic control and aggressive cardiovascular risk modification in all individuals with DM. Past trepidation about using beta blockers in individuals who have diabetes should not prevent use of these agents since they clearly benefit diabetic patients after MI. ACE inhibitors may also be particularly beneficial and should be considered in individuals with type 2 DM and other risk factors (smoking, dyslipidemia, history of cardiovascular disease, microalbuminuria).

Antiplatelet therapy reduces cardiovascular events in individuals with DM who have coronary artery disease. Current recommendations by the ADA include the use of aspirin for secondary prevention of coronary events. Although data demonstrating efficacy in primary prevention of coronary events in DM are lacking, antiplatelet therapy should be strongly considered, especially in diabetic individuals with other coronary risk factors such as hypertension, smoking, or dyslipidemia. The aspirin dose (81 to 325 mg) is the same as that in nondiabetic individuals. Aspirin therapy does not have detrimental effects on renal function or hypertension, nor does it influence the course of diabetic retinopathy.

Cardiovascular Risk Factors ■ *DYSLIPIDEMIA* Individuals with DM may have several forms of dyslipidemia (Chap. 335). Because of the additive cardiovascular risk of hyperglycemia and hyperlipidemia, lipid abnormalities should be aggressively detected and treated as part of comprehensive diabetes care (Fig. 323-12). The most common pattern of dyslipidemia is hypertriglyceridemia and reduced HDL cholesterol levels. DM itself does not increase levels of LDL, but the small dense LDL particles found in type 2 DM are more atherogenic because they are more easily glycated and susceptible to oxidation. According to guidelines of the ADA and the American Heart Association, the target lipid values in diabetic individuals without cardiovascular disease should be: LDL $<$ 2.6 mmol/L (100 mg/dL); HDL $>$ 1.1 mmol/L (40 mg/dL) in men and $>$1.38 mmol/L (50 mg/dL) in women; and triglycerides $<$ 1.7 mmol/L (150 mg/dL). The National Cholesterol Education Program Adult Treatment Panel III also recommends lowering the LDL to $<$ 2.6 mmol/L (100 mg/dL) in diabetics. This is because the incidence of MI in type 2 DM is the same as that in patients without diabetes who have had a prior MI.

Almost all studies of diabetic dyslipidemia have been performed in individuals with type 2 DM because of the greater frequency of dyslipidemia in this form of diabetes. Interventional studies have shown that the beneficial effects of LDL reduction are similar in the diabetic and nondiabetic populations. Large prospective trials of primary and secondary intervention for coronary heart disease have included some individuals with type 2 DM, and subset analyses have consistently found that reductions in LDL reduce cardiovascular events and morbidity in individuals with DM. Most clinical trials used HMG CoA reductase inhibitors, although a fibric acid derivative has also shown to be beneficial. No prospective studies have addressed similar questions in individuals with type 1 DM.

Based on the guidelines provided by the ADA and the American Heart Association, the order of priorities in the treatment of hyperlipidemia is: (1) lower the LDL cholesterol, (2) raise the HDL cholesterol, and (3) decrease the triglycerides. A treatment strategy depends on the pattern of lipoprotein abnormalities (Fig. 323-11). Initial therapy for all forms of dyslipidemia should include dietary changes, as well as the same life-style modifications recommended in the nondiabetic population (smoking cessation, control of blood pressure, weight loss, increased physical activity). The dietary recommendations for individuals with DM are similar to those advocated by the National Cholesterol Education Program (Chap. 335) and include an increase in monounsaturated fat and carbohydrates and a reduction in saturated fats and cholesterol. Though viewed as important, the response to dietary alterations is often modest [<0.6-mmol/L (<25-mg/dL) reduction in the LDL]. Improvement in glycemic control will lower triglycerides and have a modest beneficial effect on raising HDL. HMG CoA reductase inhibitors are the agents of choice for lowering the LDL. Recent data suggest that all individuals >40 years with diabetes and total cholesterol >135 mg/dL may benefit from an HMG CoA reductase inhibitor. Fibric acid derivatives have some efficacy and should be considered when the HDL is low. Combination therapy with an HMG CoA reductase inhibitor and fibric acid derivative may be useful but increases the possibility of myositis. Nicotinic acid effectively raises HDL, but in high doses (>2 g/d) may worsen glycemic control and increase insulin resistance. Bile acid–binding resins should not be used if hypertriglyceridemia is present.

HYPERTENSION Hypertension can accelerate other complications of DM, particularly cardiovascular disease and nephropathy. Hypertension therapy should first emphasize life-style modifications such as weight loss, exercise, stress management, and sodium restriction. Antihypertensive agents should be selected based on the advantages and disadvantages of the therapeutic agent in the context of an individual patient's risk factor profile. DM-related considerations include the following:

1. ACE inhibitors are either glucose- and lipid-neutral or glucose- and lipid-beneficial and thus positively impact the cardiovascular risk profile. For example, captopril improves insulin resistance, reduces LDL slightly, and increases HDL slightly. α-Adrenergic blockers slightly improve insulin resistance and positively impact the lipid profile, whereas beta blockers and thiazide diuretics can increase insulin resistance and negatively impact the lipid profile. Calcium channel blockers, central adrenergic antagonists, and vasodilators are lipid- and glucose-neutral.
2. Beta blockers may slightly increase the risk of developing type 2 DM. Although often questioned because of the potential masking of hypoglycemic symptoms, beta blockers are safe in most patients with diabetes and reduce cardiovascular events. In one study of nondiabetic individuals, the ACE inhibitor ramipril reduced the risk of developing type 2 DM.
3. Sympathetic inhibitors and α-adrenergic blockers may worsen orthostatic hypotension in the diabetic individual with autonomic neuropathy.
4. Equivalent reduction in blood pressure by different classes of agents may not translate into equivalent protection from cardiovascular and renal endpoints. Thiazides, beta blockers, ACE inhibitors, and ARBs positively impact cardiovascular endpoints (MI or stroke). The cardiovascular protective effect of calcium channel blockers, central adrenergic antagonists, and α-adrenergic blockers is either controversial or not known. ACE inhibitors (in types 1 and 2 DM) and ARBs (in type 2 DM) slow the progression of diabetic renal disease; the effect of other classes of agents on diabetic nephropathy is not known.
5. Non-dihydropyridine calcium channel blockers (verapamil and diltiazem), rather than dihydropyridine agents (amlodipine and nifedipine), are preferred in diabetics.

If microalbuminuria or overt albuminuria is present, the optimal antihypertensive agent is an ACE inhibitor (in types 1 and 2 DM) or an ARB (in type 2 DM). Most prefer ARBs over ACE inhibitors in type 2 DM with hypertension and microalbuminuria. If albumin excretion is normal, then an ACE inhibitor is usually prescribed initially. A low-dose thiazide diuretic, beta blockers, or an ARB may also be used as the initial agent. Non-dihydropyridine calcium channel blockers, α-adrenergic blockers, and central adrenergic antagonists should be considered as additional or second-line agents. Since hypertension is often difficult to control with a single agent (especially in type 2 DM), multiple antihypertensive agents are usually required when blood pressure goals (<130/80 mmHg) are not achieved. Because of the high prevalence of atherosclerotic disease in individuals with DM, the possibility of renovascular hypertension should be considered when the blood pressure is not readily controlled.

LOWER EXTREMITY COMPLICATIONS DM is the leading cause of nontraumatic lower extremity amputation in the United States. Foot ulcers and infections are also a major source of morbidity in individuals with DM. The reasons for the increased incidence of these disorders in DM involve the interaction of several pathogenic factors: neuropathy, abnormal foot biomechanics, peripheral arterial disease, and poor wound healing. The peripheral sensory neuropathy interferes with normal protective mechanisms and allows the patient to sustain major or repeated minor trauma to the foot, often without knowledge of the injury. Disordered proprioception causes abnormal weight bearing while walking and subsequent formation of callus or ulceration. Motor and sensory neuropathy lead to abnormal foot muscle mechanics and to structural changes in the foot (hammer toe, claw toe deformity, prominent metatarsal heads, Charcot joint). Autonomic neuropathy results in anhidrosis and altered superficial blood flow in the foot, which promote drying of the skin and fissure formation. Peripheral arterial disease and poor wound healing impede resolution of minor breaks in the skin, allowing them to enlarge and to become infected.

Approximately 15% of individuals with DM develop a foot ulcer, and a significant subset will ultimately undergo amputation (14 to 24% risk with that ulcer or subsequent ulceration). Risk factors for foot ulcers or amputation include: male sex, diabetes >10 years' duration, peripheral neuropathy, abnormal structure of foot (bony abnormalities, callus, thickened nails), peripheral arterial disease, smoking, history of previous ulcer or amputation, and poor glycemic control.

Rx TREATMENT

The optimal therapy for foot ulcers and amputations is prevention through identification of high-risk patients, education of the patient, and institution of measures to prevent ulceration. High-risk patients should be identified during the routine foot examination performed on all patients with DM (see "Ongoing Aspects of Comprehensive Diabetes Care," below). Patient education should emphasize: (1) careful selection of footwear, (2) daily inspection of the feet to detect early signs of poor-fitting footwear or minor trauma, (3) daily foot hygiene to keep the skin clean and moist, (4) avoidance of self-treatment of foot abnormalities and high-risk behavior (e.g., walking barefoot), and (5) prompt consultation with a health care provider if an abnormality arises. Patients at high risk for ulceration or amputation may benefit from evaluation by a foot care specialist. Interventions directed at risk factor modification include orthotic shoes and devices, callus management, nail care, and prophylactic measures to reduce increased skin pressure from abnormal bony architecture. Attention to other risk factors for vascular disease (smoking, dyslipidemia, hypertension) and improved glycemic control are also important.

Despite preventive measures, foot ulceration and infection are common and represent a potentially serious problem. Due to the multifactorial pathogenesis of lower extremity ulcers, management of these lesions is multidisciplinary and often demands expertise in orthopedics, vascular surgery, endocrinology, podiatry, and infectious diseases. The plantar surface of the foot is the most common site of ulceration. Ulcers may be primarily neuropathic (no accompanying infection) or may have surrounding cellulitis or osteomyelitis. Cellulitis without ulceration is also frequent and should be treated with

antibiotics that provide broad-spectrum coverage, including anaerobes (see below).

An infected ulcer is a clinical diagnosis, since superficial culture of any ulceration will likely find multiple possible bacterial pathogens. The infection surrounding the foot ulcer is often the result of multiple organisms (gram-positive and -negative organisms and anaerobes), and gas gangrene may develop in the absence of clostridial infection. Cultures taken from the debrided ulcer base or from purulent drainage are most helpful. Wound depth should be determined by inspection and probing with a blunt-tipped sterile instrument. Plain radiographs of the foot should be performed to assess the possibility of osteomyelitis in chronic ulcers that have not responded to therapy. Nuclear medicine bone scans may be helpful, but overlying subcutaneous infection is often difficult to distinguish from osteomyelitis. Indium-labeled white cell studies are more useful in determining if the infection involves bony structures or only soft tissue, but they are technically demanding. Magnetic resonance imaging of the foot may be the most specific modality, although distinguishing bony destruction due to osteomyelitis from destruction secondary to Charcot arthropathy is difficult. If surgical debridement is necessary, bone biopsy and culture may provide the answer.

Osteomyelitis is best treated by a combination of prolonged antibiotics (IV then oral) and possibly debridement of infected bone. The possible contribution of vascular insufficiency should be considered in all patients. Noninvasive blood-flow studies are often unreliable in DM, and angiography may be required, recognizing the risk of contrast-induced nephrotoxicity. Peripheral arterial bypass procedures are often effective in promoting wound healing and in decreasing the need for amputation of the ischemic limb.

A growing number of possible treatments for diabetic foot ulcers exist, but they have yet to demonstrate clear efficacy in prospective, controlled trials. A recent consensus statement from the ADA identified six interventions with demonstrated efficacy in diabetic foot wounds: (1) off-loading, (2) debridement, (3) wound dressings, (4) appropriate use of antibiotics, (5) revascularization, and (6) limited amputation. Off-loading is the complete avoidance of weight bearing on the ulcer, which removes the mechanical trauma that retards wound healing. Bed rest and a variety of orthotic devices or contact casting limit weight bearing on wounds or pressure points. Surgical debridement is important and effective, but clear efficacy of other modalities for wound cleaning (enzymes, soaking, whirlpools) is lacking. Dressings promote wound healing by creating a moist environment and protecting the wound. Antiseptic agents and topical antibiotics should be avoided. Referral for physical therapy, orthotic evaluation, and rehabilitation may be useful once the infection is controlled.

Mild or non-limb-threatening infections can be treated with oral antibiotics (cephalosporin, clindamycin, amoxicillin/clavulanate, and fluoroquinolones), surgical debridement of necrotic tissue, local wound care (avoidance of weight bearing over the ulcer), and close surveillance for progression of infection. More severe ulcers may require intravenous antibiotics as well as bed rest and local wound care. Urgent surgical debridement may be required. Intravenous antibiotics should provide broad-spectrum coverage directed toward *Staphylococcus aureus*, streptococci, gram-negative aerobes, and anaerobic bacteria. Initial antimicrobial regimens include cefotetan, ampicillin/sulbactam, or the combination of clindamycin and a fluoroquinolone. Severe infections, or infections that do not improve after 48 h of antibiotic therapy, require expansion of antimicrobial therapy to treat methicillin-resistant *S. aureus* (e.g., vancomycin) and *Pseudomonas aeruginosa*. If the infection surrounding the ulcer is not improving with intravenous antibiotics, reassessment of antibiotic coverage and reconsideration of the need for surgical debridement or revascularization are indicated. With clinical improvement, oral antibiotics and local wound care can be continued on an outpatient basis with close follow-up.

New information about wound biology has led to a number of new technologies (e.g., living skin equivalents and growth factors such as basic fibroblast growth factor) that may prove useful. Recombinant platelet-derived growth factor has some benefit and complement the therapies of off-loading, debridement, and antibiotics. Hyperbaric oxygen has been used, but rigorous proof of efficacy is lacking.

INFECTIONS Individuals with DM have a greater frequency and severity of infection. The reasons for this include incompletely defined abnormalities in cell-mediated immunity and phagocyte function associated with hyperglycemia, as well as diminished vascularization. Hyperglycemia aids the colonization and growth of a variety of organisms (*Candida* and other fungal species). Many common infections are more frequent and severe in the diabetic population, whereas several rare infections are seen almost exclusively in the diabetic population. Examples of this latter category includes rhinocerebral mucormycosis, emphysematous infections of the gall bladder and urinary tract, and "malignant" or invasive otitis externa. Invasive otitis externa is usually secondary to *P. aeruginosa* infection in the soft tissue surrounding the external auditory canal, usually begins with pain and discharge, and may rapidly progress to osteomyelitis and meningitis. These infections should be sought, in particular, in patients presenting with HHS.

Pneumonia, urinary tract infections, and skin and soft tissue infections are all more common in the diabetic population. In general, the organisms that cause pulmonary infections are similar to those found in the nondiabetic population; however, gram-negative organisms, *S. aureus*, and *Mycobacterium tuberculosis* are more frequent pathogens. Urinary tract infections (either lower tract or pyelonephritis) are the result of common bacterial agents such as *Escherichia coli*, though several yeast species (*Candida* and *Torulopsis glabrata*) are commonly observed. Complications of urinary tract infections include emphysematous pyelonephritis and emphysematous cystitis. Bacteriuria occurs frequently in individuals with diabetic cystopathy. Susceptibility to furunculosis, superficial candidal infections, and vulvovaginitis are increased. Poor glycemic control is a common denominator in individuals with these infections. Diabetic individuals have an increased rate of colonization of *S. aureus* in the skin folds and nares. Diabetic patients also have a greater risk of postoperative wound infections. Strict glycemic control reduces postoperative infections in diabetic individuals undergoing CABG and should be the goal in all diabetic patients with an infection.

DERMATOLOGIC MANIFESTATIONS The most common skin manifestations of DM are protracted wound healing and skin ulcerations. Diabetic dermopathy, sometimes termed *pigmented pretibial papules*, or "diabetic skin spots," begins as an erythematous area and evolves into an area of circular hyperpigmentation. These lesions result from minor mechanical trauma in the pretibial region and are more common in elderly men with DM. Bullous diseases (shallow ulcerations or erosions in the pretibial region) are also seen. *Necrobiosis lipoidica diabeticorum* is a rare disorder of DM that predominantly affects young women with type 1 DM, neuropathy, and retinopathy. It usually begins in the pretibial region as an erythematous plaque or papules that gradually enlarge, darken, and develop irregular margins, with atrophic centers and central ulceration. They may be painful. *Acanthosis nigricans* (hyperpigmented velvety plaques seen on the neck, axilla, or extensor surfaces) is sometimes a feature of severe insulin resistance and accompanying diabetes. Generalized or localized *granuloma annulare* (erythematous plaques on the extremities or trunk) and *scleredema* (areas of skin thickening on the back or neck at the site of previous superficial infections) are more common in the diabetic population. *Lipoatrophy* and *lipohypertrophy* can occur at insulin injection sites but are unusual with the use of human insulin. Xerosis and pruritus are common and are relieved by skin moisturizers.

APPROACH TO THE PATIENT

DM and its complications produce a wide range of symptoms and signs; those secondary to acute hyperglycemia may occur at any stage of the disease, whereas those related to chronic complications

begin to appear during the second decade of hyperglycemia. Individuals with previously undetected type 2 DM may present with chronic complications of DM at the time of diagnosis. The history and physical examination should assess for symptoms or signs of acute hyperglycemia and should screen for the chronic complications and conditions associated with DM.

History A complete medical history should be obtained with special emphasis on DM-relevant aspects such as weight, family history of DM and its complications, risk factors for cardiovascular disease, exercise, smoking, and ethanol use. Symptoms of hyperglycemia include polyuria, polydipsia, weight loss, fatigue, weakness, blurry vision, frequent superficial infections (vaginitis, fungal skin infections), and slow healing of skin lesions after minor trauma. Metabolic derangements relate mostly to hyperglycemia (osmotic diuresis, reduced glucose entry into muscle) and to the catabolic state of the patient (urinary loss of glucose and calories, muscle breakdown due to protein degradation and decreased protein synthesis). Blurred vision results from changes in the water content of the lens and resolves as the hyperglycemia is controlled.

In a patient with established DM, the initial assessment should also include special emphasis on prior diabetes care, including the type of therapy, prior hemoglobin A1C levels, self-monitoring blood glucose results, frequency of hypoglycemia, presence of DM-specific complications, and assessment of the patient's knowledge about diabetes. The chronic complications may afflict several organ systems, and an individual patient may exhibit some, all, or none of the symptoms related to the complications of DM (see above). In addition, the presence of DM-related comorbidities should be sought (cardiovascular disease, hypertension, dyslipidemia).

Physical Examination In addition to a complete physical examination, special attention should be given to DM-relevant aspects such as weight or BMI, retinal examination, orthostatic blood pressure, foot examination, peripheral pulses, and insulin injection sites. Blood pressure $>$ 130/80 mmHg is considered hypertension in individuals with diabetes. Careful examination of the lower extremities should seek evidence of peripheral neuropathy, calluses, superficial fungal infections, nail disease, and foot deformities (such as hammer or claw toes and Charcot foot) in order to identify sites of potential skin ulceration. Vibratory sensation (128-MHz tuning fork at the base of the great toe) and the ability to sense touch with a monofilament (5.07, 10-g monofilament) are useful to detect moderately advanced diabetic neuropathy. Since periodontal disease is more frequent in DM, the teeth and gums should also be examined.

Classification of DM in an Individual Patient The etiology of diabetes in an individual with new-onset disease can usually be assigned on the basis of clinical criteria. Individuals with type 1 DM tend to have the following characteristics: (1) onset of disease prior to age 30; (2) lean body habitus; (3) requirement of insulin as the initial therapy; (4) propensity to develop ketoacidosis; and (5) an increased risk of other autoimmune disorders such as autoimmune thyroid disease, adrenal insufficiency, pernicious anemia, and vitiligo. In contrast, individuals with type 2 DM often exhibit the following features: (1) develop diabetes after the age of 30; (2) are usually obese (80% are obese, but elderly individuals may be lean); (3) may not require insulin therapy initially; and (4) may have associated conditions such as insulin resistance, hypertension, cardiovascular disease, dyslipidemia, or PCOS. In type 2 DM, insulin resistance is often associated with abdominal obesity (as opposed to hip and thigh obesity) and hypertriglyceridemia. Although most individuals diagnosed with type 2 DM are older, the age of diagnosis is declining in some ethnic groups, and there is a marked increase among overweight children and adolescents. Some individuals with phenotypic type 2 DM present with DKA but lack autoimmune markers and may be later treated with oral glucose-lowering agents rather than insulin. On the other hand, some individuals (5–10%) with the phenotypic appearance of type 2 DM do not have absolute insulin deficiency but have autoimmune markers (ICA, GAD autoantibodies) suggestive of type 1A DM (termed *autoimmune diabetes not requiring insulin at diagnosis* or *latent autoimmune diabetes of the adult*). Such individuals are much more likely to require insulin treatment within 5 years. Thus, despite the revised classification of DM, it is remains difficult to categorize some patients unequivocally. Individuals who deviate from the clinical profile of type 1 and type 2 DM, or who have other associated defects such as deafness, pancreatic exocrine disease, and other endocrine disorders, should be classified accordingly (Table 323-1).

Laboratory Assessment The laboratory assessment should first determine whether the patient meets the diagnostic criteria for DM (Table 323-2) and then assess the degree of glycemic control (A1C, discussed below). In addition to the standard laboratory evaluation, the patient should be screened for DM-associated conditions (e.g., microalbuminuria, dyslipidemia, thyroid dysfunction). Individuals at high risk for cardiovascular disease should be screened for asymptomatic coronary artery disease by appropriate cardiac stress testing, when indicated.

The classification of the type of DM may be facilitated by laboratory assessments. Serum insulin or C-peptide measurements do not always distinguish type 1 from type 2 DM, but a low C-peptide level confirms a patient's need for insulin. Many individuals with new-onset type 1 DM retain some C-peptide production. Measurement of islet cell antibodies at the time of diabetes onset may be useful if the type of DM is not clear based on the characteristics described above.

LONG-TERM TREATMENT

OVERALL PRINCIPLES The goals of therapy for type 1 or type 2 DM are to: (1) eliminate symptoms related to hyperglycemia, (2) reduce or eliminate the long-term microvascular and macrovascular complications of DM, and (3) allow the patient to achieve as normal a life-style as possible. To reach these goals, the physician should identify a target level of glycemic control for each patient, provide the patient with the educational and pharmacologic resources necessary to reach this level, and monitor/treat DM-related complications. Symptoms of diabetes usually resolve when the plasma glucose is $<$11.1 mmol/L (200 mg/dL), and thus most DM treatment focuses on achieving the second and third goals.

The care of an individual with either type 1 or type 2 DM requires a multidisciplinary team. Central to the success of this team are the patient's participation, input, and enthusiasm, all of which are essential for optimal diabetes management. Members of the health care team include the primary care provider and/or the endocrinologist or diabetologist, a certified diabetes educator, and a nutritionist. In addition, when the complications of DM arise, subspecialists (including neurologists, nephrologists, vascular surgeons, cardiologists, ophthalmologists, and podiatrists) with experience in DM-related complications are essential.

A number of names are sometimes applied to different approaches to diabetes care, such as intensive insulin therapy, intensive glycemic control, and "tight control." The current chapter, however, will use the term *comprehensive diabetes care* to emphasize the fact that optimal diabetes therapy involves more than plasma glucose management. Though glycemic control is central to optimal diabetes therapy, comprehensive diabetes care of both type 1 and type 2 DM should also detect and manage DM-specific complications and modify risk factors for DM-associated diseases. In addition to the physical aspects of DM, social, family, financial, cultural, and employment-related issues may impact diabetes care.

PATIENT EDUCATION ABOUT DM, NUTRITION, AND EXERCISE The patient with type 1 or type 2 DM should receive education about nutrition, exercise, care of diabetes during illness, and medications to lower the plasma glucose. Along with improved compliance, patient education allows individuals with DM to assume greater responsibility for their care. Patient education should be viewed as a continuing process with regular visits for reinforcement; it should *not* be a process that is completed after one or two visits to a nurse educator or nutritionist.

Diabetes Education The diabetes educator is a health care professional (nurse, dietician, or pharmacist) with specialized patient education skills who is certified in diabetes education (e.g., American Association of Diabetes Educators). Education topics important for optimal diabetes care include self-monitoring of blood glucose; urine ketone monitoring (type 1 DM); insulin administration; guidelines for diabetes management during illnesses; management of hypoglycemia; foot and skin care; diabetes management before, during, and after exercise; and risk factor–modifying activities.

Nutrition *Medical nutrition therapy* (MNT) is a term used by the ADA to describe the optimal coordination of caloric intake with other aspects of diabetes therapy (insulin, exercise, weight loss). Historically, nutrition education imposed restrictive, complicated regimens on the patient. Current practices have greatly changed, though many patients and health care providers still view the diabetic diet as monolithic and static. For example, MNT now includes foods with sucrose and seeks to modify other risk factors such as hyperlipidemia and hypertension rather than focusing exclusively on weight loss in individuals with type 2 DM. Like other aspects of DM therapy, MNT must be adjusted to meet the goals of the individual patient. Furthermore, MNT education is an important component of comprehensive diabetes care and should be reinforced by regular patient education. In general, the components of optimal MNT are similar for individuals with type 1 or type 2 DM (Table 323-8).

The goal of MNT in the individual with type 1 DM is to coordinate and match the caloric intake, both temporally and quantitatively, with the appropriate amount of insulin. MNT in type 1 DM and self-monitoring of blood glucose must be integrated to define the optimal insulin regimen. MNT must be flexible enough to allow for exercise, and the insulin regimen must allow for deviations in caloric intake. An important component of MNT in type 1 DM is to minimize the weight gain often associated with intensive diabetes management.

The goals of MNT in type 2 DM are slightly different and address the greatly increased prevalence of cardiovascular risk factors (hypertension, dyslipidemia, obesity) and disease in this population. The majority of these individuals are obese, and weight loss is strongly encouraged and should remain an important goal. Medical treatment of obesity is a rapidly evolving area and is discussed in Chap. 64. Hypocaloric diets and modest weight loss often result in rapid and dramatic glucose lowering in individuals with new-onset type 2 DM. Nevertheless, numerous studies document that long-term weight loss is uncommon. Current MNT for type 2 DM should emphasize modest caloric reduction, reduced fat intake, increased physical activity, and reduction of hyperlipidemia and hypertension. Increased consumption of soluble, dietary fiber may improve glycemic control in individuals with type 2 DM.

TABLE 323-8 Nutritional Recommendations for All Persons with Diabetes

- Protein to provide ~15–20% of kcal/d (~10% for those with nephropathy)
- Saturated fat to provide <10% of kcal/d (<7% for those with elevated LDL)
- Polyunsaturated fat to provide ~10% of kcal; avoid trans-unsaturated fatty acids
- 60–70% of calories to be divided between carbohydrate and monounsaturated fat, based on medical needs and personal tolerance; glycemic index of food not as important
- Use of caloric sweeteners, including sucrose, is acceptable.
- Fiber (20–35 g/d) and sodium (≤3000 mg/d) levels as recommended for the general healthy population
- Cholesterol intake ≤300 mg/d
- The same precautions regarding alcohol use in the general population also apply to individuals with diabetes. Alcohol may increase risk for hypoglycemia and therefore should be taken with food.

Note: LDL, low-density lipoprotein.

Exercise Exercise has multiple positive benefits including cardiovascular risk reduction, reduced blood pressure, maintenance of muscle mass, reduction in body fat, and weight loss. For individuals with type 1 or type 2 DM, exercise is also useful for lowering plasma glucose (during and following exercise) and increasing insulin sensitivity.

Despite its benefits, exercise presents challenges for individuals with DM because they lack the normal glucoregulatory mechanisms (insulin falls and glucagon rises during exercise). Skeletal muscle is a major site for metabolic fuel consumption in the resting state, and the increased muscle activity during vigorous, aerobic exercise greatly increases fuel requirements. Individuals with type 1 DM are prone to either hyperglycemia or hypoglycemia during exercise, depending on the preexercise plasma glucose, the circulating insulin level, and the level of exercise-induced catecholamines. If the insulin level is too low, the rise in catecholamines may increase the plasma glucose excessively, promote ketone body formation, and possibly lead to ketoacidosis. Conversely, if the circulating insulin level is excessive, this relative hyperinsulinemia may reduce hepatic glucose production (decreased glycogenolysis, decreased gluconeogenesis) and increase glucose entry into muscle, leading to hypoglycemia.

To avoid exercise-related hyper- or hypoglycemia, individuals with type 1 DM should: (1) monitor blood glucose before, during, and after exercise; (2) delay exercise if blood glucose is >14 mmol/L (250 mg/dL), <5.5 mmol/L (100 mg/dL), or if ketones are present; (3) monitor glucose during exercise and ingest carbohydrate to prevent hypoglycemia; (4) decrease insulin doses (based on previous experience) before exercise and inject insulin into a nonexercising area; and (5) learn individual glucose responses to different types of exercise and increase food intake for up to 24 h after exercise, depending on intensity and duration of exercise. In individuals with type 2 DM, exercise-related hypoglycemia is less common but can occur in individuals taking either insulin or sulfonylureas.

Because asymptomatic cardiovascular disease appears at a younger age in both type 1 and type 2 DM, formal exercise tolerance testing may be warranted in diabetic individuals with any of the following: age >35 years, diabetes duration >15 years (type 1 DM) or >10 years (type 2 DM), microvascular complications of DM (retinopathy, microalbuminuria, or nephropathy), peripheral arterial disease, other risk factors of coronary artery disease, or autonomic neuropathy. Untreated proliferative retinopathy is a relative contraindication to vigorous exercise, as this may lead to vitreous hemorrhage or retinal detachment.

MONITORING THE LEVEL OF GLYCEMIC CONTROL Optimal monitoring of glycemic control involves plasma glucose measurements by the patient and an assessment of long-term control by the physician (measurement of hemoglobin A1C and review of the patient's self-measurements of plasma glucose). These measurements are complementary: the patient's measurements provide a picture of short-term glycemic control, whereas the A1C reflects average glycemic control over the previous 2 to 3 months.

Self-Monitoring of Blood Glucose Self-monitoring of blood glucose (SMBG) is the standard of care in diabetes management and allows the patient to monitor his or her blood glucose at any time. In SMBG, a small drop of blood and an easily detectable enzymatic reaction allow measurement of the capillary plasma glucose. A number of devices accurately measure glucose in blood obtained from the fingertip; al-

ternative testing sites (e.g., forearm) are less reliable. By combining glucose measurements with diet history, medication changes, and exercise history, the physician and patient can improve the treatment program.

The frequency of SMBG measurements must be individualized and adapted to address the goals of diabetes care. Individuals with type 1 DM should routinely measure their plasma glucose four to eight times per day to estimate and select mealtime boluses of short-acting insulin and to modify long-acting insulin doses. Most individuals with type 2 DM require less frequent monitoring, though the optimal frequency of SMBG has not been clearly defined. Individuals with type 2 DM who are on oral medications should utilize SMBG as a means of assessing the efficacy of their medication and the impact of diet. Since plasma glucose levels fluctuate less in these individuals, one to two SMBG measurements per day (or fewer) may be sufficient. Individuals with type 2 DM who are on insulin should utilize SMBG more frequently than those on oral agents. Urine glucose testing does not provide an accurate assessment of glycemic control.

Two devices for continuous blood glucose monitoring have been recently approved by the U.S. Food and Drug Administration (FDA). The Glucowatch uses iontophoresis to assess glucose in interstitial fluid, whereas the Minimed device uses an indwelling subcutaneous catheter to monitor interstitial fluid glucose. Both devices utilize immobilized glucose oxidase to generate electrons in response to changing glucose levels. Though clinical experience with these devices is limited, they perform well in clinical trials and appear to provide useful short-term information about the patterns of glucose changes as well as an enhanced ability to detect hypoglycemic episodes. These devices are not yet used routinely in diabetes management.

Ketones are an indicator of early diabetic ketoacidosis and should be measured in individuals with type 1 DM when the plasma glucose is consistently >16.7 mmol/L (300 mg/dL), during a concurrent illness; or with symptoms such as nausea, vomiting, or abdominal pain. Blood measurement of β-hydroxybutyrate is preferred over urine testing with nitroprusside-based assays that measure only acetoacetate and acetone.

Assessment of Long-Term Glycemic Control Measurement of glycated hemoglobin is the standard method for assessing long-term glycemic control. When plasma glucose is consistently elevated, there is an increase in nonenzymatic glycation of hemoglobin; this alteration reflects the glycemic history over the previous 2 to 3 months, since erythrocytes have an average life span of 120 days. There are numerous laboratory methods for measuring the various forms of glycated hemoglobin, and these have significant interassay variations. Since glycated hemoglobin measurements are usually compared to prior measurements, it is essential for the assay results to be comparable. Depending on the assay methodology, hemoglobinopathies, anemias, and uremia may interfere with the A1C result.

Glycated hemoglobin or A1C should be measured in all individuals with DM during their initial evaluation and as part of their comprehensive diabetes care. As the primary predictor of long-term complications of DM, the A1C should mirror, to a certain extent, the short-term measurements of SMBG. These two measurements are complementary in that recent intercurrent illnesses may impact the SMBG measurements but not the A1C. Likewise, postprandial and nocturnal hyperglycemia may not be detected by the SMBG of fasting and preprandial capillary plasma glucose but will be reflected in the A1C. In standardized assays, the A1C approximates the following mean plasma glucose values: an A1C of 6% is 7.5 mmol/L (135 mg/dL), 7% is 9.5 mmol/L (170 mg/dL), 8% is 11.5 mmol/L (205 mg/dL), etc. [A 1% rise in the A1C translates into a 2.0-mmol/L (35 mg/dL) increase in the mean glucose.] In patients achieving their glycemic goal, the ADA recommends measurement of the A1C twice per year. More frequent testing (every 3 months) is warranted when glycemic control is inadequate, when therapy has changed, or in most patients with type 1 DM. The degree of glycation of other proteins, such as albumin, has been used as an alternative indicator of glycemic control when the A1C is inaccurate (hemolytic anemia, hemoglobinopathies). The fructosamine assay (measuring glycated albumin) reflects the glycemic status over the prior 2 weeks. Current consensus statements do not favor the use of alternative assays of glycemic control, as there are no studies to indicate whether such assays accurately predict the complications of DM.

TREATMENT

ESTABLISHMENT OF A TARGET LEVEL OF GLYCEMIC CONTROL Because the complications of DM are related to glycemic control, normoglycemia or near normoglycemia is the desired, but often elusive, goal for most patients. However, normalization of the plasma glucose for long periods of time is extremely difficult, as demonstrated by the DCCT. Regardless of the level of hyperglycemia, improvement in glycemic control will lower the risk of diabetes complications (Fig. 323-8).

The target for glycemic control (as reflected by the A1C) must be individualized, and the goals of therapy should be developed in consultation with the patient after considering a number of medical, social, and life-style issues. Some important factors to consider include the patient's age, ability to understand and implement a complex treatment regimen, presence and severity of complications of diabetes, ability to recognize hypoglycemic symptoms, presence of other medical conditions or treatments that might alter the response to therapy, life-style and occupation (e.g., possible consequences of experiencing hypoglycemia on the job), and level of support available from family and friends.

The ADA has established suggested glycemic goals based on the premise that glycemic control predicts development of DM-related complications. In general, the target A1C should be <7.0% (Table 323-9). Other consensus groups (such as the Veterans Administration) have suggested A1C goals that take into account the patient's life expectancy at the time of diagnosis and the presence of microvascular complications. Such recommendations strive to balance the financial and personal costs of glycemic therapy with anticipated benefits (reduced health care costs, reduced morbidity). One limitation to this approach is that the onset of hyperglycemia in type 2 DM is difficult to ascertain and likely predates the diagnosis.

TYPE 1 DIABETES MELLITUS ■ General Aspects The ADA recommendations for fasting and bedtime glycemic goals and A1C targets are summarized in Table 323-9. The goal is to design and implement insulin regimens that mimic physiologic insulin secretion. Because individuals with type 1 DM lack endogenous insulin production, administration of basal, exogenous insulin is essential for regulating glycogen breakdown, gluconeogenesis, lipolysis, and ketogenesis. Likewise, insulin replacement for meals should be appropriate for the carbohydrate intake and promote normal glucose utilization and storage.

Intensive Management Intensive diabetes management has the goal of achieving euglycemia or near-normal glycemia. This approach requires multiple resources including thorough and continuing patient education, comprehensive recording of plasma glucose measurements and nutrition intake by the patient, and a variable insulin regimen that

TABLE 323-9 *Ideal Goals for Glycemic Control*[a]

Index	Goal
Preprandial plasma glucose, mmol/L (mg/dL)	5.0–7.2 (90–130)
Peak postprandial plasma glucose, mmol/L (mg/dL)	<10 (<180)
A1C, %	<7

[a] Plasma glucose values are 10–15% higher than whole blood values. The upper limit of the A1C reference range is 6.0% (mean 5.0%, with a standard deviation of 0.5%). These goals must be individualized for each patient and must consider the patient's age and other medical conditions.

Note: A1C, hemoglobin A1c.

TABLE 323-10 Indications for Intensive Diabetes Management

- Otherwise healthy adults with either type 1 or type 2 diabetes (selected adolescents and older children)
- Purposeful, therapeutic attempt to avoid or lessen microvascular complications
- All pregnant women with diabetes; all women with diabetes who are planning pregnancy
- Management of labile diabetes
- Availability of health care professionals with appropriate expertise
- Patients who have had kidney transplantation for diabetic nephropathy

matches glucose intake and insulin dose. Insulin regimens usually include multiple-component insulin regimens, multiple daily injections (MDI), or insulin infusion devices (each discussed below).

The benefits of intensive diabetes management and improved glycemic control include a reduction in the microvascular complications of DM and a possible delay or reduction in the macrovascular complications of DM. From a psychological standpoint, the patient experiences greater control over his or her diabetes and often notes an improved sense of well-being, greater flexibility in the timing and content of meals, and the capability to alter insulin dosing with exercise. In addition, intensive diabetes management in pregnancy reduces the risk of fetal malformations and morbidity. Intensive diabetes management is strongly encouraged in newly diagnosed patients with type 1 DM because it may prolong the period of C-peptide production, which may result in better glycemic control and a reduced risk of serious hypoglycemia.

Although intensive management confers impressive benefits, it is also accompanied by significant personal and financial costs and is therefore not appropriate for all individuals. Circumstances in which intensive diabetes management should be strongly considered are listed in Table 323-10.

Insulin Preparations Current insulin preparations are generated by recombinant DNA technology and consist of the amino acid sequence of human insulin or variations thereof. Animal insulin (beef or pork) is no longer used. Human insulin has been formulated with distinctive pharmacokinetics to mimic physiologic insulin secretion (Table 323-11). In the United States, all insulin is formulated as U-100 (100 units/mL), whereas in some other countries it is available in other units (e.g., U-40 = 40 units/mL). One short-acting insulin formulation, lispro, is an insulin analogue in which the 28th and 29th amino acids (lysine and proline) on the insulin B chain have been reversed by recombinant DNA technology. Insulin aspart is another genetically modified insulin analogue with very similar properties to lispro. These insulin analogues have full biologic activity but less tendency toward subcutaneous aggregation, resulting in more rapid absorption and onset of action and a shorter duration of action. These characteristics are particularly advantageous for allowing entrainment of insulin injection and action to rising plasma glucose levels following meals. The shorter duration of action also appears to be associated with a decreased number of hypoglycemic episodes, primarily because the decay of lispro action corresponds to the decline in plasma glucose after a meal. Insulin glargine is a long-acting biosynthetic human insulin that differs from normal insulin in that asparagine is replaced by glycine at amino acid 21, and two arginine residues are added to the C-terminus of the B chain. Compared to NPH insulin, the onset of insulin glargine action is later, the duration of action is longer (~24 h), and there is no pronounced peak. A lower incidence of hypoglycemia, especially at night, has been reported with insulin glargine when compared to NPH insulin. Additional insulin analogues are currently under development.

Basal insulin requirements are provided by intermediate (NPH insulin or lente insulin) or long-acting (ultralente insulin or insulin glargine) insulin formulations. These are usually combined with short-acting insulin in an attempt to mimic physiologic insulin release with meals. Although mixing of intermediate and short-acting insulin formulations is common practice, this mixing may alter the insulin absorption profile (especially the short-acting insulins). For example, the absorption of regular insulin is delayed when mixed for even short periods of time (<5 min) with lente or ultralente insulin, but not when mixed with NPH insulin. Lispro absorption is delayed by mixing with NPH but not ultralente. Insulin glargine should not be mixed with other insulins and is not stable at room temperature. The miscibility of human regular and NPH insulin allows for the production of combination insulins that contain 70% NPH and 30% regular (70/30) or equal mixtures of NPH and regular (50/50). These combinations of insulin are more convenient for the patient but prevent adjustment of only one component of the insulin formulation. The alteration in insulin absorption when the patient mixes different insulin formulation should not discourage the patient from mixing insulin. However, the following guidelines should be followed: (1) mix the different insulin formulations in the syringe immediately before injection (inject within 2 min after mixing); (2) do not store insulin as a mixture; and (3) follow the same routine in terms of insulin mixing and administration to standardize the physiologic response to injected insulin. Several insulin formulations are available as insulin "pens," which may be more convenient for some patients.

Insulin Regimens Representations of the various insulin regimens that may be utilized in type 1 DM are illustrated in Fig. 323-13. Although the insulin profiles are depicted as "smooth," symmetric curves, there is considerable patient-to-patient variation in the peak and duration. In all regimens, intermediate- or long-acting insulins (NPH, lente, ultralente, or glargine insulin) supply basal insulin, whereas regular, insulin aspart, or lispro insulin provides prandial insulin. Lispro and insulin aspart should be injected just before or just after a meal; regular insulin is given 30 to 45 min prior to a meal.

A shortcoming of current insulin regimens is that injected insulin immediately enters the systemic circulation, whereas endogenous insulin is secreted into the portal venous system. Thus, exogenous insulin administration exposes the liver to subphysiologic insulin levels. No insulin regimen reproduces the precise insulin secretory pattern of

TABLE 323-11 Pharmacokinetics of Insulin Preparations

Preparation	Time of Action		
	Onset, h	Peak, h	Effective Duration, h
Short-acting			
Lispro	<0.25	0.5–1.5	3–4
Insulin aspart	<0.25	0.5–1.5	3–4
Regular	0.5–1.0	2–3	3–6
Intermediate-acting			
NPH	2–4	6–10	10–16
Lente	3–4	6–12	12–18
Long-acting			
Ultralente	6–10	10–16	18–20
Glargine	4	—[a]	24
Combinations			
75/25–75% protamine lispro, 25% lispro	0.5–1	Dual	10–14
70/30–70% NPH, 30% regular	0.5–1	Dual	10–16
50/50–50% NPH, 50% regular	0.5–1	Dual	10–16

B, breakfast; L, lunch; S, supper; HS, bedtime; CSII, continuous subcutaneous insulin infusion. *either lispro or insulin aspart can be used. The time of insulin injection is shown with a vertical arrow. The type of insulin is noted above each insulin curve. *A*. The injection of two shots of intermediate-acting insulin (NPH or lente) and short-acting insulin (lispro, insulin aspart, or regular). Only one formulation of short-acting insulin is used. *B*: A multiple-component insulin regimen consisting of one shot of glargine at bedtime to provide basal insulin coverage and three shots of lispro or insulin aspart to provide glycemic coverage for each meal. *C*: Insulin administration by insulin infusion device is shown with the basal insulin and a bolus injection at each meal. The basal insulin rate is decreased during the evening and increased slightly prior to the patient awakening in the morning. *(Adapted from Intensive Diabetes Management, 2d ed, R. Farkas-Hirsch (ed). Alexandria, VA, American Diabetes Association, 1998.)*

the pancreatic islet. However, the most physiologic regimens entail more frequent insulin injections, greater reliance on short-acting insulin, and more frequent capillary plasma glucose measurements. In general, individuals with type 1 DM require 0.5 to 1.0 U/kg per day of insulin divided into multiple doses. Initial insulin-dosing regimens should be conservative; approximately 40 to 50% of the insulin should be given as basal insulin. A single daily injection of insulin is not appropriate therapy in type 1 DM.

One commonly used regimen consists of twice-daily injections of an intermediate insulin (NPH or lente) mixed with a short-acting insulin before the morning and evening meal (Fig. 323-13*A*). Such regimens usually prescribe two-thirds of the total daily insulin dose in the morning (with about two-thirds given as intermediate-acting insulin and one-third as short-acting) and one-third before the evening meal (with approximately one-half given as intermediate-acting insulin and one-half as short-acting). The drawback to such a regimen is that it enforces a rigid schedule on the patient, in terms of daily activity and the content and timing of meals. Although it is simple and effective at avoiding severe hyperglycemia, it does not generate near-normal glycemic control in most individuals with type 1 DM. Moreover, if the patient's meal pattern or content varies or if physical activity is increased, hyperglycemia or hypoglycemia may result. Moving the intermediate insulin from before the evening meal to bedtime may avoid nocturnal hypoglycemia and provide more insulin as glucose levels rise in the early morning (so-called dawn phenomenon). The insulin dose in such regimens should be adjusted based on SMBG results with the following general assumptions: (1) the fasting glucose is primarily determined by the prior evening intermediate-acting insulin; (2) the pre-lunch glucose is a function of the morning short-acting insulin; (3) the pre-supper glucose is a function of the morning intermediate-acting insulin; and (4) the bedtime glucose is a function of the pre-supper, short-acting insulin.

Multiple-component insulin regimens refer to the combination of basal insulin; preprandial short-acting insulin; and changes in short-acting insulin doses to accommodate the results of frequent SMBG, anticipated food intake, and physical activity. Also referred to as MDI, such regimens offer the patient more flexibility in terms of life-style and the best chance for achieving near normoglycemia. One such regimen, shown in Fig. 323-13*B*, consists of a basal insulin with glargine at bedtime and preprandial lispro or insulin aspart. The lispro or insulin aspart dose is based on individualized algorithms that integrate the preprandial glucose and the anticipated carbohydrate intake. An alternative regimen is two equal doses of ultralente (breakfast and evening; 10 to 12 h apart) and preprandial lispro or insulin aspart. Another alternative multiple-component insulin regimen consists of bedtime intermediate insulin, a small dose of intermediate insulin at breakfast (20 to 30 % of bedtime dose), and preprandial short-acting insulin. There are numerous variations of these regimens that can be optimized for individual patients. Frequent SMBG (four to eight times per day) is absolutely essential for these types of insulin regimens.

Continuous subcutaneous insulin infusion (CSII) is another multiple-component insulin regimen (Fig. 323-13*C*). Sophisticated insulin infusion devices can accurately deliver small doses of insulin (microliters per hour). For example, multiple basal infusion rates can be programmed to: (1) accommodate nocturnal versus daytime basal insulin requirement, (2) alter infusion rate during periods of exercise, or (3) select different waveforms of insulin infusion. A preprandial insulin ("bolus") is delivered by the insulin infusion device based on instructions from the patient, which follow individualized algorithms that account for preprandial plasma glucose and anticipated carbohydrate intake. These devices require a health professional with considerable experience with insulin infusion devices and very frequent patient interactions with the diabetes management team. Insulin infusion devices present unique challenges, such as infection at the infusion site, unexplained hyperglycemia because the infusion set becomes obstructed, or diabetic ketoacidosis if the pump becomes disconnected. Since most physicians use lispro or insulin aspart in CSII, the extremely short half-life of these insulins quickly lead to insulin deficiency if the delivery system is interrupted. Essential to the safe use of infusion devices is thorough patient education about pump function and frequent SMBG.

TYPE 2 DIABETES MELLITUS ■ General Aspects The goals of therapy for type 2 DM are similar to those in type 1. While glycemic control tends to dominate the management of type 1 DM, the care of individuals with type 2 DM must also include attention to the treatment of conditions associated with type 2 DM (obesity, hypertension, dyslipidemia, cardiovascular disease) and detection/management of DM-related complications (Fig. 323-14). DM-specific complications may be present in up to 20 to 50% of individuals with newly diagnosed type 2 DM. Reduction in cardiovascular risk is of paramount importance as this is the leading cause of mortality in these individuals.

Diabetes management should begin with MNT (discussed above). An exercise regimen to increase insulin sensitivity and promote weight loss should also be instituted. After MNT and increased physical ac-

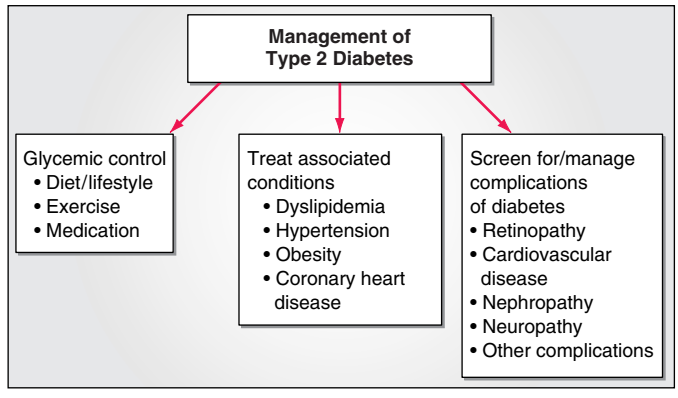

FIGURE 323-14 Essential elements in comprehensive diabetes care of type 2 diabetes.

tivity have been instituted, glycemic control should be reassessed; if the patient's glycemic target is not achieved after 3 to 4 weeks of MNT, pharmacologic therapy is indicated. Pharmacologic approaches to the management of type 2 DM include both oral glucose-lowering agents and insulin; most physicians and patients prefer oral glucose-lowering agents as the initial choice. Any therapy that improves glycemic control reduces "glucose toxicity" to the islet cells and improves endogenous insulin secretion. However, type 2 DM is a progressive disorder and ultimately requires multiple therapeutic agents and often insulin.

Glucose-Lowering Agents Advances in the therapy of type 2 DM have generated considerable enthusiasm for oral glucose-lowering agents that target different pathophysiologic processes in type 2 DM. Based on their mechanisms of action, oral glucose-lowering agents are subdivided into agents that increase insulin secretion, reduce glucose production, or increase insulin sensitivity (Table 323-12). Oral glucose-lowering agents (with the exception of α-glucosidase inhibitors) are ineffective in type 1 DM and should not be used for glucose management of severely ill individuals with type 2 DM. Insulin is sometimes the initial glucose-lowering agent.

INSULIN SECRETAGOGUES Insulin secretagogues stimulate insulin secretion by interacting with the ATP-sensitive potassium channel on the beta cell (Fig. 323-1). These drugs are most effective in individuals with type 2 DM of relatively recent onset (<5 years), who tend to be obese and have residual endogenous insulin production. At maximum doses, first-generation sulfonylureas are similar in potency to second-generation agents but have a longer half-life, a greater incidence of hypoglycemia, and more frequent drug interactions (Table 323-13). Thus, second-generation sulfonylureas are generally preferred. An advantage to a more rapid onset of action is better coverage of the postprandial glucose rise, but the shorter half-life of such agents requires more than once-a-day dosing. Sulfonylureas reduce both fasting and postprandial glucose and should be initiated at low doses and increased at 1- to 2-week intervals based on SMBG. In general, sulfonylureas increase insulin acutely and thus should be taken shortly before a meal; with chronic therapy, though, the insulin release is more sustained. Repaglinide and nateglinide are not sulfonylureas but also interact with the ATP-sensitive potassium channel. Because of their short half-life, these agents are given with each meal or immediately before to reduce meal-related glucose excursions.

Insulin secretagogues are generally well tolerated. All of these agents, however, have the potential to cause profound and persistent hypoglycemia, especially in elderly individuals. Hypoglycemia is usually related to delayed meals, increased physical activity, alcohol intake, or renal insufficiency. Individuals who ingest an overdose of some agents develop prolonged and serious hypoglycemia and should be monitored closely in the hospital (Chap. 324). Most sulfonylureas are metabolized in the liver to compounds that are cleared by the kidney. Thus, their use in individuals with significant hepatic or renal dysfunction is not advisable. Weight gain, a common side effect of sulfonylurea therapy, results from the increased insulin levels and improvement in glycemic control. Some sulfonylureas have significant drug interactions with alcohol and some medications including warfarin, aspirin, ketoconazole, α-glucosidase inhibitors, and fluconazole. Despite prior concerns that use of sulfonylureas might increase cardiovascular risk, most recent trials have refuted this claim.

BIGUANIDES Metformin is representative of this class of agents. It reduces hepatic glucose production through an undefined mechanism and improves peripheral glucose utilization slightly (Table 323-12). Metformin reduces fasting plasma glucose and insulin levels, improves the lipid profile, and promotes modest weight loss. The initial starting dose of 500 mg once or twice a day can be increased to 1000 mg bid. An extended-release form and a combination formulation with glyburide and glipizid are available. Because of its relatively slow onset of action and gastrointestinal symptoms with higher doses, the dose

TABLE 323-12 *Oral Glucose-Lowering Therapies in Type 2 Diabetes*

	Mechanism of Action	Examples	Anticipated Reduction in A1C, %	Agent-Specific Advantages	Agent-Specific Disadvantages	Contraindications
Insulin secretagogues	↑ Insulin		1–2			
Sulfonylureas		See Table 323-13		Lower fasting blood glucose	Hypoglycemia weight gain, hyperinsulinemia	Renal/liver disease
Nonsulfonylureas		See Table 323-13		Short onset of action, lower postprandial glucose	Hypoglycemia	Renal/liver disease
Biguanides	↓ Hepatic glucose production, weight loss, ↑ glucose utilization, ↓ insulin resistance	Metformin	1–2	Weight loss, improved lipid profile, no hypoglycemia	Lactic acidosis, diarrhea, nausea	Serum creatinine >1.5 mg/dL (men), >1.4 mg/dL (women), radiographic contrast studies, seriously ill patients, acidosis
α-Glucosidase inhibitors	↓ Glucose absorption	Acarbose, miglitol	0.5–1.0	No risk of hypoglycemia	GI flatulence, ↑ liver function tests	Renal/liver disease
Thiazolidinediones	↓ Insulin resistance, ↑ glucose utilization	Rosiglitazone, pioglitazone	1–2	↓ Insulin and sulfonylurea requirements, ↓ triglycerides	Frequent hepatic monitoring for idiosyncratic hepatocellular injury (see text)	Liver disease, congestive heart failure
Medical nutrition therapy and physical activity	↓ Insulin resistance	Low-calorie, low-fat diet, exercise	1–2	Other health benefits	Compliance difficult, long-term success low	

Note: A1C, hemoglobin A1c.

TABLE 323-13 *Characteristics of Agents that Increase Insulin Secretion*

Generic Name	Approved Daily Dosage Range, mg	Duration of Action, h	Clearance
Sulfonylurea—first generation			
Chlorpropamide	100–500	>48	Renal
Tolazamide	100–1000	12–24	Hepatic, renal
Tolbutamide	500–3000	6–12	Hepatic
Sulfonylurea—second generation			
Glimepiride	1–8	24	Hepatic, renal
Glipizide	2.5–40	12–18	Hepatic
Glipizide (extended release)	5–10	24	Hepatic
Glyburide	1.25–20	12–24	Hepatic, renal
Glyburide (micronized)	0.75–12	12–24	Hepatic, renal
Nonsulfonylureas			
Repaglinide	0.5–16	2–6	Hepatic
Nateglinide	180–360	2–4	Renal

should be escalated every 2 to 3 weeks based on SMBG measurements. The major toxicity of metformin, lactic acidosis, can be prevented by careful patient selection. Metformin should not be used in patients with renal insufficiency [serum creatinine >133 μmol/L (1.5 mg/dL) in men or >124 μmol/L (1.4 mg/dL) in women, with adjustments for age], any form of acidosis, congestive heart failure, liver disease, or severe hypoxia. Metformin should be discontinued in patients who are seriously ill, in patients who can take nothing orally, and in those receiving radiographic contrast material. Insulin should be used until metformin can be restarted. Though well tolerated in general, some individuals develop gastrointestinal side effects (diarrhea, anorexia, nausea, and metallic taste) that can be minimized by gradual dose escalation.

α-GLUCOSIDASE INHIBITORS α-Glucosidase inhibitors (acarbose and miglitol) reduce postprandial hyperglycemia by delaying glucose absorption; they do not affect glucose utilization or insulin secretion (Table 323-12). Postprandial hyperglycemia, secondary to impaired hepatic and peripheral glucose disposal, contributes significantly to the hyperglycemic state in type 2 DM. These drugs, taken just before each meal, reduce glucose absorption by inhibiting the enzyme that cleaves oligosaccharides into simple sugars in the intestinal lumen. Therapy should be initiated at a low dose (25 mg of acarbose or miglitol) with the evening meal and may be increased to a maximal dose over weeks to months (50 to 100 mg for acarbose or 50 mg for miglitol with each meal). The major side effects (diarrhea, flatulence, abdominal distention) are related to increased delivery of oligosaccharides to the large bowel and can be reduced somewhat by gradual upward dose titration. α-Glucosidase inhibitors may increase levels of sulfonylureas and increase the incidence of hypoglycemia. Simultaneous treatment with bile acid resins and antacids should be avoided. These agents should not be used in individuals with inflammatory bowel disease, gastroparesis, or a serum creatinine >177 μmol/L (2.0 mg/dL). This class of agents is not as potent as other oral agents in lowering the hemoglobin A1C but is unique because it reduces the postprandial glucose rise even in individuals with type 1 DM. If hypoglycemia occurs while taking these agents, the patient should consume glucose since the degradation and absorption of complex carbohydrates will be retarded.

THIAZOLIDINEDIONES Thiazolidinediones reduce insulin resistance. These drugs bind to the PPAR-γ (peroxisome proliferator-activated receptor-γ) nuclear receptor. The PPAR-γ receptor is found at highest levels in adipocytes but is expressed at lower levels in many other tissues. Agonists of this receptor promote adipocyte differentiation and may reduce insulin resistance indirectly because of enhanced fatty acid uptake and storage (Table 323-12). Circulating insulin levels decrease with use of the thiazolidinediones, indicating a reduction in insulin resistance. Although direct comparisons are not available, the two currently available thiazolidinediones appear to have similar efficacy; the therapeutic range for pioglitazone is 15 to 45 mg/d in a single daily dose and for rosiglitazone the total daily dose is 2 to 8 mg/d administered either once daily or twice daily in divided doses. The ability of thiazolidinediones to influence other features of the insulin resistance syndrome is under investigation.

The prototype of this class of drugs, troglitazone, was withdrawn from the U.S. market after reports of hepatotoxicity and an association with an idiosyncratic liver reaction that sometimes led to hepatic failure. Although rosiglitazone and pioglitazone do not appear to induce the liver abnormalities seen with troglitazone, the FDA recommends measurement of liver function tests prior to initiating therapy with a thiazolidinedione and at regular intervals (every 2 months for the first year and then periodically). The thiazolidinediones raise LDL and HDL slightly and lower triglycerides by 10 to 15%, but the clinical significance of these changes is not known. Thiazolidinediones are associated with minor weight gain (1 to 2 kg), a small reduction in the hematocrit, and a mild increase in plasma volume. Cardiac function is not affected, but peripheral edema CHF may occur and is more common in individuals treated with insulin. They are contraindicated in patients with liver disease or congestive heart failure (class III or IV). Thiazolidinediones have been shown to induce ovulation in premenopausal women with PCOS. Women should be warned about the risk of pregnancy, since the safety of thiazolidinediones in pregnancy is not established.

INSULIN THERAPY IN TYPE 2 DM Insulin should be considered as the initial therapy in type 2 DM, particularly in lean individuals or those with severe weight loss, in individuals with underlying renal or hepatic disease that precludes oral glucose-lowering agents, or in individuals who are hospitalized or acutely ill. Insulin therapy is ultimately required by a substantial number of individuals with type 2 DM because of the progressive nature of the disorder and the relative insulin deficiency that develops in patients with long-standing diabetes.

Because endogenous insulin secretion continues and is capable of providing some coverage of mealtime caloric intake, insulin is usually initiated in a single dose of intermediate- or long-acting insulin (0.3 to 0.4 U/kg per day), given either before breakfast (NPH, lente, or ultralente) or just before bedtime (NPH, lente, ultralente, or glargine). Since fasting hyperglycemia and increased hepatic glucose production are prominent features of type 2 DM, bedtime insulin is more effective in clinical trials than a single dose of morning insulin. Some physicians prefer a relatively low, fixed starting dose of intermediate-acting insulin (~15 to 20 units in the morning and 5 to 10 units at bedtime) to avoid hypoglycemia. The insulin dose may then be adjusted in 10% increments as dictated by SMBG results. Both morning and bedtime intermediate insulin may be used in combination with oral glucose-lowering agents (biguanides, α-glucosidase inhibitors, or thiazolidinediones).

CHOICE OF INITIAL GLUCOSE-LOWERING AGENT The level of hyperglycemia should influence the initial choice of therapy. Assuming maximal benefit of MNT and increased physical activity has been realized, patients with mild to moderate hyperglycemia [fasting plasma glucose <11.1 to 13.9 mmol/L (200 to 250 mg/dL)] often respond well to a single oral glucose-lowering agent. Patients with more severe hyperglycemia [fasting plasma glucose >13.9 mmol/L (250 mg/dL)] may respond partially but are unlikely to achieve normoglycemia with oral monotherapy. A stepwise approach that starts with a single agent and adds a second agent to achieve the glycemic target can be used (see "Combination Therapy," below). Insulin can be used as initial therapy in individuals with severe hyperglycemia [fasting plasma glucose >13.9 to 16.7 mmol/L (250 to 300 mg/dL)]. This approach is based on the rationale that more rapid glycemic control will reduce "glucose toxicity" to the islet cells, improve endogenous insulin secretion, and

possibly allow oral glucose-lowering agents to be more effective. If this occurs, the insulin may be discontinued.

Insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, and insulin are approved for monotherapy of type 2 DM. Although each class of oral glucose-lowering agents has unique advantages and disadvantages, certain generalizations apply: (1) insulin secretagogues, biguanides, and thiazolidinediones improve glycemic control to a similar degree (1 to 2% reduction in A1C) and are more effective than α-glucosidase inhibitors; (2) assuming a similar degree of glycemic improvement, no clinical advantage to one class of drugs has been demonstrated, and any therapy that improves glycemic control is likely beneficial; (3) insulin secretagogues and α-glucosidase inhibitors begin to lower the plasma glucose immediately, whereas the glucose-lowering effects of the biguanides and thiazolidinediones are delayed by several weeks to months; (4) not all agents are effective in all individuals with type 2 DM (primary failure); (5) biguanides, α-glucosidase inhibitors, and thiazolidinediones do not directly cause hypoglycemia; and (6) most individuals will eventually require treatment with more than one class of oral glucose-lowering agents or insulin, reflecting the progressive nature of type 2 DM.

Considerable clinical experience exists with sulfonylureas and metformin because they have been available for several decades. It is assumed that the α-glucosidase inhibitors and thiazolidinediones, which are newer classes of oral glucose-lowering drugs, will reduce DM-related complications by improving glycemic control, although long-term data are not yet available. The thiazolidinediones are theoretically attractive because they target a fundamental abnormality in type 2 DM, namely insulin resistance. However, these agents are currently more costly than others and require liver function monitoring.

A reasonable treatment algorithm for initial therapy proposes either a sulfonylurea or metformin as initial therapy because of their efficacy, known side-effect profile, and relatively low cost (Fig. 323-14). Metformin has the advantage that it promotes mild weight loss, lowers insulin levels, improves the lipid profile slightly, and may have a lower secondary failure rate. Metformin is the initial choice of many physicians for the treatment of the obese, type 2 diabetic. However, there is no difference in response rate or degree of glycemic control when metformin and sulfonylureas are compared in randomized, prospective clinical trials. Based on SMBG results and the A1C, the dose of either the sulfonylurea or metformin should be increased until the glycemic target is achieved. Thiazolidinediones are alternative, initial agents, but are much more expensive; α-glucosidase inhibitors are the least potent agents and not as desirable for monotherapy (Fig. 323-15).

Approximately one-third of individuals will reach their target glycemic goal using either a sulfonylurea or metformin as monotherapy. Approximately 25% of individuals will not respond to sulfonylureas or metformin; under these circumstances, the drug usually should be discontinued. Some individuals respond to one agent but not the other. The remaining individuals treated with either sulfonylureas or metformin alone will exhibit some improvement in glycemic control but will not achieve their glycemic target and should be considered for combination therapy.

COMBINATION THERAPY WITH GLUCOSE-LOWERING AGENTS A number of combinations of therapeutic agents are successful in type 2 DM, and the dosing of agents in combination is the same as when the agents are used alone. Because mechanisms of action of the first and second agents are different, the effect on glycemic control is usually additive. Commonly used regimens include: (1) insulin secretagogue with metformin or thiazolidinedione, (2) sulfonylurea with α-glucosidase inhibitor, and (3) insulin with metformin or thiazolidinedione. The combination of metformin and a thiazolidinedione is also effective and complementary. If adequate control is not achieved with two oral agents, bedtime insulin or a third oral agent may be added stepwise. However, long-term experience with any triple combination is lacking, and experience with two-drug combinations is relatively limited.

Insulin becomes required as type 2 DM enters the phase of relative insulin deficiency (as seen in long-standing DM) and is signaled by

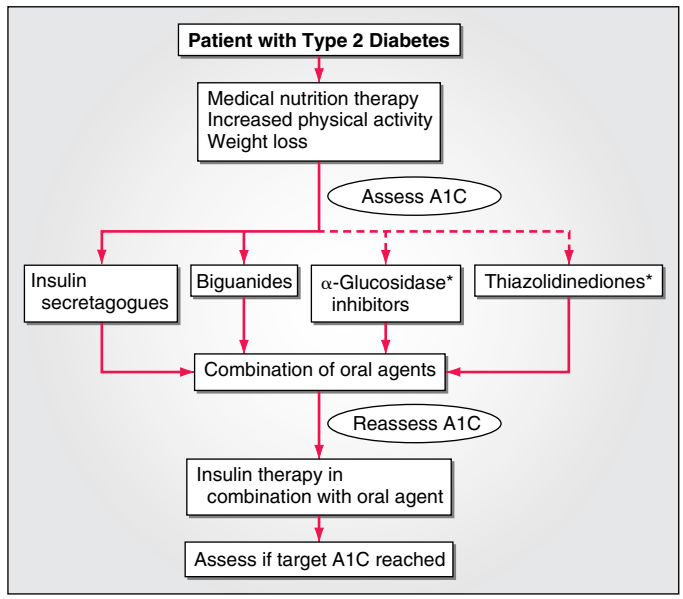

FIGURE 323-15 Glycemic management of type 2 diabetes. See text for discussion. *See text about use as monotherapy. The broken line indicates that biguanides or insulin secretagogues, but not α glucosidase inhibitors or thiazolidinediones, are preferred for initial therapy. A1C, hemoglobin A1c.

inadequate glycemic control with one or two oral glucose-lowering agents. Insulin can be used in combination with any of the oral agents in patients who fail to reach the glycemic target. For example, a single dose of intermediate- or long-acting insulin at bedtime is effective in combination with metformin. As endogenous insulin production falls further, multiple injections of intermediate-acting and short-acting insulin regimens are necessary to control postprandial glucose excursions. These combination regimens are identical to the intermediate-, long-acting, and short-acting combination regimens discussed above for type 1 DM. Since the hyperglycemia of type 2 DM tends to be more "stable," these regimens can be increased in 10% increments every 2 to 3 days using SMBG results. The daily insulin dose required can become quite large (1 to 2 units/kg per day) as endogenous insulin production falls and insulin resistance persists. Individuals who require $>$1 unit/kg per day of intermediate-acting insulin should be considered for combination therapy with metformin or a thiazolidinedione. The addition of metformin or a thiazolidinedione can reduce insulin requirements in some individuals with type 2 DM, while maintaining or even improving glycemic control.

Intensive diabetes management (Table 323-10) is a treatment option in type 2 patients who cannot achieve optimal glycemic control and are capable of implementing such regimens. A recent study from the Veterans Administration found that intensive diabetes management is not associated with a greater degree of side effects (hypoglycemia, weight gain) than standard insulin therapy. The effect of higher insulin levels associated with intensive diabetes management on the prognosis of diseases commonly associated with type 2 DM (cardiovascular disease, hypertension) is still debated. In selected patients with type 2 DM, insulin pumps improve glycemic control and are well tolerated.

EMERGING THERAPIES Whole pancreas transplantation (conventionally performed concomitantly with a renal transplant) may normalize glucose tolerance and is an important therapeutic option in type 1 DM, though it requires substantial expertise and is associated with the side effects of immunosuppression. Pancreatic islet transplantation has been plagued by limitations in pancreatic islet isolation and graft survival, but recent advances in specific immunomodulation have greatly improved the results. Islet transplantation is an area of active clinical investigation.

New insights into normal mechanisms of glucose homeostasis have

led to a number of emerging therapies for diabetes and its complications. For example, glucagon-like peptide 1, a potent insulin secretagogue, may be efficacious in type 2 DM. Inhaled insulin and additional insulin analogues are in advanced stages of clinical trials. Aminoguanidine, an inhibitor of the formation of advanced glycosylation end products, and inhibitors of protein kinase C may reduce the complications of DM. Closed-loop pumps that infuse the appropriate amount of insulin in response to changing glucose levels are potentially feasible now that continuous glucose-monitoring technology has been developed.

COMPLICATIONS OF THERAPY FOR DIABETES MELLITUS

As with any therapy, the benefits of efforts directed towards glycemic control must be weighed against the risks of treatment. Side effects of intensive treatment include an increased frequency of serious hypoglycemia, weight gain, increased economic costs, and greater demands on the patient. In the DCCT, quality of life was very similar in the intensive and standard therapy groups. The most serious complication of therapy for DM is hypoglycemia (Chap. 324). Weight gain occurs with most (insulin, insulin secretagogues, thiazolidinediones) but not all (metformin and α-glucosidase inhibitors) therapies that improve glycemic control. It is due to the anabolic effects of insulin and the reduction in glucosuria without a corresponding decrease in caloric intake. In the DCCT, individuals with the greatest weight gain exhibited increases in LDL cholesterol and triglycerides as well as increases in blood pressure (both systolic and diastolic) similar to those seen in individuals with type 2 DM and insulin resistance. These effects could increase the risk of cardiovascular disease in intensively managed patients. As discussed previously, transient worsening of diabetic retinopathy or neuropathy sometimes accompanies improved glycemic control.

ONGOING ASPECTS OF COMPREHENSIVE DIABETES CARE

The morbidity and mortality of DM-related complications can be greatly reduced by timely and consistent surveillance procedures (Table 323-14). These screening procedures are indicated for all individuals with DM, but numerous studies have documented that most individuals with diabetes do not receive comprehensive diabetes care. Screening for dyslipidemia and hypertension should be performed annually. In addition to routine health maintenance, individuals with diabetes should also receive the pneumococcal and tetanus vaccines (at recommended intervals) and the influenza vaccine (annually). As discussed above, aspirin therapy should be considered in many patients with diabetes.

An annual comprehensive eye examination should be performed by a qualified optometrist or ophthalmologist. If abnormalities are detected, further evaluation and treatment require an ophthalmologist skilled in diabetes-related eye disease. Because many individuals with type 2 DM have had asymptomatic diabetes for several years before diagnosis, the ADA recommends the following ophthalmologic examination schedule: (1) individuals with onset of DM at <29 years should have an initial eye examination within 3 to 5 years of diagnosis, (2) individuals with onset of DM at >30 years should have an initial eye examination at the time of diabetes diagnosis, and (3) women with DM who are contemplating pregnancy should have an eye examination prior to conception and during the first trimester.

An annual foot examination should: (1) assess blood flow, sensation (monofilament testing), and nail care; (2) look for the presence of foot deformities such as hammer or claw toes and Charcot foot; and (3) identify sites of potential ulceration. Calluses and nail deformities should be treated by a podiatrist; the patient should be discouraged from self-care of even minor foot problems. The ADA advises a visual foot inspection for potential problems at each outpatient visit.

An annual microalbuminuria measurement (albumin-to-creatinine ratio in spot urine) is advised in individuals with type 1 or type 2 DM and no protein on a routine urinalysis (Fig. 323-10). If the urinalysis detects proteinuria, the amount of protein should be quantified by standard urine protein measurements. If the urinalysis was negative for protein in the past, microalbuminuria should be the annual screening examination. Routine urine protein measurements do not detect low levels of albumin excretion. Screening should commence 5 years after the onset of type 1 DM and at the time of onset of type 2 DM.

TABLE 323-14 Guidelines for Ongoing Medical Care for Patients with Diabetes

- Self-monitoring of blood glucose (individualized frequency)
- A1C testing (2–4 times/year)
- Patient education in diabetes management (annual)
- Medical nutrition therapy and education (annual)
- Eye examination (annual)
- Foot examination (1–2 times/year by physician; daily by patient)
- Screening for diabetic nephropathy (annual; see Fig. 323-11)
- Blood pressure measurement (quarterly)
- Lipid profile (annual)
- Influenza/pneumococcal immunizations
- Consider antiplatelet therapy (see text)

Note: A1C, hemoglobin A1c.

SPECIAL CONSIDERATIONS IN DIABETES MELLITUS

PSYCHOSOCIAL ASPECTS As with any chronic, debilitating disease, the individual with DM faces a series of challenges that affect all aspects of daily life. The individual with DM must accept that he or she may develop complications related to DM. Even with considerable effort, normoglycemia can be an elusive goal, and solutions to worsening glycemic control may not be easily identifiable. The patient should view him- or herself as an essential member of the diabetes care team and not as someone who is cared for by the diabetes team. Emotional stress may provoke a change in behavior so that individuals no longer adhere to a dietary, exercise, or therapeutic regimen. This can lead to the appearance of either hyper- or hypoglycemia. Depression and eating disorders, including binge eating disorders, bulimia, and anorexia nervosa, appear to occur more frequently individuals with type 1 or type 2 DM (Chap. 65).

MANAGEMENT IN THE HOSPITALIZED PATIENT Virtually all medical and surgical subspecialties may be involved in the care of hospitalized patients with diabetes. Hyperglycemia, whether in an individual with known diabetes or in one without diabetes, may be a predictor of poor outcome in hospitalized patients. General anesthesia, surgery, and concurrent illness raise the levels of counterregulatory hormones (cortisol, growth hormone, catecholamines, and glucagon), and infection may lead to transient insulin resistance and hyperglycemia. These factors increase insulin requirements by increasing glucose production and impairing glucose utilization and thus may worsen glycemic control. The concurrent illness or surgical procedure may lead to variable insulin absorption and also prevent the patient with DM from eating normally and may promote hypoglycemia. Glycemic control should be assessed (with A1C) and, if feasible, should be optimized prior to surgery. Electrolytes, renal function, and intravascular volume status should be assessed as well. The high prevalence of asymptomatic cardiovascular disease in individuals with DM (especially in type 2 DM) may require preoperative cardiovascular evaluation. Maintenance of a near normal glucose with insulin reduced the risk of postoperative infection after CABG, and in one study, reduced the morbidity and mortality in patients in a surgical intensive care unit.

The goals of diabetes management during hospitalization are avoidance of hypoglycemia, optimization of glycemic control and transition back to the outpatient diabetes treatment regimen. Optimal glycemic control in the hospitalized patient is <6.1 mmol/L (100 mg/dL, preprandial) and <10 mmol/L (180 mg/dL, postprandial). Attention to each stage in this process requires integrating information regarding the plasma glucose, diabetes treatment regimen, and clinical status of the patient. For example, some surgical procedures utilizing local anesthesia or epidural anesthesia may have minimal effects on glycemic control. If the patient is eating soon after the procedure and there is no disruption of the patient's regular meal plans, then glycemic control is usually maintained. A "consistent-carbohydrate diabetes meal plan" for hospital-

ized patients provides a similar amount of carbohydrate for a particular meal each day (but not necessarily the same amount for breakfast, lunch, and supper). The hospital diet should be determined by a nutritionist; terms such as "ADA diet" or "low sugar diet" are no longer used.

The physician caring for an individual with diabetes in the perioperative period, during times of infection or serious physical illness, or simply when fasting for a diagnostic procedure must monitor the plasma glucose vigilantly, adjust the diabetes treatment regimen, and provide glucose infusion as needed. Several different treatment regimens (intravenous or subcutaneous insulin regimens) can be employed successfully. Individuals with type 1 DM require continued insulin administration to maintain the levels of circulating insulin necessary to prevent DKA. Prolongation of a surgical procedure or delay in the recovery room is not uncommon and may result in periods of insulin deficiency. Even relatively brief periods without insulin may lead to mild DKA. Individuals with type 1 DM who are undergoing general anesthesia and surgery, or who are seriously ill, should receive continuous insulin, either through an intravenous insulin infusion or by subcutaneous administration of a reduced dose of long-acting insulin. Short-acting insulin alone is insufficient.

Perioperative Management Insulin infusions can effectively control plasma glucose in the perioperative period and when the patient is unable to take anything by mouth. The absorption of subcutaneous insulin may be variable in such situations because of changes in blood flow. The physician must consider carefully the clinical setting in which an insulin infusion will be utilized, including whether adequate ancillary personnel are available to monitor the plasma glucose frequently and whether they can adjust the insulin infusion rate, either based on an algorithm or in consultation with the physician. The initial rate for an insulin infusion may range from 0.5 to 5 units/h, depending on the degree of insulin resistance and the clinical situation. Based on hourly capillary glucose measurements, the insulin infusion rate is adjusted to maintain the plasma glucose within the optimal range. The insulin infusion can be temporarily discontinued if hypoglycemia occurs and may be resumed at a lower infusion rate once the plasma glucose exceeds 5.6 mmol/L (100 mg/dL).

Insulin infusion is the preferred method for managing patients with type 1 DM in the perioperative period or when serious concurrent illness is present (0.5 to 1.0 units/h of regular insulin). Insulin-infusion algorithms jointly developed and implemented by nursing and physician staff are advised. If the diagnostic or surgical procedure is brief and performed under local or regional anesthesia, a reduced dose of subcutaneous, long-acting insulin may suffice. This approach facilitates the transition back to the long-acting insulin after the procedure. The dose of long-acting insulin should be reduced by 30 to 40%, and short-acting insulin is either held or, likewise, reduced by 30 to 40%. Glucose may be infused to prevent hypoglycemia.

Individuals with type 2 DM can be managed with either regular insulin infusion 0.5 to 2 units/h or a reduced dose of subcutaneous intermediate- or long-acting insulin supplemented with short-acting insulin. Oral glucose-lowering agents are discontinued upon admission. Oral glucose-lowering agents are not useful in regulating the plasma glucose in clinical situations where the insulin requirements and glucose intake are changing rapidly. Moreover, these oral agents may be dangerous if the patient is fasting (e.g., hypoglycemia with sulfonylureas). Metformin should be withheld when radiographic contrast media will be given or if severe congestive heart failure, acidosis, or declining renal function is present.

Total Parenteral Nutrition (See also Chap. 63) Total parenteral nutrition (TPN) greatly increases insulin requirements. In addition, individuals not previously known to have DM may become hyperglycemic during TPN and require insulin treatment. Intravenous insulin infusion is the preferred treatment for hyperglycemia, and rapid titration to the required insulin dose is done most efficiently using a separate insulin infusion. After the total insulin dose has been determined, insulin may be added directly to the TPN solution or, preferably, given as a separate infusion. Often, individuals receiving either TPN or enteral nutrition receive their caloric loads continuously and not at "meal times"; consequently, subcutaneous insulin regimens must be adjusted.

GLUCOCORTICOIDS Glucocorticoids increase insulin resistance, decrease glucose utilization, increase hepatic glucose production, and impair insulin secretion. These changes lead to a worsening of glycemic control in individuals with DM and may precipitate diabetes in other individuals ("steroid-induced diabetes"). The effects of glucocorticoids on glucose homeostasis are dose-related, usually reversible, and most pronounced in the postprandial period. If the fasting plasma glucose is near the normal range, oral diabetes agents (e.g., sulfonylureas, metformin) may be sufficient to reduce hyperglycemia. If the fasting plasma glucose $>$11.1 mmol/L (200 mg/dL), oral agents are usually not efficacious and insulin therapy is required. Short-acting insulin may be required to supplement long-acting insulin in order to control postprandial glucose excursions.

REPRODUCTIVE ISSUES Reproductive capacity in either men or women with DM appears to be normal. Menstrual cycles may be associated with alterations in glycemic control in women with DM. Pregnancy is associated with marked insulin resistance; the increased insulin requirements often precipitate DM and lead to the diagnosis of GDM. Glucose, which at high levels is a teratogen to the developing fetus, readily crosses the placenta, but insulin does not. Thus, hyperglycemia from the maternal circulation may stimulate insulin secretion in the fetus. The anabolic and growth effects of insulin may result in macrosomia. GDM complicates approximately 4% of pregnancies in the United States. The incidence of GDM is greatly increased in certain ethnic groups, including African Americans and Hispanic Americans, consistent with a similar increased risk of type 2 DM. Current recommendations advise screening for glucose intolerance between weeks 24 and 28 of pregnancy in women with high risk for GDM ($\geq$25 years; obesity; family history of DM; member of an ethnic group such as Hispanic American, Native American, Asian American, African American, or Pacific Islander). Therapy for GDM is similar to that for individuals with pregnancy-associated diabetes and involves MNT and insulin, if hyperglycemia persists. Oral glucose-lowering agents have not been approved for use during pregnancy. With current practices, the morbidity and mortality of the mother with GDM and the fetus are no different from those in the nondiabetic population. Individuals who develop GDM are at marked increased risk for developing type 2 DM in the future and should be screened periodically for DM. After delivery, glucose homeostasis should be reassessed in the mother. Most individuals with GDM revert to normal glucose tolerance, but some will continue to have overt diabetes or impairment of glucose tolerance. In addition, children of women with GDM appear to be at risk for obesity and glucose intolerance and have an increased risk of diabetes beginning in the later stages of adolescence.

Pregnancy in individuals with known DM requires meticulous planning and adherence to strict treatment regimens. Intensive diabetes management and normalization of the A1C are the standard of care for individuals with existing DM who are planning pregnancy. The most crucial period of glycemic control is soon after fertilization. The risk of fetal malformations is increased 4 to 10 times in individuals with uncontrolled DM at the time of conception and normal plasma glucose during the preconception period and throughout the periods of organ development in the fetus should be maintained.

LIPODYSTROPHIC DM Lipodystrophy, or the loss of subcutaneous fat tissue, may be generalized in certain genetic conditions such as leprechaunism. Generalized lipodystrophy is associated with severe insulin resistance and is often accompanied by acanthosis nigricans and dyslipidemia. Localized lipodystrophy associated with insulin injections has been reduced considerably by the use of human insulin.

Protease Inhibitors and Lipodystrophy Protease inhibitors used in the treatment of HIV disease (Chap. 173) have been associated with a centripetal accumulation of fat (visceral and abdominal area), accu-

mulation of fat in the dorsocervical region, loss of extremity fat, decreased insulin sensitivity (elevations of the fasting insulin level and reduced glucose tolerance on intravenous glucose tolerance testing), and dyslipidemia. Although many aspects of the physical appearance of these individuals resemble Cushing's syndrome, increased cortisol levels do not account for this appearance. The possibility remains that this is related to HIV infection by some undefined mechanism, since some features of the syndrome were observed before the introduction of protease inhibitors. Therapy for HIV-related lipodystrophy is not well established.

324 HYPOGLYCEMIA

Philip E. Cryer

Hypoglycemia is most commonly the result of taking drugs used to treat diabetes mellitus or other drugs, including alcohol. However, a number of other disorders, including end-stage organ failure and sepsis, endocrine deficiencies, large mesenchymal tumors, insulinoma, and inherited metabolic disorders are also associated with hypoglycemia (Table 324-1). Hypoglycemia is sometimes defined as a plasma glucose level <2.5 to 2.8 mmol/L (<45 to 50 mg/dL). However, glucose thresholds for hypoglycemia-induced symptoms and physiologic responses vary widely, depending on the clinical setting. Therefore, an important framework for making the diagnosis of hypoglycemia is *Whipple's triad*: (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration, and (3) relief of symptoms after the plasma glucose level is raised. Hypoglycemia can cause significant morbidity and can be lethal, if severe and prolonged; it should be considered in any patient with confusion, altered level of consciousness, or seizures.

TABLE 324-1 Causes of Hypoglycemia

Drugs
Especially insulin, sulfonylureas, ethanol
Sometimes pentamidine, quinine
Rarely salicylates, sulfonamides, and others
Critical illnesses
Hepatic, renal, or cardiac failure
Sepsis
Starvation and inanition
Endocrine deficiencies
Cortisol, growth hormone
Glucagon and epinephrine (type 1 diabetes)
Non-β-cell tumors
Fibrosarcoma, mesothelioma, rhabdomyosarcoma, liposarcoma, other sarcomas
Hepatoma, adrenocortical tumors, carcinoid
Leukemia, lymphoma, melanoma, teratoma
Endogenous hyperinsulinism
Insulinoma
Other β cell disorders
Secretagogue (sulfonylurea)
Autoimmune (autoantibodies to insulin, insulin receptor, β cell?)
Ectopic insulin secretion
Disorders of infancy or childhood
Transient intolerance of fasting
Infants of diabetic mothers (hyperinsulinism)
Congenital hyperinsulinism
Inherited enzyme defects
Postprandial
Reactive (after gastric surgery)
Ethanol-induced
Autonomic symptoms without true hypoglycemia
Factitious
Insulin, sulfonylureas

SYSTEMIC GLUCOSE BALANCE AND COUNTERREGULATION

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. By contrast, other organs can use fatty acids, in addition to glucose, to generate energy. The brain cannot synthesize glucose and stores only a few minutes' supply as glycogen and therefore requires a continuous supply of glucose, which is delivered by facilitated diffusion from arterial blood. As the plasma glucose concentration falls below the physiologic range, blood-to-brain glucose transport becomes insufficient for adequate brain energy metabolism and functioning. Fortunately, redundant physiologic mechanisms prevent or rapidly correct hypoglycemia.

Plasma glucose levels are maintained within a narrow range, usually between 3.3 and 8.3 mmol/L (60 and 150 mg/dL), despite wide variation of food intake and activity level. This delicate balance requires dynamic regulation of glucose influx into the circulation as glucose utilization in various tissues can change rapidly. The diet is normally a major source of glucose. However, between meals or during fasting, plasma glucose levels are maintained primarily by the breakdown of glycogen and by gluconeogenesis (Fig. 324-1). In most persons, hepatic glycogen stores are sufficient to maintain plasma glucose levels for 8 to 12 h, but this time period can be shorter if glucose demand is increased by exercise or if glycogen stores are depleted by illness or starvation.

As glycogen stores are depleted, glucose is generated by gluconeogenesis, which occurs mainly in the liver but also in the kidneys. Gluconeogenesis requires a coordinated supply of precursors from

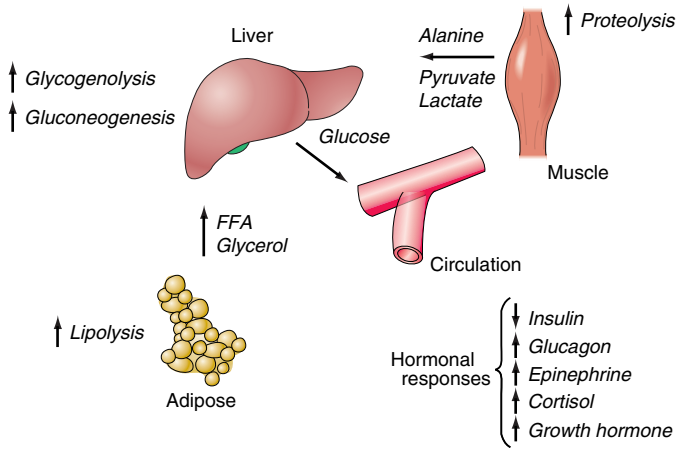

FIGURE 324-1 Overview of glucose metabolism and pathways of counterregulatory responses to fasting and hypoglycemia.

liver, muscle, and adipose tissue. Muscle provides lactate, pyruvate, alanine, and other amino acids. Triglycerides in adipose tissue are broken down into glycerol, which is a precursor for gluconeogenesis. Free fatty acids generate acetyl CoA for gluconeogenesis and provide an alternative fuel source to tissues other than the brain.

The balance of glucose production and its uptake and utilization in peripheral tissues are exquisitely regulated by a network of hormones, neural pathways, and metabolic signals (Chap. 323). Among the factors that control glucose production and utilization, insulin plays a dominant and pivotal role. In the fasting state, insulin is suppressed, allowing increased gluconeogenesis in the liver and the kidneys and enhancing glucose generation by the breakdown of liver glycogen. Low insulin levels also reduce glucose uptake and utilization in peripheral tissues and allow lipolysis and proteolysis to occur, which leads to the release of precursors for gluconeogenesis and provides alternative energy sources. In the fed state, insulin release from the pancreatic β cells reverses this process. Glycogenolysis and gluconeogenesis are inhibited, thereby reducing hepatic and renal glucose output; peripheral glucose uptake and utilization are enhanced; lipolysis and proteolysis are restrained; and energy storage is promoted by the conversion of substrates into glycogen, triglycerides, and proteins. Other hormones, such as glucagon, epinephrine, growth hormone, and cortisol, play less important roles in the control of glucose flux during normal physiologic circumstances. However, these hormones are critically important in the response to hypoglycemia.

As glucose levels approach, and ultimately enter, the hypoglycemic range, a characteristic sequence of *counterregulatory hormone responses* occurs. Glucagon is the first and most important of these responses. It promotes glycogenolysis and gluconeogenesis. Epinephrine can also play an important role in the acute response to hypoglycemia, particularly when glucagon is insufficient. It, too, stimulates glycogenolysis and gluconeogenesis and limits glucose utilization by insulin-sensitive tissues. When hypoglycemia is prolonged, growth hormone and cortisol also reduce glucose utilization and support its production.

The glucose thresholds at which various counterregulatory hormone responses occur are quite similar in healthy subjects (Table 324-2). Nevertheless, these thresholds are dynamic and can be influenced by recent metabolic events. A person with poorly controlled diabetes can have symptoms of hypoglycemia at higher-than-normal glucose levels. Recurrent hypoglycemia, which may occur in individuals with diabetes or an insulinoma, shifts thresholds for symptoms and counterregulatory responses to lower glucose levels.

TABLE 324-2 *Physiologic Responses to Decreasing Plasma Glucose Concentrations*

Response	Glycemic Threshold, mmol/L (mg/dL)	Physiologic Effects	Role in the Prevention or Correction of Hypoglycemia (Glucose Counterregulation)
↓ Insulin	4.4–4.7 (80–85)	↑ R_a (↓R_d)	Primary glucose regulatory factor/first defense against hypoglycemia
↑ Glucagon	3.6–3.9 (65–70)	↑ R_a	Primary glucose counterregulatory factor
↑ Epinephrine	3.6–3.9 (65–70)	↑ R_a, ↓ R_d	Involved, critical when glucagon is deficient
↑ Cortisol and growth hormone	3.6–3.9 (65–70)	↑ R_a, ↓ R_d	Involved, not critical
Symptoms	2.8–3.1 (50–55)	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	< 2.8 (< 50)	—	(Compromises behavioral defense)

Note: R_a, rate of glucose appearance, glucose production by the liver and kidneys; R_d, rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle. (R_d includes glucose utilization by the central nervous system, but the glucoregulatory hormones have no direct effects on that.)

CLINICAL MANIFESTATIONS

Symptoms of hypoglycemia can be divided into two categories, neuroglycopenic and neurogenic (or autonomic) responses. Neuroglycopenic symptoms are a direct result of central nervous system neuronal glucose deprivation. Symptoms include behavioral changes, confusion, fatigue, seizure, loss of consciousness, and, if hypoglycemia is severe and prolonged, death. Hypoglycemia-induced autonomic responses include adrenergic symptoms such as palpitations, tremor, and anxiety as well as cholinergic symptoms such as sweating, hunger, and paresthesia. Adrenergic symptoms are mediated by norepinephrine released from sympathetic postganglionic neurons and the release of epinephrine from the adrenal medullae. Increased sweating is mediated by cholinergic sympathetic nerve fibers. Patients with diabetes mellitus learn to recognize the characteristic symptoms of hypoglycemia, but these are less familiar to individuals with other causes of hypoglycemia. Symptoms may be less pronounced with repeated hypoglycemic episodes (see below).

Common signs of hypoglycemia include pallor and diaphoresis. Heart rate and the systolic blood pressure are typically raised, but these findings may not be prominent. The neuroglycopenic manifestations are valuable, albeit nonspecific, signs. Transient focal neurologic deficits occur occasionally.

CAUSES

Hypoglycemia is traditionally classified as *postprandial* or *fasting*. However, in the clinical setting, hypoglycemia is most commonly a result of diabetes treatment. This topic is therefore addressed before considering the other causes of hypoglycemia.

HYPOGLYCEMIA IN DIABETES

FREQUENCY AND IMPACT Were it not for hypoglycemia, diabetes would be rather easy to treat by administering enough insulin (or any effective drug) to lower plasma glucose concentrations to, or below, the normal range. But because current insulin-replacement regimens are imperfect, individuals with type 1 diabetes are at ongoing risk for periods of relative hyperinsulinemia with resultant hypoglycemia. Those attempting to achieve near-normal glycemic control may experience several episodes of asymptomatic or symptomatic hypoglycemia each week. Plasma glucose levels may be <2.8 mmol/L (<50 mg/dL) as often as 10% of the time. Such patients suffer an average of one episode of severe, temporarily disabling hypoglycemia, often with seizure or coma, in a given year. Although seemingly complete recovery from the latter is the rule, the possibility of persistent cognitive deficits has been raised, but permanent neurologic defects are rare. About 2 to 4% of deaths associated with type 1 diabetes are estimated to be a result of hypoglycemia. Fear of hypoglycemia can also lead to disabling psychosocial morbidity.

Hypoglycemia is a less frequent problem in type 2 diabetes but still occurs in those treated with insulin or sulfonylureas. Transient, mild hypoglycemia may be seen with the shorter-acting sulfonylureas and repaglinide or nateglinide, which also act by enhancing insulin secretion. Patients who take the long-acting sulfonylureas, chlorpropamide and glyburide, may experience episodes of severe hypoglycemia that last between 24 and 36 h.

CONVENTIONAL RISK FACTORS Insulin excess is the primary determinant of risk from iatrogenic hypoglycemia. Relative or absolute insulin excess occurs when: (1) insulin (or oral agent) doses are excessive, ill timed, or of the wrong type; (2) the influx of exogenous glucose is reduced (e.g., during an overnight fast or following missed meals or snacks); (3) insulin-independent glucose utilization is increased (e.g., during exercise); (4) insulin sensitivity is increased (e.g., with effective

intensive therapy, in the middle of the night, late after exercise, or with increased fitness or weight loss); (5) endogenous glucose production is reduced (e.g., following alcohol ingestion); and (6) insulin clearance is reduced (e.g., in renal failure). However, analyses of the Diabetes Control and Complications Trial (DCCT) indicate that these conventional risk factors explain only a minority of episodes of severe iatrogenic hypoglycemia; other causes are involved in the majority of episodes.

HYPOGLYCEMIA-ASSOCIATED AUTONOMIC FAILURE It is now clear that inadequate physiologic counterregulatory and behavioral responses greatly compound the problem of hypoglycemia caused by insulin excess. Hypoglycemia-associated autonomic failure has two main components: (1) reduced counterregulatory hormone responses, which result in impaired glucose generation; and (2) hypoglycemia unawareness, which precludes appropriate behavioral responses, such as eating.

Defective Glucose Counterregulation The counterregulatory hormone response is fundamentally altered in patients with established (e.g., absent C peptide) type 1 diabetes. As insulin deficiency progresses over the first few months or years of the disease, circulating insulin levels are no longer tightly coordinated with glucose levels and are a passive function of administered insulin. Thus, insulin levels do not decline as glucose levels fall; the first defense against hypoglycemia is lost. Over the same time frame, the glucagon response to falling glucose levels diminishes, and the second defense against hypoglycemia is lost. The cause of defective glucagon production by the pancreatic islet α cells is unknown, but it is tightly linked to the loss of insulin production by the β cells. It is a functional abnormality rather than an absolute deficiency of glucagon, as responses to stimuli other than hypoglycemia are intact. The third defense against hypoglycemia is compromised when the epinephrine response to hypoglycemia is reduced. In contrast to the absent glucagon response, epinephrine deficiency is a threshold abnormality; an epinephrine response can still be elicited, but a lower plasma glucose concentration is required. This threshold shift is largely a result of recent antecedent hypoglycemia, although an additional anatomic component may also be present in patients affected by classic diabetic autonomic neuropathy. The development of a reduced epinephrine response is a critical pathophysiologic event. Prospective studies have shown that patients with combined deficiencies of glucagon and epinephrine suffer severe hypoglycemia at rates 25-fold or greater than individuals with absent glucagon but intact epinephrine responses.

Hypoglycemia Unawareness *Hypoglycemia unawareness* refers to a loss of the warning symptoms that alert individuals to the presence of hypoglycemia and prompt them to eat and abort the episode. Under these circumstances, the first manifestation of hypoglycemia is neuroglycopenia, when it is often too late for patients to treat themselves. Like defective counterregulation, the presence of hypoglycemia unawareness has been shown in prospective studies to be associated with a high frequency of severe hypoglycemia.

The interplay of factors involved in hypoglycemia-associated autonomic failure in type 1 diabetes, and consequent hypoglycemia unawareness, is summarized in Fig. 324-2. Periods of relative or absolute therapeutic insulin excess, in the setting of absent glucagon responses, lead to episodes of iatrogenic hypoglycemia. These episodes, in turn, cause reduced autonomic (including adrenomedullary) responses to falling glucose concentrations. These impaired autonomic responses result in reduced symptoms of impending hypoglycemia (e.g., hypoglycemia unawareness) because epinephrine responses are reduced in the setting of absent glucagon responses. Thus, a vicious cycle of recurrent hypoglycemia is created and perpetuated. The syndrome of hypoglycemia unawareness and the reduced epinephrine component of defective glucose counterregulation are reversible but require >2 weeks of scrupulous avoidance of hypoglycemia. This involves a shift of glycemic thresholds back to higher plasma glucose concentrations.

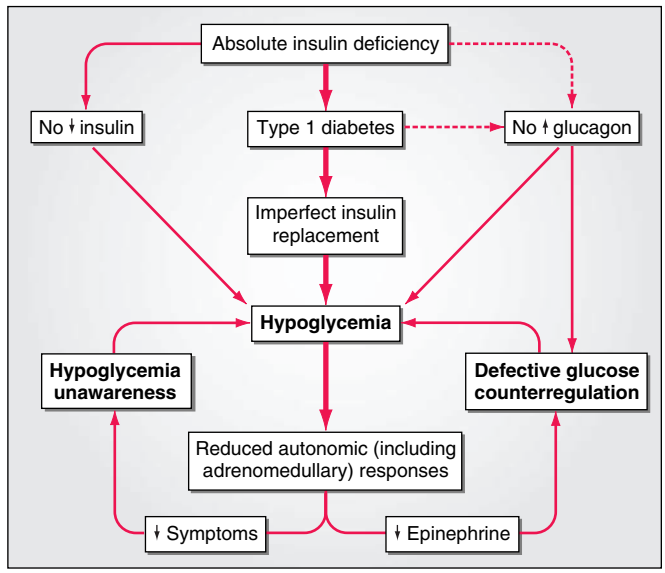

FIGURE 324-2 Hypoglycemia-associated autonomic failure and hypoglycemia unawareness in type 1 diabetes. (*PE Cryer: Diabetes 41:255, 1992.*)

HYPOGLYCEMIA RISK FACTOR REDUCTION A diagnosis of hypoglycemia unawareness can usually be made from the history. One should note that hypoglycemia unawareness implies that previous episodes of hypoglycemia have occurred, whether these are documented or not. If low glucose levels are not apparent from the patient's self-monitoring log, one should suspect hypoglycemia during the night. The presence of clinical hypoglycemia unawareness makes defective glucose counterregulation likely. It is possible to minimize the risk of hypoglycemia by applying the principles of modern therapy—patient education and empowerment, frequent self-monitoring of blood glucose, flexible insulin (and other drug) regimens, rational glycemic goals, and ongoing professional guidance and support. If hypoglycemia is a recognized problem, first consider each of the conventional risk factors summarized earlier and recommend the appropriate adjustments of medications, diet, and life-style. Nonselective beta blockers may attenuate the recognition of hypoglycemia and they impair glycogenolysis; a relatively selective β_1-antagonist (e.g., metoprolol or atenolol) is preferable when a beta blocker is indicated.

REACTIVE HYPOGLYCEMIA

Postprandial (reactive) hypoglycemia occurs only after meals and is self-limited. Postprandial hypoglycemia occurs in children with certain rare enzymatic defects in carbohydrate metabolism such as hereditary fructose intolerance and galactosemia (Chap. 341). Reactive hypoglycemia also occurs in some individuals who have undergone gastric surgery, which allows the rapid passage of food from the stomach to the small intestine. This type of *alimentary hypoglycemia* causes a rapid postprandial rise in plasma glucose levels and the release of gut incretins, which induce an exuberant insulin response and subsequent hypoglycemia. Administration of an α-glucosidase inhibitor, which delays carbohydrate digestion and thus glucose absorption from the intestine, can be considered for treatment of reactive hypoglycemia, although its efficacy remains to be established in controlled trials.

If postprandial symptoms occur as an idiopathic disorder, caution should be exercised before labeling a person with a diagnosis of hypoglycemia. Indeed, a self-diagnosis of hypoglycemia has often been reinforced by the finding of a "low" venous glucose concentration late after glucose ingestion. An oral glucose tolerance test should not be used in this setting. Plasma glucose falls as low as 2.4 mmol/L (43 mg/dL) after a 100-g glucose load in 5% of normal asymptomatic individuals, making it difficult to identify hypoglycemia based on the results of this test. The diagnosis of postprandial hypoglycemia requires documentation of Whipple's triad after a typical mixed meal. The cause of repetitive postprandial symptoms in certain individuals

is unknown, but they may be particularly sensitive to the normal autonomic responses that follow ingestion of a meal.

FASTING HYPOGLYCEMIA

There are many causes of fasting hypoglycemia (Table 324-1). In addition to insulin and sulfonylureas used in the treatment of diabetes, ethanol use is a relatively common cause of hypoglycemia. Sepsis and renal failure are often complicated by hypoglycemia. Endocrine deficiencies, non-β-cell tumors, and endogenous hyperinsulinemia (including that caused by an insulinoma) are rare causes of hypoglycemia. Enzymatic metabolic errors that cause hypoglycemia are also rare but are being recognized more frequently in infants and children (Chaps. 341 and 343).

DRUGS In contrast to the sulfonylureas and rapid-acting insulin secretagogues (e.g., repaglinide, nateglinide), other oral hypoglycemic agents—biguanides (e.g., metformin), α-glucosidase inhibitors (e.g., acarbose, miglitol), and thiazolidinediones (e.g., rosiglitazone, pioglitazone)—do not act by stimulating insulin secretion. Therefore, with these agents, insulin levels usually decrease appropriately as plasma glucose levels fall. However, these drugs can contribute to hypoglycemia in other ways. Treatment with an α-glucosidase inhibitor alters the management of hypoglycemia; pure glucose should be used rather than ingestion of complex carbohydrates. Thiazolidinediones, as well as metformin, can predispose patients to hypoglycemia if they are receiving combined treatment with insulin or an insulin secretagogue.

Ethanol blocks gluconeogenesis but not glycogenolysis. Thus, alcohol-induced hypoglycemia typically occurs after a several-day ethanol binge during which the person eats little food, thereby causing glycogen depletion. Hypoglycemia in this setting can be profound, with mortality rates as high as 10%. Blood ethanol levels correlate poorly with plasma glucose concentrations at the time of diagnosis, as hypoglycemia occurs late in the sequence and often precludes further alcohol consumption.

Pentamidine, which is used to treat *Pneumocystis* pneumonia and other parasitic infections, is toxic to the pancreatic β cell. It causes insulin release initially, with hypoglycemia in about 10% of treated patients, and predisposes to the development of diabetes mellitus later. Quinine also stimulates insulin secretion. However, the relative contribution of hyperinsulinemia to the pathogenesis of hypoglycemia in quinine-treated patients who are critically ill with malaria is debated. Salicylates and sulfonamides can cause hypoglycemia, but do so rarely. There are reports of hypoglycemia attributed to nonselective β-adrenergic antagonists (e.g., propranolol) and a variety of other drugs.

CRITICAL ILLNESS Rapid and extensive hepatic destruction (e.g., severe toxic hepatitis) causes fasting hypoglycemia because the liver is the major site of endogenous glucose production. The mechanism of hypoglycemia reported in patients with cardiac failure is unknown but likely involves hepatic congestion. Although the kidneys are a source of glucose production, it is perhaps too simplistic to attribute hypoglycemia in persons with renal failure to this mechanism alone. The clearance of insulin is reduced substantially in renal failure, and reduced mobilization of gluconeogenic precursors has been reported.

Sepsis is sometimes complicated by hypoglycemia, which is multifactorial in origin. There is impaired endogenous glucose production, perhaps a result of hepatic hypoperfusion, and increased glucose utilization, which is induced by cytokines in macrophage-rich tissues such as the liver, spleen, and ileum and in muscle. Nutrition is also often inadequate in the setting of sepsis. Hypoglycemia can be seen with prolonged starvation, perhaps because of a loss of whole-body fat stores and the subsequent depletion of gluconeogenic precursors (e.g., amino acids), which necessitate increased glucose utilization.

ENDOCRINE DEFICIENCIES Neither cortisol nor growth hormone is critical to the prevention of acute hypoglycemia, at least in adults. However, hypoglycemia can occur with prolonged fasting in patients with untreated primary adrenocortical failure (Addison's disease) or hypopituitarism. Anorexia and weight loss are typical features of chronic cortisol deficiency and likely result in glycogen depletion with increased reliance on gluconeogenesis. Cortisol deficiency is associated with low levels of gluconeogenic precursors, suggesting that substrate-limited gluconeogenesis, in the setting of glycogen depletion, is the cause of the impaired ability to tolerate fasting in cortisol-deficient individuals. Growth hormone deficiency can cause hypoglycemia in young children. In addition to extended fasting, high rates of glucose utilization (e.g., during exercise, pregnancy) or low rates of glucose production (e.g., following alcohol ingestion) can precipitate hypoglycemia in adults with hypopituitarism. Cortisol and growth hormone secretion should be evaluated in patients with fasting hypoglycemia when the history suggests pituitary or adrenal disease and when other causes of hypoglycemia are not apparent.

Hypoglycemia is not a feature of the epinephrine-deficient state that results from bilateral adrenalectomy when glucocorticoid replacement is adequate, nor does it occur during pharmacologic adrenergic blockage when other glucoregulatory systems are intact. There are case reports of fasting hypoglycemia attributed to isolated glucagon or epinephrine deficiency, although hyperinsulinemia was not excluded convincingly in neonatal cases and other counterregulatory defects may have contributed in the adults. Thus, the regular assessment of glucagon and epinephrine secretion is not warranted.

NON-β-CELL TUMORS Fasting hypoglycemia, often termed *non-islet cell tumor hypoglycemia*, occurs in some patients with large mesenchymal or other tumors (e.g., hepatoma, adrenocortical tumors, carcinoids; Chap. 86. The glucose kinetic patterns resemble those of hyperinsulinism, but insulin secretion is suppressed appropriately during hypoglycemia. In most instances, hypoglycemia is due to overproduction of an incompletely processed form of insulin-like growth factor (IGF) II. Although total IGF-II levels are not consistently elevated, circulating free IGF-II levels are high. Hypoglycemia results from IGF-II actions through the insulin or IGF-I receptors.

ENDOGENOUS HYPERINSULINISM Hypoglycemia due to excessive endogenous insulin secretion can be caused by: (1) a primary pancreatic islet β cell disorder, typically a β cell tumor (insulinoma), sometimes multiple insulinomas, or, especially in infants or young children, a functional β cell disorder without an anatomic correlate; (2) a β cell secretagogue, often a sulfonylurea, and, theoretically, a β cell–stimulating autoantibody; (3) an autoantibody to insulin; or (4) ectopic insulin secretion. None of these disorders is common. Endogenous hyperinsulinism is more likely to occur in an overtly healthy individual without other apparent causes of hypoglycemia such as a relevant drug history, critical illness, endocrine deficiencies, or a non-β-cell tumor. Accidental, surreptitious, or even malicious administration of a sulfonylurea or insulin should also be considered in such individuals.

The fundamental pathophysiologic feature of endogenous hyperinsulinism is the failure of insulin secretion to fall to very low rates during hypoglycemia. This is assessed by measuring insulin, proinsulin, and C peptide, which is derived from the processing of proinsulin. Critical diagnostic findings are a plasma insulin concentration $\geq$36 pmol/L ($\geq$6 μU/mL) and a plasma C-peptide concentration $\geq$0.2 mmol/L ($\geq$0.6 ng/mL) when the plasma glucose concentration is $\leq$2.5 mmol/L ($\leq$45 mg/dL) in the fasting state with symptoms of hypoglycemia. Insulin and C-peptide levels do not need to be absolutely increased (e.g., relative to euglycemic normal values) but only inappropriately increased in the setting of fasting hypoglycemia. Plasma proinsulin concentrations are also inappropriately elevated, particularly in patients with an insulinoma. Sulfonylureas, because they stimulate insulin secretion, result in a pattern of glucose, insulin, and C-peptide levels that is indistinguishable from that produced by a primary β cell disorder. The measurement of sulfonylureas in plasma or urine distinguishes these conditions. Antibodies to insulin produce *autoimmune hypoglycemia* following the transition from the postprandial to the postabsorptive state, as insulin slowly dissociates from the antibodies. Total and free plasma insulin concentrations are inappropri-

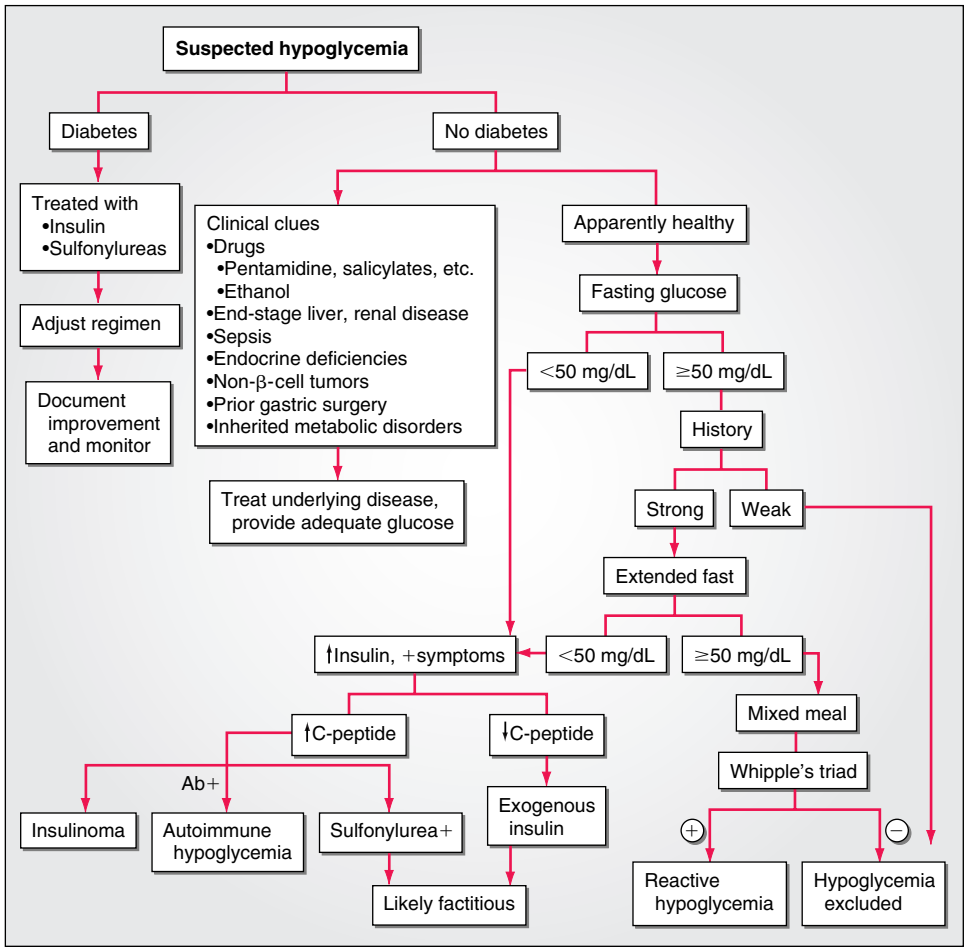

FIGURE 324-3 Diagnostic approach to a patient with suspected hypoglycemia based on a history of symptoms, a low plasma glucose concentration, or both.

ately high. The distinguishing feature is the presence of circulating antibodies to insulin, but the need to measure these routinely is debated, since autoimmune hypoglycemia is rare. Autoantibodies to the insulin receptor are another rare cause of hypoglycemia and usually occur in the context of other autoimmune diseases. A few cases of ectopic insulin secretion (from a non-β-cell tumor) have been reported.

Insulinoma and Other Primary β Cell Disorders Insulinomas are uncommon, but because approximately 90% are benign, they are a treatable cause of potentially fatal hypoglycemia. The yearly incidence is estimated to be 1 in 250,000. About 60% of cases occur in women. The median age at presentation is 50 years in sporadic cases, but it usually presents in the third decade when associated with multiple endocrine neoplasia type 1 (Chap. 330). Insulinomas arise within the substance of the pancreas in >99% of cases and are usually small (1 to 2 cm). About 5 to 10% of insulinomas are malignant, as evidenced by the presence of metastases.

Insulinomas are almost always recognized because of hypoglycemia rather than mass effects. Unusually low plasma glucose concentrations may be required to produce symptoms and signs of hypoglycemia because recurrent hypoglycemia shifts the glycemic thresholds. Although symptomatic hypoglycemia can occur after an overnight fast, it often follows exercise. Rarely, symptomatic hypoglycemia occurs following meals, but most such patients have evidence of fasting hypoglycemia as well.

Octreotide scans localize approximately half of insulinomas. Arteriography has been used extensively in the past, but false-negative and false-positive results occur, and it is generally preferable to use less invasive computed tomography (CT) or magnetic resonance imaging (MRI) scans, which detect 45 to 75% of tumors. Preoperative ultrasound is valuable for some patients. Intraoperative ultrasonography has high sensitivity and may localize tumors not identified by palpation. Surgical resection of a solitary insulinoma is generally curative. Diazoxide, which inhibits insulin secretion, and the somatostatin analogue, octreotide, can be used to treat hypoglycemia in patients with unresectable insulinomas.

FACTITIOUS HYPOGLYCEMIA *Factitious hypoglycemia*, caused by malicious or self-administration of insulin or ingestion of a sulfonylurea, shares many clinical and laboratory features with insulinoma. It is most common among health care workers, patients with diabetes or their relatives, and people with a history of other factitious illnesses. When this diagnosis is suspected, it is useful to seek previous medical records, which may reveal admissions for similar episodes. In individuals taking exogenous insulin, factitious hypoglycemia can be distinguished from insulinoma by the presence of high insulin levels without a concomitant increase in the C-peptide level, which is suppressed by the exogenous insulin. As noted above, sulfonylureas stimulate endogenous insulin and can therefore be detected only by measuring drug levels in plasma or urine. Factitious or surreptitious hypoglycemia should be considered in every patient requiring a fasting test for hypoglycemia. In addition to laboratory tests, observing the patient's behavior may help make this diagnosis.

APPROACH TO THE PATIENT

In addition to recognition and documentation of hypoglycemia, and often urgent treatment, diagnosis of the hypoglycemic mechanism is critical for choosing a treatment that prevents, or at least minimizes, recurrent hypoglycemia. A diagnostic algorithm is shown in Fig. 324-3.

RECOGNITION AND DOCUMENTATION

Urgent treatment is often necessary in patients with suspected hypoglycemia. Blood should be drawn, whenever possible, before the administration of glucose to allow documentation of the plasma glucose level. Convincing documentation of hypoglycemia requires the fulfillment of Whipple's triad. Thus, *the ideal time to test the plasma glucose is during an episode associated with hypoglycemic symptoms*. A normal plasma glucose concentration measured when the patient is free of symptoms does not exclude hypoglycemia at the time of earlier symptoms. When the cause of hypoglycemia is obscure, additional assays should include glucose, insulin, C peptide, sulfonylurea levels, cortisol, and ethanol.

Hypoglycemia is sometimes detected serendipitously. A distinctly low plasma glucose measurement in a person without a history of corresponding symptoms raises the possibility of a laboratory error caused by ongoing metabolism of glucose by the formed elements of the blood after the sample is drawn. This type of artifactually low glucose level is particularly likely when leukocyte, erythrocyte, or platelet counts are abnormally high, but also if separation of the plasma or serum from the formed elements is delayed.

DIAGNOSIS OF THE HYPOGLYCEMIC MECHANISM

In an adult patient with documented hypoglycemia, a plausible hypoglycemic mechanism and further diagnostic evaluation can be guided by the history, physical examination, and available laboratory data (Fig. 324-3). In the absence of documented spontaneous hypoglycemia, overnight fasting, or food deprivation during observation in the outpatient setting, will sometimes elicit hypoglycemia and allow diagnostic evaluation. If there is a high degree of clinical suspicion, an extended fast lasting 48 to 72 h is often required to make the diagnosis. This procedure should be performed in the hospital with careful supervision and should be terminated if the plasma glucose drops to <2.5 mmol/L (<45 mg/dL) and the patient has symptoms. It is essential to draw blood samples for appropriate tests before administering glucose or allowing the patient to eat.

URGENT TREATMENT

Oral treatment with glucose tablets or glucose-containing fluids, candy, or food is appropriate if the patient is able and willing to take these. A reasonable initial dose is 20 g of glucose. If neuroglycopenia precludes oral feedings, parenteral therapy is necessary. Intravenous glucose (25 g) should be given using a 50% solution followed by a constant infusion of 5 or 10% dextrose. If intravenous therapy is not practical, subcutaneous or intramuscular glucagon can be used, particularly in patients with type 1 diabetes mellitus. Because it acts primarily by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., those with alcohol-induced hypoglycemia). It also stimulates insulin secretion and is therefore less useful in type 2 diabetes mellitus. These treatments raise plasma glucose concentrations only transiently, and patients should be encouraged to eat as soon as practical to replete glycogen stores.

PREVENTION OF RECURRENT HYPOGLYCEMIA

Prevention of recurrent hypoglycemia requires an understanding of the hypoglycemic mechanism. Offending drugs can be discontinued or their doses reduced. It should be remembered that hypoglycemia caused by sulfonylureas may recur after a period of several hours or days. Underlying critical illnesses can often be treated. Cortisol and growth hormone can be replaced if deficient. Surgical, radiotherapeutic, or chemotherapeutic reduction of a non-β-cell tumor can alleviate hypoglycemia, even if the tumor cannot be cured; glucocorticoid or growth hormone administration may also reduce hypoglycemic episodes in such patients. Surgical resection of an insulinoma is often curative; medical therapy with diazoxide or octreotide can be used if resection is not possible and in patients with a nontumor primary β cell disorder. The treatment of autoimmune hypoglycemia (e.g., with a glucocorticoid) is more problematic, but this disorder is often self-limited. Failing these treatments, frequent feedings and avoidance of fasting may be required. Uncooked cornstarch at bedtime or an overnight infusion of intragastric glucose may be necessary in some patients.

325 DISORDERS OF THE TESTES AND MALE REPRODUCTIVE SYSTEM

Shalendar Bhasin, J. Larry Jameson

The male reproductive system regulates sexual differentiation, virilization, and the hormonal changes that accompany puberty, ultimately leading to spermatogenesis and fertility. Under the control of the pituitary hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—the Leydig cells of the testes produce testosterone and germ cells are nurtured by Sertoli cells to divide, differentiate, and mature into sperm. During embryonic development, testosterone and dihydrotestosterone (DHT) induce the wolffian duct and virilization of the external genitalia. During puberty, testosterone promotes somatic growth and the development of secondary sexual characteristics. In the adult, testosterone is necessary for spermatogenesis and stimulation of libido and normal sexual function. This chapter focuses on the physiology of the testes and disorders associated with decreased androgen production, which may be caused by gonadotropin deficiency or by primary testis dysfunction. A variety of testosterone formulations now allow more physiologic androgen replacement. Infertility occurs in ~5% of men and is increasingly amenable to treatment by hormone replacement or by using sperm transfer techniques (Chap. 45). →***For further discussion of sexual dysfunction, disorders of the prostate, and testicular cancer, see Chaps. 43, 81, 82, respectively.***

DEVELOPMENT AND STRUCTURE OF THE TESTIS

The fetal testis develops from the undifferentiated gonad after expression of a genetic cascade that is initiated by the SRY (Sex-related gene on the Y chromosome) (Chap. 328). SRY induces differentiation of Sertoli cells, which surround germ cells, and together with peritubular myoid cells form testis cords that will later develop into seminiferous tubules. Fetal Leydig cells and endothelial cells migrate into the gonad from the adjacent mesonephros but may also arise from interstitial cells that reside between testis cords. Leydig cells produce testosterone, which supports the growth and differentiation of wolffian duct structures that develop into the epididymis, vas deferens, and seminal vesicles. Testosterone is also converted to DHT (see below), which induces formation of the prostate and the external male genitalia including the penis, urethra, and scrotum. Testicular descent through the inguinal canal is controlled in part by Leydig cell production of insulin-like factor 3 (INSL3), which acts via a receptor termed *Great* (*G* protein–coupled *re*ceptor *a*ffecting *t*estis descent). Sertoli cells produce müllerian inhibiting substance (MIS), which causes regression of the müllerian structures including the fallopian tube, uterus, and upper segment of the vagina.

NORMAL MALE PUBERTAL DEVELOPMENT

Although puberty commonly refers to the maturation of the reproductive axis and the development of secondary sex characteristics, it involves a coordinated response of multiple hormonal systems including the adrenal gland and the growth hormone (GH) axis (Fig. 325-1). The development of secondary sexual characteristics is initiated by *adrenarche*, which usually occurs between 6 and 8 years of age when the adrenal gland begins to produce greater amounts of androgens from the zona reticularis, the principal site of dehydroepiandrosterone (DHEA) production. The sexual maturation process is greatly accelerated by the activation of the hypothalamic-pituitary axis and the production of gonadotropin-releasing hormone (GnRH). The so-called GnRH pulse generator in the hypothalamus is active during fetal life and early infancy but is quiescent until the early stages of puberty, when the sensitivity to steroid inhibition is gradually lost, causing reactivation of GnRH secretion. Leptin, a hormone produced by adi-

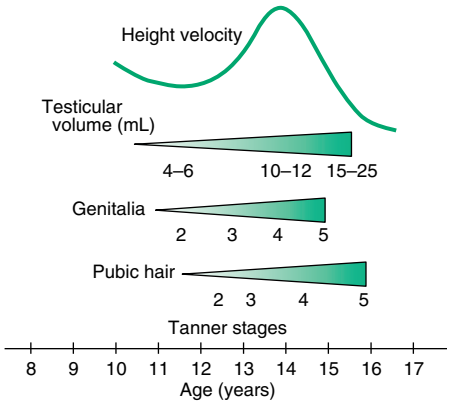

FIGURE 325-1 Pubertal events in males. Sexual maturity ratings for genitalia and pubic hair and divided into five stages. (*From WA Marshall, JM Tanner: Variations in the pattern of pubertal changes in boys. Arch Dis Child 45:13, 1970.*)

pose cells, may play a permissive role in this process, as leptin-deficient individuals fail to enter puberty (Chap. 64). Early puberty is characterized by nocturnal surges of LH and FSH. Growth of the testes is usually the first sign of puberty, reflecting an increase in seminiferous tubule volume. Increasing levels of testosterone deepen the voice and increase muscle growth. Conversion of testosterone to DHT leads to growth of the external genitalia and pubic hair. DHT also stimulates prostate and facial hair growth and initiates recession of the temporal hairline. The growth spurt occurs at a testicular volume of about 10 to 12 mL. GH increases early in puberty and is stimulated in part by the rise in gonadal steroids. GH increases the level of insulin-like growth factor 1 (IGF-1), which enhances linear bone growth. The prolonged pubertal exposure to gonadal steroids (mainly estradiol) ultimately causes epiphyseal closure and limits further bone growth.

REGULATION OF TESTICULAR FUNCTION

REGULATION OF THE HYPOTHALAMIC-PITUITARY-TESTIS AXIS IN ADULT MAN

Hypothalamic GnRH regulates the production of the pituitary gonadotropins, LH and FSH (Fig. 325-2). GnRH is released in discrete pulses approximately every 2 h, resulting in corresponding pulses of LH and FSH. These dynamic hormone pulses account in part for the wide variations in LH and testosterone, even within the same individual. LH acts primarily on the Leydig cell to stimulate testosterone synthesis. The regulatory control of androgen synthesis is mediated by testosterone and estrogen feedback on both the hypothalamus and the pituitary. FSH acts on the Sertoli cell to regulate spermatogenesis and the production of Sertoli products such as inhibin B, which acts to selectively suppress pituitary FSH. Despite these somewhat distinct Leydig and Sertoli cell–regulated pathways, testis function is integrated at several levels: GnRH regulates both gonadotropins; spermatogenesis requires high levels of testosterone; there are numerous paracrine interactions between Leydig and Sertoli cells that are necessary for normal testis function.

THE LEYDIG CELL: ANDROGEN SYNTHESIS LH binds to its seven transmembrane, G protein–coupled receptor to activate the cyclic AMP pathway. Stimulation of the LH receptor induces *st*eroid *a*cute *r*egulatory (StAR) protein, along with several steroidogenic enzymes involved in androgen synthesis. LH receptor mutations cause Leydig cell hypoplasia or agenesis, underscoring the importance of this pathway for Leydig cell development and function. The rate-limiting process in testosterone synthesis is the delivery of cholesterol by the StAR protein to the inner mitochondrial membrane. Peripheral benzodiazepine receptor, a mitochondrial cholesterol-binding protein, is also an acute regulator of Leydig cell steroidogenesis. The five major enzymatic steps involved in testosterone synthesis are summarized in Fig. 325-3. After cholesterol transport into the mitochondrion, side chain cleavage by CYP11A1 to form pregnenolone is a limiting enzymatic step.

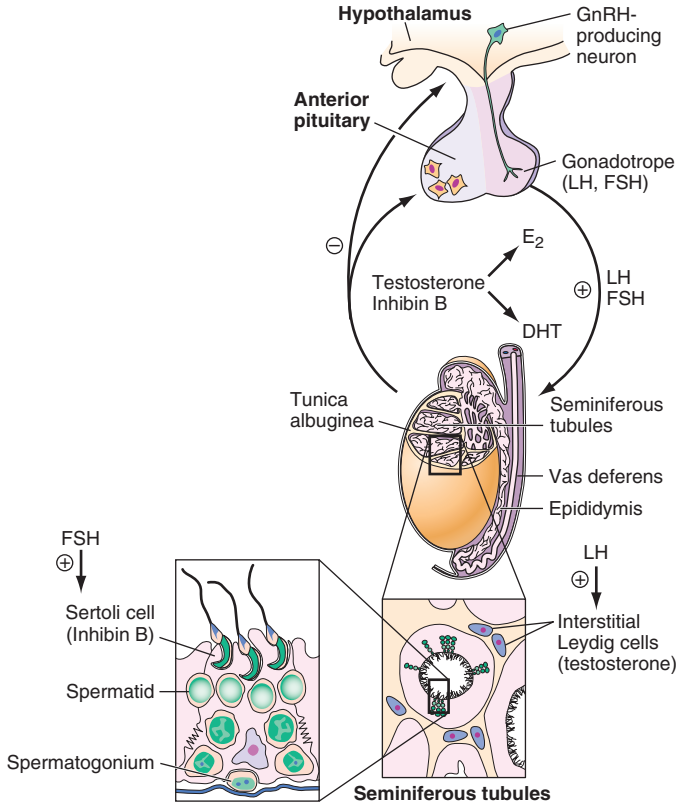

FIGURE 325-2 Human pituitary gonadotropin axis, structure of testis, seminiferous tubule. E_2, 17β estradiol; DHT, dihydrotestosterone.

The 17α-hydroxylase and the 17,20-lyase reactions are catalyzed by a single enzyme, CYP17; posttranslational modification (phosphorylation) of this enzyme and the presence of specific enzyme cofactors confer 17,20-lyase activity selectively in the testis and zona reticularis of the adrenal gland. Testosterone can be converted to the more potent DHT by 5α-reductase, or it can be aromatized to estradiol by CYP19 (aromatase).

Testosterone Transport and Metabolism In males, 95% of circulating testosterone is derived from testicular secretion (3 to 10 mg/d). Direct secretion of testosterone by the adrenal and the peripheral conversion of androstenedione to testosterone collectively account for another 0.5 mg/d of testosterone. Only a small amount of DHT (70 μg/d) is secreted directly by the testis; most circulating DHT is derived from peripheral conversion of testosterone.

Circulating testosterone is bound to two plasma proteins: sex hormone–binding globulin (SHBG) and albumin (Fig. 325-4). SHBG binds testosterone with much greater affinity than albumin. Only 0.5 to 3% of testosterone is unbound. According to the "free hormone" hypothesis, only the unbound fraction is biologically active; however, albumin-bound hormone dissociates readily in the capillaries and may be bioavailable. SHBG concentrations are decreased by androgens, obesity, insulin, and nephrotic syndrome. Conversely, estrogen administration, hyperthyroidism, many chronic inflammatory illnesses, and aging are associated with high SHBG concentrations.

Testosterone is metabolized predominantly in the liver, although some degradation occurs in peripheral tissues, particularly the prostate and the skin. In the liver, testosterone is converted by a series of enzymatic steps into androsterone, etiocholanolone, DHT, and 3-α-androstanediol. These compounds undergo glucuronidation or sulfation before being excreted by the kidneys.

Mechanism of Androgen Action The androgen receptor (AR) is homologous to other nuclear receptor proteins including the receptors for estrogen, glucocorticoids, and progesterone (Chap. 317). The AR is encoded by a gene on the long arm of the X chromosome and has a molecular mass of about 110 kDa. A polymorphic region in the amino

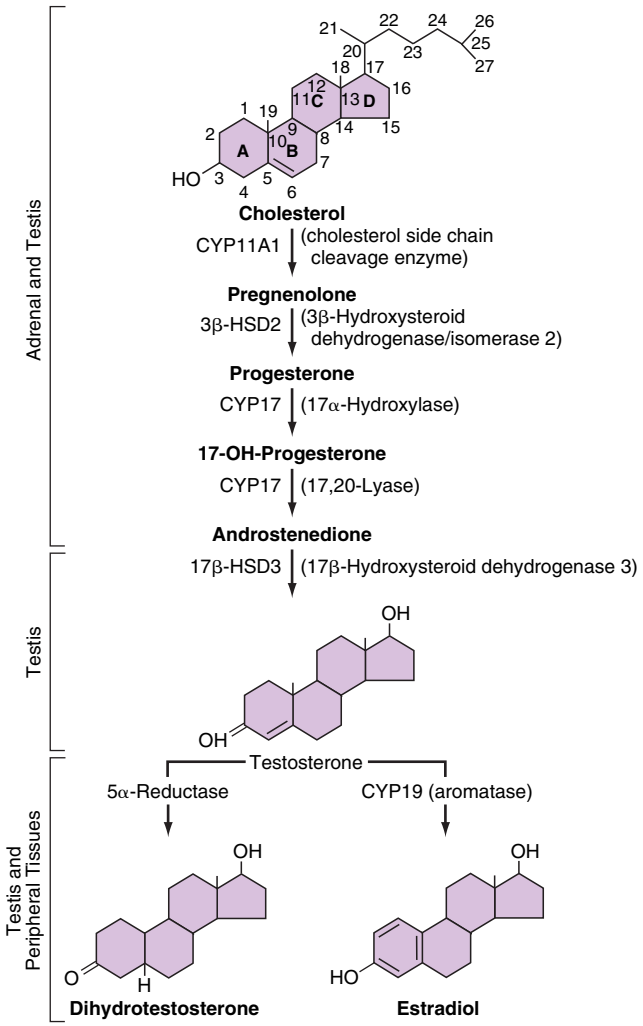

FIGURE 325-3 The biochemical pathway in the conversion of 27-carbon sterol cholesterol to androgens and estrogens.

terminus of the receptor, which contains a variable number of glutamine repeats, modifies the transcriptional activity of the receptor. The AR protein is distributed in both the cytoplasm and the nucleus. Androgen binding to the AR causes it to translocate into the nucleus where it binds to DNA or other transcription factors already bound to DNA. The ligand also induces conformational changes that allow the recruitment and assembly of tissue-specific cofactors. Thus, the AR is a ligand-regulated transcription factor. Some androgen effects may be mediated by nongenomic AR signal transduction pathways. Testosterone binds to AR with half the affinity of DHT. The DHT-AR complex also has greater thermostability, and a slower dissociation rate, than the testosterone-AR complex. However, the molecular basis for selective testosterone versus DHT actions remains incompletely explained.

THE SEMINIFEROUS TUBULES: SPERMATOGENESIS The seminiferous tubules are convoluted, closed loops with both ends emptying into the rete testis, a network of progressively larger efferent ducts that ultimately form the epididymis (Fig. 325-2). The seminiferous tubules total about 600 m in length and comprise about two-thirds of testis volume. The walls of the tubules are formed by polarized Sertoli cells that are apposed to peritubular myoid cells. Tight junctions between Sertoli cells create a blood-testis barrier. Germ cells comprise the majority of the seminiferous epithelium (~60%) and are intimately embedded within the cytoplasmic extensions of the Sertoli cells, which function as "nurse cells." Germ cells progress through characteristic morphologic stages of spermiogenesis, requiring ~24 days. A pool of type A spermatogonia serve as stem cells capable of self-renewal. Primary spermatocytes are derived from type B spermatogonia and undergo meiosis before progressing to spermatids that mature and are ultimately released from Sertoli cells as mature spermatozoa. Peristaltic-type action by peritubular myoid cells transports sperm into the efferent ducts. The normal adult testes produce >100 million sperm per day.

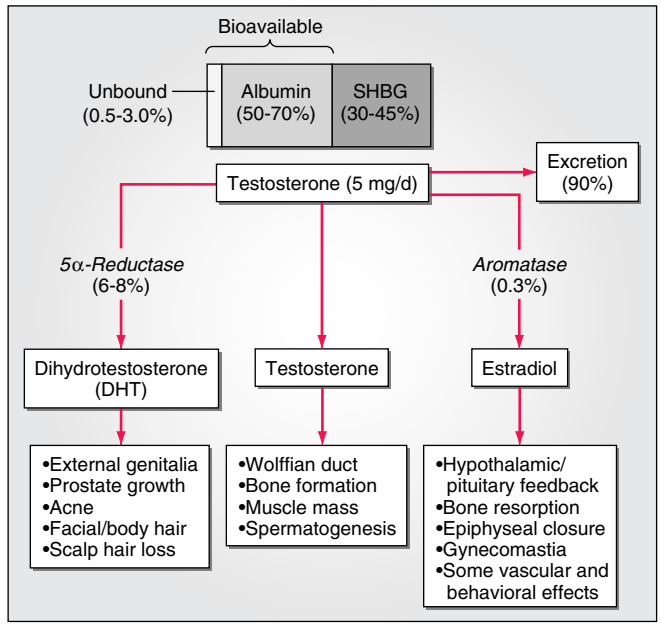

FIGURE 325-4 Androgen metabolism and actions. SHBG, sex hormone–binding globulin.

Naturally occurring mutations in the *FSHβ* gene and in the FSH receptor confirm an important, but not essential, role for this pathway in spermatogenesis. Females with these mutations are hypogonadal and infertile because ovarian follicles do not mature; males exhibit variable degrees of reduced spermatogenesis, presumably because of impaired Sertoli cell function. Because Sertoli cells produce inhibin B, an inhibitor of FSH, seminiferous tubule damage (e.g., by radiation) causes a selective increase of FSH. Androgens reach very high concentrations locally in the testis and are essential for spermatogenesis. Several cytokines and growth factors are also involved in the regulation of spermatogenesis by paracrine and autocrine mechanisms. A number of knockout mouse models exhibit impaired germ cell development or spermatogenesis, presaging possible mutations associated with male infertility. In humans, microdeletions of several Y chromosome azoospermia factor (*AZF*) genes (e.g., RNA-binding motif, *RBM*; deleted in azoospermia, *DAZ*) are associated with oligospermia or azoospermia.

CLINICAL AND LABORATORY EVALUATION OF MALE REPRODUCTIVE FUNCTION

HISTORY AND PHYSICAL EXAMINATION The history should focus on developmental stages such as puberty and growth spurts, as well as androgen-dependent events such as early morning erections, frequency and intensity of sexual thoughts, and frequency of masturbation or intercourse. Although libido and the overall frequency of sexual acts is decreased in androgen-deficient men, young hypogonadal men may achieve erections in response to visual erotic stimuli. Men with acquired androgen deficiency often report decreased energy and increased irritability.

The physical examination should focus on secondary sex characteristics such as hair growth, possible gynecomastia, testicular volume, prostate, and height and body proportions. Eunuchoidal proportions are defined as an arm span >2 cm greater than height and suggest that androgen deficiency occurred before epiphyseal fusion. Hair growth in the face, axilla, chest, and pubic regions is androgen-dependent;

however, changes may not be noticeable unless androgen deficiency is severe and prolonged. Ethnicity also influences the intensity of hair growth (Chap. 44). Testicular volume is best measured by using a Prader orchidometer. Testes range from 3.5 to 5.5 cm in length, which corresponds to a volume of 12 to 25 mL. Advanced age does not influence testicular size, although the consistency becomes less firm. Asian men generally have smaller testes than western Europeans, independent of differences in body size. Because of its possible role in infertility, the presence of varicocele should be sought by palpation while the patient is standing; it is more common on the left side. Patients with Klinefelter syndrome have markedly reduced testicular volumes (1 to 2 mL). In congenital hypogonadotropic hypogonadism, testicular volumes provide a good index for the degree of gonadotropin deficiency and the likelihood of response to therapy.

GONADOTROPIN AND INHIBIN MEASUREMENTS LH and FSH are measured using two-site immunoradiometric, immunofluorometric, or chemiluminescent assays, which have very low cross-reactivity with other pituitary glycoprotein hormones and human chorionic gonadotropin (hCG) and have sufficient sensitivity to measure the low levels present in patients with hypogonadotropic hypogonadism. In men with a low testosterone level, an LH level can distinguish hypergonadotropic (high LH) versus hypogonadotropic (low or inappropriately normal LH) hypogonadism. An elevated LH level indicates a primary defect at the testicular level, whereas a low or inappropriately normal LH level suggests a defect at the hypothalamic-pituitary level. LH pulses occur about every 1 to 3 h in normal men. Thus, gonadotropin levels fluctuate, and samples should be pooled or repeated when results are equivocal. FSH is less pulsatile than LH because it has a longer half-life. Increased FSH suggests damage to the seminiferous tubules. Inhibin B, a Sertoli cell product that suppresses FSH, is reduced with seminiferous tubule damage. Inhibin B is a dimer with α-β_B subunits and is measured by two-site immunoassays.

GnRH Stimulation Testing The GnRH test is performed by measuring LH and FSH concentrations at baseline and at 30 and 60 min after intravenous administration of 100 μg of GnRH. A minimally acceptable response is a twofold LH increase and a 50% FSH increase. In the prepubertal period or with severe GnRH deficiency, the gonadotrope may not respond to a single bolus of GnRH because it has not been primed by endogenous hypothalamic GnRH; in these patients, GnRH responsiveness may be restored by chronic, pulsatile GnRH administration. With the availability of sensitive and specific LH assays, GnRH stimulation testing is used rarely except to evaluate gonadotrope function in patients who have undergone pituitary surgery or have a space-occupying lesion in the hypothalamic-pituitary region.

TESTOSTERONE ASSAYS ■ Total Testosterone Total testosterone includes both unbound and protein-bound testosterone and is measured by radioimmunoassays or immunometric assays. A single random sample provides a good approximation of the average testosterone concentration with the realization that testosterone levels fluctuate in response to pulsatile LH. Testosterone is generally lower in the late afternoon and is reduced by acute illness. The testosterone concentration in healthy young men ranges from 300 to 1000 ng/dL in most laboratories. Alterations in SHBG levels due to aging, obesity, some types of medications, chronic illness, or on a congenital basis can affect total testosterone levels.

Measurement of Free Testosterone Levels Most circulating testosterone is bound to SHBG and to albumin; only 0.5 to 3% of circulating testosterone is unbound or "free." Free testosterone concentrations can be calculated from algorithms based on total testosterone and SHBG concentrations. The free fraction is best measured by equilibrium dialysis. Tracer analogue methods are relatively inexpensive and convenient but they are less reliable because changes in SHBG affect the results. Bioavailable testosterone refers to unbound testosterone plus testosterone that is loosely bound to albumin; it can be estimated by the ammonium sulfate precipitation method.

hCG Stimulation Test The hCG stimulation test is performed by administering a single injection of 1500 to 4000 IU of hCG intramuscularly and measuring testosterone levels at baseline and 24, 48, 72, and 120 h after hCG injection. An alternative regimen involves three injections of 1500 units of hCG on successive days, and measuring testosterone levels 24 h after the last dose. An acceptable response to hCG is a doubling of the testosterone concentration in adult men. In prepubertal boys, an increase in testosterone to >150 ng/dL indicates the presence of testicular tissue. No response may indicate an absence of testicular tissue or marked impairment of Leydig cell function. Measurement of MIS, a Sertoli cell product, is also used to detect the presence of testes in prepubertal boys with cryptorchidism.

SEMEN ANALYSIS Semen analysis is the most important step in the evaluation of male infertility (Chap. 45). Samples are collected by masturbation following a period of abstinence for 2 to 3 days. Semen volumes and sperm concentrations vary considerably among fertile men, and several samples may be needed before concluding that the results are abnormal. Analysis should be performed within an hour of collection. The normal ejaculate volume is 2 to 6 mL and contains sperm counts of >20 million/mL, with a motility of >50% and >15% normal morphology. Some men with low sperm counts are nevertheless fertile. A variety of tests for sperm function can be performed in specialized laboratories, but these add relatively little to the treatment options.

TESTICULAR BIOPSY Testicular biopsy is useful in some patients with oligospermia or azoospermia, as an aid in diagnosis and indication for the feasibility of treatment. Using local anesthesia, fine-needle aspiration biopsy is performed to aspirate tissue for histology. Alternatively, open biopsies can be performed under local or general anesthesia when more tissue is required. A normal biopsy in an azoospermic man with a normal FSH level suggests obstruction of the vas deferens, which may be correctable surgically. Biopsies are also used to harvest sperm for intracytoplasmic sperm injection (ICSI) and to classify disorders such as hypospermatogenesis (all stages present but in reduced numbers), germ cell arrest (usually at primary spermatocyte stage), and Sertoli cell–only syndrome (absent germ cells) or hyalinization (sclerosis with absent cellular elements).

DISORDERS OF SEXUAL DIFFERENTIATION

See Chap. 328

DISORDERS OF PUBERTY

PRECOCIOUS PUBERTY Puberty in boys before age 9 is considered precocious. *Isosexual precocity* refers to premature sexual development consistent with phenotypic sex and includes features such as the development of facial hair and phallic growth. Isosexual precocity is divided into gonadotropin-dependent and gonadotropin-independent causes of androgen excess (Table 325-1). *Heterosexual precocity* refers to the premature development of feminizing features in boys, such as breast development.

Gonadotropin-Dependent Precocious Puberty This disorder is also called *central precocious puberty* (CPP) and it is less common in boys than in girls. It is caused by premature activation of the GnRH pulse generator, sometimes because of central nervous system (CNS) lesions such as hypothalamic hamartomas, but it is often idiopathic. CPP is characterized by gonadotropin levels that are inappropriately elevated for age. Because pituitary priming has occurred, GnRH elicits LH and FSH responses typical of those seen in puberty or in adults. Magnetic resonance imaging (MRI) should be performed to exclude a mass, structural defect, or infectious or inflammatory process.

Gonadotropin-Independent Precocious Puberty This group of disorders includes hCG-secreting tumors; congenital adrenal hyperplasia; sex steroid–producing tumors of the testis, adrenal, and ovary; accidental or deliberate exogenous sex steroid administration; hypothyroidism; and

TABLE 325-1 Causes of Precocious or Delayed Puberty in Boys

I. Precocious puberty
  A. Gonadotropin-dependent
    1. Idiopathic
    2. Hypothalamic hamartoma or other lesions
    3. CNS tumor or inflammatory state
  B. Gonadotropin-independent
    1. Congenital adrenal hyperplasia
    2. hCG-secreting tumor
    3. McCune-Albright syndrome
    4. Activating LH receptor mutation
    5. Exogenous androgens
II. Delayed puberty
  A. Constitutional delay of growth and puberty
  B. Systemic disorders
    1. Chronic disease
    2. Malnutrition
    3. Anorexia nervosa
  C. CNS tumors and their treatment (radiotherapy and surgery)
  D. Hypothalamic-pituitary causes of pubertal failure (low gonadotropins)
    1. Congenital disorders (Table 325-2)
      a. Hypothalamic syndromes (e.g., Prader-Willi)
      b. Idiopathic hypogonadotropic hypogonadism
      c. Kallmann syndrome
      d. GnRH receptor mutations
      e. Adrenal hypoplasia congenita
      f. *PROP1* mutations
      g. Other mutations affecting pituitary development/function
    2. Acquired disorders
      a. Pituitary tumors
      b. Hyperprolactinemia
  E. Gonadal causes of pubertal failure (elevated gonadotropins)
    1. Klinefelter syndrome
    2. Bilateral undescended testes or anorchia
    3. Orchitis
    4. Chemotherapy or radiotherapy
  F. Androgen insensitivity

Note: CNS, central nervous system; hCG, human chronic gonadotropin; LH, luteinizing hormone; GnRH, gonadotropin-releasing hormone.

activating mutations of the LH receptor or $G_s\alpha$ subunit. In these cases, androgens from the testis or the adrenal are increased but gonadotropins are low.

FAMILIAL MALE-LIMITED PRECOCIOUS PUBERTY This is transmitted in an autosomal dominant manner. It is caused by activating mutations in the LH receptor, leading to constitutive stimulation of the cyclic AMP pathway and testosterone production. The disorder is also called *testotoxicosis*. Clinical features include premature virilization in boys, growth acceleration in early childhood, and advanced bone age followed by premature epiphyseal fusion. Testosterone is elevated and LH is suppressed. Treatment options include inhibitors of testosterone synthesis (e.g., ketoconazole), androgen receptor antagonists (e.g., flutamide), and aromatase inhibitors (e.g., anastrazole).

McCUNE-ALBRIGHT SYNDROME This is a sporadic disorder caused by somatic (postzygotic) activating mutations in the $G_s\alpha$ subunit that links G protein–coupled receptors to intracellular signaling pathways (Chap. 334). The mutations impair the guanosine triphosphatase activity of the $G_s\alpha$ protein, leading to constitutive activation of adenylyl cyclase. Like activating LH receptor mutations, this stimulates testosterone production and causes gonadotropin-independent precocious puberty. In addition to sexual precocity, affected individuals may have autonomy in the adrenals, pituitary, and thyroid glands. Café au lait spots are characteristic skin lesions that reflect the onset of the somatic mutations in melanocytes during embryonic development. Polyostotic fibrous dysplasia is caused by activation of the parathyroid hormone receptor pathway in bone. Treatment is similar to that in patients with activating LH receptor mutations. Bisphosphonates have been used to treat bone lesions.

CONGENITAL ADRENAL HYPERPLASIA Boys with congenital adrenal hyperplasia (CAH) who are not well controlled with glucocorticoid suppression of adrenocorticotropic hormone (ACTH) can develop premature virilization because of excessive androgen production by the adrenal gland (Chaps. 321 and 328). LH is low and the testes are small. Rarely, adrenal rests may develop within the testis because of chronic ACTH stimulation.

Heterosexual Sexual Precocity Breast enlargement in prepubertal boys can result from familial aromatase excess, estrogen-producing tumors in the adrenal gland, Sertoli cell tumors in the testis, marijuana smoking, or estrogen use. Occasionally, germ cell tumors that secrete hCG can be associated with breast enlargement due to excessive stimulation of estrogen production (see "Gynecomastia," below).

APPROACH TO THE PATIENT

After verification of precocious development, serum LH and FSH levels should be measured to determine whether gonadotropins are increased in relation to chronologic age (gonadotropin-dependent) or whether sex steroid secretion is occurring independent of LH and FSH (gonadotropin-independent). In children with gonadotropin-dependent precocious puberty, CNS lesions should be excluded by history, neurologic examination, and MRI scan of the head. If organic causes are not found, one is left with the diagnosis of idiopathic central precocity. Patients with high testosterone but suppressed LH concentrations have gonadotropin-independent sexual precocity; in these patients; DHEA sulfate (DHEAS) and 17α-hydroxyprogesterone should be measured. High levels of testosterone and 17α-hydroxyprogesterone suggest the possibility of CAH due to 21α-hydroxylase or 11β-hydroxylase deficiency. If testosterone and DHEAS are elevated, adrenal tumors should be excluded by obtaining a computed tomography (CT) scan of the adrenal glands. Patients with elevated testosterone but without increased 17α-hydroxyprogesterone or DHEAS should undergo careful evaluation of the testis by palpation and ultrasound to exclude a Leydig cell neoplasm. Activating mutations of the LH receptor should be considered in children with gonadotropin-independent precocious puberty in whom CAH, androgen abuse, and adrenal and testicular neoplasms have been excluded.

TREATMENT

In patients with a known cause (e.g., a CNS lesion or a testicular tumor), therapy should be directed towards the underlying disorder. In patients with idiopathic CPP, long-acting GnRH analogues can be used to suppress gonadotropins and decrease testosterone, halt early pubertal development, delay accelerated bone maturation, and prevent early epiphyseal closure. The treatment is most effective for increasing final adult height if it is initiated before age 6. Puberty resumes after discontinuation of the GnRH analogue. Counseling is an important aspect of the overall treatment strategy. In children with gonadotropin-independent precocious puberty, inhibitors of steroidogenesis, such as ketoconazole, and AR antagonists have been used empirically without data from clinical trials.

DELAYED PUBERTY Puberty is delayed in boys if it has not ensued by age 14, an age that is 2 to 2.5 standard deviations above the mean for healthy children. Delayed puberty is more common in boys than in girls. There are four main categories of delayed puberty: (1) Constitutional delay of growth and puberty (~60% of cases); (2) functional hypogonadotropic hypogonadism caused by systemic illness or malnutrition (~20% of cases); (3) hypogonadotropic hypogonadism caused by genetic or acquired defects in the hypothalamic-pituitary region (~10% of cases); and (4) hypergonadotropic hypogonadism secondary to primary gonadal failure (~15% of cases) (Table 325-1). Functional hypogonadotropic hypogonadism is more common in girls than in boys. Permanent causes of hypogonadotropic or hypergonadotropic hypogonadism are identified in <25% of boys with delayed puberty.

APPROACH TO THE PATIENT

Any history of systemic illness, eating disorders, excessive exercise, social and psychological problems, and abnormal patterns of linear growth during childhood should be verified. Boys with pubertal delay may have accompanying emotional and physical immaturity relative to their peers, which can be a source of anxiety. Physical examination should focus on height; arm span; weight; visual fields; and secondary sex characteristics including hair growth, testicular volume, phallic size, and scrotal reddening and thinning. Testicular size >2.5 cm generally indicates that the child has entered puberty.

The main diagnostic challenge is to distinguish those with constitutional delay, who will progress through puberty at a later age, from those with an underlying pathologic process. Constitutional delay should be suspected when there is a family history and when there are delayed bone age and short stature. Pituitary priming by pulsatile GnRH is required before LH and FSH are synthesized and secreted normally. Thus, blunted responses to exogenous GnRH can be seen in patients with constitutional delay, GnRH deficiency, or pituitary disorders (see "GnRH Stimulation Testing," above). On the other hand, low-normal basal gonadotropin levels or a normal response to exogenous GnRH is consistent with an early stage of puberty, which is often heralded by nocturnal GnRH secretion. Thus, constitutional delay is a diagnosis of exclusion that requires ongoing evaluation until the onset of puberty and the growth spurt.

℞ TREATMENT

If therapy is considered appropriate, it can begin with 25 to 50 mg testosterone enanthate or testosterone cypionate every 2 weeks, or by using a 2.5-mg testosterone patch or 25-mg testosterone gel. Because aromatization of testosterone to estrogen is obligatory for mediating androgen effects on epiphyseal fusion, concomitant treatment with aromatase inhibitors may allow attainment of greater final adult height. Testosterone treatment should be interrupted after 6 months to determine if endogenous LH and FSH secretion have ensued. Other causes of delayed puberty should be considered when there are associated clinical features or when boys do not enter puberty spontaneously after a year of observation or treatment.

Reassurance without hormonal treatment is appropriate for many individuals with presumed constitutional delay of puberty. However, the impact of delayed growth and pubertal progression on a child's social relationships and school performance is often underappreciated.

DISORDERS OF THE MALE REPRODUCTIVE AXIS DURING ADULTHOOD

HYPOGONADOTROPIC HYPOGONADISM Because LH and FSH are trophic hormones for the testes, impaired secretion of these pituitary gonadotropins results in secondary hypogonadism, which is characterized by low testosterone in the setting of low LH and FSH. Those with the most severe deficiency have complete absence of pubertal development, sexual infantilism and, in some cases, hypospadias and undescended testes. Patients with partial gonadotropin deficiency have delayed or arrested sexual development. The 24-h LH secretory profiles are heterogeneous in patients with hypogonadotropic hypogonadism, reflecting variable abnormalities of LH pulse frequency or amplitude. In severe cases, basal LH is low and there are no LH pulses. A smaller subset of patients has low-amplitude LH pulses or markedly reduced pulse frequency. Occasionally, only sleep-entrained LH pulses occur, reminiscent of the pattern seen in the early stages of puberty. Hypogonadotropic hypogonadism can be classified into congenital and acquired disorders. Congenital disorders most commonly involve GnRH deficiency, which leads to gonadotropin deficiency. Acquired disorders are much more common than congenital disorders and may result from a variety of sellar mass lesions or infiltrative diseases of the hypothalamus or pituitary.

Congenital Disorders Associated with Gonadotropin Deficiency Most cases of congenital hypogonadotropic hypogonadism are idiopathic, despite extensive endocrine testing and imaging studies of the sellar region. Among known causes, familial hypogonadotropic hypogonadism can be transmitted as an X-linked (20%), autosomal recessive (30%), or autosomal dominant (50%) trait. Some individuals with idiopathic hypogonadotropic hypogonadism (IHH) have sporadic mutations in the same genes that cause inherited forms of the disorder. *Kallmann syndrome* is an X-linked disorder caused by mutations in the *KAL1* gene, which encodes anosmin, a protein that mediates the migration of neural progenitors of the olfactory bulb and GnRH-producing neurons. These individuals have GnRH deficiency and variable combinations of anosmia or hyposmia, renal defects, and neurologic abnormalities including mirror movements. Gonadotropin secretion and fertility can be restored by administration of pulsatile GnRH or by gonadotropin replacement. Mutations in the *FGFR1* gene cause an autosomal dominant form of hypogonadotropic hypogonadism that clinically resembles Kallmann syndrome. The *FGFR1* gene product may be the receptor for the *KAL1* gene product, anosmin, thereby explaining the similarity in clinical features. Other autosomal dominant causes remain unexplained. X-linked hypogonadotropic hypogonadism also occurs in adrenal hypoplasia congenita, a disorder caused by mutations in the *DAX1* gene, which encodes a nuclear receptor in the adrenal gland and reproductive axis. *Adrenal hypoplasia congenita* is characterized by absent development of the adult zone of the adrenal cortex, leading to neonatal adrenal insufficiency. Puberty usually does not occur or is arrested, reflecting variable degrees of gonadotropin deficiency. Although sexual differentiation is normal, some patients have testicular dysgenesis and impaired spermatogenesis despite gonadotropin replacement. *GnRH receptor mutations* account for ~40% of autosomal recessive and 10% of sporadic cases of hypogonadotropic hypogonadism. These patients have decreased LH response to exogenous GnRH. Some receptor mutations alter GnRH binding affinity, allowing apparently normal responses to pharmacologic doses of exogenous GnRH. Mutations in the G protein–coupled receptor, GPR54, cause gonadotropin deficiency without anosmia. Patients retain responsiveness to exogenous GnRA, suggesting an abnormality in the neural pathways controlling GnRH release. Rarely, recessive mutations in the *LHβ* or *FSHβ* genes have been described in patients with selective deficiencies of these gonadotropins. Deletions or mutations of the *GnRH* gene have not been found in patients with hypogonadotropic hypogonadism.

A number of homeodomain transcription factors are involved in the development and differentiation of the specialized hormone-producing cells within the pituitary gland (Table 325-2). Patients with mutations of *PROP1* have combined pituitary hormone deficiency that includes GH, prolactin (PRL) thyroid-stimulating hormone (TSH), LH, and FSH, but not ACTH. *LHX3* mutations cause combined pituitary hormone deficiency in association with cervical spine rigidity. *HESX1* mutations cause septooptic dysplasia and combined pituitary hormone deficiency.

Prader-Willi syndrome is characterized by obesity, hypotonic musculature, mental retardation, hypogonadism, short stature, and small hands and feet. Prader-Willi syndrome is a genomic imprinting disorder caused by deletions of the proximal portion of paternally derived chromosome 15q or by uniparental disomy of the maternal alleles (Chap. 57). *Laurence-Moon syndrome* is an autosomal recessive disorder characterized by obesity, hypogonadism, mental retardation, polydactyly, and retinitis pigmentosa. Recessive mutations of leptin, or its receptor, cause severe obesity and pubertal arrest, apparently because of hypothalmic GnRH deficiency (Chap. 64).

Acquired Hypogonadotropic Disorders ■ *SEVERE ILLNESS, STRESS, MALNUTRITION, AND EXERCISE* These may cause reversible gonadotropin deficiency. Although gonadotropin deficiency and reproductive dysfunction are well documented in these conditions in women, men exhibit similar but less pronounced responses. Unlike women, most male runners and other endurance athletes have normal gonadotropin and sex steroid

TABLE 325-2 *Causes of Congenital Hypogonadotropic Hypogonadism*

Gene	Locus	Inheritance	Associated Features
KAL1	Xp22	X-linked	Anosmia, renal agenesis, synkinesia, cleft lip/palate, oculomotor/visuospatial defects, gut malrotations
FGFR1	8p11-p12	AD	Anosmia, cleft lip/palate, synkinesia, syndactyly
LEP	7q31	AR	Obesity
LEPR	1p31	AR	Obesity
PC1	5q15-21	AR	Obesity, diabetes mellitus, ACTH deficiency
HESX1	3p21	AR	Septooptic dysplasia, CPHD
		AD	Isolated GH insufficiency
LHX3	9q34	AR	CPHD (ACTH spared), cervical spine rigidity
PROP1	5q35	AR	CPHD (ACTH usually spared)
GPR54	19p13	AR	None
GNRHR	4q21	AR	None
FSHβ	11p13	AR	↑ LH
LHβ	19q13	AR	↑ FSH
SF1 (NR5A1)	9p33	AD/AR	Primary adrenal failure, XY sex reversal
DAX1 (NR0B1)	Xp21	X-linked	Primary adrenal failure, impaired spermatogenesis

Abbreviations: ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; CPHD, combined pituitary hormone deficiency; KAL1, Interval-1 gene; FGFR1, fibroblast growth factor receptor 1; LEP, leptin; LEPR, leptin receptor; PC1, prohormone convertase 1; HESX1, homeo box gene expressed in embryonic stem cells 1; LHX3, LIM homeobox gene 3; PROP1, Prophet of Pit 1; GPR54, G protein–coupled receptor 54; GNRHR, gonadotropin-releasing hormone receptor; FSHβ, follicle-stimulating hormone β-subunit; LHβ, luteinizing hormone β-subunit; SF1, steroidogenic factor 1; DAX1, *d*osage-sensitive sex-reversal, *a*drenal hypoplasia congenita, *X*-chromosome.

levels, despite low body fat and frequent intensive exercise. Testosterone levels fall at the onset of illness and recover during recuperation. The magnitude of gonadotropin suppression generally correlates with the severity of illness. Although hypogonadotropic hypogonadism is the most common cause of androgen deficiency in patients with acute illness, some have elevated levels of LH and FSH, which suggest primary gonadal dysfunction. The pathophysiology of reproductive dysfunction during acute illness is unknown but likely involves a combination of cytokine and/or glucocorticoid effects. There is a high frequency of low testosterone levels in patients with chronic illnesses such as HIV infection, end-stage renal disease, chronic obstructive lung disease, and many types of cancer and in patients receiving glucocorticoids. Some 20% of HIV-infected men with low testosterone levels have elevated LH and FSH levels; these patients presumably have primary testicular dysfunction. The remaining 80% have either normal or low LH and FSH levels; these men have a central hypothalamic-pituitary defect or a dual defect involving both the testis and the hypothalamic-pituitary centers. Muscle wasting is common in chronic diseases associated with hypogonadism, which also leads to debility, poor quality of life, and adverse outcome of disease. There is great interest in exploring strategies that can reverse androgen deficiency or attenuate the sarcopenia associated with chronic illness.

Men who are heavy users of marijuana have decreased testosterone secretion and sperm production. The mechanism of marijuana-induced hypogonadism is decreased GnRH secretion. Gynecomastia observed in marijuana users can also be caused by plant estrogens in crude preparations.

OBESITY In men with mild to moderate obesity, SHBG levels decrease in proportion to the degree of obesity, resulting in lower total testosterone levels. However, free testosterone levels usually remain within the normal range. The decrease in SHBG levels is caused by increased circulating insulin, which inhibits SHBG production. Estradiol levels are higher in obese men compared to healthy, non-obese controls, because of aromatization of testosterone to estradiol in adipose tissue. Weight loss is associated with reversal of these abnormalities including an increase in total and free testosterone levels and a decrease in estradiol levels. A subset of massively obese men may have a defect in the hypothalamic-pituitary axis as suggested by low free testosterone in the absence of elevated gonadotropins.

HYPERPROLACTINEMIA (See also Chap. 318) Elevated PRL levels are associated with hypogonadotropic hypogonadism. PRL inhibits hypothalamic GnRH secretion either directly or through modulation of tuberoinfundibular dopaminergic pathways. A PRL-secreting tumor may also destroy the surrounding gonadotropes by invasion or compression of the pituitary stalk. Treatment with dopamine agonists reverses gonadotropin deficiency, although there may be a delay relative to PRL suppression.

SELLAR MASS LESIONS Neoplastic and nonneoplastic lesions in the hypothalamus or pituitary can directly or indirectly affect gonadotrope function. In adults, pituitary adenomas constitute the largest category of space-occupying lesions affecting gonadotropin and other pituitary hormone production. Pituitary adenomas that extend into the suprasellar region can impair GnRH secretion and mildly increase PRL secretion (usually <50 μg/L) because of impaired tonic inhibition by dopaminergic pathways. These tumors should be distinguished from prolactinomas, which typically secrete higher PRL levels. The presence of diabetes insipidus suggests the possibility of a craniopharyngioma, infiltrative disorder, or other hypothalamic lesions (Chap. 319).

HEMOCHROMATOSIS (See also Chap. 336) Both the pituitary and testis can be affected by excessive iron deposition. However, the pituitary defect is the predominant lesion in most patients with hemochromatosis and hypogonadism. The diagnosis of hemochromatosis is suggested by the association of characteristic skin pigmentation, hepatic enlargement or dysfunction, diabetes mellitus, arthritis, cardiac conduction defects, and hypogonadism.

PRIMARY TESTICULAR CAUSES OF HYPOGONADISM Common causes of primary testicular dysfunction include Klinefelter syndrome, uncorrected cryptorchidism, cancer chemotherapy, radiation to the testes, trauma, torsion, infectious orchitis, HIV infection, anorchia syndrome, and myotonic dystrophy. Primary testicular disorders may be associated with impaired spermatogenesis, decreased androgen production, or both. ***→See Chap. 328 for disorders of testis development, androgen synthesis, and androgen action.***

Klinefelter Syndrome (See also Chap. 328) Klinefelter syndrome is the most common chromosomal disorder associated with testicular dysfunction and male infertility. It occurs in about 1 in 1000 live-born males. Azoospermia is the rule in men with Klinefelter syndrome who have the 47,XXY karyotype; however, men with mosaicism may have germ cells, especially at a younger age. Testicular histology shows hyalinization of seminiferous tubules and absence of spermatogenesis. Although their function is impaired, the number of Leydig cells appears to increase. Testosterone is decreased and estradiol is increased, leading to clinical features of undervirilization and gynecomastia.

Cryptorchidism Cryptorchidism occurs when there is incomplete descent of the testis from the abdominal cavity into the scrotum. About 3% of full-term and 30% of premature male infants have at least one cryptorchid testis at birth, but descent is usually complete by the first few weeks of life. The incidence of cryptorchidism is $<1\%$ by 9 months of age. Cryptorchidism is associated with increased risk of malignancy and infertility. Unilateral cryptorchidism, even when corrected before puberty, is associated with decreased sperm counts, possibly reflecting unrecognized damage to the fully descended testis.

Acquired Testicular Defects *Viral orchitis* may be caused by the mumps virus, echovirus, lymphocytic choriomeningitis virus, and group B arboviruses. Orchitis occurs in as many as one-fourth of adult men with mumps; the orchitis is unilateral in about two-thirds, and bilateral in the remainder. Orchitis usually develops a few days after the onset of parotitis but may precede it. The testis may return to normal size and function or undergo atrophy. Semen analysis returns to normal for

three-fourths of men with unilateral involvement but normal for only one-third of men with bilateral orchitis. *Trauma*, including testicular torsion, can also cause secondary atrophy of the testes. The exposed position of the testes in the scrotum renders them susceptible to both thermal and physical trauma, particularly in men with hazardous occupations.

The testes are sensitive to *radiation damage*. Doses >200 mGy (20 rad) are associated with increased FSH and LH levels and damage to the spermatogonia. After ~800 mGy (80 rad), oligospermia or azoospermia develops, and higher doses may obliterate the germinal epithelium. Permanent androgen deficiency in adult men is uncommon after therapeutic radiation; however, most boys given direct testicular radiation therapy for acute lymphoblastic leukemia have permanently low testosterone levels. Sperm banking should be considered before patients undergo radiation treatment or chemotherapy.

Drugs interfere with testicular function by several mechanisms including inhibition of testosterone synthesis (e.g., ketoconazole), blockade of androgen action (e.g., spironolactone), increased estrogen (e.g., marijuana), or direct inhibition of spermatogenesis (e.g., chemotherapy). Cyclophosphamide causes azoospermia or extreme oligospermia within a few weeks after the initiation of therapy. In about half of patients, spermatogenesis returns within 3 years after cessation of therapy. Combination chemotherapy for acute leukemia, Hodgkin disease, and other malignancies may impair Leydig cell function. Alcohol, when consumed in excess for prolonged periods, decreases testosterone, independent of liver disease or malnutrition. Elevated estradiol and decreased testosterone levels may occur in men taking digitalis.

The occupational and recreational history should be carefully evaluated in all men with infertility because of the toxic effects of many *chemical agents* on spermatogenesis. Known environmental hazards include microwaves and ultrasound and chemicals such as nematocide dibromochloropropane, cadmium, and lead. In some populations, sperm density is said to have declined by as much as 40% in the past 50 years. Environmental estrogens or antiandrogens may be partly responsible.

Testicular failure also occurs as a part of *polyglandular autoimmune insufficiency* (Chap. 330). Sperm antibodies can cause isolated male infertility. In some instances, these antibodies are secondary phenomena resulting from duct obstruction or vasectomy. Granulomatous diseases can affect the testes, and testicular atrophy occurs in 10 to 20% of men with lepromatous leprosy because of direct tissue invasion by the mycobacteria. The tubules are involved initially, followed by endarteritis and destruction of Leydig cells.

Systemic disease can cause primary testis dysfunction in addition to suppressing gonadotropin production. In cirrhosis, a combined testicular and pituitary abnormality leads to decreased testosterone production independent of the direct toxic effects of ethanol. Impaired hepatic extraction of adrenal androstenedione leads to extraglandular conversion to estrone and estradiol, which partially suppresses LH. Testicular atrophy and gynecomastia are present in approximately one-half of men with cirrhosis. In chronic renal failure, androgen synthesis and sperm production decrease despite elevated gonadotropins. The elevated LH level is due to reduced clearance, but it does not restore normal testosterone production. About one-fourth of men with renal failure have hyperprolactinemia. Improvement in testosterone production with hemodialysis is incomplete, but successful renal transplantation may return testicular function to normal. Testicular atrophy is present in one-third of men with sickle cell anemia. The defect may be at either the testicular or the hypothalamic-pituitary level. Sperm density can decrease temporarily after acute febrile illness in the absence of a change in testosterone production. Infertility in men with celiac disease is associated with a hormonal pattern typical of androgen resistance, namely elevated testosterone and LH levels.

Neurologic diseases associated with altered testicular function include myotonic dystrophy, spinobulbar muscular atrophy, and paraplegia. In myotonic dystrophy, small testes may be associated with impairment of both spermatogenesis and Leydig cell function. Spinobulbar muscular atrophy is caused by an expansion of the glutamine repeat sequences in the amino-terminal region of the AR; this expansion impairs function of the AR, but it is unclear how the alteration is related to the neurologic manifestations. Men with spinobulbar muscular atrophy often have undervirilization and infertility as a late manifestation. Spinal cord lesions that cause paraplegia can lead to a temporary decrease in testosterone levels and may cause persistent defects in spermatogenesis; some patients retain the capacity for penile erection and ejaculation.

ANDROGEN INSENSITIVITY SYNDROMES Mutations in the AR cause resistance to the action of testosterone and DHT. These X-linked mutations are associated with variable degrees of defective male phenotypic development and undervirilization (Chap. 328). Although not technically hormone insensitivity syndromes, two genetic disorders impair testosterone conversion to active sex steroids. Mutations in the *SRD5A2* gene, which encodes 5α-reductase type 2, prevent the conversion of testosterone to DHT, which is necessary for the normal development of the male external genitalia. Mutations in the *CYP19* gene, which encodes aromatase, prevent testosterone conversion to estradiol. Males with *CYP19* mutations have delayed epiphyseal fusion, tall stature, eunuchoidal proportions, and osteoporosis, consistent with evidence from an estrogen receptor–deficient individual that these testosterone actions are mediated indirectly via estrogen.

GYNECOMASTIA

Gynecomastia refers to enlargement of the male breast. It is caused by excess estrogen action and is usually the result of an increased estrogen/androgen ratio. True gynecomastia is associated with glandular breast tissue that is >4 cm in diameter and is often tender. Glandular tissue enlargement should be distinguished from excess adipose tissue; glandular tissue is firmer and contains fibrous-like cords. Gynecomastia occurs as a normal physiologic phenomenon in the newborn, during puberty, and with aging, but it can also result from pathologic conditions associated with androgen deficiency or estrogen excess. The prevalence of gynecomastia increases with age and body mass index (BMI), likely because of increased aromatase activity in adipose tissue. Medications that alter androgen metabolism or action may also cause gynecomastia. The relative risk of breast cancer is increased in men with gynecomastia, although the absolute risk is relatively small.

PATHOLOGIC GYNECOMASTIA Any cause of *androgen deficiency* can lead to gynecomastia, reflecting an increased estrogen/androgen ratio, as estrogen synthesis still occurs by aromatization of residual adrenal and gonadal androgens. Gynecomastia is a characteristic feature of Klinefelter syndrome (Chap. 328). *Androgen insensitivity* disorders also cause gynecomastia. *Excess estrogen production* may be caused by tumors, including Sertoli cell tumors in isolation or in association with Peutz-Jegher syndrome or Carney complex. Tumors that produce hCG, including some testicular tumors, stimulate Leydig cell estrogen synthesis. *Increased conversion of androgens to estrogens* can be a result of increased availability of substrate (androstenedione) for extraglandular estrogen formation (CAH, hyperthyroidism, and most feminizing adrenal tumors) or to diminished catabolism of androstenedione (liver disease) so that estrogen precursors are shunted to aromatase in peripheral sites. Obesity is associated with increased aromatization of androgen precursors to estrogens. Extraglandular aromatase activity can also be increased in tumors of the liver or adrenal gland or rarely as an inherited disorder. Several families with *increased peripheral aromatase activity* inherited as an autosomal or as an X-linked disorder have been described. *Drugs* can cause gynecomastia by acting directly as estrogenic substances (e.g., oral contraceptives, phytoestrogens, digitalis), inhibiting androgen synthesis (e.g., ketoconazole), or action (e.g., spironolactone).

It is challenging to determine when to evaluate gynecomastia, since up to two-thirds of pubertal boys and half of hospitalized men have palpable glandular tissue (Fig. 325-5). In addition to the extent of gynecomastia, recent onset, rapid growth, tender tissue, and occur-

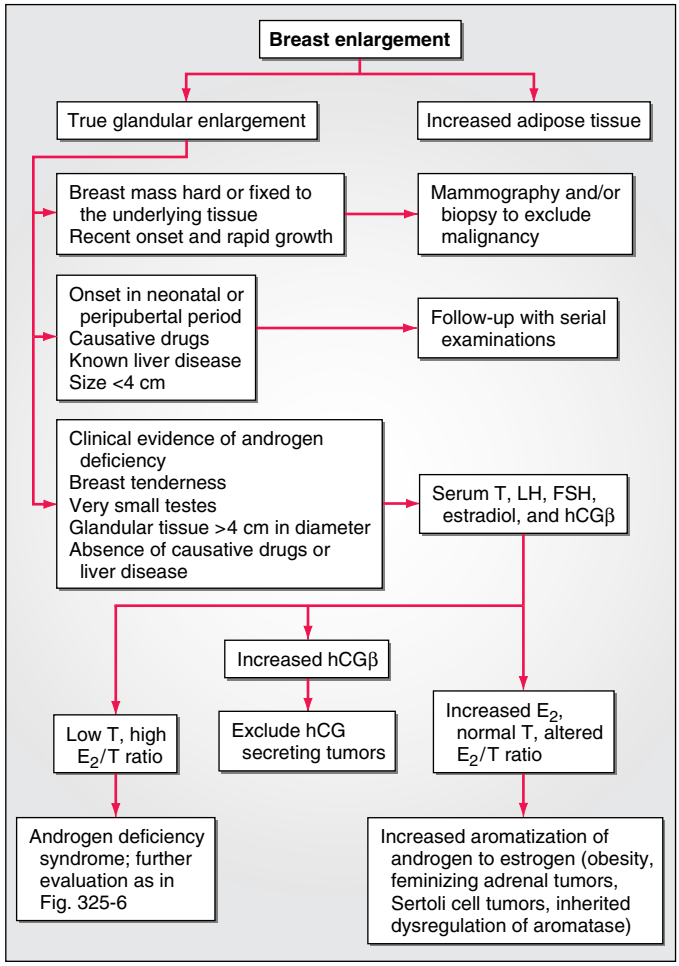

FIGURE 325-5 Evaluation of gynecomastia. T, testosterone; LH, luteinizing hormone; FSH, follicle-stimulating hormones; hCGβ, human chorionic gonadoltopin β; E_2, 17β-estradiol.

rence in a lean subject should prompt more extensive evaluation. This should include a careful drug history, measurement and examination of the testes, assessment of virilization, evaluation of liver function, and hormonal measurements including testosterone, estradiol, and androstenedione, LH, and hCG. If testes are small, a karyotype should be obtained to exclude Klinefelter syndrome. Despite this evaluation, the diagnosis is established in fewer than one-half of patients, probably because of subtle alterations of the estrogen/androgen ratio.

Rx TREATMENT

When the primary cause can be identified and corrected, breast enlargement usually subsides over several months. However, if gynecomastia is of long duration, surgery is the most effective therapy. Indications for surgery include severe psychologic and/or cosmetic problems, continued growth or tenderness, or suspected malignancy. In patients who have painful gynecomastia and who are not candidates for other therapy, treatment with antiestrogens such as tamoxifen (20 mg/d) reduces pain and breast tissue size in about two-thirds of patients. Aromatase inhibitors can be effective in the early proliferative phase of the disorder, although the experience is largely based on the use of testolactone, a relatively weak aromatase inhibitor; placebo-controlled trials with more potent aromatase inhibitors such as anastrazole, fadrozole, letrozole, or fromestane are needed.

AGING-RELATED CHANGES IN MALE REPRODUCTIVE FUNCTION

A number of cross-sectional and longitudinal studies (e.g., The Baltimore Longitudinal Study of Aging and the Massachusetts Male Aging Study) have established that testosterone concentrations decrease with advancing age. This age-related decline starts in the third decade of life and progresses slowly; the rate of decline in testosterone concentrations is greater for men with chronic illness and for those taking medications than in healthy older men. Because SHBG concentrations are higher in older men than in younger men, free or bioavailable testosterone concentrations decline with aging to a greater extent than total testosterone concentrations. The age-related decline in testosterone is due to defects at all levels of the hypothalamic-pituitary-testicular axis: pulsatile GnRH secretion is attenuated, LH response to GnRH is reduced, and testicular response to LH is impaired. However, the gradual rise of LH with aging suggests that testis dysfunction is the main cause of declining androgen levels. The term *andropause* has been used to denote age-related decline in testosterone concentrations; this term is a misnomer because there is no discrete time when testosterone concentrations decline abruptly.

It is speculated that age-related decline in testosterone concentrations contributes to sexual dysfunction, loss of muscle mass and function, frailty, gain in fat mass, cognitive impairment, and loss of body hair. Initial studies of testosterone supplementation in older men with low or low normal testosterone levels have demonstrated a modest increase of fat-free mass and grip strength; a decrease in fat mass; an improved sense of well being, energy, visuo-spatial orientation, and verbal memory; and a modest increment in bone mineral density. However, the long-term risks of testosterone supplementation in older men remain largely unknown. In particular, physiologic testosterone replacement might increase the risk of prostate cancer or exacerbate cardiovascular disease. Population screening of all older men for low testosterone levels is not recommended, and testing should be restricted to men who have symptoms or physical features attributable to androgen deficiency. In men with documented androgen deficiency, testosterone replacement may be considered on an individualized basis and should be instituted after careful discussion of the risks and benefits (see "Testosterone Replacement," below).

Testicular morphology, semen production, and fertility are maintained up to a very old age in men. Although concern has been expressed about age-related increases in germ cell mutations and impairment of DNA repair mechanisms, the frequency of chromosomal aneuploidy or structural abnormalities does not increase in the sperm of older men. However, the incidence of autosomal dominant diseases, such as achondroplasia, polyposis coli, Marfan syndrome, and Apert syndrome, increases in the offspring of men who are advanced in age, consistent with transmission of sporadic missense mutations.

APPROACH TO THE PATIENT

Hypogonadism is often heralded by decreased sex drive, reduced frequency of sexual intercourse or inability to maintain erections, reduced beard growth, loss of muscle mass, decreased testicular size, and gynecomastia. Less than 10% of patients with erectile dysfunction alone have testosterone deficiency. Thus, it is useful to look for a constellation of symptoms and signs suggestive of androgen deficiency. Except when extreme, these clinical features may be difficult to distinguish from changes that occur with normal aging. Moreover, androgen deficiency may develop gradually. Population studies, such as the Massachusetts Male Aging Study, suggest that about 4% of men between the ages of 40 and 70 have testosterone levels <150 ng/dL. Thus, androgen deficiency is not uncommon. The changes for the clinician are (1) to decide when to evaluate a man for possible androgen deficiency, (2) to assess when there is laboratory evidence for androgen deficiency and determine its cause, and (3) to decide when and how to treat patients with androgen deficiency.

When symptoms or clinical features suggest possible androgen deficiency, the laboratory evaluation is initiated by the measurement of total testosterone, preferably in the morning (Fig. 325-6). A total testosterone level <200 ng/dL, in association with symp-

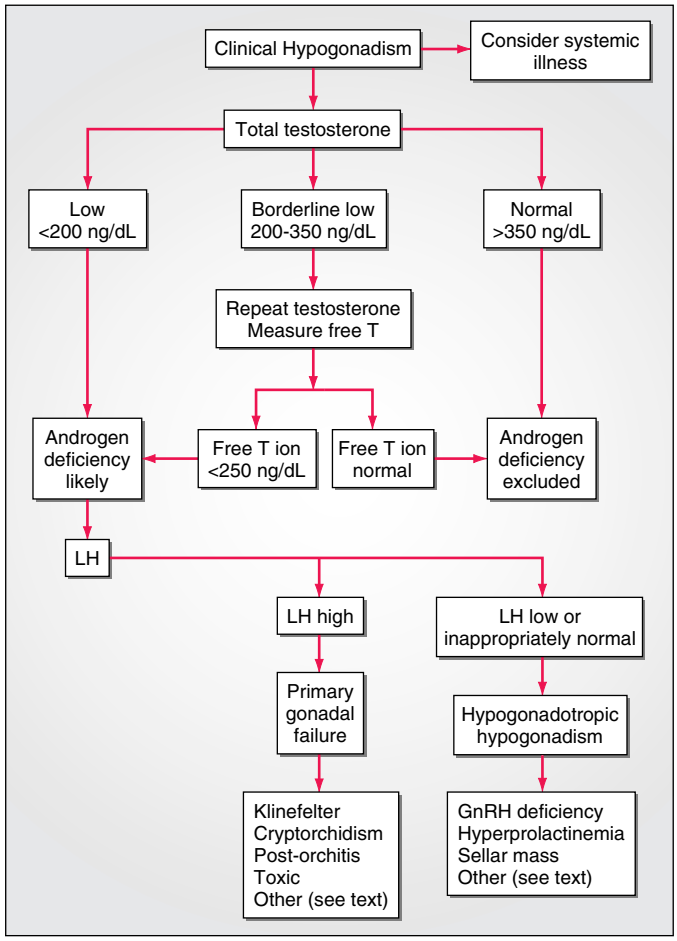

FIGURE 325-6 Evaluation of hypogonadism. T, testosterone; LH, luteinizing hormone; GnRH, gonadotropin-releasing hormone.

toms, is evidence of testosterone deficiency. An early-morning testosterone level >350 ng/dL makes the diagnosis of androgen deficiency unlikely. In men with testosterone levels between 200 and 350 ng/dL, the total testosterone level should be repeated and a free testosterone level should be measured. In older men and in patients with other clinical states that are associated with alterations in SHBG levels, a direct measurement of free testosterone level by equilibrium dialysis can be useful in unmasking testosterone deficiency.

When androgen deficiency has been confirmed by low testosterone concentrations, LH should be measured to classify the patient as having hypergonadotropic (high LH) or hypogonadotropic (low or inappropriately normal LH) hypogonadism. An elevated LH level indicates that the defect is at the testicular level. Common causes of primary testicular failure include Klinefelter syndrome, HIV infection, uncorrected cryptorchidism, cancer chemotherapeutic agents, radiation, surgical orchiectomy, or prior infectious orchitis. Unless causes of primary testicular failure are known, a karyotype should be performed in men with low testosterone and elevated LH to exclude Klinefelter syndrome. Men who have a low testosterone but "inappropriately normal" or low LH levels have hypogonadotropic hypogonadism; their defect resides at the hypothalamic-pituitary level. Common causes of acquired hypogonadotropic hypogonadism include space-occupying lesions of the sella, hyperprolactinemia, chronic illness, hemochromatosis, excessive exercise, and substance abuse. Measurement of PRL and MRI scan of the hypothalamic-pituitary region can help exclude the presence of a space-occupying lesion. Patients in whom known causes of hypogonadotropic hypogonadism have been excluded are classified as having IHH. It is not unusual for congenital causes of hypogonadotropic hypogonadism, such as Kallmann syndrome, to be diagnosed in young adults.

TREATMENT

Gonadotropins Gonadotropin therapy is used to establish or restore fertility in patients with gonadotropin deficiency of any cause. Several gonadotropin preparations are available. Human menopausal gonadotropin (hMG) (purified from the urine of postmenopausal women) contains 75 IU FSH and 75 IU LH per vial. hCG (purified from the urine of pregnant women) has little FSH activity and resembles LH in its ability to stimulate testosterone production by Leydig cells. Recombinant hCG is now available. Because of the expense of hMG, treatment is usually begun with hCG alone, and hMG is added later to promote the FSH-dependent stages of spermatid development. Recombinant human FSH (hFSH) is now available and is indistinguishable from purified urinary hFSH in its biologic activity and pharmacokinetics in vitro and in vivo, although the mature β subunit of recombinant hFSH has seven fewer amino acids. Recombinant hFSH is available in ampoules containing 75 IU (~7.5 μg FSH), which accounts for >99% of protein content. Once spermatogenesis is restored using combined FSH and LH therapy, hCG alone is often sufficient to maintain spermatogenesis.

Although a variety of treatment regimens are used, 1500 to 2000 IU of hCG administered intramuscularly three times weekly is a reasonable starting dose. Testosterone levels should be measured 6 to 8 weeks later, and 48 to 72 h after the hCG injection; the hCG dose should be adjusted to achieve testosterone levels in the mid-normal range. Sperm counts should be monitored on a monthly basis. It may take several months for spermatogenesis to be restored; therefore, it is important to forewarn patients about the potential length and expense of the treatment and to provide conservative estimates of success rates. If testosterone levels are in the mid-normal range but the sperm concentrations are low after 6 months of therapy with hCG alone, FSH should be added. This can be done by using hMG, highly purified urinary hFSH, or recombinant hFSH. The selection of FSH dose is empirical. A common practice is to start with the addition of 75 IU FSH three times each week in conjunction with the hCG injections. If sperm densities are still low after 3 months of combined treatment, the FSH dose should be increased to 150 IU. Occasionally, it may take ≥18 to 24 months for spermatogenesis to be restored.

The two best predictors of success using gonadotropin therapy in hypogonadotropic men are testicular volume at presentation and time of onset. In general, men with testicular volumes >8 mL have better response rates than those who have testicular volumes <4 mL. Patients who became hypogonadotropic after puberty experience higher success rates than those who have never undergone pubertal changes. Spermatogenesis can usually be reinitiated by hCG alone, with high rates of success for men with postpubertal onset of hypogonadotropism. The presence of a primary testicular abnormality, such as cryptorchidism, will attenuate testicular response to gonadotropin therapy. Prior androgen therapy does not affect subsequent response to gonadotropin therapy.

GnRH In patients with documented GnRH deficiency, both pubertal development and spermatogenesis can be successfully induced by pulsatile administration of low doses of GnRH. This response requires normal pituitary and testicular function. Therapy usually begins with an initial dose of 25 ng/kg per pulse administered subcutaneously every 2 h by a portable infusion pump. Testosterone, LH, and FSH levels should be monitored. The dose of GnRH is increased until testosterone levels reach the mid-normal range. Doses ranging from 25 to 200 ng/kg may be required to induce virilization. Once pubertal changes have been initiated, the dose of GnRH can often be reduced. Increased sperm counts and testicular volume have been reported in >70% of treated men, and improvements in sexual function and virilization can be induced in >90% of patients. Cutaneous infections

occur but are infrequent and minor. Carrying a portable infusion device can be cumbersome, and follow-up of these patients requires physician supervision and laboratory monitoring. Some patients with IHH have cryptorchidism; men with this additional testicular defect may not respond to GnRH or gonadotropin therapy.

Comparative studies of gonadotropin therapy and pulsatile GnRH administration demonstrate that these two therapies are similar in terms of the time to first appearance of sperm or pregnancy rates; both approaches are equally effective in inducing spermatogenesis in men with hypogonadotropic hypogonadism caused by GnRH deficiency. However, most patients find intermittent gonadotropin injections preferable to wearing a continuous infusion pump.

Testosterone Replacement Androgen therapy is indicated to restore testosterone levels to normal to correct features of androgen deficiency. Testosterone replacement improves libido and overall sexual activity, increases energy, lean muscle mass, and bone density and provides the patient a better sense of well-being. The benefits of testosterone replacement therapy have only been proven in men who have documented androgen deficiency, as demonstrated by testosterone levels that are well below the lower limit of normal (<250 ng/dL).

Testosterone is available in a variety of formulations with distinct pharmacokinetics (Table 325-3). Testosterone serves as a prohormone and is converted to 17β-estradiol by aromatase and to 5α-dihydrotestosterone by 5α-reductase. Therefore, when evaluating testosterone formulations, it is important to consider whether the formulation being used can achieve physiologic estradiol and DHT concentrations, in addition to normal testosterone concentrations. Although testosterone concentrations at the lower end of the normal male range can restore sexual function, it is not clear whether low-normal testosterone levels can maintain bone mineral density and muscle mass. The current recommendation is to restore testosterone levels to the mid-normal range.

ORAL DERIVATIVES OF TESTOSTERONE Testosterone is well-absorbed after oral administration but quickly degrades during the first pass through the liver. Therefore, it is not possible to achieve sustained blood levels of testosterone after oral administration of crystalline testosterone. 17α-alkylated derivatives of testosterone (e.g., 17α-methyl testosterone, oxandrolone, fluoxymesterone) are relatively resistant to hepatic degradation and can be administered orally; however, because of the potential for hepatotoxicity, including cholestatic jaundice, peliosis, and hepatoma, these formulations should not be used for testosterone replacement. Hereditary angioedema due to C1 esterase deficiency is the only exception to this general recommendation; in this condition, oral 17α-alkylated androgens are useful because they stimulate hepatic synthesis of the C1 esterase inhibitor.

TABLE 325-3 *Clinical Pharmacology of Testosterone Formulations*

Formulation	*Regimen*	*Pharmacokinetics*	*DHT and Estradiol*	*Advantages*	*Disadvantages*
Testosterone enanthate or cypionate	100 mg IM weekly or 200 mg IM every 2 weeks	After a single IM injection, testosterone levels rise into the supraphysiologic range and then decline gradually into the hypogonadal range by the end of the dosing interval	DHT and estradiol levels rise in proportion to the increase in testosterone levels; T:DHT and T:E_2 ratios do not change	Corrects symptoms of androgen deficiency Relatively inexpensive, if self-administered Flexibility of dosing	Requires IM injection Peaks and valleys in testosterone levels
Scrotal testosterone patch	One scrotal patch designed to deliver 6 mg over 24 h applied daily	Normalizes testosterone levels in many but not all androgen-deficient men	Estradiol levels are in the physiologic male range, but DHT levels rise into the supraphysiologic range	Corrects symptoms of androgen deficiency	To promote optimum adherence of the patch, scrotal skin needs to be shaved High DHT levels
Nongenital transdermal system	One or two patches, designed to deliver 5–10 mg testosterone over 24 h applied daily on nonpressure areas	Restores testosterone, DHT, and estradiol levels into the physiologic male range	T:DHT and T:estradiol levels are in the physiologic male range	Ease of application, corrects symptoms of androgen deficiency, and mimics the normal diurnal rhythm of testosterone secretion. Lesser increase in hemoglobin than injectable esters	Testosterone levels in some androgen-deficient men may be in the low-normal range; these men may need application of two patches daily Skin irritation at the application site in some patients
Testosterone gel	Testosterone gel containing 50 to 100 mg testosterone should be applied daily	Restores testosterone and estradiol levels into the physiologic male range	DHT levels and T:DHT ratios are lower in hypogonadal men treated with the testosterone gel than in healthy eugonadal men	Corrects symptoms of androgen deficiency, provides flexibility of dosing, ease of application, good skin tolerability	Potential of transfer to a female partner or child by direct skin-to-skin contact; moderately high DHT levels
17α-methyl testosterone	Orally active, 17α-alkylated compound that should not be used because of potential for liver toxicity	Orally active			Clinical responses variable; potential for liver toxicity; should not be used for treatment of androgen deficiency
Buccal adhesive tetosterone	An adhesive, 10-mg tablet applied to buccal mucosa twice daily	Absorbed through buccal mucosa	Serum T and DHT in the normal male range	Ease of application	Limited experience, no evidence of liver toxicity, effects of food and brushing unclear

Note: DHT, dihydrotestosterone; T, testosterone, E_2, 17β-estradiol.

INJECTABLE FORMS OF TESTOSTERONE The esterification of testosterone at the 17β-hydroxy position makes the molecule hydrophobic and extends its duration of action. The slow release of testosterone ester from an oily depot in the muscle accounts for its extended duration of action. The longer the side chain, the greater the hydrophobicity of the ester and longer the duration of action. Thus, testosterone enanthate and cypionate with longer side chains have longer duration of action than testosterone propionate. Within 24 h after intramuscular administration of 200 mg testosterone enanthate or cypionate, testosterone levels rise into the high-normal or supraphysiologic range and then gradually decline into the hypogonadal range over the next 2 weeks. A bimonthly regimen of testosterone enanthate or cypionate therefore results in peaks and troughs in testosterone levels that are accompanied by changes in a patient's mood, sexual desire, and energy level. The kinetics of testosterone enanthate and cypionate are similar. Estradiol and DHT levels are normal if testosterone replacement is physiologic.

TRANSDERMAL TESTOSTERONE Three transdermal testosterone patches are commercially available: a scrotal testosterone patch (Testoderm) and two nongenital patches (Androderm and Testoderm TTS). The scrotal transdermal testosterone patch, when applied daily to the scrotal skin, produces mid-normal testosterone levels in hypogonadal men 4 to 8 h after application followed by a gradual decrease in testosterone levels over the next 24 h. Estradiol levels are normal but DHT levels are increased due to the conversion of testosterone to DHT by the high amounts of 5α-reductase in scrotal skin. There was initial concern that exposure to high DHT levels might have deleterious effects on the prostate; however, long-term follow-up of men treated with the scrotal patch has not revealed an unexpected increase in prostate problems.

With nongenital testosterone patches, testosterone, DHT, and estradiol levels are in the mid-normal range 4 to 12 h after application. Sexual function and a sense of well-being are restored in androgen-deficient men treated with the nongenital patch. One 5-mg patch may not be sufficient to increase testosterone into the mid-normal male range in all hypogonadal men; some patients may need daily administration of two 5-mg patches to achieve the targeted testosterone concentrations. The transdermal systems are more expensive than testosterone esters. The use of nongenital patches may be associated with skin irritation in some individuals.

TESTOSTERONE GEL Two testosterone gels (Androgel) and Testim are available in 2.5- and 5-g unit doses that nominally deliver 25 and 50 mg of testosterone to the application site. Initial pharmacokinetic studies have demonstrated that 50-, 75-, and 100-mg doses applied daily to the skin can maintain total and free testosterone concentrations in the mid- to high-normal range in hypogonadal men. Total and free testosterone concentrations are uniform throughout the 24-h period. The current recommendations are to begin with a 50-mg dose and adjust the dose based on testosterone levels. The advantages of the testosterone gel are in its ease of application, its invisibility after application, and its flexibility of dosing. A major concern is the potential for inadvertent transfer of the gel to a sexual partner or to children who may come in close contact with the patient. The ratio of DHT to testosterone concentrations is higher in men treated with the testosterone gel.

A buccal adhesive testosterone tablet, which adheres to the buccal mucosa and releases testosterone as it is slowly dissolved, has been approved. After twice daily application of 10 to 20 mg tablets, serum testosterone levels are maintained within the normal male range in a majority of treated hypogonadal men. The adverse effects include buccal ulceration in a few subjects. The clinical experience with this formulation is limited, and the effects of food and brushing on absorption have not been studied in detail.

TESTOSTERONE FORMULATIONS NOT AVAILABLE IN THE UNITED STATES Testosterone undecanoate, when administered orally in oleic acid, is absorbed preferentially through the lymphatics into the systemic circulation and is spared the first-pass degradation in the liver. Doses of 40 to 80 mg orally, two or three times daily, are typically used. However, the clinical responses are variable and suboptimal. DHT-to-testosterone ratios are higher in hypogonadal men treated with oral testosterone undecanoate, as compared to eugonadal men.

Implants of crystalline testosterone can be inserted in the subcutaneous tissue by means of a trocar through a small skin incision. Testosterone is released by surface erosion of the implant and absorbed into the systemic circulation. Four to six 200-mg implants can maintain testosterone in the mid- to high-normal range for up to 6 months. Potential drawbacks include incising the skin for insertion and removal, and spontaneous extrusions and fibrosis at the site of the implant.

NOVEL ANDROGEN FORMULATIONS A number of androgen formulations with better pharmacokinetics or more selective activity profiles are under development. A biodegradable testosterone microsphere formulation provides physiologic testosterone levels for 10 to 11 weeks. Two long-acting esters, testosterone buciclate and testosterone undecanoate, when injected intramuscularly, can maintain circulating testosterone concentrations in the male range for 7 to 12 weeks. Initial clinical trials have demonstrated the feasibility of administering testosterone by the sublingual or buccal routes. 7α-methyl-19-nortestosterone is an androgen that cannot be 5α-reduced; therefore, compared to testosterone, it has relatively greater agonist activity in muscle and gonadotropin suppression but lesser activity on the prostate.

Analogous to the selective estrogen receptor modulators, such as raloxifene, it may be possible to develop selective androgen receptor modulators (SARMs) that exert the desired physiologic effects on muscle, bone, or sexual function but without adversely affecting the prostate and the cardiovascular system.

PHARMACOLOGIC USES OF ANDROGENS In addition to hypogonadism, androgens have been used to treat a variety of disorders with the hope that anabolic actions of the agents (such as increase in nitrogen retention and muscle mass, increased hemoglobin) would outweigh any deleterious (e.g., virilization) actions of the drugs. The most common nonreplacement uses of androgen have been attempts to improve nitrogen balance in catabolic states (e.g., AIDS), self-administration by athletes to increase muscle mass and/or athletic performance, attempts to enhance erythropoiesis in refractory anemias (including the anemia of renal failure), treatment of hereditary angioedema and endometriosis, and management of growth retardation of various etiologies. Most of the expected benefits in these disorders have not been realized. The modest pharmacologic doses of androgens have little physiologic effect in men when superimposed on normal testicular androgen; in women, the virilizing side effects of androgens are formidable.

The most pervasive form of androgen abuse is by male athletes with the expectation that it will improve muscle development and athletic performance. In controlled studies using modest pharmacologic doses (two to four times the usual replacement doses), these agents do not consistently improve performance. However, at the doses frequently taken by athletes (which sometimes exceed 10 times the replacement dose), androgens enhance nitrogen balance and muscle mass; since the drugs have multiple side effects at high doses, these benefits do not outweigh the risks associated with androgen abuse in men, while androgen use by female athletes is associated with disfiguring virilization. The only established indications for androgen therapy aside from male hypogonadism are in selected patients with anemia due to bone marrow failure (an indication largely supplanted by erythropoietin) or for hereditary angioedema.

RECOMMENDED REGIMENS FOR ANDROGEN REPLACEMENT Testosterone esters are administered weekly at doses of 75 to 100 mg intramuscularly, or 150 to 200 mg every 2 weeks. One 6-mg scrotal patch should be applied daily after shaving the scrotal skin. One or two 5-mg nongenital testosterone patches can be applied daily over the skin of the back, thigh, or upper arm away from pressure areas. Testosterone gel is typically applied over a covered area of skin at a dose of 50 to 100 mg daily; patients should wash their hands after gel application.

ESTABLISHING EFFICACY OF TESTOSTERONE REPLACEMENT THERAPY Because a clinically useful marker of androgen action is not available, restoration of testosterone levels into the mid-normal range remains the goal of therapy. Measurements of LH and FSH are not useful in assessing the adequacy of testosterone replacement. Testosterone should be measured 3 months after initiating therapy to assess adequacy of therapy. In patients who are treated with testosterone enanthate or cypionate, testosterone levels should be 350 to 600 ng/dL 1 week after the injection. If testosterone levels are outside this range, adjustments should be made to either the dose or the interval between injections. In men on transdermal patch or gel therapy, testosterone levels should be in the mid-normal range (500 to 800 ng/dL) 4 to 12 h after application. If testosterone levels are outside this range, the dose should be adjusted.

Restoration of sexual function, secondary sex characteristics, and energy level and one's sense of well being are important objectives of testosterone replacement therapy. The patient should also be asked about sexual desire and activity, the presence of early morning erections, and whether he is able to achieve and maintain erections that are adequate for sexual intercourse. Some hypogonadal men continue to complain about sexual dysfunction even after testosterone replacement has been instituted; these patients may benefit from counseling. The hair growth in response to androgen replacement is variable and depends on ethnicity. Hypogonadal men with prepubertal onset of androgen deficiency who begin testosterone therapy in their late 20s or 30s may find it difficult to adjust to their newly found sexuality and may benefit from counseling. If the patient has a sexual partner, the partner should be included in counseling because of the dramatic physical and sexual changes that occur with androgen treatment.

CONTRAINDICATIONS FOR ANDROGEN ADMINISTRATION Testosterone administration is contraindicated in men with a history of prostate cancer because androgens can promote tumor growth (Table 325-4). Testosterone should not be prescribed to men with severe symptoms of benign prostatic hypertrophy (AUA symptom score > 22), because even small increases in prostate volume may exacerbate obstructive symptoms. Testosterone replacement should not be administered to men with baseline hematocrit ≥52%. Testosterone can induce and exacerbate sleep apnea because of its neuromuscular effects on the upper airway.

MONITORING POTENTIAL ADVERSE EXPERIENCES The clinical effectiveness and safety of testosterone replacement therapy should be performed 3 and 6 months after initiating testosterone therapy and annually thereafter.

Hemoglobin Levels Administration of testosterone to androgen-deficient men is typically associated with a 3 to 5% increase in hemoglobin levels. Clinically significant erythrocytosis is uncommon in young hypogonadal men but can occur in men who have sleep apnea, a significant smoking history, chronic obstructive lung disease, or who are older in age. The magnitude of hemoglobin increase during testosterone therapy appears related to the peak testosterone levels. Transdermal testosterone replacement may produce a smaller hemoglobin increase than testosterone esters.

Digital Examination of the Prostate and Serum PSA Levels Testosterone replacement therapy increases prostate volume to the size seen in age-matched controls but should not increase prostate volume beyond that expected for age. There is no evidence that testosterone replacement causes prostate cancer. However, androgen administration can exacerbate preexisting prostate cancer. Many older men harbor microscopic foci of cancer in their prostates. It is not known whether long-term testosterone administration will induce these microscopic foci to grow into clinically significant cancers.

Prostate-specific antigen (PSA) levels are lower in testosterone-deficient men and are restored to normal after testosterone replacement. There is considerable test-retest variability in PSA measurements; the average interassay coefficient of variation of PSA assays is 15%. The 95% confidence interval for the change in PSA values, measured 3 to 6 months apart, is 1.4 ng/mL. Increments in PSA levels after testosterone supplementation in androgen-deficient men are generally <0.5 ng/mL, and increments >1.0 ng/mL over a 3 to 6-month period are unusual. Nevertheless, administration of testosterone to men with baseline PSA levels between 2.5 and 4.0 ng/mL will cause PSA levels to exceed 4.0 ng/mL for some, and many of these men may undergo prostate biopsies. PSA velocity criterion can be used for patients who have sequential PSA measurements for >2 years; a change of >0.40 ng/mL per year merits closer urologic follow-up.

Cardiovascular Risk Assessment The long-term effects of testosterone supplementation on cardiovascular risk are unknown. Testosterone effects on lipids depend on the dose (physiologic or supraphysiologic), the route of administration (oral or parenteral), and the formulation (whether aromatizable or not). Physiologic testosterone replacement by an aromatizable androgen has a modest effect on high-density lipoprotein (HDL) or no effect at all. In middle-aged men with low testosterone levels, physiologic testosterone replacement has been shown to improve insulin sensitivity and reduce visceral obesity. In epidemiologic studies, testosterone concentrations are inversely related to waist-to-hip ratio and directly correlated with HDL cholesterol levels. These data suggest that physiologic testosterone concentrations is correlated with factors associated with reduced cardiovascular risk. However, no prospective studies have examined the effect on testosterone replacement on cardiovascular risk.

TABLE 325-4 Contraindications for Androgen Replacement

- The presence or history of prostate cancer
- Baseline PSA ≥ 4 ng/mL or a palpable abnormality of the prostate without urologic evaluation to rule out prostate cancer
- Severe symptoms of lower urinary tract obstruction as indicated by IPSS or AUA symptom score of ≥22
- Baseline hematocrit > 52%
- Severe sleep apnea
- Class IV congestive heart failure

Note: PSA, prostate-specific antigen, IPSS, International Prostate Symptom Score; AUA, American Urological Association.

326 DISORDERS OF THE OVARY AND FEMALE REPRODUCTIVE TRACT

Bruce R. Carr, Karen D. Bradshaw

Normal female reproduction requires the integrated action of the central nervous system, the pituitary gland, and the ovary to orchestrate the monthly cycle of ovarian follicle development and the release of ova. The hormonal changes associated with the menstrual cycle prepare the uterus for implantation if fertilization occurs. After menopause, these cycles cease, and there is a marked reduction in sex steroid levels, leading to physiologic changes. Disorders of the female reproductive system may be developmental, structural, or hormonal in etiology. The reproductive tract is also susceptible to sexually transmitted diseases, which may cause active or chronic infections and predispose to infertility and neoplasia. Gynecologic malignancies, particularly of the ovary, uterus, and cervix, are relatively common. Although many women receive specialized care from obstetrician-gynecologists, a good understanding of the female reproductive system and its disorders is essential for comprehensive healthcare by internists and family practitioners.

DEVELOPMENT, STRUCTURE, AND FUNCTION OF THE OVARY

EMBRYOLOGY

The primordial germ cells migrate to the genital ridge adjacent to the mesonephric kidney by the fifth week of gestation and undergo mitotic division. The gonads exist in an undifferentiated state until the seventh week of fetal life, at which time the primitive ovary can be distinguished from the testis (Chap. 328). From the fifth month of fetal life, the primordial follicle consists of the primary oocyte arrested in meiosis, a single surrounding layer of granulosa cells, and a basement membrane that separates the primordial follicle from surrounding stromal (interstitial) tissues. The ovary contains a finite number of germ cells, the number peaking at about 7 million oogonia by the fifth to sixth month of gestation. Subsequently, the germ cells decrease in number through a process of atresia so that approximately 1 million remain at birth, 400,000 are present at menarche, and only a few remain at menopause.

PUBERTAL MATURATION

The final maturation of ovarian follicles commences during puberty. The two major hormones that regulate follicular development are the pituitary gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH) (Fig. 326-1). In the neonate, concomitant with the decrease in estrogen and progesterone levels caused by separation from the placenta, there is a rebound increase in gonadotropin secretion for the first few months of life. With continued maturation of the hypothalamic-pituitary system, the hypothalamic-pituitary axis (the so-called gonadostat) becomes exquisitely sensitive to negative feedback by low levels of circulating steroid hormones, and plasma gonadotropins again decrease. As the time of puberty nears, a decrease in the sensitivity of the gonadostat allows for increased secretion of FSH and LH, possibly secondary to increased episodic or pulsatile secretion of gonadotropin-releasing hormone (GnRH) by the hypothalamus (Chap. 318). The increase in estrogen secretion exerts a positive feedback, which leads to an exaggeration of the pulsatile release of LH and eventually to menarche and ovulation, after which plasma gonadotropin concentrations reach adult values but vary across the menstrual cycle. After the menopause, plasma gonadotropin levels rise, then plateau 5 to 10 years after menopause and remain fairly constant until the eighth to ninth decade of life, when the levels may fall. Although ovarian function is regulated primarily by LH and FSH, the ovary is a source of protein hormones and growth factors such as inhibin and activin that play an important role in ovarian function and regulation. The production of inhibin by the mature ovary accounts, in part, for the selective reduction in FSH that is seen during the reproductive years (Fig. 326-1).

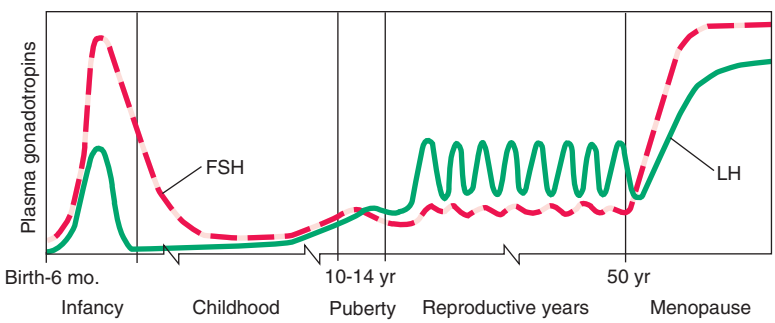

FIGURE 326-1 Pattern of gonadotropin secretion during different stages of life in women. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

At age 10 to 11, the first secondary sexual characteristics begin to appear in girls, namely, development of the breast buds (*thelarche*), followed by the development of pubic hair (*pubarche*), and later by the development of axillary hair (*adrenarche*). The growth of pubic and axillary hair is believed to be initiated by adrenal androgens, the levels of which begin to rise at approximately 6 to 8 years of age. A growth spurt ensues, and peak growth rate is attained by age 12.

The culmination of puberty is the onset of predictable, cyclic menses. The average time between the beginning of breast development and the onset of menses (*menarche*) is 2 years. During the first few years after menarche, menstrual cycles are often irregular and unpredictable due to anovulation. The age of menarche is variable and is influenced by socioeconomic and genetic factors and by general health. In the United States, the mean age of menarche is believed to have decreased at a rate of 3 to 4 months per decade over the past 100 years and is now approximately 12 years of age, a change believed to be due to improved nutrition. Leptin levels have been correlated with the onset of the pubertal process. A critical combination of total body weight and percent body fat is associated with development of hypothalamic insensitivity to feedback by steroids that leads to increased secretion of gonadotropins and finally to menarche. Obese girls have earlier menarche than girls with normal body weight. In contrast, active participation in sports or ballet, malnutrition, and chronic debilitating disease can delay menarche.

MATURE OVARY

MORPHOLOGY The anatomic components and function of the adult ovary are illustrated schematically in Fig. 326-2. Under the influence of gonadotropins, a group of primary follicles are recruited, and by day 6 to 8 of the menstrual cycle, one follicle becomes mature or "dominant," a process characterized by accelerated growth of granulosa cells and enlargement of the fluid-filled antrum. The follicles not destined to ovulate undergo degeneration, similar to the atresia that occurs during embryogenesis. Just prior to ovulation, meiosis resumes in the ovum of the dominant follicle, and the first meiotic division results in formation of the first polar body. The antrum rapidly enlarges (up to 10 to 25 mm in size), follicular fluid increases in amount, and the follicular surface thins and forms a conical stigma. Ovulation from the dominant follicle occurs 16 to 23 h after the LH peak and 24 to 38 h after the onset of the LH surge when the follicular wall ruptures in the area of the stigma. The ovum is then expelled together with a mass of surrounding granulosa cells called *cumulus cells*. The rupture is believed to result from the action of hydrolytic enzymes on the surface of the follicle, possibly under the control of prostaglandins. The second meiotic division occurs after the egg is fertilized by a sperm, and the second polar body is then extruded. The formation of the *corpus luteum* begins in the retained remnant of the

ovulated follicle; the remaining granulosa and theca cells increase in size and accumulate lipids and a yellow pigment, lutein, to become "luteinized." After a period of 14 ± 2 days (the functional life of the corpus luteum), the corpus luteum begins to atrophy, to be replaced in time by a fibrous scar, the *corpus albicans*. The factors that limit the life span of the human corpus luteum are not known, but if pregnancy occurs, the corpus luteum persists under the influence of placental chorionic gonadotropin, and progesterone is produced by the corpus luteum for the support of pregnancy.

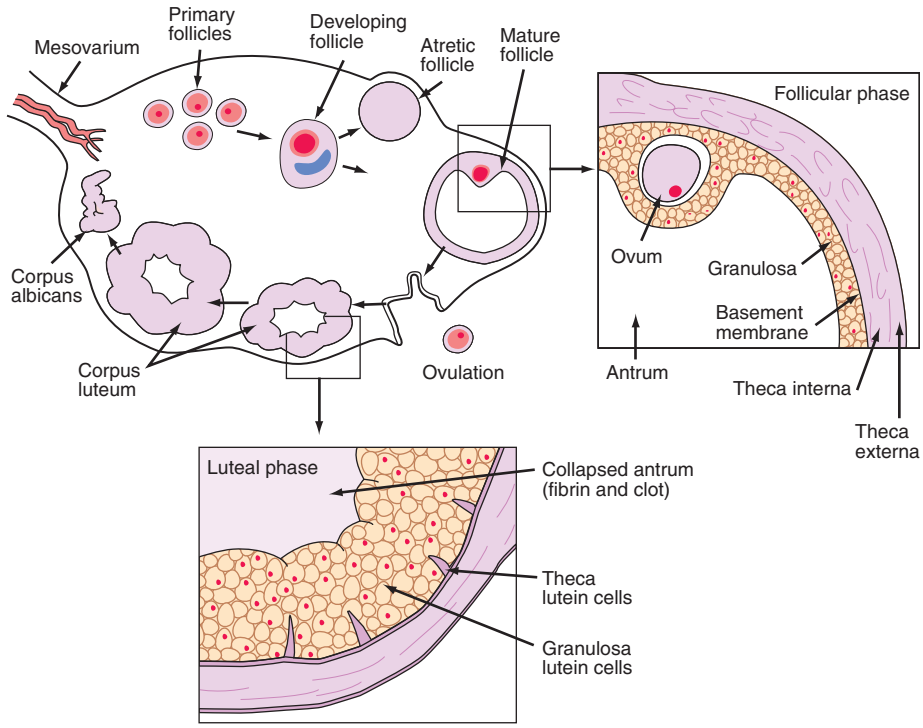

FIGURE 326-2 Developmental changes in the adult ovary during a complete 28-day cycle.

HORMONE FORMATION ■ Steroid Hormones

Like other steroid hormones, ovarian steroids are derived from cholesterol (Fig. 326-3). The ovary can synthesize cholesterol de novo and can also utilize cholesterol obtained from circulating lipoproteins as substrate for steroid hormone formation. Virtually all ovarian cells are believed to possess the complete complement of enzymes required for the synthesis of estradiol from cholesterol (Fig. 326-3); however, different cell types in the ovary contain different amounts of these enzymes so that the main steroids produced vary in different compartments. For example, the corpus luteum forms mainly progesterone and 17-hydroxyprogesterone, whereas theca and stromal cells convert cholesterol to androstenedione and testosterone. Granulosa cells are particularly rich in the aromatase enzyme responsible for estrogen synthesis and utilize as substrates for this process androgens synthesized in the adjacent theca cells.

LH acts primarily to regulate the early steps in steroid hormone biosynthesis, namely, the transport of cholesterol into the mitochondria by steroidogenic acute regulatory (StAR) protein and its conversion to pregnenolone. FSH acts mainly to regulate the final process by which androgens are aromatized to estrogens. As a consequence, LH enhances substrate flow and the formation of androgens and/or progesterone in the absence of FSH, whereas FSH action is impeded in the absence of LH because of diminished substrate for aromatization.

ESTROGENS The principal estrogen secreted by the ovary and the most potent estrogen is estradiol. Estrone is also produced by the ovary, but most estrone is formed by extraglandular conversion of androstenedione in peripheral tissues. Estriol (16-hydroxyestradiol), the main estrogen in urine, arises from the 16-hydroxylation of estrone and estradiol. Catechol estrogens are formed by hydroxylation of estrogens at the C-2 or C-4 position and may act as the intracellular mediators of some estrogen action. Estrogens promote development of the secondary sexual characteristics in women and cause uterine growth, thickening of the vaginal mucosa, thinning of the cervical mucus, and development of the ductule system of the breasts. Estrogens also alter lipid profiles and exert effects on the vascular endothelium. The classic mechanism of estrogen action in target tissues is similar to that for other steroid hormones and involves binding to a nuclear steroid receptor—either estrogen receptor (ER)α or ERβ—and enhancement of the transcription of various target genes (Chap. 317). There is growing evidence that ERs also act through nonclassic mechanisms to alter signal transduction, independent of receptor binding to DNA. ERs have specific tissue site expression and bind various estrogens with different affinities, thereby conferring selective actions. The relatively promiscuous binding of synthetic and environmental estrogens by the ER has allowed the development of selective estrogen receptor modulators (SERMs), such as tamoxifen and raloxifene.

PROGESTERONE Progesterone is the principal hormone secreted by the corpus luteum and is responsible for progestational effects, i.e., induction of secretory activity in the endometrium of the estrogen-primed uterus in preparation for implantation of the fertilized egg. Progesterone also induces a decidual reaction in endometrium. Other effects include inhibition of uterine contractions, an increase in the viscosity of cervical mucus, glandular development of the breasts, and an increase in basal body temperature (thermogenic effect).

ANDROGENS The ovary synthesizes a variety of 19-carbon steroids, including dehydroepiandrosterone, androstenedione, testosterone, and dihydrotestosterone, principally in stromal and thecal cells. The major ovarian 19-carbon steroid is androstenedione (Fig. 326-3), part of which is secreted into the plasma and part of which is converted to estrogen in granulosa cells or to testosterone in the interstitium. Androstenedione can also be converted to testosterone and estrogens in peripheral tissues. Only testosterone and dihydrotestosterone are true androgens that interact with the androgen receptor and induce virilizing signs in women (Chap. 44).

Other Hormones *Inhibin* is secreted in two forms (A and B) by the follicle and inhibits the release of FSH by the hypothalamic-pituitary unit. *Activin* is also secreted by the follicle and may enhance FSH secretion as well as having local effects on ovarian steroidogenesis. *Follistatin* is an activin-binding protein that attenuates the actions of activin and other members of the transforming growth factor (TGF)β family.

Some ovarian hormones play an uncertain role in human physiology. *Relaxin*, a polypeptide hormone produced by the human corpus luteum and by the decidua, causes softening of the cervix and loosening of the symphysis pubis in preparation for parturition in animals. *Oxytocin*, *vasopressin*, and other hypothalamic and pituitary hormones are also present in granulosa and/or luteal cells, but their function in these cells is unknown. Granulosa cells secrete *oocyte maturation inhibitor* (OMI), a factor that prevents premature ovulation. In addition, in the gonads of both sexes a *meiosis-inducing substance* triggers the onset of meiosis, an event that occurs earlier in ovarian than in testicular development. Local growth factors [including insulin-like growth factors (IGFs) 1 and 2 and TGFα and -β] may also influence steroid secretion by the ovary.

THE NORMAL MENSTRUAL CYCLE The menstrual cycle is divided into a follicular or proliferative phase and a luteal, or secretory, phase (Fig.

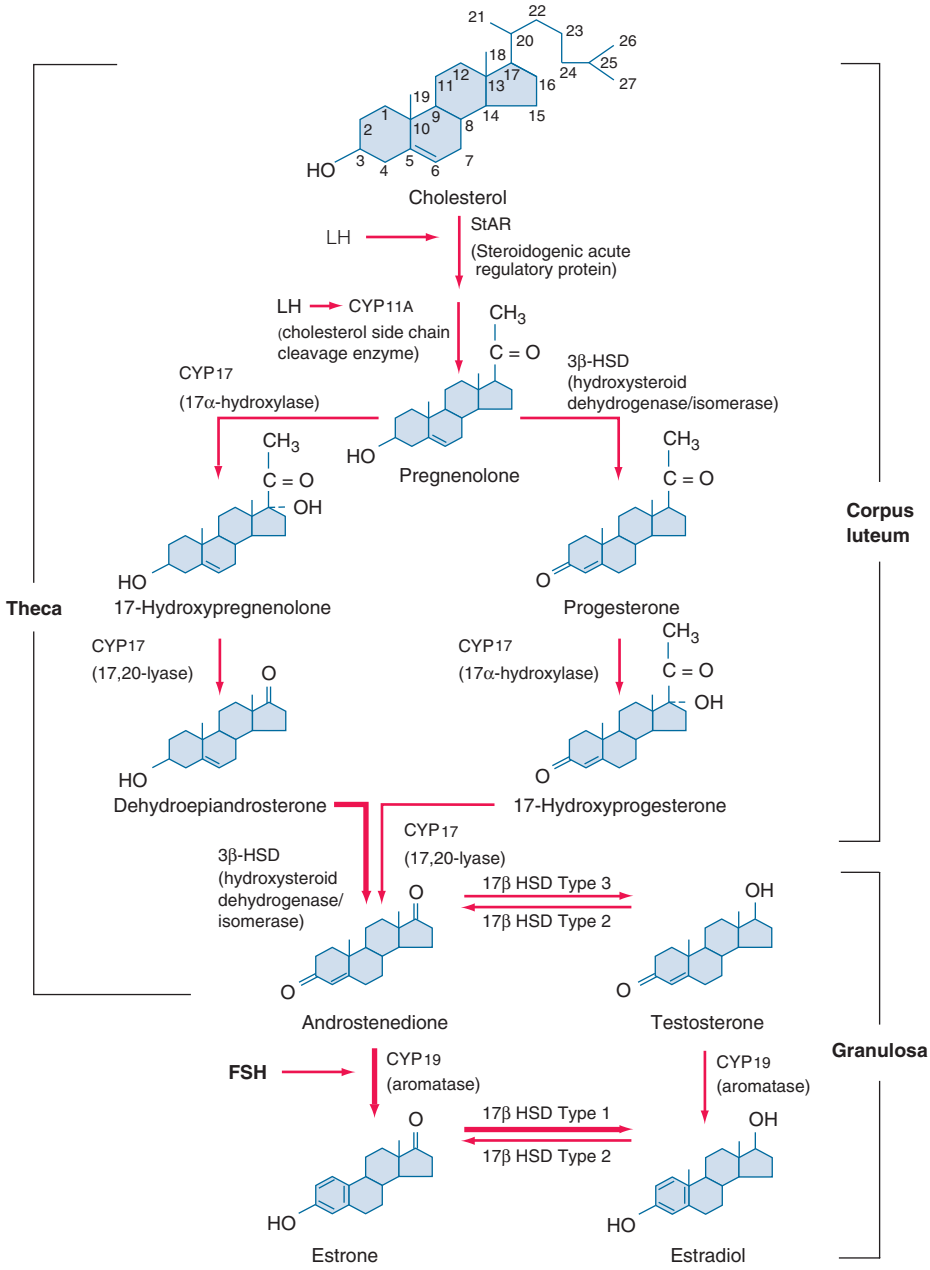

FIGURE 326-3 The principal pathway of steroid hormone biosynthesis in the ovary. The major enzyme complements for the corpus luteum, stroma, and granulosa cells are shown by the brackets; as a consequence, these cells produce predominantly progesterone and 17-OH progesterone, androgen, and estrogen, respectively. The major sites of action of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in mediating this pathway are shown in the horizontal arrows. The thin arrow emphasizes that the metabolism of 17-hydroxyprogesterone is limited in the human ovary. 17β HSD, 17β-hydroxysteroid dehydrogenase.

326-4). The secretion of FSH and LH is fundamentally under negative feedback control by ovarian steroids (particularly estradiol) and by inhibin (which selectively suppresses FSH), but the response of gonadotropins to different levels of estradiol varies. FSH secretion is inhibited progressively as estrogen levels increase—typical negative feedback. In contrast, LH secretion is suppressed maximally by sustained low levels of estrogen and is enhanced by a rising level of estradiol—positive feedback. Feedback of estrogen involves both the hypothalamus and pituitary. Negative feedback suppresses GnRH and inhibits gonadotropin production. Positive feedback is associated with an increased frequency of GnRH secretion and enhanced pituitary sensitivity to GnRH.

The length of the menstrual cycle is defined as the time from the onset of one menstrual bleeding episode to onset of the next. In women of reproductive age, the cycle averages 28 ± 3 days and the mean duration of flow is 4 ± 2 days. Longer menstrual cycles (usually characterized by anovulation) occur at menarche and near the onset of menopause. At the end of a cycle, plasma levels of estrogen and progesterone fall and circulating levels of FSH increase. Under the influence of FSH, follicular recruitment results in development of the follicle that will be dominant during the next cycle.

After the onset of menses, follicular development continues, but FSH levels decrease. Approximately 8 to 10 days prior to the midcycle LH surge, plasma estradiol levels begin to rise as the result of estradiol formation by the granulosa cells of the dominant follicle. During the second half of the follicular phase, LH levels also begin to rise (owing to positive feedback). Just before ovulation, estradiol secretion reaches a peak and then falls. Immediately thereafter, a further rise in the plasma level of LH mediates the final maturation of the follicle, followed by follicular rupture and ovulation 16 to 23 h after the LH peak. The rise in LH is accompanied by a smaller increase in the level of plasma FSH, the physiologic significance of which is unclear. The plasma progesterone level also begins to rise just prior to midcycle and facilitates the positive feedback action of estradiol on LH secretion.

At the onset of the luteal phase, plasma gonadotropins decrease and plasma progesterone increases. A secondary rise in estrogens causes further gonadotropin suppression. Near the end of the luteal phase, progesterone and estrogen levels fall, and FSH levels begin to rise to initiate the development of the next follicle (usually in the contralateral ovary) and the next menstrual cycle. Inhibin A levels are low in the follicular phase but reach a peak in the luteal phase. Inhibin B levels, in contrast, are increased in the follicular phase and low in the luteal phase.

The endometrium lining the uterine cavity undergoes marked alterations in response to the changing plasma levels of ovarian hormones (Fig. 326-4). Concurrent with the decrease in plasma estrogen and progesterone and the decline of corpus luteum function in the late luteal phase, intense vasospasm occurs in the spiral arterioles supplying blood to the endometrium, causing ischemic necrosis, endometrial desquamation, and bleeding. This vasospasm is caused by locally synthesized prostaglandins. The onset of bleeding marks the first day of the menstrual cycle. By the fourth to fifth day, the endometrium is thin. During the proliferative phase, glandular growth of the endometrium is mediated by estrogen. After ovulation, increased progesterone levels lead to further thickening of the endometrium, but the rapid growth slows. The endometrium then enters the secretory phase, characterized by tortuosity of the glands, curling of the spiral arterioles, and glandular secretion. As corpus luteum function begins to wane in the absence of conception, the sequence of events leading to menstruation is again set into action.

Biphasic changes in basal body temperature are characteristic of the ovulatory cycle and are mediated by alterations in progesterone levels (Fig. 326-4). An increase in basal body temperature by 0.3 to 0.5°C begins after ovulation, persists during the luteal phase, and re-

turns to the normal baseline (36.2 to 36.4°C) after the onset of the subsequent menses.

MENOPAUSE

The *menopause* is defined as the final episode of menstrual bleeding in women. Menopause is the consequence of exhaustion of ovarian follicles, a process that begins during fetal development. The median age of women at the time of cessation of menstrual bleeding is 50 to 51 years. Preceding the menopause, the pattern of menstrual cycles is variable, but the interval between menses usually becomes shorter, as follicular recruitment is hastened by increases in FSH. Day 3 FSH and 17β-estradiol (E_2) levels are often elevated. Ovulatory cycles continue for some period of time, then anovulation becomes common.

The ovaries of postmenopausal women are small and wrinkled, and the residual cells are predominantly stromal. Estrogen and androgen levels in plasma are reduced but not absent. Before the menopause, plasma androstenedione is derived almost equally from the adrenals and the ovaries; after menopause, the ovarian contribution ceases so that the plasma levels of androstenedione fall by 50%. However, the menopausal ovary continues to secrete testosterone, presumably formed in stromal cells. After menopause, extraglandular estrogen formation is the major pathway for estrogen synthesis. Because adipose tissue is a major site of extraglandular estrogen production, peripheral estrogen formation may actually be enhanced in obese postmenopausal women. The predominant estrogen formed is estrone rather than estradiol. →***For discussion of the management of menopause, see Chap. 327.***

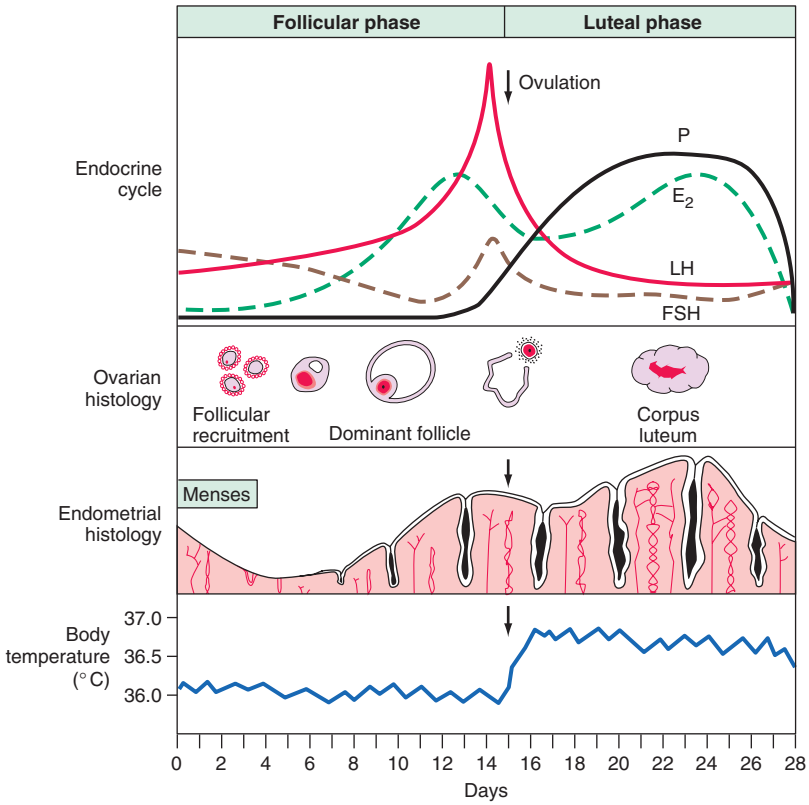

FIGURE 326-4 The hormonal, ovarian, endometrial, and basal body temperature changes and relationships throughout the normal menstrual cycle.

LABORATORY AND CLINICAL ASSESSMENT OF HORMONAL STATUS

The hormonal status of women can usually be assessed by history and physical examination. In general, the presence of secondary sexual characteristics such as normal female breast development indicates adequate estrogen secretion in the past, and the presence of regular, predictable, cyclic menses implies that ovulation and the production of gonadotropins, estrogen, progesterone, and androgens are adequate and that the outflow tract is intact. Such a history may be more valuable than laboratory tests in evaluating ovarian hormone status. However, laboratory tests provide valuable ancillary information in the evaluation of women with endocrine dysfunction or infertility (Chap. 45).

PITUITARY GONADOTROPINS

Plasma gonadotropins are assessed by immunoassay. Because both FSH and LH are secreted in a pulsatile manner, the results obtained from a single serum sample may be difficult to interpret. Moreover, the values vary widely during the menstrual cycle, particularly at the time of the midcycle gonadotropin surge. Consequently, plasma gonadotropin measurements are of greatest use in evaluating women with suspected ovarian failure and in supporting the diagnosis of polycystic ovarian syndrome (PCOS) or hypogonadotropic hypogonadism. FSH levels that are persistently >40 IU/L are diagnostic of ovarian failure, and an LH value <0.8 IU/L suggests hypogonadotropic hypogonadism. In practice, however, gonadotropin values may be equivocal and must be interpreted in the context of other historic, physical, and laboratory findings.

OVARIAN HORMONES

ESTROGEN The presence of normal secondary sexual characteristics implies that estrogen production was adequate in the past. The current estrogen status can be estimated by pelvic examination. The presence of a moist, rugated vagina with copious, clear, thin cervical mucus that can be stretched and that exhibits arborization or ferning when spread on a slide is strong evidence of adequate estrogen production. Cytologic demonstration of mature vaginal epithelial cells and abundant cornified squamous epithelial cells with pyknotic nuclei confirms the presence of adequate estrogen levels.

The progesterone-withdrawal test provides a functional assessment of the endometrium, outflow tract, and estrogen status. If menses appear within a week to 10 days after the end of a trial of medroxyprogesterone acetate (10 mg by mouth once or twice a day for 5 days) or after a single intramuscular injection of progesterone (100 mg), then prior estrogen priming was adequate to allow withdrawal bleeding.

Owing to its variable level in plasma during the normal cycle and the difficulty of estimating the day of the cycle in women with abnormal cycles, the measurement of estrogen levels in plasma or urine is of little use in the routine assessment of estrogen status. Measurement of plasma estradiol is useful during attempts to induce ovulation with gonadotropins to prevent the development of the ovarian hyperstimulation syndrome and is used along with ultrasound assessment to monitor follicular growth in women during in vitro fertilization.

PROGESTERONE Cyclic, predictable menses also imply that adequate progesterone is secreted during the luteal phase of the menstrual cycle. Assessment of progesterone is useful to detect ovulation and to evaluate the adequacy of the luteal phase in infertile women. Several functional assays of progesterone can be used. The least expensive and most useful is the daily measurement of basal body temperature throughout a cycle. Owing to the thermogenic properties of progesterone, a normal biphasic monthly curve showing a temperature elevation lasting for approximately 2 weeks after ovulation is a valid indication of progesterone secretion during the luteal phase (Fig. 326-4). The presence of viscous cervical mucus that does not stretch or fern and of predominantly intermediate cells on vaginal cytology or demonstration of a secretory epithelium in an endometrial biopsy during the luteal phase on days 20 to 22 of the cycle provides additional assessment of progesterone secretion. In addition, plasma progesterone can be measured to assess the function of the corpus luteum; a level

> 10 μmol/L (> 3 ng/mL) suggests successful ovulation and adequate corpus luteum function.

ANDROGEN Under normal conditions, the ovary secretes androstenedione, testosterone, and dehydroepiandrosterone. In conditions of androgen excess, hirsutism and/or virilization are common. The evaluation of androgen excess is discussed in Chap. 44.

DIAGNOSIS OF PREGNANCY

Pregnancy is usually recognized on the basis of history and physical examination. That is, a woman with previously cyclic, predictable menses develops amenorrhea accompanied by breast tenderness, malaise, lassitude, and nausea, and on physical examination the uterus is soft and enlarged.

Human chorionic gonadotropin (hCG) is secreted by the trophoblastic cells of the placenta into the maternal plasma and excreted in the urine. Plasma or urine assays of hCG make it possible to detect pregnancies 8 to 10 days after ovulation, before the first missed menstrual period and long before pregnancy can be diagnosed by clinical assessments. Sensitive and specific hCG-based pregnancy tests are now available for patients to use at home.

DISORDERS OF OVARIAN FUNCTION

PREPUBERTAL YEARS

Puberty is said to be *precocious* if breast budding begins before age 8 or if menarche occurs before age 9. Those disorders in which the developing sexual characteristics are appropriate for the genetic and gonadal sex—i.e., feminization in girls or virilization in boys—are termed *isosexual precocity*, whereas *heterosexual precocity* occurs when sexual characteristics are not in accord with the genetic sex, namely, virilization in girls or feminization in boys. Pubertal disorders of boys are described in Chap. 325.

ISOSEXUAL PRECOCIOUS PUBERTY Isosexual precocious puberty in girls can be divided into three major categories (Table 326-1).

True Precocious Puberty True precocious puberty (gonadotropin-dependent) is characterized by an early but otherwise normal sequence of pubertal development, including increased secretion of gonadotropins and ovulatory menstrual cycles. Constitutional or idiopathic precocious puberty accounts for 90% of cases. The disorder is more common in girls than boys. No cause for the premature maturation of the central nervous system–hypothalamic-pituitary axis can be identified, and the diagnosis is confirmed by finding an adult pattern of LH and FSH release on a GnRH stimulation test. Premature appearance of secondary sexual characteristics and of ovulatory cycles with the accompanying risk of fertility may cause significant emotional disturbance. Therefore, prompt initiation of therapy is imperative. GnRH analogues suppress gonadotropins and inhibit estrogen synthesis, thereby blocking precocious puberty; they may also prevent premature closure of the epiphyses and the resulting short stature.

About 10% of cases are due to organic brain diseases, including brain tumors (hypothalamic gliomas, astrocytomas, ependymomas, germinomas, and hamartomas), encephalitis, meningitis, hydrocephalus, head injury, tuberous sclerosis, and neurofibromatosis. It is essential to distinguish this group of patients from those with the idiopathic disorder, and patients whose disorder is designated as idiopathic occasionally prove to have such tumors. Most patients with organic lesions serious enough to cause precocious puberty have obvious neurologic signs and symptoms. Evaluation of all patients with precocious puberty should include, at a minimum, computed tomography (CT) or magnetic resonance imaging (MRI) of the brain. The success of treatment depends on the nature of the lesion, but surgical and radiation treatment of well-localized tumors is occasionally successful.

A rare cause of isosexual precocity is congenital adrenal hyperplasia due to 21-hydroxylase deficiency in girls when treatment has been delayed until 4 to 8 years of age (Chap. 321). After initiation of glucocorticoid replacement, such individuals may undergo isosexual precocious puberty.

TABLE 326-1 Differential Diagnosis of Sexual Precocity

I. Isosexual precocity
A. True precocious puberty
1. Constitutional
2. Organic brain disease
3. Congenital adrenal hyperplasia
B. Precocious pseudopuberty
1. Ovarian tumors
2. Adrenal tumors
3. McCune-Albright syndrome
4. Hypothyroidism
5. Russell-Silver syndrome
6. Estrogen-containing medications
C. Incomplete sexual precocity
1. Premature thelarche
2. Premature adrenarche
3. Premature pubarche
II. Heterosexual precocity
A. Ovarian tumors
B. Adrenal tumors
C. Congenital adrenal hyperplasia

Precocious Pseudopuberty Precocious pseudopuberty (gonadotropin-independent) occurs when girls undergo feminization as a consequence of enhanced estrogen formation but do not ovulate or develop cyclic menses. Ovarian cysts or tumors that secrete estrogen (granulosa-theca cell tumors) are the most frequent cause of precocious pseudopuberty. Granulosa-theca cell tumors associated with intestinal polyps and pigmentation of the mucous membranes occur in the Peutz-Jeghers syndrome. Other ovarian tumors that secrete estrogens (or androgens that can be converted to estrogens at extraglandular sites) include dysgerminomas, teratomas, cystadenomas, and ovarian carcinomas (Chap. 83). Ovarian tumors can usually be detected by rectoabdominal examination or by ultrasound, CT, MRI, and/or laparoscopy. Ovarian teratomas and choriocarcinomas and other carcinomas that secrete hCG do not cause precocious puberty in girls unless they also secrete estrogen (hCG or LH in the absence of FSH does not induce ovarian estrogen production). Rarely, feminizing tumors of the adrenal cause isosexual precocious puberty by direct formation of estrogens or by secretion of weak androgens, which are converted to estrogens in extraglandular tissues. The *McCune-Albright syndrome* (polyostotic fibrous dysplasia) is due to an activating mutation in the G protein, $G_{s\alpha}$, that occurs during embryogenesis, leading to a mosaic pattern of expression in various tissues. It is characterized by café au lait spots, cystic fibrous dysplasia of bones, and sexual precocity. In the ovary, the $G_{s\alpha}$ mutation mimics the action of FSH, leading to autonomous follicle development and estrogen formation. Occasionally, this disorder leads to true precocious puberty. *Primary hypothyroidism* is occasionally associated with enhanced secretion of FSH, inducing ovarian estrogen secretion. High levels of thyroid-stimulating hormone (TSH) caused by hypothyroidism may also stimulate the FSH receptor. The *Russell-Silver syndrome*, or congenital asymmetry, is associated with short stature and precocious feminization. *Estrogen-containing medications*, including use of estrogen-containing creams for diaper rash or the ingestion of meat from estrogen-treated animals or poultry or of any estrogen by mouth, can cause this disorder.

Incomplete Isosexual Precocity This term is used to describe the premature development of a single pubertal event and encompasses several entities. Breast budding before age 7 (*premature thelarche*) without other evidence of estrogen secretion and without premature bone maturation is believed to be due to a transient increase in estrogen secretion or to increased sensitivity to the small amounts of circulating estrogens formed before puberty. Usually, the disorder is self-limited and resolves spontaneously. Occasionally, axillary hair and/or pubic hair (*premature adrenarche* and *premature pubarche*) appear without any other secondary sexual development. The phenomenon is associ-

ated with adrenal androgen secretion in the range of normal puberty and can be distinguished from syndromes of virilization by the absence of clitoromegaly. It requires no treatment, and patients enter puberty at about the average time.

HETEROSEXUAL PRECOCITY Virilization in a prepubertal female is usually due to congenital adrenal hyperplasia or to androgen secretion by an ovarian or adrenal tumor. The manifestations of virilization are described in Chap. 44. Virilization in girls with congenital adrenal hyperplasia usually occurs in a background of variable sexual ambiguity (Chap. 328).

EVALUATION OF SEXUAL PRECOCITY The evaluation of sexual precocity involves a careful history and physical examination, including rectoabdominal examination, abdominal sonography, determination of bone age, and GnRH stimulation test, and measurement of thyroid hormones, TSH, and gonadotropins (and androgen or estrogen levels when appropriate). MRI and/or CT scans should be obtained if a neurologic disorder is suspected and no evidence of an ovarian or adrenal tumor is found.

REPRODUCTIVE YEARS

DISORDERS OF THE MENSTRUAL CYCLE ■ Abnormal Uterine Bleeding Between menarche and the menopause, almost every woman experiences one or more episodes of abnormal uterine bleeding, here defined as any bleeding pattern that differs in frequency, duration, or amount from the pattern observed during a normal menstrual cycle. In normal women, the average menstrual cycle is 28 ± 3 days, the mean duration of menstrual flow is 4 ± 2 days, and the average blood loss is 35 to 80 mL. A variety of descriptive terms (such as *menorrhagia*, *metrorrhagia*, and *menometrorrhagia*) have been used to characterize patterns of abnormal uterine bleeding. A more logical approach is to divide abnormal uterine bleeding into those patterns associated with ovulatory cycles and those associated with anovulatory cycles.

Ovulatory Cycles Normal menstrual bleeding with ovulatory cycles is spontaneous, regular, cyclic, and predictable and is frequently associated with discomfort (*dysmenorrhea*). Deviations from this pattern associated with cycles that are still regular and predictable are most often due to organic disease of the outflow tract. For example, regular but prolonged and excessive bleeding episodes unassociated with bleeding dyscrasias (hypermenorrhea or menorrhagia) can result from abnormalities of the uterus such as submucous leiomyomas, adenomyosis, or endometrial polyps. Regular, cyclic, predictable menstruation characterized by spotting or light bleeding is termed *hypomenorrhea* and is due to obstruction of the outflow tract as from intrauterine synechiae or scarring of the cervix. Intermenstrual bleeding between episodes of regular, ovulatory menstruation is also often due to cervical or endometrial lesions. An exception to the association between organic disease and abnormal uterine bleeding is the occurrence of regular menstruation more frequently than 21 days apart (*polymenorrhea*). Such cycles may be a normal variant.

Anovulatory Cycles Dysfunctional uterine bleeding refers to bleeding that is unpredictable with respect to amount, onset, and duration and is usually painless. This disorder is not due to abnormalities of the uterus but rather to chronic anovulation and occurs when there is interruption of the normal sequence of follicular and luteal phases under the influence of a dominant follicle and its resulting corpus luteum. As discussed above, uterine bleeding in ovulatory cycles occurs because of progesterone withdrawal and requires that the endometrium first be primed with estrogen. (When castrates or postmenopausal women are given progesterone, withdrawal bleeding usually does not occur.)

Dysfunctional uterine bleeding can occur in women who have a transient disruption of the synchronous hypothalamic-pituitary-ovarian patterns necessary for ovulatory cycles, most often at the extremes of the reproductive life—in the early menarche and in the perimenopausal period—but also after temporary stress or intercurrent illness.

Primary dysfunctional uterine bleeding can result from three disorders.

1. *Estrogen withdrawal bleeding* occurs when estrogen is given to a castrated or postmenopausal woman and then withdrawn. As in other types of dysfunctional uterine bleeding, this form of menstrual bleeding is usually painless.
2. *Estrogen breakthrough bleeding* occurs when there is continuous estrogen stimulation of the endometrium not interrupted by cyclic progesterone secretion and withdrawal. This is the most common type of dysfunctional uterine bleeding and is usually due to anovulation associated with chronic acyclic estrogen production, as in women with PCOS. Such women may have histories of irregular, unpredictable menses; oligomenorrhea; or amenorrhea (see below). Alternatively, estrogen breakthrough bleeding can occur in hypogonadal women given estrogens chronically rather than intermittently and in women with estrogen-secreting tumors of the ovary. Estrogen breakthrough bleeding may be profuse and is unpredictable with respect to duration, amount of flow, and time of occurrence. The endometrium is typically thin because its repair between episodes of bleeding is incomplete.
3. *Progesterone breakthrough bleeding* occurs in the presence of abnormally high ratios of progesterone to estrogen, i.e., in women using continuous low-dose oral contraceptives.

The approach to a patient with dysfunctional uterine bleeding begins with a careful history of menstrual patterns and prior hormonal therapy. Since not all urogenital tract bleeding is from the uterus, rectal, bladder, and vaginal or cervical sources must be excluded by physical examination. If the bleeding is from the uterus, a pregnancy-related disorder such as abortion or ectopic pregnancy must be ruled out.

℞ TREATMENT

Once the diagnosis of dysfunctional uterine bleeding is established, a rational approach to management is as follows: During a first episode of dysfunctional bleeding, it is reasonable to observe the patient without intervention, provided the bleeding is not copious and no evidence of bleeding dyscrasia is present. If bleeding is moderately severe, control can be achieved with relatively high dose estrogen oral contraceptives for 3 weeks. Alternatively, a regimen of three or four low-dose oral contraceptive pills per day for 1 week followed by tapering to the usual dosage for up to 3 weeks is also effective. If uterine bleeding is more severe, hospitalization, bed rest, and intramuscular injections of estradiol valerate (10 mg) and hydroxyprogesterone caproate (500 mg) or intravenous or intramuscular conjugated estrogens (25 mg) usually control the bleeding. After initial treatment, iron replacement should be instituted, and recurrence can be prevented by cyclic oral contraceptives for 2 to 3 months (or more if pregnancy is not desired). Alternatively, menses can be induced every 2 to 3 months with medroxyprogesterone acetate, 10 mg taken orally once or twice a day for 10 days. If hormone therapy fails to control uterine bleeding, an endometrial biopsy, hysteroscopy, or dilatation and curettage may be required for diagnosis and therapy. Indeed, uterine sampling should be performed prior to hormone therapy in women at risk for endometrial cancer (e.g., in women who are approaching the age of menopause or who are massively obese); endometrial cancer is rare in ovulatory women of reproductive age.

Amenorrhea An acceptable definition of amenorrhea is failure of menarche by age 15, irrespective of the presence or absence of secondary sexual characteristics, or the absence of menstruation for 6 months in a woman with previous periodic menses. However, women who do not fulfill these criteria should be evaluated if (1) the patient and/or her family are greatly concerned, (2) no breast development has occurred by age 13, or (3) any sexual ambiguity or virilization is present. Amenorrhea is commonly categorized as either primary (the woman has never menstruated) or secondary (when menstruation has been

present for a variable period of time in the past and has ceased). However, some disorders can cause either primary or secondary amenorrhea. For example, most women with gonadal dysgenesis have primary amenorrhea, but some have a few follicles and ovulate for short periods so that pregnancy occurs rarely. Furthermore, patients with chronic anovulation (PCOS) usually have secondary amenorrhea but on occasion have primary amenorrhea. For these reasons, categorization of amenorrhea into primary and secondary types is less helpful than a classification based on the underlying physiologic derangements: (1) anatomic defects, (2) ovarian failure, and (3) chronic anovulation with or without estrogen present.

ANATOMIC DEFECTS Anatomic or structural defects of the genital tract can preclude menstrual bleeding. Starting from the caudal end of the female genital tract, labial fusion is often associated with disorders of sexual development, particularly female pseudohermaphroditism (congenital adrenal hyperplasia or exposure to maternal androgens in utero; Chap. 328). Congenital defects of the vagina, imperforate hymen, and transverse vaginal septae can also cause amenorrhea. These women frequently have accumulation of menstrual blood behind the obstruction and may have cyclic, predictable episodes of abdominal pain.

More severe müllerian anomalies include müllerian agenesis (the Mayer-Rokitansky-Küster-Hauser syndrome), second in frequency only to gonadal dysgenesis as a cause of primary amenorrhea. It can be caused by mutations in the genes encoding anti-müllerian hormone (AMH) or its receptor (AMHR). Women with this syndrome have a 46,XX karyotype, female secondary sex characteristics, and normal ovarian function, including cyclic ovulation, but have absence or hypoplasia of the vagina. The uterus usually consists of only rudimentary bicornuate cords, but if the uterus contains endometrium, cyclic abdominal pain and accumulation of blood may occur, as in other forms of outlet obstruction. One-third of women with this syndrome have abnormalities of the urogenital tract, and one-tenth have skeletal anomalies, usually involving the spine. The major diagnostic problem is distinguishing müllerian agenesis from complete androgen insensitivity syndrome, in which 46,XY genetic males with testes differentiate as phenotypic women but with a blind vaginal pouch and no uterus (Chap. 328). Androgen insensitivity can be diagnosed by demonstrating a male level of serum testosterone and a 46,XY karyotype, whereas demonstration of a 46,XX karyotype, the biphasic basal body temperature curve characteristic of ovulation, and elevated levels of progesterone during the luteal phase establish the diagnosis of müllerian agenesis.

Other abnormalities of the uterus that cause amenorrhea include obstruction due to scarring or stenosis of the cervix, often as a result of surgery, electrocautery, laser therapy, or cryosurgery. Such destruction of the endometrium (Asherman's syndrome) usually follows vigorous curettage for postpartum hemorrhage or after therapeutic abortion complicated by infection. This diagnosis is confirmed by hysterosalpingography or by direct visual examination of the endometrial scarring or synechiae using a hysteroscope.

Treatment of disorders of the outflow tract is surgical.

OVARIAN FAILURE Primary ovarian failure is associated with elevated plasma gonadotropin levels and can result from several causes. The most frequent cause is *gonadal dysgenesis*, in which the germ cells are absent and the ovary is replaced by a fibrous streak (Chap. 328). A 45,X karyotype is found in about half of women with this disorder, and most have somatic defects, including short stature, webbed neck, shield chest, and cardiovascular defects, collectively termed the *Turner phenotype*. The remainder of women with X chromosome abnormalities have chromosomal mosaicism with or without associated structural abnormalities of the X. Approximately 90% of women with gonadal dysgenesis due to partial or complete deletion of the X never have menstrual bleeding, and the remaining 10% have sufficient follicles to experience menses and, rarely, fertility; the menstrual and reproductive lives of such individuals are invariably brief.

One-tenth of individuals identified as having bilateral streak gonads have a normal 46,XX or 46,XY karyotype and are said to have *pure gonadal dysgenesis*. These individuals have either normal or above-average stature, owing to failure of estrogen-mediated epiphyseal closure in the presence of a normal chromosomal constitution. Pure gonadal dysgenesis does not constitute a phenotypic or chromosomally homogeneous disorder.

Other causes of ovarian failure and amenorrhea include deficiency of the *CYP17* gene that encodes 17α-hydroxylase and 17,20-lyase activities, premature ovarian failure, the resistant-ovary syndrome, and ovarian failure secondary to chemotherapy or radiation therapy for malignancy. *17α-Hydroxylase deficiency* is a rare, autosomal recessive disorder characterized by primary amenorrhea, sexual infantilism, and hypertension, the latter due to increased production of desoxycorticosterone (DOC); women with *17,20-lyase deficiency* have primary amenorrhea and sexual infantilism with normal blood pressure. The diagnosis of *premature ovarian failure* or *premature menopause* applies to women who cease menstruating before age 40. The ovaries in such women are similar to those of postmenopausal women, containing few or no follicles as the result of accelerated follicular atresia. Premature ovarian failure due to ovarian antibodies may be one component of polyglandular failure, together with adrenal insufficiency, hypothyroidism, and other autoimmune disorders (Chap. 330). A rare form of ovarian failure is the *resistant-ovary syndrome*, in which the ovaries contain many follicles that are arrested in development prior to the antral stage, possibly because of resistance to the action of FSH in the ovary. A subset of these individuals have mutations in FSH or its receptor. To differentiate this disorder from the 46,XX variety of pure gonadal dysgenesis, which is also associated with sexual immaturity, it is necessary to perform ovarian biopsy or genetic testing. Women with ovarian failure who desire pregnancy have been treated with hormone replacement and transfer of donor embryos to the uterine cavity or fallopian tubes.

TREATMENT

In women with decreased estrogen production, whether due to ovarian dysfunction or to hypogonadotropic hypogonadism, treatment with cyclic estrogens should be instituted to induce the development and maintenance of female secondary sexual characteristics and to prevent osteoporosis. The most commonly used medications are conjugated estrogens (0.625 to 1.25 mg/d by mouth) together with medroxyprogesterone acetate (2.5 mg/d or 5 to 10 mg during the last several days of monthly estrogen treatment to prevent development of endometrial hyperplasia). Alternatively, oral contraceptives may be given to premenopausal-age women (Chap. 45). Abnormal bleeding in women receiving estrogen replacement mandates histologic evaluation of the endometrium.

Chronic Anovulation At least 80% or more of gynecologic endocrine disorders result from chronic anovulation. Women with chronic anovulation fail to ovulate spontaneously but may ovulate with appropriate therapy. The ovaries of such women do not secrete estrogen in a normal cyclic pattern. It is clinically useful to differentiate those women who produce enough estrogen to have withdrawal bleeding after progestogen therapy from those who do not; the latter often have hypothalamic-pituitary dysfunction.

CHRONIC ANOVULATION WITH ESTROGEN PRESENT This disorder is most commonly caused by *polycystic ovarian syndrome*, which is characterized by infertility, hirsutism, obesity, insulin resistance, and amenorrhea or oligomenorrhea. When spontaneous uterine bleeding occurs in women with PCOS, it is unpredictable as to time of onset, duration, and amount; on occasion the bleeding can be severe.

PCOS, as originally described by Stein and Leventhal, was characterized by enlarged, polycystic ovaries, but it is now known to be associated with a variety of pathologic findings in the ovaries, only some of which result in enlargement and none of which are pathognomonic. The most common finding is a white, smooth, sclerotic ovary

with a thickened capsule, multiple follicular cysts in various stages of atresia, a hyperplastic theca and stroma, and rare or absent corpora albicans. Other ovaries have hyperthecosis in which the ovarian stroma is hyperplastic and may contain lipid-laden luteal cells. Thus, the diagnosis of PCOS is a clinical one, based on the coexistence of chronic anovulation and varying degrees of androgen excess. The fundamental defect that causes PCOS is unknown, and it is likely to have several distinct causes.

In most women with PCOS, menarche occurs at the expected time, but oligomenorrhea ensues after a variable period. Signs of androgen excess (hirsutism) usually become evident soon after menarche. One scenario suggests that this disorder originates as an exaggerated adrenarche in obese girls (Fig. 326-5). The combination of elevated levels of adrenal androgens and obesity leads to increased formation of extraglandular estrogen. This estrogen exerts a positive feedback on LH secretion and negative feedback on FSH secretion, resulting in a ratio of LH to FSH levels in plasma that is characteristically greater than 2. The increased LH levels can then lead to hyperplasia of the ovarian stroma and theca cells and increased androgen production, which in turn provides more substrate for peripheral aromatization and perpetuates the chronic anovulation. In the advanced stage of the disorder, the ovary is the major site of androgen production, but the adrenal may continue to secrete excess androgen as well. Ovarian follicles from women with PCOS have low aromatase activity, but normal aromatase can be induced by treatment with FSH. An association exists between PCOS/hyperthecosis, virilization, acanthosis nigricans, and insulin resistance; in the ovary, insulin may interact via the insulin-like growth factor receptors to enhance androgen synthesis in insulin-resistant states. Women with PCOS have an increased incidence of impaired glucose tolerance and type 2 diabetes mellitus.

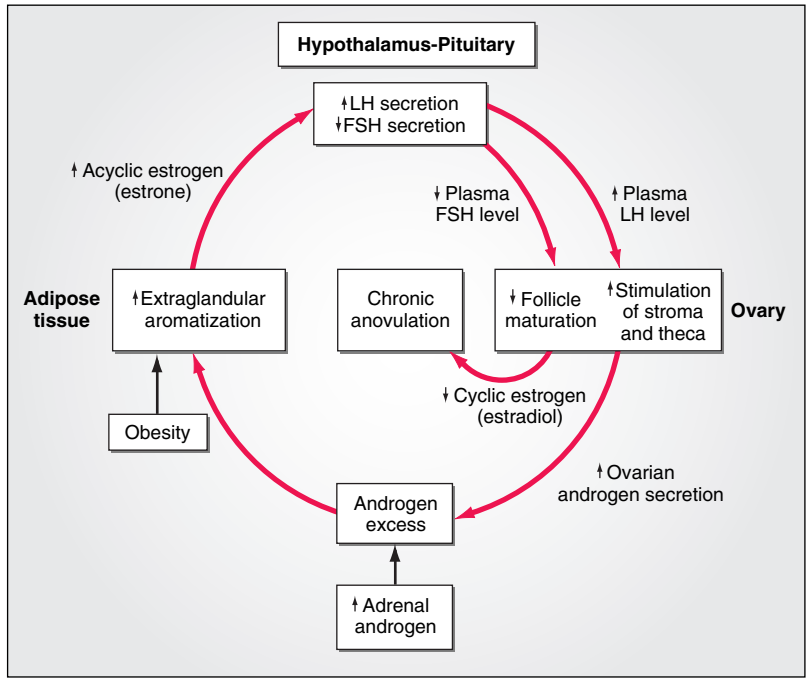

FIGURE 326-5 Proposed mechanism for the initiation and perpetuation of chronic anovulation in polycystic ovarian syndrome (PCOS). This cycle may be entered or initiated via adrenal androgen excess or obesity, both of which result in enhanced extraglandular formation of estrogens. The therapy of PCOS involves interruption of the cycle at any of several steps. *[From SSC Yen et al (eds), Reproductive Endocrinology. Philadelphia, Saunders, 1999; and from U Goebelmann, in Reproductive Endocrinology, Infertility, and Contraception, 2d ed, DR Mishell Jr, V Davajan (eds), Philadelphia, Davis, 1986.]*

TREATMENT

Treatment of PCOS is directed toward interrupting the self-perpetuating cycle and can be accomplished in several ways, such as by decreasing ovarian androgen secretion (by wedge resection or the use of oral contraceptive agents), decreasing peripheral estrogen formation (by weight reduction), or enhancing FSH secretion [by administration of clomiphene, human menopausal gonadotropin (hMG), GnRH (gonadorelin) by portable infusion pump, or purified FSH (urofollitropin)]. The choice of therapy depends on the clinical findings and the needs of the patient. An attempt at weight reduction is appropriate in all who are obese. If the woman is not hirsute and does not desire pregnancy, periodic withdrawal menses can be induced with medroxyprogesterone acetate 10 days per month; such treatment prevents the development of endometrial hyperplasia. If the woman is hirsute and does not desire pregnancy, the ovarian (and possibly the adrenal) component of androgen production can be suppressed with combined estrogen-progestogen oral contraceptive agents. Combined oral contraceptives are also indicated if prolonged or excessive menstrual bleeding is present. Once androgen excess is controlled, treatment of previously existing hair growth by shaving, depilatories, or electrolysis may be indicated (Chap. 44). If pregnancy is desired, ovulation must be induced. Insulin-sensitizing drugs, such as metformin and the thiazolidinediones, improve fertility in women with PCOS. Clomiphene promotes ovulation in three-fourths of cases, or ovulation can be induced with hMG, urofollitropin, or gonadorelin (Chap. 45). Pretreatment with GnRH analogues prior to use of hMG, urofollitropin, or gonadorelin may improve the rates of ovulation and pregnancy. Women with PCOS are at increased risk of ovarian hyperstimulation after treatment with gonadotropins. They also experience increased rates of spontaneous abortion. An alternative therapy is ovarian drilling by laser or cautery performed at laparoscopy when hormonal therapy is not effective; however, the procedure is associated with a high incidence of ovarian adhesions.

Chronic anovulation with estrogen present may also occur with tumors of the ovary. These include granulosa-theca cell tumors, Brenner tumors, cystic teratomas, mucous cystadenomas, and Krukenberg tumors (Chap. 83). Such tumors can either secrete excess estrogen themselves or produce androgens that are aromatized in extraglandular sites. Chronic anovulation and the clinical features of PCOS result. Occasionally, areas of the ovary not involved with tumors show the characteristic histologic changes of PCOS. Other causes of chronic anovulation with estrogen present include adrenal production of excess androgen (usually adult-onset adrenal hyperplasia due to partial 21-hydroxylase deficiency) and hypothyroidism.

CHRONIC ANOVULATION WITH ESTROGEN ABSENT Women with chronic anovulation who have low or absent estrogen production and do not experience withdrawal bleeding after progestogen treatment usually have hypogonadotropic hypogonadism due to disease of either the pituitary or the central nervous system.

Isolated hypogonadotropic hypogonadism associated with defects of smell (olfactory bulb defects) is known as the *Kallmann syndrome* (Chap. 318), which is due to a single gene defect in the X-linked *KAL* gene. Affected women are sexually infantile and have a defect in the synthesis and/or release of GnRH. Hypothalamic lesions that impair GnRH production and cause hypogonadotropic hypogonadism include craniopharyngioma, germinoma (pinealoma), glioma, Hand-Schüller-Christian disease, teratomas, endodermal-sinus tumors, tuberculosis, sarcoidosis, and metastatic tumors that cause suppression or destruction of the hypothalamus. Central nervous system trauma and irradiation can also cause hypothalamic amenorrhea and deficiencies in secretion of growth hormone, adrenocorticotropic hormone (ACTH), vasopressin, and thyroid hormone. Rare, autosomal recessive defects in the GnRH receptor have also been described.

More commonly, gonadotropin deficiency leading to chronic anovulation is believed to arise from functional disorders of the hypo-

TABLE 326-2 *Incidence and Mode of Transmission of Single-Gene Mutations Associated with Reproductive Dysfunction in Women*

Phenotype	Gene	Incidence	Mode of Transmission
Kallmann's syndrome	*KAL*	1 in 50,000	X-linked
Gonadotropin-releasing hormone resistance	*GNRHR*	Rare	Autosomal recessive
Isolated follicle-stimulating hormone deficiency	*FSHB*	Rare	Autosomal recessive
Hypergonadotropic hypogonadal ovarian failure	*FSHR*	1 in 8300 (Finland)	Autosomal recessive
Luteinizing hormone resistance	*LHR*	Rare	Autosomal recessive
Congenital lipoid adrenal hyperplasia	*STAR*	Rare	Autosomal recessive
Galactosemia	*GALT*	1 in 187,000	Autosomal recessive
McCune-Albright syndrome	*GNASI*	Rare	Dominant postzygotic mutation
Aromatase deficiency	*CYP19*	Rare	Autosomal recessive
3β-Hydroxysteroid dehydrogenase type II deficiency	*HSD3B2*	Rare	Autosomal recessive
17α-Hydroxylase deficiency	*CYP17*	Rare	Autosomal recessive

thalamus or higher centers. A history of a stressful event in a young woman is frequent. Gonadotropin and estrogen levels are in the low to low-normal range as compared with normal women in the early follicular phase of the cycle. In addition, rigorous exercise, such as jogging or ballet, and diets that result in excessive weight loss may lead to chronic anovulation, particularly in girls with a history of prior menstrual irregularity. The amenorrhea in these women does not appear to be a result of weight loss alone but a combination of a decrease in body fat and chronic stress. An extreme form of weight loss with chronic anovulation occurs in anorexia nervosa (Chap. 65). In anorexia nervosa amenorrhea can precede, follow, or coincide with weight loss.

In addition, chronic debilitating diseases such as end-stage kidney disease, malignancy, inflammatory bowel disease, and malabsorption can lead to hypogonadotropic hypogonadism via a hypothalamic mechanism.

Treatment of chronic anovulation due to hypothalamic disorders includes ameliorating the stressful situation, decreasing exercise, and correcting weight loss, as appropriate. These women are susceptibleto the development of osteoporosis; estrogen replacement therapy is recommended to induce and maintain normal secondary sexual characteristics and prevent bone loss in those who do not desire pregnancy, and gonadotropin or gonadorelin therapy is indicated when pregnancy is desired. When appropriate, therapy is directed at the primary disease of the hypothalamus.

Disorders of the pituitary can lead to the estrogen-deficient form of chronic anovulation by at least two mechanisms—direct interference with gonadotropin secretion by lesions that either obliterate or interfere with the gonadotrope cells (chromophobe adenomas, Sheehan's syndrome) or inhibition of gonadotropin secretion in association with excess prolactin (prolactinoma). *Pituitary tumors* may secrete no hormone, one hormone, or more than one hormone (Chap. 318). Prolactin levels are elevated in 50 to 70% of patients with pituitary tumors, either because of prolactin secretion by the tumor itself (in the case of prolactinomas) or because the tumor mass interferes with the normal hypothalamic inhibition of prolactin secretion.

Prolactin excess associated with low levels of LH and FSH constitutes a specific subtype of hypogonadotropic hypogonadism. One-tenth or more of amenorrheic women have increased levels of prolactin, and more than half of women with both galactorrhea and amenorrhea have elevated prolactin levels. The amenorrhea is most often associated with decreased or absent estrogen production, but prolactin-secreting tumors on occasion are associated with normal ovulatory menses or chronic anovulation with estrogen present. In the latter half of pregnancy, prolactin-secreting pituitary tumors may expand, leading to headaches, compression of the optic chiasm, bitemporal hemianopia, and blindness. Therefore, before inducing ovulation for the purposes of achieving pregnancy, it is mandatory to exclude the presence of a pituitary tumor. →***The evaluation, differential diagnosis, and management of hyperprolactinemia are described in Chap. 318.***

Large pituitary tumors such as null cell adenomas—whether or not hyperprolactinemia is present—are likely to be associated with deficiency of hormones in addition to gonadotropins (Chap. 318).

Craniopharyngiomas, which are thought to arise from remnants of Rathke's pouch, occur most frequently in the second decade of life and often extend into the suprasellar region. Many of these tumors calcify and can be diagnosed by conventional skull film or CT. Patients often present with sexual infantilism, delayed puberty, and amenorrhea due to gonadotropin deficiency; secretion of TSH, ACTH, growth hormone, and vasopressin may also be impaired.

Panhypopituitarism can be caused by mutations in transcription factors (Pit-1; Prop-1) involved in pituitary gland development, result from surgical or radiation treatment of pituitary adenomas, or develop after postpartum hemorrhage (Sheehan's syndrome) (Chap. 318). Table 326-2 outlines the incidence and mode of single gene mutations associated with reproductive dysfunction in women.

Evaluation of Amenorrhea A general scheme for the evaluation of women with amenorrhea is given in Fig. 326-6. On physical examination, attention should be given to three features: (1) the degree of maturation of the breasts, pubic and axillary hair, and external genitalia; (2) the current estrogen status; and (3) the presence or absence of a uterus. Pregnancy should be excluded in all women with amenorrhea; it is prudent to perform a suitable pregnancy screening test even when the history and physical examination are not suggestive. Once that is done, the cause of amenorrhea can frequently be diagnosed clinically. For example, Asherman's syndrome is suggested by a history of curettage in a woman who previously menstruated; in women with primary amenorrhea and sexual infantilism, the essential differential diagnosis is between gonadal dysgenesis and hypopituitarism; and the diagnosis of gonadal dysgenesis (Turner's syndrome) or of anatomic defects of the outflow tract (müllerian agenesis, testicular feminization, and cervical stenosis) is frequently suggested on the basis of physical findings. When a specific cause is suspected, it is appropriate to proceed directly to confirm the diagnosis (obtaining a chromosomal karyotype or measurement of plasma gonadotropins). It is also useful to measure serum prolactin and FSH levels during the initial evaluation.

Estrogen status is evaluated by determining if the vaginal mucosa is moist and rugated and if the cervical mucus can be stretched and shown to fern upon drying. If these criteria are indeterminate, a progestational challenge is indicated, most often the administration of 10 mg medroxyprogesterone acetate by mouth once or twice daily for 5 days or 100 mg progesterone in oil intramuscularly. (It should be emphasized that progestogen should never be administered until pregnancy is excluded.) If estrogen levels are adequate (and the outflow tract is intact), menstrual bleeding should occur within 1 week of ending the progestogen treatment. If withdrawal bleeding occurs, the diagnosis is chronic anovulation with estrogen present, usually caused by PCOS.

If no withdrawal bleeding or only minimal vaginal spotting occurs, the nature of the subsequent workup depends on the results of the initial prolactin assay. If plasma prolactin is elevated, or if galactorrhea is present, radiography of the pituitary should be undertaken. When the plasma prolactin level is normal in an anovulatory woman with estrogen absent and with elevated FSH levels, the diagnosis is ovarian

failure. If the gonadotropins are in the low or normal range, the diagnosis is either hypothalamic-pituitary disorder or an anatomic defect of the outflow tract. As indicated previously, the diagnosis of outflow tract disorder is usually suspected or established on the basis of the history and physical findings. When the physical findings are not clear-cut, it is useful to administer cyclic estrogen plus progestogen (1.25 mg oral conjugated estrogens per day for 3 weeks, with 10 mg medroxyprogesterone acetate added for the last 7 to 10 days of estrogen treatment), followed by 10 days of observation. If no bleeding occurs, the diagnosis of Asherman's syndrome or another anatomic defect of the outflow tract is confirmed by hysterosalpingography or hysteroscopy. If withdrawal bleeding occurs following the estrogen-progestogen combination, the diagnosis of chronic anovulation with estrogen absent (functional hypothalamic amenorrhea) is suggested. Radiologic evaluations of the pituitary-hypothalamic areas may be indicated in the latter cases—irrespective of the prolactin level—because of the risk of overlooking a pituitary-hypothalamic tumor and because the diagnosis of functional hypothalamic amenorrhea is one of exclusion.

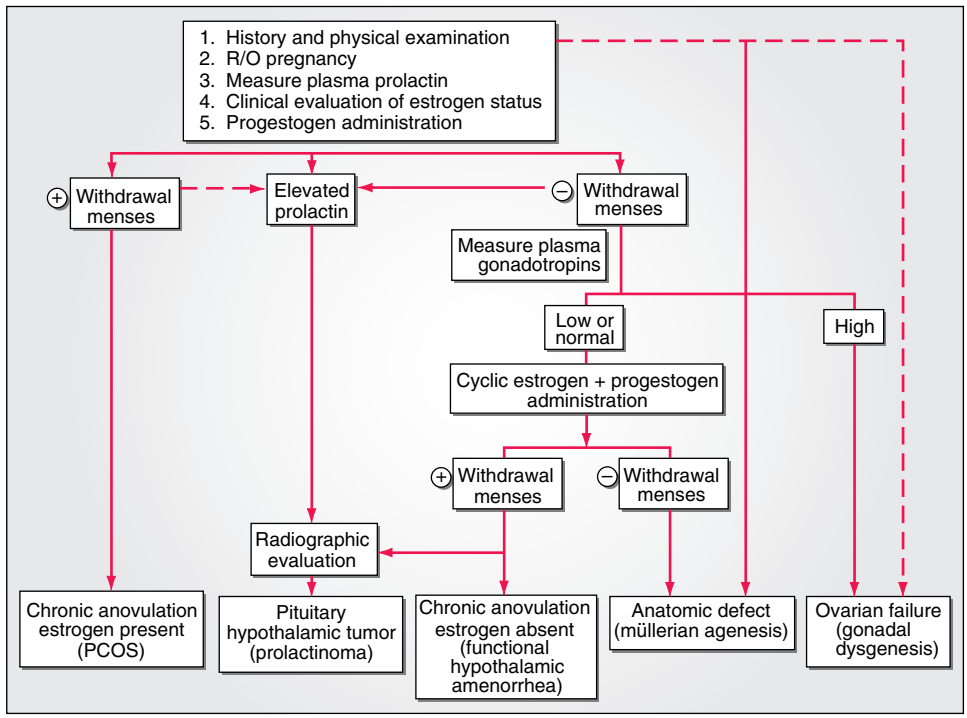

FIGURE 326-6 Flow diagram for the evaluation of women with amenorrhea. The most common diagnosis for each category is shown in parentheses. The dotted lines indicate that in some instances a correct diagnosis can be reached on the basis of history and physical examination alone. PCOS, polycystic ovarian syndrome.

INFERTILITY Infertility, the failure to become pregnant after 1 year of unprotected intercourse, affects approximately 10 to 15% of couples and is a common reason for seeking gynecologic assistance. Male factors account for at least 25% of infertility problems (Chap. 325). In women, failure of ovulation accounts for 40% of cases; pelvic factors, such as tubal disease or endometriosis, account for half. In 10 to 20% of infertile women no etiology is found. ***→The evaluation and management of infertility are discussed in Chap. 45.***

PREGNANCY (See also Chap. 6) The possibility of pregnancy should be considered in all women of reproductive age who are evaluated for medical illness or considered for surgery. Procedures such as x-ray exposure, drugs, and anesthetics may be harmful to the developing fetus, and a variety of medical problems may worsen during pregnancy, including hypertension; diseases of the heart, lungs, kidney, and liver; and metabolic and endocrine disorders. Abnormal vaginal bleeding or amenorrhea during the reproductive years should prompt consideration of a complication of pregnancy, such as incomplete abortion, ectopic pregnancy, or trophoblastic disease (hydatidiform mole or choriocarcinoma). Women who present with these complications of pregnancy often have histories of abdominal pain and vaginal bleeding and may have evidence of intraabdominal hemorrhage.

Choriocarcinoma is a particular problem because of its protean manifestations. Half these malignancies follow pregnancies complicated by hydatidiform mole, and the remainder occur after spontaneous abortion, ectopic pregnancy, or normal deliveries. Patients may present with intraabdominal bleeding due to rupture of the uterus, liver, or ovary, with pulmonary manifestations (cough, hemoptysis, pleuritic pain, dyspnea, and respiratory failure) or gastrointestinal symptoms, usually chronic blood loss or melena. In addition, patients can present with cerebral metastases or renal involvement. The diagnosis can be established by demonstrating an elevated level of the β subunit of hCG in plasma. Treatment and cure are possible with chemotherapeutic agents (dactinomycin and/or methotrexate). ***→The manifestations of choriocarcinoma in men are discussed in Chap. 82.***

OTHER DISORDERS OF THE FEMALE REPRODUCTIVE TRACT

VULVA

Most disorders of the vulva are a result of sexually transmitted diseases, most commonly syphilis (painless chancre), condylomata acuminata (venereal warts), and herpes vulvitis (painful ulcers; Chap. 115). All other lesions of the vulva, particularly in older women, must be biopsied. Early biopsy of cancer of the vulva is mandatory, because when it becomes symptomatic (pruritus and bleeding), it has often progressed to an advanced stage.

VAGINA

Infections of the vagina usually present as vaginal discharge and pruritus. The most frequent organisms are *Trichomonas*, *Candida albicans*, and *Gardnerella vaginalis* (Chap. 115). The diagnosis is made by microscopic examination of the discharge, and appropriate therapy can be instituted using vaginal or oral antibiotics.

Abnormalities of the vagina and cervix in female offspring of women given diethylstilbestrol during pregnancy include adenosis of the vagina and structural abnormalities of the vagina, cervix, and uterus; the risk of developing a rare vaginal cancer (adenocarcinoma, clear cell type) is increased (2 per 10,000 exposed women). Periodic examination of women at risk should begin at age 12 to 14, and reexamination should be done after any episode of abnormal bleeding.

CERVIX

Preinvasive lesions of the cervix (also known as *cervical intraepithelial neoplasia*) and invasive carcinoma of the cervix can be detected reliably by obtaining a Papanicolaou (Pap) smear.

EVALUATION OF THE PAP SMEAR The incidence of invasive cervical cancer has declined as a result of Pap smear screening. In the United States, approximately 2 to 3 million abnormal Pap smears are found each year. Most represent low-grade lesions but require appropriate follow-up. The follow-up of abnormal Pap smears requires an understanding of the Bethesda system for evaluating such smears (see below) and of the limitations of cytologic screening systems. Further

evaluation may require repeat cytologic examination, colposcopy, or both.

CURRENT SCREENING RECOMMENDATIONS Risk factors for cervical neoplasia include a history of multiple sexual partners, coitus beginning at an early age, a history of infection with human papilloma virus (HPV), infection with HIV or another immunosuppressed state, and a history of cancer of the lower genital tract. Cervical cancer screening is recommended annually beginning at 18 years of age or when the woman becomes sexually active, if earlier than age 18. Less frequent screening is sufficient when three consecutive, negative, satisfactory annual Pap smears have been obtained or if the woman is in a low-risk category. There is no upper age limit for screening, because the prevalence of invasive cancer shows a linear increase with age, most of these cancers being diagnosed after age 50. Even after hysterectomy, annual screening should be performed if there is a history of abnormal Pap smears or other lower genital tract neoplasia.

THE BETHESDA SYSTEM OF CYTOLOGIC EXAMINATION Pap smears are evaluated in regard to the adequacy of the specimen (satisfactory for evaluation, satisfactory but limited, or unsatisfactory for evaluation because of a stated reason), the general diagnosis (normal or abnormal), and a descriptive diagnosis if the smear is abnormal. The descriptive diagnoses include benign cellular changes, reactive cellular changes, and epithelial cell abnormalities, the latter including (1) atypical squamous cells of undetermined significance (ASCUS); (2) low-grade squamous intraepithelial lesion (LSIL), which is further categorized to include HPV infection, cervical intraepithelial neoplasia (CIN 1), and high-grade squamous intraepithelial lesion (HSIL), which is itself subdivided into CIN 2 and CIN 3); and (3) squamous cell carcinoma.

GUIDELINES FOR THE MANAGEMENT OF WOMEN WITH ABNORMAL PAP SMEARS For ASCUS smears that are unqualified or suggest a reactive process, a repeat smear should be obtained every 4 to 6 months for 2 years until three consecutive negative smears have been obtained. For ASCUS smears that are unqualified but have severe inflammation, any specific cause should be treated, and the smear should be repeated in 2 to 3 months; because invasive carcinoma can be obscured by severe inflammation, clinical evaluation is mandatory. For postmenopausal women not using hormone replacement, a course of topical estrogen should be applied before the test is repeated. For LSIL smears, the Pap test is repeated every 4 to 6 months for 2 years until three consecutive negative smears have been obtained; treatment of HPV is of no established benefit, and there is a high rate of regression of LSIL, so that in compliant, low-risk individuals, the outcome is usually favorable. If LSIL is persistent, colposcopy with directed biopsy is performed, and endocervical curettage is undertaken if a specific diagnosis is made by biopsy. Cervical cone biopsy or loop electrosurgical excision procedures are performed for higher-grade lesions such as HSIL. If cervical cancer is diagnosed by biopsy, clinical staging is performed, and the patient is treated with radiation therapy or surgery.

UTERUS

Only 40% of cases of endometrial adenocarcinoma are detected by Pap smear. In women at high risk for endometrial carcinoma (because of obesity, a history of chronic anovulatory cycles, diabetes mellitus, hypertension, or unopposed estrogen treatment), yearly endometrial sampling should be performed. Measurement of endometrial thickness by sonography can indicate which patients are at risk for endometrial pathology. Endometrial thickness <5 mm is rarely associated with either hyperplasia or cancer. Low-dose oral estrogen therapy rarely causes breakthrough or withdrawal bleeding in postmenopausal women. Therefore, irrespective of whether the patient is using estrogen therapy, the occurrence of postmenopausal bleeding makes it mandatory to obtain a tissue diagnosis by either endometrial sampling or curettage to exclude endometrial cancer.

One of the most common disorders of the uterus and the most frequent tumor of women (one of four women affected) is the uterine leiomyoma, or fibroid tumor. Three-fourths of women with leiomyoma are asymptomatic, and the diagnosis is made on routine pelvic examination. When the tumor is associated with excessive menstrual blood loss, is large or fast-growing, or causes significant pelvic pain (see below), the preferred treatment is hysterectomy if there is no desire for further childbearing. Embolism of the vascular supply to the tumor may be possible. In young women, myomectomy is sometimes indicated when infertility or repeated fetal wastage is a manifestation or where future childbearing is desired.

FALLOPIAN TUBES AND OVARIES

PELVIC INFLAMMATORY DISEASE (PID) This is a common disorder of the fallopian tubes and usually becomes symptomatic after a menstrual period; symptoms include fever, chills, abdominal pain, and vaginal discharge, and pelvic tenderness on physical examination is common. The initiating organism most often is *Chlamydia trachomatis* or *Neisseria gonorrhoeae*, but tuboovarian abscess and sterility are probably caused by mixed aerobic and anaerobic superinfections and require wide-spectrum antibiotic treatment (Chap. 115).

ENDOMETRIOSIS This is a benign disorder characterized by the presence and proliferation of endometrial tissue (stroma and glands) outside the endometrial cavity. The clinical manifestations are variable. Endometriosis occurs most commonly between the ages of 30 and 40 and is found incidentally at the time of surgery in approximately one-fifth of all gynecologic operations. The fertility rate is reduced in affected women. The disorder usually involves the posterior cul-de-sac or the ovaries and it occasionally involves distant sites (lung, umbilicus). The major symptom is pelvic pain, characteristically dysmenorrhea (see below). However, the frequency and severity of symptoms correlate poorly with the extent of disease. Other manifestations include dyspareunia, pain with defecation, and infertility. The characteristic physical findings are multiple tender nodules palpable along the uterosacral ligament at the time of rectal-vaginal examination, a posteriorly fixed uterus, or enlarged, cystic ovaries. The diagnosis can be confirmed only by direct visualization, usually at diagnostic laparoscopy. Treatment depends on the degree of involvement and the desires of the patient and includes observation for mild disease with no associated infertility or pain, hormonal suppressive therapy, conservative surgery by laparoscopy or laparotomy if fertility is desired, or removal of the uterus, tubes, and ovaries in severe disease. Endometriosis is rare after the menopause.

Any adnexal mass that persists for more than 6 weeks or is larger than 6 cm must be evaluated. Although ovarian cysts and neoplasms are the most common pelvic adnexal masses, tumors of the fallopian tubes, uterus, gastrointestinal tract, or urinary tract should also be considered. Sonography or radiographic evaluation is often helpful in identifying the nature of the adnexal mass prior to surgical exploration. ***→For a discussion of ovarian tumors, see Chap. 83.***

EVALUATION OF PELVIC PAIN

The evaluation of pelvic pain requires a careful history and pelvic examination. This often leads to the correct diagnosis and institution of appropriate treatment. Pelvic pain may originate in the pelvis or be referred from another region of the body. A pelvic source is suggested by the history (e.g., dysmenorrhea and dyspareunia) and physical findings, but a high index of suspicion must be entertained for extrapelvic disorders that refer to the pelvis, such as appendicitis, diverticulitis, cholecystitis, intestinal obstruction, and urinary tract infections. If the pain is severe and the diagnosis is unclear, the workup should follow that outlined for the acute abdomen (Chap. 13).

"PHYSIOLOGIC" PELVIC PAIN

PAIN ASSOCIATED WITH OVULATION ("MITTELSCHMERZ") Many women experience low abdominal discomfort with ovulation, typically a dull aching pain at midcycle in one lower quadrant lasting from minutes to hours. It is rarely severe or incapacitating. The pain may result from

peritoneal irritation by follicular fluid released into the peritoneal cavity at ovulation. The onset of discomfort at midcycle, and short duration of pain, suggest this diagnosis.

PREMENSTRUAL OR MENSTRUAL PAIN In normal ovulatory women, somatic symptoms during the few days prior to menses may be insignificant or disabling. Such symptoms include edema, breast engorgement, and abdominal bloating or discomfort. A symptom complex of cyclic irritability, depression, and lethargy is known as *premenstrual syndrome*, which appears to be caused by changes in gonadal steroid levels. Although there is no consensus about therapy, randomized, controlled trials suggest improvement in some women with the daily use of serotonin-reuptake inhibitors.

Severe or incapacitating uterine cramping during ovulatory menses and in the absence of demonstrable disorders of the pelvis is termed *primary dysmenorrhea*. Primary dysmenorrhea is caused by prostaglandin-induced uterine ischemia and is treated with nonsteroidal antiinflammatory drugs and/or oral contraceptive agents.

PELVIC PAIN DUE TO ORGANIC CAUSES

Severe dysmenorrhea associated with disease of the pelvis is termed *secondary dysmenorrhea*. Organic causes of pelvic pain can be classified as (1) uterine, (2) adnexal, (3) vulvar or vaginal, and (4) pregnancy-associated.

UTERINE PAIN Pain of uterine etiology is often chronic and continuous and increases in intensity during menstruation and intercourse. Causes include leiomyomas of the uterus (particularly submucous and degenerating leiomyomas), adenomyosis, and cervical stenosis. Infections of the uterus associated with intrauterine manipulation following dilatation and curettage or with the insertion of intrauterine devices can also cause pelvic pain. Pelvic pain due to endometrial or cervical cancer is usually a late manifestation.

ADNEXAL PAIN The most common cause of pain in the adnexae (fallopian tubes and ovaries) is infection (Chap. 115). Acute salpingo-oophoritis presents as low abdominal pain, fever, and chills and begins a few days after a menstrual period. Chronic PID results from either a single episode or multiple episodes of infection and may present as infertility associated with chronic pelvic pain that increases in intensity with menses and intercourse. On physical examination, cervical motion tenderness, adnexal tenderness, and adnexal thickening and/or masses may be present. PID may become a surgical emergency if peritonitis results from rupture of a tuboovarian abscess. Ovarian cysts or neoplasms may cause pelvic pain that becomes more severe with torsion or rupture of the mass, and ectopic pregnancy must be considered in the differential diagnosis. If there is a question of an adnexal mass or if the patient is so obese as to preclude a thorough pelvic examination, abdominal or vaginal ultrasound may be useful. Endometriosis involving fallopian tubes, ovaries, or peritoneum may cause both chronic low abdominal pain and infertility; the magnitude of tissue involvement does not always correlate with the severity of symptoms. Endometriosis pain typically increases with menstruation and, if the posterior ligaments of the uterus are involved, with intercourse.

VULVAR OR VAGINAL PAIN Pain in these areas is most often due to infectious vaginitis and is characteristically associated with vaginal discharge and pruritus. Herpetic vulvitis, other dermatologic conditions of the vulva, condyloma acumination, and cysts or abscesses of Bartholin's glands may also cause vulvar pain.

PREGNANCY-ASSOCIATED DISORDERS Pregnancy must be considered in the differential diagnosis of pelvic pain during the reproductive years. Threatened abortion or incomplete abortion often presents with uterine cramping, bleeding, or passage of tissue following a period of amenorrhea. Ectopic pregnancy may be insidious in presentation or result in abrupt intraperitoneal hemorrhage and maternal death. A culdocentesis may be indicated if a ruptured ectopic pregnancy is suspected. Serial hCG measurements may help in establishing a diagnosis of tubal pregnancy and are useful in determining if an intrauterine pregnancy is viable.

327 THE MENOPAUSE TRANSITION AND POSTMENOPAUSAL HORMONE THERAPY

JoAnn E. Manson, Shari S. Bassuk

Menopause is the permanent cessation of menstruation due to loss of ovarian follicular function. It is diagnosed retrospectively after 12 months of amenorrhea. The average age at menopause is 51 years among U.S. women. *Perimenopause* refers to the time period preceding menopause, when fertility wanes and menstrual cycle irregularity increases, until the first year after cessation of menses. The onset of perimenopause precedes the final menses by 2 to 8 years, with a mean duration of 4 years. Smoking accelerates the menopausal transition by 2 years.

Although the peri- and postmenopausal periods share many symptoms, the physiology and clinical management of the two periods differ. Low-dose oral contraceptives have become a therapeutic mainstay in perimenopause, whereas postmenopausal hormone therapy (HT) has been a common method of symptom alleviation after menstruation ceases.

PERIMENOPAUSE

PHYSIOLOGY Ovarian mass and fertility decline sharply after age 35 and even more precipitously during perimenopause; depletion of primary follicles, a process that begins before birth, occurs steadily until menopause (Chap. 326). In perimenopause, intermenstrual intervals shorten significantly (typically by 3 days) due to an accelerated follicular phase. Follicle-stimulating hormone (FSH) levels rise, due to altered folliculogenesis and reduced inhibin secretion. In contrast to the consistently high FSH and low estradiol levels seen in menopause, perimenopause is characterized by "irregularly irregular" hormone levels. The propensity for anovulatory cycles can produce a hyperestrogenic, hypoprogestagenic environment that may account for the increased incidence of endometrial hyperplasia or carcinoma, uterine polyps, and leiomyoma observed among women of perimenopausal age. Mean serum levels of selected ovarian and pituitary hormones during the menopausal transition are shown in Fig. 327-1. With transition into menopause, estradiol levels fall markedly, whereas estrone levels are relatively preserved, reflecting peripheral aromatization of adrenal and ovarian androgens. FSH levels increase more than those of luteinizing hormone (LH), presumably because of the loss of inhibin, as well as estrogen feedback.

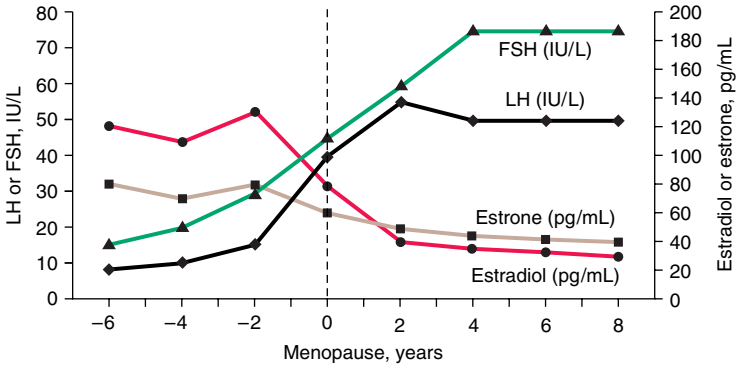

FIGURE 327-1 Mean serum levels of ovarian and pituitary hormones during the menopausal transition. FSH, follicle-stimulating hormone; LH, luteinizing hormone. *(From JL Shifren, I Schiff: The aging ovary. J Women's Health Gend-Based Med 9:5–3, 2000, with permission.)*

DIAGNOSTIC TESTS Because of their extreme intraindividual variability, FSH and estradiol levels are imperfect diagnostic indicators of perimenopause in menstruating women. However, a low FSH in the early follicular phase (days 2 to 5) of the menstrual cycle is inconsistent with a diagnosis of perimenopause. FSH measurement can also aid in assessing fertility; levels of <20 mIU/mL, 20 to <30 mIU/mL, and ≥30 mIU/mL measured on day 3 of the cycle indicate a good, fair, and poor likelihood of achieving pregnancy, respectively.

SYMPTOMS Anovulatory cycles may be associated with irregular bleeding. Some perimenopausal women experience classic postmenopausal symptoms such as hot flashes and night sweats, insomnia, vaginal dryness, mood swings, or depression. In one U.S. study, nearly 60% of women reported hot flashes in the 2 years before their final menses. Symptom intensity, duration, and frequency are highly variable.

℞ TREATMENT

For women with irregular or heavy menses or hormonally related symptoms that impair quality of life, low-dose combined oral contraceptives are a staple of therapy. Static doses of estrogen and progestin (e.g., 20 μg of ethinyl estradiol and 1 mg of norethindrone acetate daily for 21 days each month) can eliminate vasomotor symptoms and restore regular cyclicity. Oral contraceptives provide other benefits, including protection against ovarian and endometrial cancers and increased bone density, although it is not clear whether use during perimenopause decreases fracture risk later in life. Moreover, the contraceptive benefit is important, given that the unintentional pregnancy rate among women in their forties rivals that of adolescents. Contraindications to oral contraceptive use include cigarette smoking, liver disease, a history of thromboembolism or cardiovascular disease, breast cancer, or unexplained vaginal bleeding. Progestin-only formulations (e.g., 0.35 mg norethindrone daily) or medroxyprogesterone (Depo-Provera) injections (e.g., 150 mg intramuscularly every 3 months) may provide an alternative for the treatment of perimenopausal menorrhagia in women who smoke or have cardiovascular risk factors. Although progestins neither regularize cycles nor reduce the number of bleeding days, they reduce the volume of menstrual flow.

Nonhormonal strategies to reduce menstrual flow include use of nonsteroidal anti-inflammatory agents such as mefenamic acid (initial dose of 500 mg at start of menses, then 250 mg qid for 2 to 3 days) or, when medical approaches fail, endometrial ablation. It should be noted that menorrhagia requires an evaluation to rule out uterine disorders. Transvaginal ultrasound with saline enhancement is useful for detecting leiomyomata or polyps, and endometrial aspiration can identify hyperplastic changes.

TRANSITION TO MENOPAUSE For sexually active women using contraceptive hormones to alleviate perimenopausal symptoms, the question of when and if to switch to HT must be individualized. Estrogen and progestin doses in HT are lower than those in oral contraceptives and have not been documented to prevent pregnancy. Though a 1-year absence of spontaneous menses reliably indicates ovulation cessation, it is not possible to assess the natural menstrual pattern while a woman is taking an oral contraceptive. Women willing to switch to a barrier method of contraception should do so; if menses occur spontaneously, oral contraceptive use can be resumed. The average age of final menses among relatives can serve as a guide for when to initiate this process, which can be repeated yearly until menopause has occurred.

MENOPAUSE AND POSTMENOPAUSAL HORMONE THERAPY

One of the most complex health care decisions facing women is whether or not to use postmenopausal hormone therapy. HT, once prescribed primarily to relieve vasomotor symptoms, has been promoted as a strategy to forestall various disorders that accelerate after menopause, including osteoporosis and cardiovascular disease. More than 30% of postmenopausal women in the United States currently use HT. This widespread use is unwarranted given the paucity of conclusive data, until very recently, on the health consequences of such therapy. Although many women rely on their health care providers for a definitive answer to the question of whether to use postmenopausal hormones, balancing the benefits and risks for an individual patient is challenging.

Although observational studies suggest that HT prevents cardiovascular and other chronic diseases, the apparent benefits may result at least in part from differences between women who opt to take postmenopausal hormones and women who do not. Those choosing HT tend to be healthier, have greater access to medical care, are more compliant with prescribed treatments, and maintain a more health-promoting life-style. Randomized trials, which eliminate these confounding factors, have not consistently confirmed the benefits found in observational studies. Indeed, one arm of the largest trial of HT to date, the Women's Health Initiative (WHI), which examined more than 16,000 postmenopausal women for an average of 5.2 years, was stopped early because of an overall unfavorable risk-benefit ratio associated with estrogen-progestin therapy.

The following summary offers a decision-making guide based on a synthesis of currently available evidence. The decision is divided into one of short- (<5 years) or long-term (≥5 years) use of HT. Prevention of cardiovascular disease is eliminated from the equation due to lack of evidence for such benefits in recent randomized clinical trials.

BENEFITS AND RISKS OF POSTMENOPAUSAL HORMONE THERAPY

(Table 327-1)

DEFINITE BENEFITS ■ Symptoms of Menopause Compelling evidence, including data from randomized clinical trials, indicates that estrogen therapy is highly effective for controlling vasomotor and genitourinary symptoms. Alternative approaches, including the use of antidepressants (such as venlafaxine, 75 to 150 mg/d), clonidine (0.1 to 0.2 mg/d), or vitamin E (400 to 800 IU/d) or the consumption of soy-based products or other phytoestrogens, may also alleviate vasomotor symptoms, although they are less effective than HT. For genitourinary symptoms, the efficacy of vaginal estrogen is similar to that of oral or transdermal estrogen.

Osteoporosis (see also Chap 333) ■ *BONE DENSITY* By reducing bone turnover and resorption rates, estrogen slows the aging-related bone loss experienced by most postmenopausal women. More than 50 randomized trials have demonstrated that postmenopausal estrogen therapy, with or without a progestin, rapidly increases bone mineral density at the spine by 4 to 6% and at the hip by 2 to 3%, and maintains those increases during treatment.

FRACTURES Data from observational studies indicate a 50 to 80% lower risk of vertebral fracture and a 25 to 30% lower risk of hip, wrist, and other peripheral fractures among current estrogen users; addition of a

TABLE 327-1 *Benefits and Risks of Postmenopausal Hormone Therapy (HT)*

Variable	Effect	Benefit or Risk		Sources of Evidence
		Relative	Absolute	
DEFINITE BENEFITS				
Symptoms of menopause (vasomotor, genitourinary)	Definite improvement	>70 to 80% decrease		Observational studies and randomized trials
Osteoporosis	Definite increase in bone mineral density and decrease in fracture risk	2–5% increase in bone density; 25–50% decrease in risk of fractures	WHI: 50 fewer hip fractures (100 vs. 150) per 100,000 woman-years	Observational studies and randomized trials, including WHI
DEFINITE RISKS				
Endometrial cancer	Definite increase in risk with use of unopposed[a] estrogen; no increase with use of estrogen plus progestin	8- to 10-fold increased risk with use of unopposed estrogen for ≥10 yr; no excess risk with estrogen-progestin therapy	46 excess cases (52 vs. 6) per 100,000 woman-years of unopposed estrogen use (≥10 years of use); no excess with estrogen-progestin therapy	Observational studies and randomized trials
Venous thromboembolism	Definite increase in risk	≥2-fold increase	Secondary prevention: 390 excess cases per 100,000 woman-years	Randomized trial (HERS)
			Primary prevention: 180 excess cases per 100,000 woman-years	Observational studies and randomized trial (WHI)
Breast cancer	Increase in risk with long-term use (≥5 yr)	1.35-fold overall increase with HT use ≥5 yr	10–30 excess cases per 10,000 women using HT for 5 yr; 30–90 excess cases after 10 yr of use; 50–200 excess cases after 15 yr of use	Observational data (meta-analysis of 51 studies)
		25–30% increase with 5.2 yr of estrogen-progestin therapy; no increase with estrogen-only	WHI: 80 excess cases (300 vs. 380) per 100,000 woman-years of estrogen-progestin therapy	Randomized trials (WHI, HERS)
PROBABLE OR UNCERTAIN RISKS AND BENEFITS				
Cardiovascular disease				
Primary prevention	Probable increase in risk	WHI: 29% increase in CHD with estrogen-progestin; no apparent increase or decrease with estrogen-only	WHI: 70 excess cases (370 vs. 300) of CHD per 100,000 woman-years with estrogen-progestin	Observational studies suggest a 35–50% decrease in risk, while randomized trials show no effect or a harmful effect; most studies have assessed conjugated equine estrogen alone or in combination with medroxyprogesterone acetate
		40% increase in stroke with either estrogen-progestin or estrogen-only	80 excess cases (290 vs. 210) of stroke per 100,000 woman-years	
Secondary prevention	Probable early increase in risk	HERS: 50% increase in CHD in year 1; no overall effect over 4 years	Equal number of CHD cases over 4 years	Observational studies and randomized secondary prevention trials
Gallbladder disease	Probable increase in risk	1.4-fold increase	360 excess cases per 100,000 woman-years	Randomized trials (HERS)
Colorectal cancer	Probable decrease in risk	20–37% decrease with estrogen-progestin	24–60 fewer cases per 100,000 woman-years	Observational data, randomized trial (WHI)
Cognitive dysfunction	Unproven decrease in risk	Apparent increase in dementia after age 65	Uncertain	Inconsistent data from observational studies and randomized trials

[a] "Unopposed estrogen" refers to the use of estrogen without progestin.
Note: WHI, Women's Health Initiative; HERS, Heart and Estrogen/progestin Replacement Study; CHD, coronary heart disease.

Source: Adapted from Manson and Martin, with permission.

progestin does not appear to modify this benefit. Discontinuation of estrogen therapy leads to a diminution of protection. In the WHI, 5 to 6 years of either combined estrogen-progestin or estrogen-only was associated with a 30 to 40% reduction in hip fracture and 20 to 30% fewer total fractures among a population unselected for osteoporosis. Bisphosphonates (such as alendronate, 10 mg/d or 70 mg once per week or residronate, 5 mg/d or 35 mg once a week) and raloxifene (60 mg/d), a selective estrogen receptor modulator, have each been shown in randomized trials to increase bone mass density and decrease fracture rates. These agents, unlike estrogen, do not appear to have adverse effects on the endometrium or breast. Increased physical activity and adequate calcium (1000 to 1500 mg/d in two to three divided doses) and vitamin D (400 to 800 IU/d) intakes may also reduce the risk of osteoporosis-related fractures.

DEFINITE RISKS ■ Endometrial Cancer A combined analysis of 30 observational studies found a tripling of risk of endometrial cancer among short-term (1 to 5 years) users of unopposed estrogen and a nearly tenfold increased risk among users for 10 or more years. These findings are supported by results from the randomized Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, in which 24% of women assigned to unopposed estrogen for 3 years developed atypical endometrial hyperplasia, a premalignant lesion, compared to only 1% of women assigned to placebo. Use of a progestin, which opposes the effects of estrogen on the endometrium, eliminates these risks.

Venous Thromboembolism A recent meta-analysis of 12 studies—8 case-control, 1 cohort, and 3 randomized trials—found that current estrogen use was associated with a doubling of risk for venous thromboembolism in postmenopausal women. Relative risks of thromboembolic events were even greater (2.7 to 5.1) in the three trials included in the meta-analysis. Results from the WHI indicate a twofold increase in risk of venous and pulmonary thromboembolism.

Breast Cancer An increased risk of breast cancer has been found among current or recent estrogen users in observational studies; this risk is directly related to duration of use. In a meta-analysis of 51 case-control and cohort studies, short-term use (<5 years) of postmenopausal hormone therapy did not appreciably elevate breast cancer incidence, whereas long-term use (≥5 years) was associated with a 35% increase in risk. In contrast to findings for endometrial cancer, combined estrogen-progestin regimens appear to increase breast cancer risk more than estrogen alone. Data from randomized trials also indicate that HT raises breast cancer risk. In the WHI, women assigned to receive combination therapy for an average of 5.2 years were 26% more likely to develop breast cancer than women assigned to placebo but estrogen-only did not increase risk. In the Heart and Estrogen/progestin Replacement Study (HERS), 4 years of combination therapy was associated with a 27% increase in breast cancer risk. Although the latter finding was not statistically significant, the totality of evidence strongly implicates estrogen-progestin therapy in breast carcinogenesis.

PROBABLE OR UNCERTAIN RISKS AND BENEFITS ■ Coronary Heart Disease/Stroke Until recently, HT had been enthusiastically recommended as a possible cardioprotective agent. In the past three decades, multiple observational studies suggested, in the aggregate, that estrogen use leads to a 35 to 50% reduction in coronary heart disease incidence among postmenopausal women. The biologic plausibility of such an association is supported by data from randomized trials demonstrating that exogenous estrogen lowers plasma low-density lipoprotein (LDL) cholesterol and raises high-density lipoprotein (HDL) cholesterol levels by 10 to 15%. Administration of estrogen also favorably affects lipoprotein(a) levels, LDL oxidation, endothelial vascular function, and fibrinogen and plasminogen activator inhibitor-1. However, estrogen therapy also has unfavorable effects on other biomarkers of cardiovascular risk; it boosts triglyceride levels; promotes coagulation via factor VII, prothrombin fragments 1 and 2, and fibrinopeptide A elevations; and raises levels of the inflammatory marker C-reactive protein.

Randomized trials of estrogen or combined estrogen-progestin in women with preexisting cardiovascular disease have not confirmed the benefits reported in observational studies. In HERS, a secondary prevention trial designed to test the efficacy and safety of estrogen-progestin therapy on clinical cardiovascular outcomes, the 4-year incidence of coronary mortality and nonfatal myocardial infarction was similar in the active treatment and placebo groups, and a 50% increase in risk of coronary events was noted during the first year of the study among participants assigned to the active treatment group. Although it is possible that progestin may mitigate estrogen's benefits, the Estrogen Replacement and Atherosclerosis (ERA) trial indicated that angiographically determined progression of coronary atherosclerosis was unaffected by either opposed or unopposed estrogen treatment. Moreover, the Papworth Hormone Replacement Therapy Atherosclerosis Study, a trial of transdermal estradiol with and without norethindone, the Women's Estrogen for Stroke Trial (WEST), a trial of oral 17β-estradiol, and the EStrogen in the Prevention of ReInfarction Trial (ESPRIT), a trial of oral estradiol valerate, found no cardiovascular benefits of the regimens studied. Thus, in clinical trials, HT has not proved effective for the secondary prevention of cardiovascular disease in postmenopausal women.

Primary prevention trials also suggest an early increase in cardiovascular risk and absence of cardioprotection with postmenopausal HT. Results from the large-scale WHI suggest a deleterious cardiovascular effect of hormone therapy. Women assigned to 5 years of estrogen-progestin therapy were 29% more likely to develop coronary heart disease and 41% more likely to suffer a stroke than those assigned to placebo. In the estrogen-only arm of the WHI, a similar increase in stroke and no effect on CHD were observed. Further research is needed on clinical characteristics as well as on biomarkers that predict increases or decreases in cardiovascular risk associated with exogenous hormone therapy. Whether different doses, formulations, or routes of administration of hormone therapy will produce different cardiovascular effects remains uncertain.

Gallbladder Disease Several large observational studies report a two- to threefold increased risk of gallstones or cholecystectomy among postmenopausal women taking estrogen. In HERS, women randomized to 4 years of estrogen-progestin therapy had a 38% greater risk of developing gallbladder disease than those assigned to placebo, a risk that climbed to 48% after 2.7 additional years of observational follow-up.

Colorectal Cancer Observational studies have suggested that HT reduces risks of colon and rectal cancer, although the estimated magnitudes of the relative benefits ranged from 8 to 33% in various meta-analyses. In the WHI, the only trial to examine the issue, estrogen-progestin therapy was associated with a significant 37% reduction in colorectal cancer over a 5-year period; no benefit was seen with estrogen-only.

Cognitive Decline and Dementia A meta-analysis of 10 case-control and 2 cohort studies suggested that postmenopausal HT is associated with a 33% decreased risk of dementia. Subsequent randomized trials, however, failed to demonstrate any benefit of estrogen therapy on the progression of mild to moderate Alzheimer's disease and indicated a potential adverse effect of estrogen-progestin therapy on the incidence of dementia.

Ovarian Cancer and Other Disorders On the basis of limited observational and randomized data, it has been hypothesized that HT increases the risk of ovarian cancer and reduces the risk of type 2 diabetes mellitus. These hypotheses require confirmation in additional clinical trials.

APPROACH TO THE PATIENT

The rational use of postmenopausal hormone therapy requires balancing the potential benefits and risks. Figure 327-2 provides one approach to decision making. The clinician should first determine whether the patient has an indication for initiating HT. Relief of menopausal symptoms and prevention of osteoporosis are the most valid reasons. The benefits and risks of such therapy should then be reviewed with the patient, giving more emphasis to absolute than to relative measures of effect, and pointing out uncertainties in clinical knowledge where relevant. Potential side effects—especially vaginal bleeding that may result from use of combined estrogen-progestin formulations recommended for women with an intact uterus—should be noted. The patient's own preference regarding therapy should be elicited and factored into the decision. Contraindications to HT should be assessed routinely and include unexplained vaginal bleeding, active liver disease, venous thromboembolism, or history of endometrial cancer (except stage 1 without deep invasion) or breast cancer. Relative contraindications include hypertriglyceridemia (>400 mg/dL) and active gallbladder disease (in such cases, transdermal estrogen is an option). Neither primary nor secondary prevention of heart disease should be

viewed as an expected benefit of HT, and an increase in stroke and a small early increase in coronary artery disease risk should be considered. Nevertheless, such therapy may be appropriate, if the noncoronary benefits of treatment clearly outweigh risks. A woman who suffers an acute coronary event or stroke while on HT should stop therapy immediately.

Short-term use (<5 years) of HT is appropriate for relief of menopausal symptoms among women without contraindications to such use. However, such therapy should be avoided or considered only as a secondary option among women with preexisting heart disease or stroke due to their elevated baseline risk of future cardiovascular events. Women who have contraindications, or are opposed to HT, may derive benefit from the use of selective antidepressants, clonidine, or soy, and, for genitourinary symptoms, intravaginal estrogen creams or devices.

Long-term use (≥5 years) of HT is more problematic because a heightened risk of breast cancer must be factored into the decision. Reasonable candidates for such use include a small percentage of postmenopausal women and comprise those who have persistent severe vasomotor symptoms and/or have an increased risk of osteoporosis (e.g., those with osteopenia, a personal or family history of nontraumatic fracture, or a body mass index <22 kg/m^2), who also have no personal or family history of breast cancer in a first-degree relative or other contraindications, and who have a strong personal preference for therapy. Poor candidates are women with cardiovascular disease, those at low risk of osteoporosis, and those at increased risk of breast cancer (e.g., women who have a first-degree relative with breast cancer, susceptibility genes such as *BRCA1* or *BRCA2*, or a personal history of cellular atypia detected by breast biopsy). Even in reasonable candidates, strategies to minimize dose and duration of use should be employed. For example, women using hormone replacement to relieve intense vasomotor symptoms in early postmenopause should consider discontinuing therapy before 5 years, resuming it only if vasomotor symptoms persist and/or an increased risk of osteoporosis is evident. In the latter situation, alternative therapies such as bisphosphonates or selective estrogen receptor modulators (SERMs) should be considered. Research on androgen-containing preparations has been limited, particularly in terms of long-term safety.

In addition to HT, control of symptoms and prevention of chronic disease can be accomplished by life-style choices, including smoking abstention, adequate physical activity, and a healthy diet. An expanding array of pharmacologic options—e.g., bisphosphonates or SERMs for osteoporosis, and cholesterol-lowering or antihypertensive agents for cardiovascular disease—should also reduce the widespread reliance on hormone use. However, short-term HT may still benefit some women.

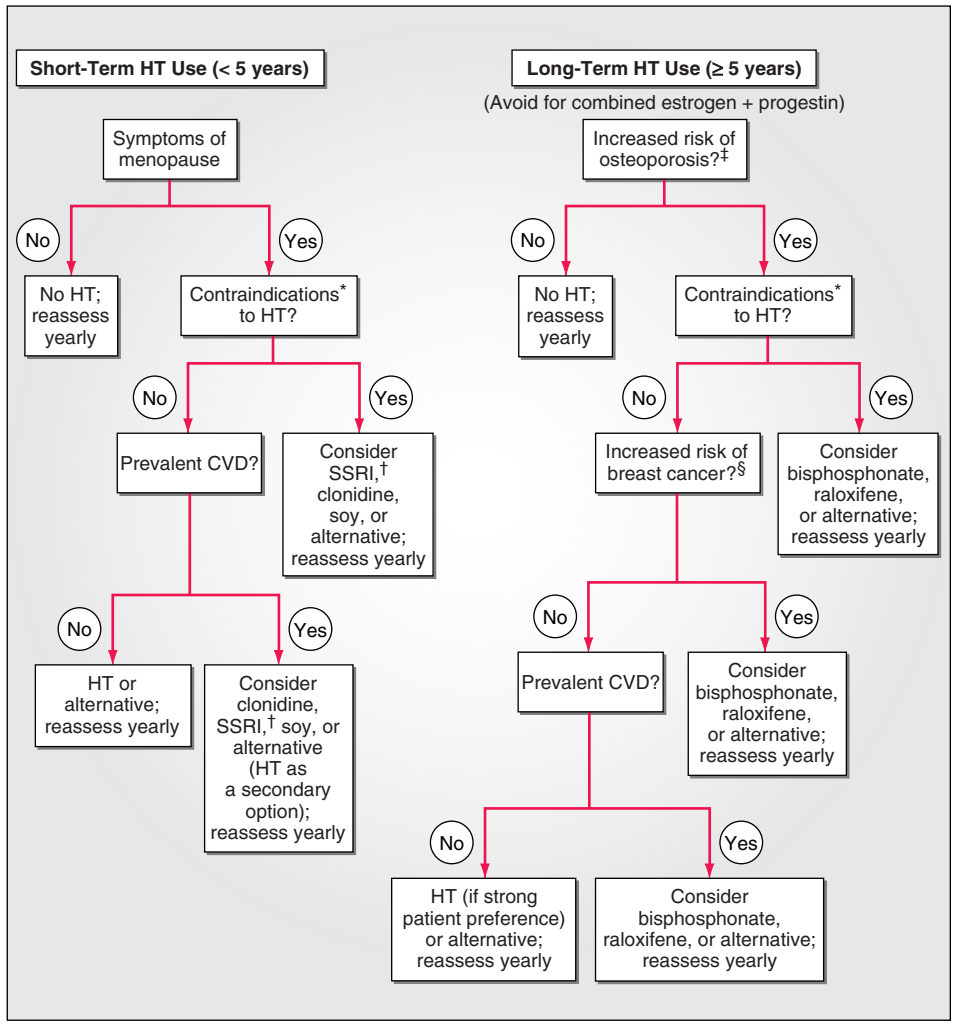

FIGURE 327-2 Flowchart for identifying appropriate candidates for short-term and long-term use of postmenopausal hormone therapy (HT). *Contraindications include unexplained vaginal bleeding, active liver disease, venous thromboembolism, or history of endometrial cancer (except stage 1 without deep invasion) or breast cancer. Relative contraindications include hypertriglyceridemia (>400 mg/dL) and active gallbladder disease (in such cases, transdermal estrogen is an option). †SSRI denotes selective serotonin reuptake inhibitor. ‡Increased risk of osteoporosis: documented osteopenia or osteoporosis, personal or family history of nontraumatic fracture, current smoking, or a body mass index <22 kg/m^2. §Increased risk of breast cancer: one or more first-degree relatives with breast cancer; susceptibility genes such as *BRCA1* or *BRCA2*; or a personal history of breast biopsy demonstrating atypia. CVD, cardiovascular disease. *(Adapted from Manson and Martin; with permission. Copyright © 2001 Massachusetts Medical Society. All rights reserved.)*

328 DISORDERS OF SEXUAL DIFFERENTIATION

John C. Achermann, J. Larry Jameson

Sexual differentiation begins in utero, but continues into young adulthood with the achievement of sexual maturity and reproductive capability. Sexual differentiation can be divided into three major components: chromosomal sex, gonadal sex, and phenotypic sex (Fig. 328-1). Abnormalities at each of these stages can result in disorders of sexual development. The child born with ambiguous genitalia requires urgent pediatric assessment, as some causes, such as congenital adrenal hyperplasia (CAH), are associated with potentially life-threatening adrenal crises. Early gender assignment and clear communication with parents about the diagnosis, prognosis, and treatment are essential. Disorders of sexual differentiation can also manifest later in life due to subtler forms of gonadal dysfunction [e.g., Klinefelter syndrome (KS)] and are often diagnosed by internists. There are many psychological, reproductive, and metabolic consequences associated with disorders of sexual differentiation; some of these patients avoid interactions with healthcare providers, and special effort is necessary to optimize long-term surgical, medical, and psychological management.

NORMAL SEXUAL DIFFERENTIATION

Chromosomal sex describes the sex chromosome complement (46,XY male; 46,XX female) that is established at the time of fertilization. The presence of a normal Y chromosome determines that testis development will occur, even in the presence of multiple X chromosomes (e.g., 47,XXY or 48,XXXY). The loss of an X chromosome impairs gonad development (45,X or 46,XY/45,X). Fetuses with no X material (45,Y) are not viable.

Gonadal sex refers to the assignment of gonadal tissue as testis or ovary. The embryonic gonad is bipotential, and can develop (at about 40 days gestation) into either a testis or ovary, depending on which genes are expressed. Ovarian development appears to be a constitutive pathway and occurs in the absence of specific genes that dictate testis determination and development (Fig. 328-2). Testis development is initiated by expression of the Y chromosome gene *SRY* (sex-determining region on the Y chromosome), which encodes an HMG box transcription factor. *SRY* is transiently expressed in cells destined to become Sertoli cells and serves as a pivotal switch to establish the testis lineage. Mutation of *SRY* prevents testis development in chromosomal 46,XY males, whereas translocation of *SRY* in 46,XX females is sufficient to induce testis development and a male phenotype. Other genes are necessary to continue testis development. *SOX9* (*SRY*-related HMG-box gene 9) is strikingly upregulated in the developing male gonad but is turned off in the female gonad. Transgenic expression of *SOX9* is sufficient to initiate testis formation in mice, and

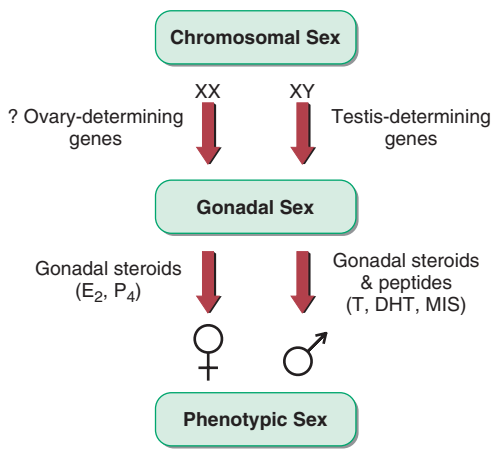

FIGURE 328-1 Sexual differentiation can be divided into three major components: chromosomal sex, gonadal sex, and phenotypic sex. T, testosterone; DHT, dihydrotestosterone; MIS, müllerian-inhibiting substance; E_2, estradiol; P_4, progesterone.

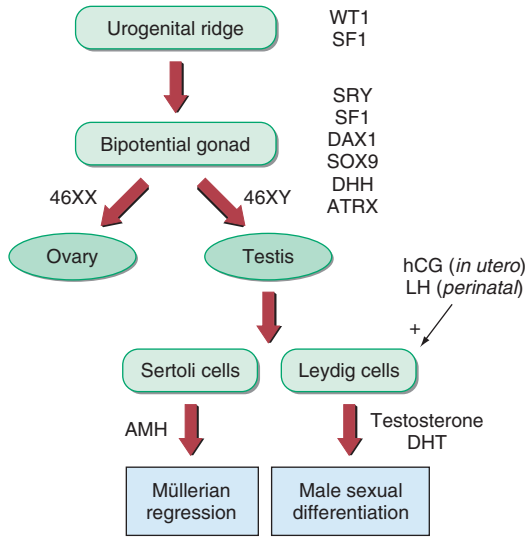

FIGURE 328-2 The genetic regulation of testis development. *WT1*, Wilms' tumor-related gene 1; *SF1*, steroidogenic factor 1; *SRY*, sex-related gene on the Y chromosome; *SOX9*, SRY-related HMG-box gene 9; *DHH*, desert hedgehog; *ATRX*, (α-thalassemia, mental retardation on the X); *DAX1*, dosage sensitive sex-reversal, adrenal hypoplasia congenita on the X chromosome, gene 1; AMH, anti-müllerian hormone (müllerian-inhibiting substance); DHT, dihydrotestosterone.

mutations that disrupt *SOX9* impair testis development. *WT1* (Wilms' tumor-related gene 1) is involved in renal and gonadal development. In the testis, *WT1* acts early in the genetic pathway and regulates the transcription of several genes including *SF1*, *DAX1*, and *AMH* (encoding *MIS*, müllerian-inhibiting substance). *SF1* (steroidogenic factor 1) encodes a nuclear receptor and is required for adrenal and gonadal development (both testis and ovary). It functions in cooperation with other transcription factors to regulate a large array of adrenal and gonadal genes, including many genes involved in steroidogenesis. The early expression pattern of *SF1* in the gonad parallels that of another orphan nuclear receptor, *DAX1* (dosage sensitive sex-reversal, adrenal hypoplasia congenita on the X chromosome, gene 1). In contrast to *SOX9*, *DAX1* is downregulated as the testis develops. Duplication of *DAX1* impairs testis development, possibly by antagonizing the function of SRY and SF1. Deletions or mutations of *DAX1*, on the other hand, lead to disordered formation of testis cords, revealing the exquisite sensitivity of the male sex-determining pathway to gene dosage effects. In addition to those mentioned above, human and murine mutations indicate that at least 10 other genes are also involved in gonadal differentiation and development as well as final positioning of the gonads.

It is unclear whether analogous "ovarian-determining genes" exist, or whether ovarian development only requires the absence of testis-determining genes. However, germ cells play a key role in supporting ovarian development and produce factors that inhibit the formation of testicular elements. This contrasts with the testis, which develops and undergoes steroidogenesis in the absence of germ cells. Once the ovary has formed, expression of a variety of specific genes is required for normal follicular development [e.g., follicle stimulating hormone (FSH) receptor, *GDF9*]. Steroidogenesis in the ovary requires the development of follicles containing granulosa cells and theca cells surrounding the oocytes (Chap. 326). Thus, there is minimal ovarian steroidogenesis until gonadotropins are produced at puberty.

Phenotypic sex refers to the structures of the external and internal genitalia, and secondary sex characteristics. The male phenotype requires the secretion of anti-müllerian hormone (AMH, müllerian-inhibiting substance) from Sertoli cells and testosterone from testicular

Leydig cells. AMH is a member of the TGF-β growth factor family and acts through specific receptors to cause regression of the müllerian structures (52 to 70 days gestation). At approximately 60 to 140 days gestation, testosterone supports the development of wolffian structures, including the epididymides, vasa deferentia, and seminal vesicles. Testosterone is also the precursor for dihydrotestosterone (DHT), a potent androgen that promotes development of the external genitalia, including the penis and scrotum (65–100 days, and beyond) (Fig. 328-3). The urogenital sinus develops into the prostate and prostatic urethra in the male and into the urethra and lower portion of the vagina in the female. The genital tubercle becomes the glans penis in the male and the clitoris in the female. The urogenital swellings form the scrotum or the labia majora, and the urethral folds fuse to form the shaft of the penis and the male urethra or the labia minora. In the female, wolffian ducts regress and the müllerian ducts form the fallopian tubes, uterus, and upper segment of the vagina. A normal female phenotype will develop in the absence of the gonad, but estrogen is needed for maturation of the uterus and breast at puberty.

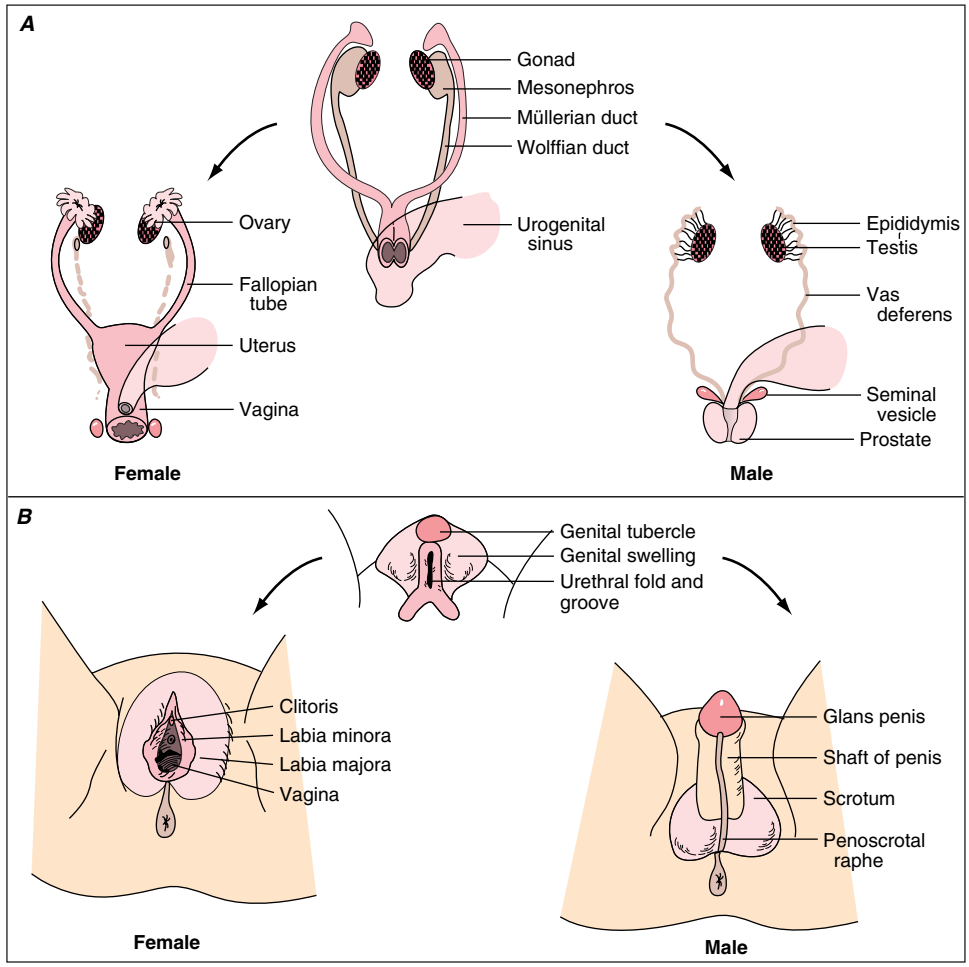

FIGURE 328-3 Normal sexual differentiation. *A.* Internal urogenital tract. *B.* External genitalia. [After JD Wilson, JE Griffin, in E Braunwald et al (eds): *Harrison's Principles of Internal Medicine*, 15th ed. New York, McGraw-Hill, 2001.]

DISORDERS OF CHROMOSOMAL SEX

Disorders of chromosomal sex result from abnormalities in the number or structure of the X or Y chromosomes (Table 328-1).

KLINEFELTER SYNDROME (47,XXY AND MOSAIC VARIANTS) ■ Pathophysiology

The classic form of Klinefelter syndrome (KS) (47,XXY) occurs following meiotic nondisjunction of the sex chromosomes during gametogenesis (40% during spermatogenesis, 60% during oogenesis) (Chap. 57). Mosaic forms of KS (46,XY/47,XXY) are thought to result from chromosomal mitotic nondisjunction within the zygote, and occur in at least 10% of individuals with this condition. Other chromosomal variants of KS (e.g., 48,XXYY; 48,XXXY) have been reported but are less common.

Clinical Features KS is characterized by small testes, infertility, gynecomastia, eunuchoid proportions, and poor virilization in phenotypic males. It has an incidence of 1 in 500 to 1000 men. In severe cases, individuals present prepubertally with small testes, or with impaired androgenization and gynecomastia at the time of puberty. Developmental delay and learning disabilities may be a feature. Later in life, eunuchoid features or infertility lead to the diagnosis. Testes are small and firm [median length 2.5 cm (4 mL volume); almost always $<$3.5 cm (12 mL)], and typically seem inappropriately small for the degree of androgenization. Biopsies are not usually necessary but reveal seminiferous tubule hyalinization and azoospermia. Other clinical features of KS are listed in Table 328-1. Plasma concentrations of follicle stimulating hormone (FSH) and luteinizing hormone (LH) are increased in most patients with 47,XXY (90 and 80%, respectively) and plasma testosterone is decreased (50–75%), reflecting primary gonadal failure. Estradiol is often increased because of chronic Leydig cell stimulation by LH and because of aromatization of androstenedione by adipose tissue; the increased ratio of estradiol/testosterone results in gynecomastia. Patients with mosaic forms of KS have less severe clinical features, larger testes, and sometimes achieve fertility.

℞ TREATMENT

Disfiguring gynecomastia should be treated by surgical reduction. Androgen supplementation (Chap. 325) improves virilization, libido, energy, and bone mineralization in underandrogenized men, but may worsen gynecomastia. Fertility has been achieved using in vitro fertilization in men with oligospermia, or with intracytoplasmic sperm injection when spermatids can be recovered from testicular biopsy. However, the risk of transmission of this chromosomal abnormality needs to be considered, and preimplantation screening may be desired.

TURNER SYNDROME (GONADAL DYSGENESIS) (45,X AND MOSAIC VARIANTS) ■ Pathophysiology

Approximately one-half of individuals with Turner syndrome (TS) have a 45,X karyotype, one-fourth have 46,XX/45,X mosaicism, and the remainder have structural abnormalities of the X chromosome such as X fragments, isochromosomes, or rings. The clinical features of TS result from haploinsufficiency of multiple X chromosomal genes (e.g., Short Stature Homeobox, *SHOX*). However, imprinted genes may also be affected when the inherited X has different parental origins.

Clinical Features TS is characterized by bilateral streak gonads, primary amenorrhea, short stature, and multiple congenital anomalies in phenotypic females. It affects approximately 1 in 2500 women and is diagnosed at different ages depending on the dominant clinical features (Table 328-1). Prenatally, a diagnosis of TS is usually made incidentally after chorionic villous sampling or amniocentesis for unrelated reasons, such as advanced maternal age. Prenatal ultrasound findings include increased nuchal translucency and reduced fetal growth. The postnatal diagnosis of TS should be considered in female neonates or

TABLE 328-1 *Clinical Features of the Disorders of Chromosomal Sex*

Disorder	Common Chromosomal Complement	Gonad	External Genitalia	Internal Genitalia	Breast Development	Clinical Features
Klinefelter syndrome	47,XXY or 46,XY/47,XXY	Hyalinized testes	Male	Male	Gynecomastia	Small testes, azoospermia, decreased facial and axillary hair, decreased libido, tall stature & increased leg length, decreased penile length, increased risk of breast tumors, learning difficulties, obesity, varicose veins
Turner syndrome	45,X or 46,XX/45,X	Streak gonad or immature ovary	Female	Hypoplastic female	Immature female	Infancy: lymphedema, web neck, shield chest, low set hair line, cardiac defects and coarctation of the aorta, urinary tract malformations & horseshoe kidney Childhood: short stature, cubitus valgus, short neck, short 4th metacarpals, hypoplastic nails, micrognathia, scoliosis, otitis media & sensorineural hearing loss, ptosis & amblyopia, multiple nevi & keloid formation, autoimmune thyroid disease, visuo-spatial learning difficulties Adulthood: pubertal failure & primary amenorrhea, hypertension, obesity, dyslipidemia, impaired glucose tolerance & insulin resistance, cardiovascular disease, aortic root dilatation, osteoporosis, inflammatory bowel disease, chronic hepatic dysfunction, increased risk of colon cancer, hearing loss
Mixed gonadal dysgenesis	46,XY/45,X	Testis or streak gonad	Variable—usually ambiguous	Variable	Usually male	Short stature, increased risk of gonadal tumors, some Turner syndrome features
True hermaphroditism	46,XY/46,XX	Testis & ovary or ovotestis	Variable—usually ambiguous	Variable	Gynecomastia	Increased risk of gonadal tumors

infants with lymphedema, nuchal folds, low hairline, or left-sided cardiac defects, and in girls with unexplained growth failure or pubertal delay. Although limited spontaneous pubertal development occurs in up to 30% of girls with TS (10%, 45,X; 30–40%, 45,X/46,XY), and approximately 2% reach menarche, the vast majority of women with TS develop complete ovarian failure. This diagnosis should be considered, therefore, in all women who present with primary or secondary amenorrhea and elevated gonadotropin levels.

TREATMENT

The management of girls and women with TS requires a multidisciplinary approach because of the number of potentially involved organ systems. Detailed cardiac and renal evaluation should be performed at the time of diagnosis. Individuals with congenital heart defects (CHD) (30%) (bicuspid aortic valve, 30 to 50%; coarctation of the aorta, 30%; aortic root dilatation, 5%) require long-term follow-up by an experienced cardiologist, antibiotic prophylaxis for dental or surgical procedures, and serial imaging of aortic root dimensions, as progressive aortic root dilatation can occur. Individuals found to have congenital renal and urinary tract malformations (30%) are at risk for urinary tract infections, hypertension, and nephrocalcinosis. Hypertension can occur independent of cardiac and renal malformations, and should be monitored and treated as in other patients with essential hypertension. Clitoral enlargement or other evidence of virilization suggests the presence of covert, translocated Y chromosomal material and is associated with increased risk of gonadoblastoma, apparently the consequence of Y chromosomal genes distinct from *SRY*. Regular assessment of thyroid function, weight, dentition, hearing, speech, vision, and educational issues should be performed during childhood, and counseling about long-term growth and fertility issues should be provided. Patient support groups are active throughout the world.

The treatment of short stature in children with TS remains a challenge, as untreated final height rarely exceeds 150 cm. High-dose recombinant growth hormone stimulates growth rate in children with TS and may be used alone or in combination with low doses of the nonaromatizable anabolic steroid oxandrolone (up to 0.05 mg/kg per d) in the older child (>8 years). However, final height increments are often modest (5–10 cm), and individualization of treatment regimens to response may be beneficial. Girls with evidence of gonadal failure require estrogen replacement to induce breast and uterine development, to support growth, and to maintain bone mineralization. Low-dose estrogen therapy (approximately one-sixth of the adult dose, 2 to 5 μg/d ethinylestradiol) is initiated between 12 to 14 years of age and increased gradually to induce feminization over a 2 to 3 year period. Progestins are later added to regulate withdrawal bleeds, and some women with TS have now achieved successful pregnancy after ovum donation and in vitro fertilization. Long-term follow-up of women with

TABLE 328-2 *Disorders Causing Undervirilization in Karyotypic Males (46,XY)*

- Disorders of testis development
  - True hermaphroditism (46,XY)
  - Gonadal dysgenesis
  - Absent testis syndrome
- Disorders of androgen synthesis
  - LH receptor mutations
  - Smith-Lemli-Opitz syndrome
  - Steroidogenic acute regulatory protein mutations
  - Cholesterol side chain cleavage *(CYP11A1)* deficiency
  - 3β-Hydroxysteroid dehydrogenase 2 *(HSD3B2)* deficiency
  - 17α-Hydroxylase/17,20-lyase *(CYP17)* deficiency
  - 17β-Hydroxysteroid dehydrogenase 3 *(HSD17B3)* deficiency
  - 5α-Reductase 2 deficiency *(SRD5A2)*
  - Aromatase overexpression
- Disorders of androgen action
  - Androgen Insensitivity Syndrome
  - Androgen receptor cofactor defects
- Other disorders of male reproductive tract
  - Persistent müllerian duct syndrome
  - Isolated hypospadias
  - Cryptorchidism

TS involves careful surveillance of sex hormone replacement and reproductive function, bone mineralization, cardiac function and aortic root dimensions, blood pressure, weight and glucose tolerance, hepatic and lipid profiles, thyroid function, and hearing.

MIXED GONADAL DYSGENESIS (46,XY/45,X) Mixed gonadal dysgenesis typically results from 46,XY/45,X mosaicism. The phenotype of patients with this condition varies considerably, depending on the proportion and distribution of 46,XY cells. Although some patients have a predominantly female phenotype with somatic features of TS, streak gonads, and müllerian structures, other 46,XY/45,X individuals have a male phenotype and testes, and the diagnosis is made incidentally after amniocentesis or during investigation of infertility. In practice, most children who present to clinicians have ambiguous genitalia and variable somatic features. A female sex-of-rearing is often chosen (60%) if phallic development is poor, uterine structures are present, and if height potential is limited. However, gonadectomy is indicated to prevent further androgen secretion and to prevent development of gonadoblastoma (up to 25%). Individuals raised as males may require reconstructive surgery for hypospadias and removal of streak gonads. Scrotal testes can be preserved, but need regular examination for tumor development. Biopsy for carcinoma in situ is recommended in adolescence and testosterone supplementation may be required for virilization in puberty.

TRUE HERMAPHRODITISM (46,XY/46,XX) True hermaphroditism (TH) occurs when both an ovary and testis, or when an ovotestis, are found in one individual. For unclear reasons, gonadal asymmetry most often occurs with a testis on the right and an ovary on the left. True hermaphroditism due to 46,XY/46,XX mosaicism is rare and has a variable phenotype depending on the proportion of each cell line.

DISORDERS OF GONADAL AND PHENOTYPIC SEX

The clinical features of patients with disorders of gonadal and phenotypic sex are divided into the undervirilization of 46,XY males or inappropriate virilization of 46,XX females. These disorders comprise a spectrum of phenotypes ranging from complete "sex-reversal" (e.g., 46,XY phenotypic females or 46,XX males) to ambiguous genitalia.

UNDERVIRILIZED MALES (46,XY) (MALE PSEUDOHERMAPHRODITISM) Undervirilization of the male (46,XY) reflects defects in androgen production or action. It can result from disorders of testis development, defects of androgen synthesis, or resistance to testosterone and DHT (Table 328-2).

Disorders of Testis Development ■ *TESTICULAR DYSGENESIS* Patients with *pure gonadal dysgenesis* have streak gonads, müllerian structures (due to insufficient MIS secretion) and a complete absence of virilization.

TABLE 328-3 *Genetic Causes of Undervirilization of Karyotypic Males (46,XY)*

Gene	Inheritance	Gonad	Uterus	External Genitalia	Associated Features
DISORDERS OF TESTIS DEVELOPMENT

SRD5A2	AR	Testis	−	Ambiguous	Partial virilization at puberty, ↑ testosterone: dihydrotestosterone ratio.
DISORDERS OF ANDROGEN ACTION					
Androgen receptor	X	Testis	−	Female, ambiguous, micropenis or normal male	Phenotypic spectrum from complete androgen insensitivity syndrome (female external genitalia) and partial androgen insensitivity (ambiguous) to normal male genitalia and infertility

Note: AR, autosomal recessive; AD, autosomal dominant; *WT1*, Wilms' tumor-related gene 1; WAGR, Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation; *SF1*, steroidogenic factor 1; *SRY*, sex-related gene on the Y chromosome; *SOX9*, *SRY*-related HMG-box gene 9; *DHH*, desert hedgehog; *ATRX*, (α-thalassemia, mental retardation on the X); *ARX*, aristaless related homeobox, X-linked; *DAX1*, dosage sensitive sex-reversal, adrenal hypoplasia congenita on the X chromosome, gene 1; *WNT4*, wingless-type mouse mammary tumor virus integration site, 4; *LHR*, LH receptor; *DHCR7*, sterol 7δ reductase; *STAR*, steroidogenic acute regulatory protein; *CYP11A1*, P450 cholesterol side-chain cleavage; *HSD3B2*, 3β-hydroxysteroid dehydrogenase type 2; *CYP17*, 17α-hydroxylase and 17,20-lyase; *HSD17B3*, 17β-hydroxysteroid dehydrogenase type 3; *CYP19*, aromatase; *SRD5A2*, 5α-reductase type 2.

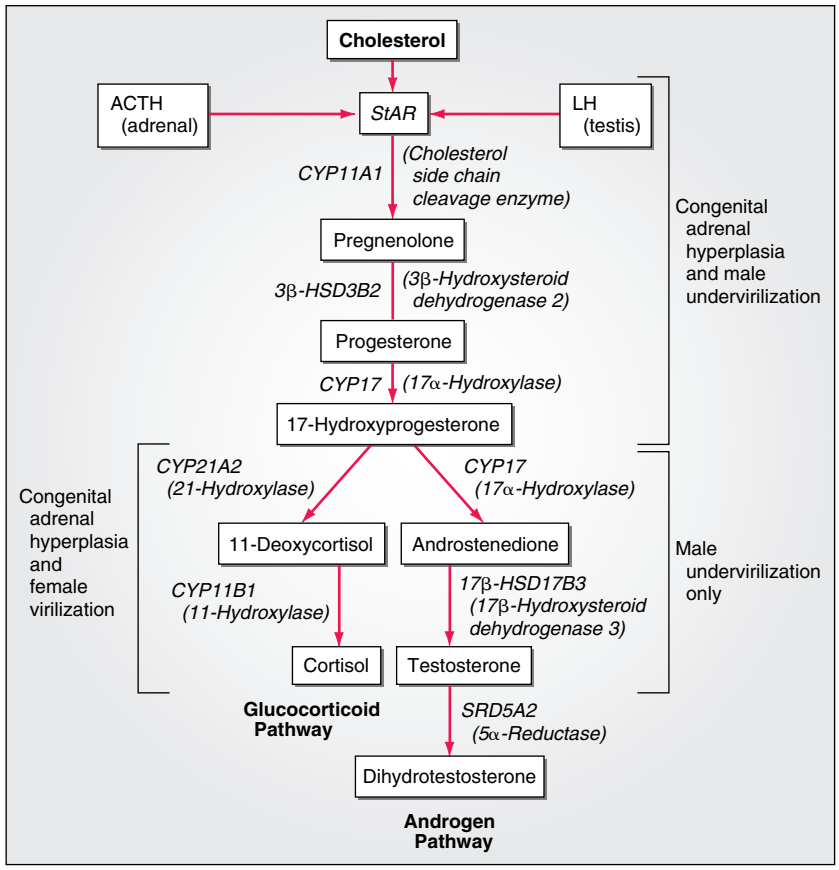

FIGURE 328-4 Pathways of glucocorticoid and androgen synthesis. Defects in *CYP21A2* and *CYP11B1* shunt steroid precursors into the androgen pathway and cause virilization of 46,XX females. Testosterone and dihydrotestosterone are synthesized in the testicular Leydig cells. Defects in enzymes involved in androgen synthesis result in undervirilization of 46,XY males. StAR, steroidogenic acute regulatory protein. [After JD Wilson, JE Griffin, in E Braunwald et al (eds): *Harrison's Principles of Internal Medicine*, 15th ed. New York, McGraw-Hill, 2001.]

Patients with *dysgenetic testes* produce enough MIS to regress the uterus and, sometimes, sufficient testosterone for partial virilization. Gonadal dysgenesis can result from mutations or deletions of testis-promoting genes (*WT1*, *SF1*, *SRY*, *SOX9*, *DAX1*, *DHH*, *ATRX*, *ARX*; also *DMRT*, and *SOX8* loci) or overexpression of factors that impair testis development when excessive (*WNT4*, *DAX1*) (Table 328-3). Associated clinical features may be present, reflecting additional functional roles for these genes. For example, renal dysfunction occurs in patients with specific *WT1* mutations (Denys-Drash and Frasier syndromes), primary adrenal failure occurs with *SF1* mutations, and severe cartilage abnormalities (campomelic dysplasia) are the predominant clinical feature of *SOX9* mutations. Dysgenetic testes should be removed to prevent malignancy, and estrogens can be used to induce secondary sex characteristics in 46,XY individuals raised as females. *Absent (vanishing) testis syndrome* reflects regression of the testis during development. The etiology is unknown but the absence of müllerian structures indicates adequate secretion of MIS in utero. Early testicular regression causes impaired virilization. Individuals raised as female should receive estrogen replacement at puberty. More frequently, late regression results in an otherwise normal male with anorchia. These individuals can be offered testicular prostheses and should receive androgen replacement in adolescence.

Disorders of Androgen Synthesis Defects in the pathway that regulates androgen synthesis (Fig. 328-4) cause undervirilization of the male fetus (Table 328-3). Müllerian regression is unaffected because Sertoli cell function is preserved.

LH RECEPTOR Mutations in the LH receptor cause Leydig cell hypoplasia and androgen deficiency. Defects of LH receptor synthesis or function preclude hCG (human chorionic gonadotropin) stimulation of Leydig cells in utero, as well as LH stimulation of Leydig cells late in gestation and during the neonatal period. As a result, testosterone and DHT synthesis are insufficient for normal virilization of the internal and external genitalia, causing a spectrum of phenotypes that range from complete undervirilization to micropenis, depending on the severity of the mutation.

CONGENITAL ADRENAL HYPERPLASIA (CAH) Mutations in the genes that regulate cholesterol uptake and modification [*steroidogenic acute regulatory protein (StAR)*, *CYP11a*] affect both adrenal and gonadal steroidogenesis, and result in *congenital lipoid adrenal hyperplasia* (Chap. 321). Defects in *3β-hydroxysteroid dehydrogenase type 2* (*HSD3B2*) also cause adrenal insufficiency, but the accumulation of dehydroepiandrosterone (DHEA) has a mild virilizing effect. Patients with congenital adrenal hyperplasia due to *17α-hydroxylase (CYP17) deficiency* have variable undervirilization and develop hypertension due to the potent salt-retaining effects of corticosterone and 11-deoxycorticosterone. Some mutations in *CYP17* selectively impair 17,20 lyase activity, without altering 17α-hydroxylase activity, leading to undervirilization without mineralocorticoid excess and hypertension.

SEX-STEROID PATHWAY ENZYMES Defects in *17β-hydroxysteroid dehydrogenase type 3 (HSD17B3)* and *5α-reductase type 2 (SRD5A2)* interfere with the synthesis of testosterone and DHT, respectively (Fig. 328-4). These conditions are characterized by minimal masculinization in childhood, but some phallic development can occur during adolescence due to the action of other enzyme isoforms. Individuals with *5α-reductase type 2* deficiency have normal wolffian structures and do not develop breast tissue. In some cultures, these individuals change gender role behavior from female to male at puberty, because the increase in testosterone induces muscle mass and other virilizing features. DHT cream can improve prepubertal phallic growth in patients raised as male. Individuals raised as female require gonadectomy, cosmetic surgery, and estrogen replacement.

Disorders of Androgen Action ■ *ANDROGEN INSENSITIVITY SYNDROME* Mutations in the androgen receptor (AR) cause resistance to androgen (testosterone, DHT) action or the *androgen insensitivity syndrome (AIS)*. AIS is a spectrum of disorders that affects at least 1 in 100,000 chromosomal males. Because the androgen receptor is X-linked, only males are affected and maternal carriers are phenotypically normal. XY individuals with *complete AIS (testicular feminization syndrome)* have a female phenotype, normal breast development, a short vagina but no uterus (because MIS production is normal), scanty pubic and axillary hair, and female psychosexual orientation. Gonadotropins and testosterone levels can be low, normal, or elevated, depending on the degree of androgen resistance and the contribution of estradiol to feedback inhibition of the hypothalamic-pituitary gonadal axis. Most patients present with inguinal herniae (containing testes) in childhood or with primary amenorrhea in adulthood. Gonadectomy is usually performed, as there is a low risk of malignancy, and estrogen replacement is prescribed. Surgical reconstruction or mechanical dilatation of the vagina permits sexual intercourse. *Partial AIS (Reifenstein syndrome)* results from less severe AR mutations. Patients often present in infancy with perineoscrotal hypospadias, small cryptorchid testes, and with gynecomastia at the time of puberty. Those individuals raised as males require hypospadias repair in childhood and breast reduction in adolescence. Supplemental androgens rarely improve virilization significantly, as endogenous androgens are already increased. More severely undervirilized patients present with clitoral enlargement and labial fusion, and may be raised as females. The surgical and psychosexual management of both these groups of patients is complex and requires

TABLE 328-4 Disorders Causing Virilization in Karyotypic Females (46,XX)

Nonvirilizing disorders of the female reproductive tract
Ovarian dysgenesis
Müllerian agenesis
Vaginal agenesis

active involvement of the parents and the patient during the appropriate stages of development. *Azoospermia* and male-factor infertility has also been described in association with mild loss of function mutations in the androgen receptor. Trinucleotide (CAG) repeat expansion, from a mean of 22 repeats to greater than 40 repeats, within a highly polymorphic region of the androgen receptor is associated with spinal and bulbar muscular atrophy (also known as Kennedy disease). These patients may show evidence of partial androgen insensitivity in adolescence or adulthood (e.g., gynecomastia).

OTHER DISORDERS AFFECTING MALES (46,XY) *Persistent Müllerian Duct syndrome* is the presence of a uterus in an otherwise normal male. This condition can result from mutations in AMH or its receptor (AMHR2). The uterus may be removed, but damage to vasa deferentia must be avoided. *Isolated hypospadias* occurs in approximately 1 in 200 males and is treated by surgical repair. Most cases are idiopathic, although evidence of penoscrotal hypospadias and bilateral cryptorchidism require investigation for an underlying genetic disorder (e.g., defect in testosterone action). *Cryptorchidism* (unilateral) affects up to 3% of boys at birth. Orchidopexy should be considered if the testis has not descended by early childhood. Bilateral cryptorchidism occurs less frequently, and should raise suspicion of gonadotropin deficiency or disorders of sexual development. A subset of patients with cryptorchidism have mutations in the insulin-like 3 (*INSL3*) gene or its receptor LGR8 (also known as *GREAT*), which mediates normal testicular descent.

VIRILIZED FEMALES (46,XX) (FEMALE PSEUDOHERMAPHRODITISM) Inappropriate virilization of females can occur when the gonad (ovary) contains androgen-secreting testicular material, or after increased androgen exposure (Table 328-4).

Gonadal Transdifferentiation Testicular tissue can develop in 46,XX true hermaphrodites, and in 46,XX males with a translocation of *SRY* or duplication of *SOX9* (Table 328-5).

Increased Androgen Exposure ■ *21-HYDROXYLASE DEFICIENCY* The *classic form* of 21-hydroxylase deficiency has an incidence of between 1 in 5000 and 15,000 and is the most frequent cause of virilization in chromosomal 46,XX females (Table 328-5; Chap. 321). Affected individuals are homozygous or compound heterozygous for severe mutations in the enzyme 21-hydroxylase (*CYP21A2*). This mutation causes a block in adrenal glucocorticoid and mineralocorticoid synthesis, increasing 17-hydroxyprogesterone, and shunting steroid precursors into the androgen synthesis pathway (Fig. 328-4). Glucocorticoid insufficiency causes a compensatory elevation of adrenocorticotropin (ACTH), resulting in adrenal hyperplasia and additional synthesis of steroid precursors proximal to the enzymatic block. Increased androgen synthesis *in utero* causes virilization of the female fetus. Ambiguous genitalia are seen at birth, with varying degrees of clitoral enlargement and labial fusion. Infants with the *salt-wasting* form of 21-hydroxylase deficiency develop primary adrenal failure in the first few weeks of life. Thus, a diagnosis of 21-hydroxylase deficiency should be considered in any baby with ambiguous genitalia; a salt-wasting crisis is a potentially life-threatening event. Males with this syndrome have no genital abnormalities at birth but are equally susceptible to adrenal insufficiency and salt-losing crises. If untreated, males undergo premature virilization (pseudopuberty) because of increased androgen levels during childhood. Females with the *classic simple virilizing* form of this disorder also present with genital ambiguity, but do not develop salt loss.

The diagnosis of classic 21-hydroxylase deficiency is made by neonatal screening tests for increased 17-hydroxyprogesterone in some centers. In most cases, 17-hydroxyprogesterone is markedly increased. In adults, ACTH stimulation (0.25 mg cosyntropin IV) with assays for 17-hydroxyprogesterone at 0 and 30 min can be useful for detecting nonclassic 21-hydroxylase deficiency and heterozygotes (Chap. 321).

℞ TREATMENT

Glucocorticoids must be given to correct the cortisol insufficiency and to suppress ACTH stimulation, thereby preventing further virilization, rapid skeletal maturation, and the development of polycystic ovaries. Typically, hydrocortisone (10 to 20 mg/m^2 per d in divided doses) is used with a goal of suppressing 17-hydroxyprogesterone to <1000 ng/

TABLE 328-5 Genetic Causes of Virilization of Karyotypic Females (46,XX)

CYP19	AR	Ovary	+	Ambiguous	Maternal virilization during pregnancy, absent breast development at puberty
Glucocorticoid receptor	AR	Ovary	+	Ambiguous	↑ ACTH, 17-hydroxyprogesterone and cortisol; failure of dexamethasone suppression

Note: AR, autosomal recessive; *SRY*, sex-related gene on the Y chromosome; *SOX9*, SRY-related HMG-box gene 9; CAH, congenital adrenal hyperplasia; *HSD3B2*, 3β-hydroxysteroid dehydrogenase type 2; *CYP21A2*, 21-hydroxylase; *CYP11B1*, 11β-hydroxylase; *CYP19*, aromatase; ACTH, adrenocorticotropin.

dL. It is difficult, however, to fully suppress androgen production without using excessive glucocorticoid treatment, which can impair growth and predispose to obesity. Older adolescents and adults are often treated with dexamethasone at night to provide more complete ACTH suppression. In very severe cases, adrenalectomy has been advocated but incurs the risks of major surgery and total adrenal insufficiency. Salt-wasting conditions are treated with mineralocorticoid replacement. Infants usually need salt supplements up to the first year of life. Plasma renin activity and electrolytes are used to monitor mineralocorticoid replacement. Newer therapeutic approaches, such as antiandrogens and aromatase inhibitors (to block premature epiphyseal closure) are under evaluation. Parents and patients should be aware of the need for increased doses of steroids during sickness and patients should carry medic alert systems.

Girls with significant virilization usually undergo clitoral reduction (maintaining the glans and nerve supply) and vaginal reconstruction, but the optimal timing of these procedures is the subject of debate. Surgical revision or regular vaginal dilatation may be needed in adolescence or adulthood, and long-term psychological support and psychosexual counseling may be appropriate.

Prenatal treatment of 21-hydroxylase deficiency by the administration of dexamethasone to mothers has been shown to reduce the degree of virilization in affected female fetuses. However, treatment on the mother and child must be started before 9 weeks gestation and ideally before 6–7 weeks; long-term effects are still under evaluation.

OTHER CAUSES Increased androgen synthesis can also occur in CAH due to defects in *11β-hydroxylase (CYP11B1)* and *3β-hydroxysteroid dehydrogenase type 2 (HSD3B2)*, and with mutations in the genes encoding *aromatase (CYP19)* and the glucocorticoid receptor. Increased androgen exposure *in utero* can occur with maternal virilizing tumors and with ingestion of androgenic compounds.

OTHER DISORDERS AFFECTING FEMALES (46,XX) *Congenital absence of the vagina* occurs in association with *müllerian agenesis* or *hypoplasia* as part of the Mayer-Rokitansky-Kuster-Hauser syndrome. This diagnosis should be considered in otherwise phenotypically normal females with primary amenorrhea. Rarer associated features include renal (agenesis) and cervical spinal abnormalities.

ACKNOWLEDGMENT

We are grateful to JD Wilson and JE Griffin, the authors of* Disorders of Sexual Differentiation *in the 15th edition of* Harrison's, *for contributions to this chapter.

329 ENDOCRINE TUMORS OF THE GASTROINTESTINAL TRACT AND PANCREAS

Robert T. Jensen

Gastrointestinal neuroendocrine tumors (NETs) are tumors derived from the diffuse neuroendocrine system of the gastrointestinal (GI) tract, which is composed of amine- and acid-producing cells with different hormonal profiles, depending on the site of origin. The tumors they produce can be generally divided into carcinoid tumors and pancreatic endocrine tumors (PETs). These tumors were originally classified as APUDomas (for *a*mine *p*recursor *u*ptake and *d*ecarboxylation), as were pheochromocytomas, melanomas, and medullary thyroid carcinomas because they share certain cytochemical features as well as various pathologic, biologic, and molecular features (Table 329-1). APUDomas were thought to have a similar embryonic origin from neural crest cells, but the peptide-secreting cells are not of neuroectodermal origin.

CLASSIFICATION/PATHOLOGY/TUMOR BIOLOGY OF NETS

NETs are composed of monotonous sheets of small round cells with uniform nuclei; mitoses are uncommon. They can be tentatively identified on routine histology; however, these tumors are principally recognized by their histologic staining patterns due to shared cellular proteins. Historically, silver staining was used and tumors were classified as showing an argentaffin reaction if they took up and reduced silver or as being argyrophilic if they did not reduce it. Immunocytochemical localization of chromogranins (A, B, C), neuron-specific enolase, or synaptophysin, which are all neuroendocrine cell markers, are now used (Table 329-1). Chromogranin A is the most widely used.

Ultrastructurally, these tumors possess electron-dense neurosecretory granules and frequently contain small clear vesicles that correspond to synaptic vesicles of neurons. NETs synthesize numerous peptides, growth factors, and bioactive amines that may be ectopically secreted, giving rise to a specific clinical syndrome (Table 329-2). The diagnosis of the specific syndrome requires the clinical features of the disease and cannot be made from the immunocytochemistry results only. The presence or absence of a specific clinical syndrome cannot be predicted from the immunocytochemistry (Table 329-1). Furthermore, pathologists cannot distinguish between benign and malignant NETs unless metastases or invasion are present.

Carcinoid tumors are frequently classified according to their anatomic area of origin (i.e., foregut, midgut, hindgut), because tumors with similar areas of origin share functional manifestations, histochemistry, and secretory products (Table 329-3). Foregut tumors generally have a low serotonin (5HT) content, are argentaffin-negative but argyrophilic, occasionally secrete adrenocorticotropic hormone (ACTH) or 5-hydroxytryptophan (5HTP) causing an atypical carcinoid syndrome (Fig. 329-1), are often multihormonal, and may metastasize to bone. They uncommonly produce a clinical syndrome due to secreted products. Midgut carcinoids are argentaffin-positive, have a high serotonin content, most frequently cause the typical carcinoid syndrome when they metastasize (Table 329-3, Fig. 329-1), release serotonin and tachykinins (substance P, neuropeptide K, substance K), rarely secrete 5HTP or ACTH, and uncommonly metastasize to bone. Hindgut carcinoids (rectum, transverse and descending colon) are argentaffin-negative, often argyrophilic, rarely contain serotonin or cause the carcinoid syndrome (Fig. 329-1, Table 329-3), rarely secrete 5HTP or ACTH, contain numerous peptides, and may metastasize to bone.

PETs can be classified into nine well-established specific functional syndromes, two possible specific functional syndromes (PETs secreting calcitonin or renin), and nonfunctional PETs [pancreatic polypeptide (PP)-secreting tumors; PPomas] (Table 329-2). Each of the functional syndromes is associated with symptoms due to the specific hormone released. In contrast, nonfunctional PETs release no products that cause a specific clinical syndrome. "Nonfunctional" is a misnomer in the strict sense because they frequently secrete a number of peptides (PP, chromogranin A, ghrelin, neurotensin); however, they cause no specific clinical syndrome. The symptoms caused by nonfunctional PETs are entirely due to the tumor per se.

Carcinoid tumors can occur in almost any GI tissue; however, at present most (70%) originate from one of three sites: bronchus, jejuno-

TABLE 329-1 General Characteristics of GI Neuroendocrine Tumors [Carcinoids, Pancreatic Endocrine Tumors (PETs)]

I. Share general neuroendocrine cell markers
  A. Chromogranins (A, B, C) are acidic monomeric soluble proteins found in the large secretory granules; chromogranin A is most widely used
  B. Neuron-specific enolase (NSE) is the γ-γ dimer of the enzyme enolase and is a cytosolic marker of neuroendocrine differentiation
  C. Synaptophysin is an integral membrane glycoprotein of 38,000 molecular weight found in small vesicles of neurons and neuroendocrine tumors
II. Pathologic similarities
  A. All are APUDomas showing *a*mine *p*recursor *u*ptake and *d*ecarboxylation
  B. Ultrastructurally they have dense-core secretory granules (>80 nm)
  C. Histologically appear similar with few mitoses and uniform nuclei
  D. Frequently synthesize multiple peptides/amines, which can be detected immunocytochemically but may not be secreted
  E. Presence or absence of clinical syndrome or type cannot be predicted by immunocytochemical studies
  F. Histologic classifications do not predict biologic behavior; only invasion or metastases establishes malignancy
III. Similarities of biologic behavior
  A. Generally slow growing, but a proportion are aggressive
  B. Secrete biologically active peptides/amines, which can cause clinical symptoms
  C. Generally have high densities of somatostatin receptors, which are used for both localization and treatment.
IV. Similarities/differences in molecular abnormalities
  A. Similarities
    1. Uncommon—alterations in common oncogenes (*ras*, *jun*, *fos*, etc)
    2. Uncommon—alterations in common tumor-suppressor genes (p53, retinoblastoma).
    3. Alterations at MEN-1 gene locus (11q13) and $p16^{INK4a}$ (9p21) occur in a proportion (10–30%).
  B. Differences
    1. PETs—loss of 3p (8–47%), 3q (8–41%), 11q (21–62%), 6q (18–68%); gains at 17q (10–55%), 7q (16–68%).
    2. Carcinoids—loss of 18q (38–67%) >18p (33–43%) >9p (21%); gains at 17q, 19p (57%).

Note: MEN, multiple endocrine neoplasia; PETs, pancreatic endocrine tumors.

ileum, or colon/rectum (Table 329-3). In the past, carcinoid tumors most frequently occurred in the appendix (i.e., 40%); however, the bronchus/lung and small intestine are now the most common sites. Overall, GI carcinoids are the most common site for these tumors, comprising 64%, with the respiratory tract a distant second at 28%.

The term *pancreatic endocrine tumor*, although widely used and therefore retained here, is also a misnomer because these tumors can occur either almost entirely in the pancreas (insulinomas, glucagonomas, nonfunctional PETs, PETs causing hypercalcemia) or at both pancreatic and extrapancreatic sites [gastrinomas, VIPomas (VIP, vasoactive intestinal peptide), somatostatinomas, GRFomas (GRF, growth hormone–releasing factor)]. PETs are also called *islet cell tumors*; however, this term is discouraged because many do not originate from the islets and they can occur at extrapancreatic sites.

The exact incidence of carcinoid tumors or PETs varies according to whether only symptomatic or all tumors are considered. The incidence of clinically significant carcinoids is 7 to 13 cases per million population per year, whereas any malignant carcinoids at autopsy are reported in 21 to 84 cases per million population per year. Clinically significant PETs have a prevalence of 10 cases per million population, with insulinomas, gastrinomas, and nonfunctional PETs having an incidence of 0.5 to 2 cases per million population per year (Table 329-2). VIPomas are 2- to 8-fold less common, glucagonomas are 17- to 30-fold less common, and somatostatinomas the least common. In autopsy studies 0.5 to 1.5% of all cases have a PET; however, in <1 in 1000 cases was a functional tumor present.

Both carcinoid tumors and PETs commonly show malignant behavior (Tables 329-2, 329-3). Except for insulinomas, in which <10% are malignant, 50 to 100% of PETs are malignant. The fraction of carcinoid tumors showing malignant behavior varies in different locations. For the three most common sites of occurrence the incidence of metastases varies greatly: jejuno-ileum (58%) > lung/bronchus (6%) > rectum (4%). A number of factors influence survival and the aggressiveness of the tumor (Table 329-4). The presence of liver metastases is the single most important prognostic factor for both carcinoid tumors and PETs. Particularly important in the development of liver metastases is the size of the primary tumor. For small-intestinal carcinoids, the most frequent cause of the carcinoid syndrome due to metastatic disease in the liver, metastases occur in 15 to 25% if the tumor diameter is <1 cm, 58 to 80% if it is 1 to 2 cm, and >75% if >2 cm. Similar data exist for gastrinomas and other PETs. The presence of lymph node metastases, the depth of invasion, various histologic features (differentiation, mitotic rates, growth indices), and the presence of aneuploidy are all important prognostic factors for the development of metastatic disease (Table 329-4). For patients with carcinoid tumors, additional poor prognosis factors include the development of the carcinoid syndrome, older age, male gender, the presence of a symptomatic tumor, or increases in a number of tumor markers [5-hydroxyindolactic acid (5-HIAA), neuropeptide K, chromogranin A]. With PETs or gastrinomas, the best studied PET, a worse prognosis is associated with female gender, overexpression of the *Ha-Ras* oncogene or p53, the absence of multiple endocrine neoplasia (MEN) type 1, and higher levels of various tumor markers (i.e., chromogranin A, gastrin).

A number of genetic disorders are associated with an increased incidence of NETs (Table 329-5). Each is caused by a loss of a putative tumor-suppressor gene. The most important is MEN-1, which is an autosomal dominant disorder due to a defect in a 10-exon gene on 11q13 that encodes for a 610-amino-acid nuclear protein, menin (Chap. 330). In patients with MEN-1, 95 to 100% develop hyperparathyroidism due to parathyroid hyperplasia, 80 to 100% develop PETs, 54 to 80% develop pituitary adenomas, and bronchial carcinoids develop in 8%, thymic carcinoids in 8%, and gastric carcinoids in 13 to 30% of the patients with Zollinger-Ellison syndrome (ZES). In patients with MEN-1, 80 to 100% develop nonfunctional PETs; functional PETs occur in 80%, with 54% developing ZES, 21% insulinomas, 3% glucagonomas, and 1% VIPomas. MEN-1 is present in 20 to 25% of all patients with ZES, in 4% with insulinomas, and in a low percentage (<5%) of the other PETs.

Three phacomatoses associated with NETs are von Hippel–Lindau disease, von Recklinghausen's disease [neurofibromatosis (NF) type 1], and tuberous sclerosis (Bourneville's disease). Von Hippel–Lindau disease is an autosomal dominant disorder due to defects on chromosome 3p25, which encodes for a 213-amino-acid protein that interacts with the elongin family of proteins as a transcriptional regulator (Chap. 358). In addition to cerebellar hemangioblastomas, renal cancer, and pheochromocytomas, 10 to 17% of these patients develop a PET. Most are nonfunctional, although insulinomas and VIPomas are reported. Patients with NF-1 have defects in a gene on chromosome 17q11.2 encoding for a 2845-amino-acid protein, neurofibromin, which functions in normal cells as a suppressor of the ras signaling cascade (Chap. 358). Up to 12% of these patients develop an upper GI carcinoid tumor, characteristically in the periampullary region (54%). Many are classified as somatostatinomas because they contain somatostatin immunocytochemically; however, they uncommonly secrete somatostatin or produce a clinical somatostatinoma syndrome. NF-1 has rarely been associated with insulinomas and ZES. Tuberous sclerosis is caused by mutations that alter either the 1164-amino-acid protein, hamartin (TSC1), or the 1807-amino-acid protein, tuberin (TSC2) (Chap. 358). Both hamartin and tuberin interact in a pathway related to cytosolic G protein regulation. A few cases including nonfunctional and functional PETs (insulinomas and gastrinomas) have been reported in these patients.

In contrast to most common nonendocrine tumors such as carcinoma of the breast, colon, lung or stomach, PETs and carcinoid tumors

TABLE 329-2 *GI Neuroendocrine Tumor Syndromes*

Name	Biologically Active Peptide(s) Secreted	Incidence New Cases/10^6 Population/Year	Tumor Location	Malignant, %	Associated with MEN-1, %	Main Symptoms/Signs
I. ESTABLISHED SPECIFIC FUNCTIONAL SYNDROME						
Carcinoid tumor						
Carcinoid syndrome	Serotonin, possibly tachykinins, motilin, prostaglandins	0.5–2	Midgut (75–87%) Foregut (2–33%) Hindgut (1–8%) Unknown (2–15%)	95–100	Rare	Diarrhea (32–84%) Flushing (63–75%) Pain (10–34%) Asthma (4–18%) Heart disease (11–41%)
Pancreatic endocrine tumor						
Zollinger-Ellison syndrome	Gastrin	0.5–1.5	Duodenum (70%) Pancreas (25%) Other sites (5%)	60–90	20–25	Pain (79–100%) Diarrhea (30–75%) Esophageal symptoms (31–56%)
Insulinoma	Insulin	1–2	Pancreas (>99%)	<10	4–5	Hypoglycemic symptoms (100%)
VIPoma (Verner-Morrison syndrome, pancreatic cholera, WDHA)	Vasoactive intestinal peptide	0.05–0.2	Pancreas (90%, adult) Other (10%, neural, adrenal, periganglionic)	40–70	6	Diarrhea (90–100%) Hypokalemia (80–100%) Dehydration (83%)
Glucagonoma	Glucagon	0.01–0.1	Pancreas (100%)	50–80	1–20	Rash (67–90%) Glucose intolerance (38–87%) Weight loss (66–96%)
Somatostatinoma	Somatostatin	Rare	Pancreas (55%) Duodenum-jejunum (44%)	>70	45	Diabetes mellitus (63–90%) Cholelithiasis (65–90%) Diarrhea (35–90%)
GRFoma	Growth hormone–releasing hormone	Unknown	Pancreas (30%) Lung (54%) Jejunum (7%) Other (13%)	>60	16	Acromegaly (100%)
ACTHoma	ACTH	Rare	Pancreas (4–16%, all ectopic Cushing's)	>95	Rare	Cushing's syndrome (100%)
PET causing carcinoid syndrome	Serotonin, ? tachykinins	Rare (43 cases)	Pancreas (<1% all carcinoids)	60–88	Rare	Same as carcinoid syndrome above
PET causing hypercalcemia	PTHrP, others unknown	Rare	Pancreas (rare cause of hypercalcemia)	84	Rare	Abdominal pain due to hepatic metastases
II. POSSIBLE SPECIFIC FUNCTIONAL SYNDROME						
PET secreting calcitonin	Calcitonin	Rare	Pancreas (rare cause of hypercalcitonemia)	>80	16	Diarrhea (50%)
PET secreting renin	Renin	Rare	Pancreas	Unknown	No	Hypertension
III. NO FUNCTIONAL SYNDROME						
PPoma/nonfunctional	None	1–2	Pancreas (100%)	>60	18–44	Weight loss (30–90%) Abdominal mass (10–30%) Pain (30–95%)

Note: MEN, multiple endocrine neoplasia; VIPoma, tumor-secreting vasoactive intestinal peptide; WDHA, watery diarrhea, hypokalemia, and achlorhydria syndrome; ACTH, adrenocorticotrophic hormone; PET, pancreatic endocrine tumor; PTHrP, parathyroid hormone–related peptide; PPoma, tumor secreting pancreatic polypeptide.

do not have alterations in common oncogenes (ras, myc, fos, src, jun) or common tumor-suppressor genes (p53, retinoblastoma susceptibility gene) (Table 329-1). Alterations that may be important in their pathogenesis including changes in the *MEN-1* gene, p16/MTS1 tumor-suppressor gene, and DPC 4/*Smad* 4 gene, amplification of the HER-2/*neu* protooncogene and growth factors and their receptors, and deletions of unknown tumor-suppressor genes as well as gains in other unknown genes. Comparative genomic hybridization and genome-wide allelotyping studies have shown genetic differences between PETs and carcinoids (Table 329-1), some of which have prognostic significance (Table 329-4). Mutations in the *MEN-1* gene are particularly important. Loss of heterozygosity at the MEN-1 locus on chromosome 11q13 occurs in 46% of sporadic PETs (those without MEN-1) and in 26 to 75% of sporadic carcinoid tumors. Mutations in the *MEN-1* gene are reported in 31 to 34% of sporadic gastrinomas. The presence of a number of these molecular alterations correlates with tumor growth, tumor size, and disease extent or invasiveness and may have prognostic significance.

CARCINOID TUMORS AND CARCINOID SYNDROME

GENERAL TUMOR CHARACTERISTICS OF THE MOST COMMON GI CARCINOID TUMORS

Appendiceal Carcinoids These occur in 1 in every 200 to 300 appendectomies, usually in the appendiceal tip. Most are <1 cm in diameter without metastases; however, up to 35% have metastases (Table 329-3). Among 1570 appendiceal carcinoids, 62% were localized and 27% had regional and 8% had distant metastases. Of tumors 1 to 2 cm in diameter, half metastasized to lymph nodes. The percentage of larger carcinoids has decreased from 43.9% (1950 to 1969) to 2.4% (1992 to 1999).

Small Intestinal Carcinoids These are frequently multiple; 70 to 80% are present in the ileum and 70% are within 60 cm (24 in.) of the ileocecal valve. Some 40% are <1 cm in diameter, 32% are 1 to 2 cm, and 29% are >2 cm. Between 35 and 70% are associated with metastases (Table 329-3). They characteristically cause a marked fibrotic reaction that can lead to intestinal obstruction. Distant metastases occur to liver in 36 to 60% of patients, to bone in 3%, and to lung in 4%. Even small carcinoid tumors of the small intestine (<1 cm) have metastases in 15 to 25%; the incidence increases to 58 to 100% for tumors 1 to 2 cm in diameter. Carcinoids also occur in the duodenum, with 31% having metastases. No duodenal tumor <1 cm metastasized, whereas 33% of those >2 cm had metastases. Small-intestinal carcinoids are the most common cause (60 to 87%) of the carcinoid syndrome (Table 329-6).

TABLE 329-3 *Carcinoid Tumor Location, Frequency of Metastases, and Association with the Carcinoid Syndrome*

	Location (% of Total)	Incidence of Metastases	Incidence of Carcinoid Syndrome
Foregut			
Esophagus	<0.1	—	—
Stomach	4.6	10	9.5
Duodenum	2.0	—	3.4
Pancreas	0.7	71.9	20
Gallbladder	0.3	17.8	5
Bronchus, lung, trachea	27.9	5.7	13
Midgut			
Jejunum	1.8	58.4	9
Ileum	14.9		9
Meckel's diverticulum	0.5	—	13
Appendix	4.8	38.8	<1
Colon	8.6	51	5
Liver	0.4	32.2	—
Ovary	1.0	32	50
Testis	<0.1	—	50
Hindgut			
Rectum	13.6	3.9	—

Source: Location is from the PAN-SEER data (1973–1999), and incidence of metastases from the SEER data (1992–1999), reported by IM Modlin et al: Cancer 97:934, 2003. Incidence of carcinoid syndrome is from 4349 cases studied from 1950–1971, reported by JD Godwin: Cancer 36:560, 1975.

Rectal Carcinoids Rectal carcinoids are found in 1 of every 2500 proctoscopies. Nearly all occur 4 to 13 cm above the dentate line. Most are small, with 66 to 80% being <1 cm in diameter; 5% metastasize. Tumors between 1 and 2 cm can metastasize in 5 to 30% of patients, and tumors >2 cm, which are uncommon, in >70%.

Bronchial Carcinoids Bronchial carcinoids are not related to smoking. A number of different classifications have been proposed. In some studies lung NETs are classified into four categories: typical carcinoid [also called bronchial carcinoid tumor, Kulchitsky cell carcinoma (KCC)-I]; atypical carcinoid (also called well-differentiated neuroendocrine carcinoma, KCC-II); intermediate small cell neuroendocrine carcinoma; and small cell neuroendocarcinoma (KCC-III). Another proposed classification includes three categories: benign or low-grade malignant (typical carcinoid); low-grade malignant (atypical carcinoid), and high-grade malignant (poorly differentiated carcinoma of the large cell or small cell type). These different categories of lung NETs have different prognoses varying from excellent for typical carcinoid to poor for small cell neuroendocrine carcinomas.

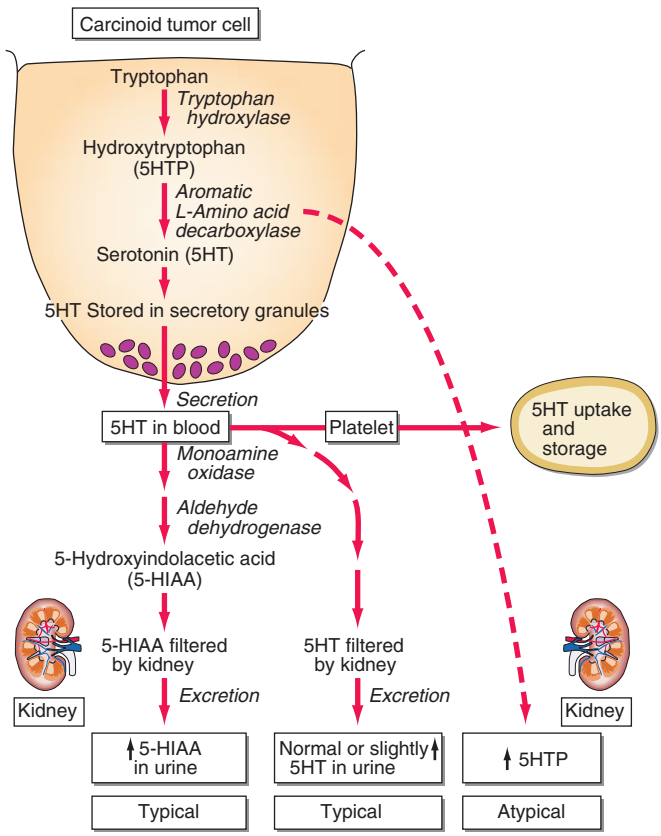

FIGURE 329-1 Synthesis, secretion, and metabolism of serotonin (5HT) in patients with typical and atypical carcinoid syndromes. Abbreviations: 5-HIAA, 5-hydroxyindolacetic acid.

TABLE 329-4 *Prognostic Factors in Neuroendocrine Tumors*

- Both carcinoid tumors and PETs
  - Presence of liver metastases ($p < .001$)
  - Extent of liver metastases ($p < .001$)
  - Presence of lymph node metastases ($p < .001$)
  - Depth of invasion ($p < .001$)
  - Primary tumor site ($p < .001$)
  - Primary tumor size ($p < .005$)
  - Various histologic features
    - Tumor differentiation ($p < .001$)
    - High growth indices (high Ki-67 index, PCNA expression)
    - High mitotic counts ($p < .001$)
    - Vascular or perineural invasion
    - Flow cytometric features (i.e., aneuploidy)
- Carcinoid tumors
  - Presence of carcinoid syndrome
  - Laboratory results [urinary 5-HIAA level ($p < .01$), plasma neuropeptide K ($p < .05$), serum chromogranin A ($p < .01$)]
  - Presence of a secondary malignancy
  - Male gender ($p < .001$)
  - Older age ($p < .01$)
  - Mode of discovery (incidental > symptomatic)
  - Molecular findings [TGF-α expression ($p < .05$), chr 16q LOH or gain chr 4p ($p < .05$)
- PETs
  - *Ha-Ras* oncogene or p53 overexpression
  - Female gender
  - MEN-1 syndrome absent
  - Laboratory findings (increased chromogranin A in some studies; gastrinomas—increased gastrin level)
  - Molecular findings [increased HER2/*neu* expression ($p = .032$), chr 1q, 3p,3q, or 6q LOH ($p = .0004$), EGF receptor overexpression ($p = .034$), gains in chr 7q, 17q, 17p, 20q]

Note: PET, pancreatic endocrine tumor; Ki-67, proliferation-associated nuclear antigen recognized by Ki-67 monoclonal antibody; PCNA, proliferating cell nuclear antigen; 5-HIAA, 5-hydroxy indolacetic acid; TGF-α, transforming growth factor α; chr, chromosome; LOH, loss of heterozygosity; MEN, multiple endocrine neoplasia; EGF, epidermal growth factor.

Gastric Carcinoids These account for 3 of every 1000 gastric neoplasms. Three different subtypes of gastric carcinoids are observed. Each originates from gastric enterochromaffin-like (ECL) cells in the gastric mucosa. Two subtypes are associated with hypergastrinemic states: (1) chronic atrophic gastritis (type I) (80% of all gastric carcinoids), or (2) ZES, almost always as part of the MEN-1 syndrome (type II) (6% of all cases). These tumors generally pursue a benign course, with 9 to 30% associated with metastases. They are usually multiple and small and infiltrate only to the submucosa. The third subtype of gastric carcinoid (type III) (sporadic) occurs without hypergastrinemia (14% of all carcinoids) and pursues an aggressive course, with 54 to 66% developing metastases. Sporadic carcinoids are usually single, large tumors, 50% have atypical histology, and they can be a cause of the carcinoid syndrome. Gastric carcinoids as a percentage of all carcinoids are increasing in frequency [1.96% (1969 to 1971), 3.6% (1973 to 1991), 5.8% (1991 to 1999)].

CARCINOID TUMORS WITHOUT THE CARCINOID SYNDROME The age of patients at diagnosis ranges from 10 to 93 years, with a mean age of 63 years for small intestine and 66 years for the rectum. The presentation

TABLE 329-5 *Genetic Syndromes Associated with an Increased Incidence of Neuroendocrine Tumors [NETs: Carcinoids or Pancreatic Endocrine Tumors (PETs)]*

Syndrome	Location of Gene Mutation and Gene Product	NETs Seen/Frequency
Multiple endocrine neoplasia type 1 (MEN-1)	11q13 (encodes 610-amino-acid protein, menin)	80–100% develop PETs: (nonfunctional > gastrinoma > insulinoma) Carcinoids: gastric (13–30%), bronchial/thymic (8%)
von Hippel–Lindau disease	3q25 (encodes 213-amino-acid-protein)	12–17% develop PETs (almost always nonfunctional)
von Recklinghausen's disease [neurofibromatosis1 (NF-1)]	17q11.2 (encodes 2485-amino-acid protein, neurofibromin)	Duodenal somatostatinomas (usually nonfunctional) Rarely insulinoma, gastrinoma
Tuberous sclerosis	9q34 (TSCI) (encodes 1164-amino-acid protein, hamartin) 16p13 (TSC2) (encodes 1807-amino-acid protein, tuberin)	Uncommonly develop PETs [nonfunctional and functional (insulinoma, gastrinoma)]

is diverse and related to the site of origin and extent of malignant spread. In the appendix, carcinoid tumors are usually found incidentally during surgery for suspected appendicitis. Small-intestinal carcinoids in the jejunoileum present with periodic abdominal pain (51%), intestinal obstruction with ileus/invagination (31%), an abdominal tumor (17%), or GI bleeding (11%). Because of the vagueness of the symptoms the diagnosis is usually delayed about 2 years from onset of the symptoms, with a range up to 20 years. Duodenal, gastric, and rectal carcinoids are most frequently found by chance at endoscopy. The most common symptoms of rectal carcinoids are melena/bleeding (39%), constipation (17%), and diarrhea (12%). Bronchial carcinoids are frequently discovered as a lesion on a chest radiograph, and 31% of the patients are asymptomatic. Thymic carcinoids present as anterior mediastinal masses, usually on chest radiograph or computed tomography (CT) scan. Ovarian and testicular carcinoids usually present as masses discovered on physical examination or ultrasound. Metastatic carcinoid tumor in the liver frequently presents as hepatomegaly in a patient who may have minimal symptoms and near-normal liver function tests.

CARCINOID TUMORS WITH SYSTEMIC SYMPTOMS DUE TO SECRETED PRODUCTS Carcinoid tumors immunocytochemically can contain numerous GI peptides: gastrin, insulin, somatostatin, motilin, neurotensin, tachykinins (substance K, substance P, neuropeptide K), glucagon, gastrin-releasing peptide, VIP, PP, other biologically active peptides (ACTH, calcitonin, growth hormone), prostaglandins, and bioactive amines (serotonin). These substances may or may not be released in sufficient amounts to cause symptoms. In patients with carcinoid tumors, elevated serum levels of PP were found in 43%, motilin in 14%, gastrin in 15%, and VIP in 6%. Foregut carcinoids are more likely to produce various GI peptides than midgut carcinoids. Ectopic ACTH production causing Cushing's syndrome is increasingly seen with foregut carcinoids (respiratory tract primarily) and in some series was the most common cause of the ectopic ACTH syndrome, accounting for 64% of all cases. Acromegaly due to GRF release occurs with foregut carcinoids; the somatostatinoma syndrome with duodenal carcinoids. The most common systemic syndrome with carcinoid tumors is the carcinoid syndrome.

TABLE 329-6 *Clinical Characteristics in Patients with Carcinoid Syndrome*

	At Presentation	During Course of Disease
Symptoms/signs		
Diarrhea	32–73%	68–84%
Flushing	23–65%	63–74%
Pain	10%	34%
Asthma/wheezing	4–8%	3–18%
Pellagra	2%	5%
None	12%	22%
Carcinoid heart disease present	11%	14–41%
Demographics		
Male	46–59%	46–61%
Age		
Mean	57 yrs	52–54 yrs
Range	25–79 yrs	9–91 yrs
Tumor location		
Foregut	5–9%	2–33%
Midgut	78–87%	60–87%
Hindgut	1–5%	1–8%
Unknown	2–11%	2–15%

CARCINOID SYNDROME ■ Clinical Features The cardinal features at presentation and during the disease course are shown in Table 329-6. Flushing and diarrhea are the two most common symptoms, occurring in up to 73% initially and in up to 89% during the course of the disease. The characteristic flush is of sudden onset; it is a deep red or violaceous erythema of the upper body (especially the neck and face), often associated with a feeling of warmth, and occasionally associated with pruritus, lacrimation, diarrhea, or facial edema. Flushes may be precipitated by stress, alcohol, exercise, or certain foods such as cheese or by certain agents such as catecholamines, pentagastrin, and serotonin reuptake inhibitors. Flushing episodes may be brief, lasting 2 to 5 min, especially initially, or may last hours, especially later in the disease course. Flushing is usually seen with midgut carcinoids but can also occur with foregut carcinoids. With bronchial carcinoids the flushes are frequently prolonged for hours to days, reddish in color, and associated with salivation, lacrimation, diaphoresis, diarrhea, and hypotension. The flush associated with gastric carcinoids is also reddish in color but patchy in distribution over the face and neck. It may be provoked by food and have accompanying pruritus.

Diarrhea is present in 32 to 73% initially and in 68 to 84% at some time in their disease course. Diarrhea usually occurs with flushing (85% of cases). The diarrhea is usually described as watery, with 60% having <1 L per day of diarrhea. Steatorrhea is present in 67%, and in 46% it is >15 g/d (normal <7 g). Abdominal pain may be present with the diarrhea or independently in 10 to 34% of cases.

Cardiac manifestations occur in 11% initially and in 14 to 41% at some time in the disease course. The cardiac disease is due to fibrosis involving the endocardium, primarily on the right side, although left side lesions can occur also. The dense fibrous deposits are most commonly on the ventricular aspect of the tricuspid valve and less commonly on the pulmonary valve cusps. They can result in constriction of the valves and pulmonic stenosis is usually predominant, whereas the tricuspid valve is often fixed open, resulting in regurgitation. Up to 80% of patients with cardiac lesions develop heart failure. Lesions on the left side are much less extensive, occur in 30% at autopsy, and most frequently affect the mitral valve.

Other clinical manifestations include wheezing or asthma-like symptoms (8 to 18%) and pellagra-like skin lesions (2 to 25%). A variety of noncardiac problems due to increased fibrous tissue may be seen including retroperitoneal fibrosis causing urethral obstruction, Peyronie's disease of the penis, intraabdominal fibrosis, and occlusion of the mesenteric arteries or veins.

Pathobiology In different studies carcinoid syndrome occurred in 8% of 8876 patients with carcinoid tumors, with a rate of 1.4 to 18.4%. It occurs only when sufficient concentrations of products secreted by the tumor reach the systemic circulation. In 91% of cases this occurs after distant metastases to the liver. Rarely primary gut carcinoids with nodal metastases with extensive retroperitoneal invasion, pancreatic carcinoids with retroperitoneal lymph nodes, or carcinoids of the lung

or ovary with direct access to the systemic circulation can cause the carcinoid syndrome without hepatic metastases. All carcinoid tumors do not have the same propensity to metastasize and cause the carcinoid syndrome (Table 329-3). Midgut carcinoids account for 60 to 67% of the cases of carcinoid syndrome, foregut tumors for 2 to 33%, hindgut for 1 to 8%, and an unknown primary location for 2 to 15% (Tables 329-2, 329-3).

One of the main secretory products of carcinoid tumors involved in the carcinoid syndrome is serotonin (Fig. 329-1), which is synthesized from tryptophan. Up to 50% of dietary tryptophan can be used in this synthetic pathway by tumor cells, which can result in inadequate supplies for conversion to niacin; thus, some patients (2.5%) develop pellagra-like lesions. Serotonin has numerous biologic effects including stimulating intestinal secretion, inhibition of absorption, increasing intestinal motility, and stimulating fibrogenesis. Serotonin overproduction is found in 56 to 88% of all carcinoid tumors; however, 12 to 26% of patients do not have the carcinoid syndrome. In 90 to 100% of patients with the carcinoid syndrome serotonin is overproduced. Through its effects on gut motility and intestinal secretion, serotonin is thought to be predominantly responsible for the diarrhea. Serotonin receptor antagonists (especially $5HT_3$ antagonists) relieve the diarrhea in most patients. However, prostaglandin E_2 and tachykinins may be important mediators of the diarrhea in some patients. Serotonin does not appear to be involved in the flushing, because flushing is not relieved by serotonin receptor antagonists. In patients with gastric carcinoids the red, patchy pruritic flush is likely due to histamine release, because it can be prevented by H_1 and H_2 receptor antagonists. Numerous studies show tachykinins are stored in carcinoid tumors and released during flushing. However, octreotide can relieve the flushing induced by pentagastrin in these patients without altering the stimulated increase in plasma substance P, suggesting other mediators must be involved in the flushing. Both histamine and serotonin may be responsible for the wheezing as well as the fibrotic reactions involving the heart, Peyronie's disease, and intraabdominal fibrosis. The exact mechanism of the heart disease is unclear. The valvular heart disease caused by the appetite-suppressant drug dexfenfluramine is histologically indistinguishable from that observed in carcinoid disease or after long exposure to $5HT_2$-preferring ergot drugs. Metabolites of fenfluramine have high affinity for $5HT_2$ receptors whose activation is known to cause fibroblast mitogenesis. High levels of $5HT_{2B}$ and $5HT_{2C}$ receptor transcripts are known to occur in heart valves. Studies on sheep aortic valve interstitial cells demonstrate serotonin interacts primarily with $5HT_{2A/2B}$ receptors and stimulates transforming growth factor-β and collagen biosynthesis. Thus, serotonin overproduction is important for the valvular changes, possibly by activating $5HT_2$ receptors in the endocardium. Both the magnitude of serotonin overproduction and prior chemotherapy are important predictors of progression of the heart disease. Atrial natriuretic peptide overproduction is also reported in patients with cardiac disease, but its role in the pathogenesis is unknown.

Patients may develop either a typical or atypical carcinoid syndrome (Fig. 329-1). In patients with the typical form, characteristically caused by a midgut carcinoid tumor, the conversion of tryptophan to 5HTP is the rate-limiting step. Once 5HTP is formed it is rapidly converted to 5HT and stored in secretory granules of the tumor or in platelets. A small amount remains in plasma and is converted to 5-HIAA, which appears in large amounts in the urine. These patients have an expanded serotonin pool size, increased blood and platelet serotonin, and increased urinary 5-HIAA. Some carcinoid tumors cause an atypical carcinoid syndrome thought due to a deficiency in the enzyme dopa decarboxylase in which 5HTP cannot be converted to 5HT (serotonin), and 5HTP is secreted into the bloodstream. In these patients plasma serotonin levels are normal but urinary levels may be increased because some 5HTP is converted to 5HT in the kidney. Characteristically, urinary 5HTP and 5HT are increased, but urinary 5-HIAA levels are only slightly elevated. Foregut carcinoids are the most likely to cause an atypical carcinoid syndrome.

One of the most life-threatening complications of the carcinoid syndrome is the development of a carcinoid crisis. This is more frequent in patients who have intense symptoms from foregut tumors or have greatly increased urinary 5-HIAA levels (i.e., >200 mg/d). The crises may occur spontaneously or be provoked by stress, anesthesia, chemotherapy, or a biopsy. Patients develop intense flushing, diarrhea, abdominal pain, and cardiac abnormalities including tachycardia, hypertension, or hypotension. If not adequately treated it can be fatal.

Diagnosis of the Carcinoid Syndrome and Carcinoid Tumors The diagnosis of carcinoid syndrome relies on measurement of urinary or plasma serotonin or its metabolites in the urine. The measurement of 5-HIAA is most frequently used. False-positive elevations may occur if the patient is eating serotonin-rich foods, such as bananas, pineapple, walnuts, pecans, avocados, or hickory nuts, or taking certain medications (cough syrup containing guaifenesin, acetaminophen, salicylates, or L-dopa). The normal range in daily urinary 5-HIAA excretion is between 2 and 8 mg/d. 5-HIAA has 73% sensitivity and 100% specificity for carcinoid syndrome.

Most physicians use only the urinary 5-HIAA excretion rate; however, plasma and platelet serotonin levels, if available, may give additional information. Platelet serotonin levels are more sensitive than urinary 5-HIAA but are not generally available. Patients with foregut carcinoids may produce an atypical carcinoid syndrome. If this syndrome is suspected and the urinary 5-HIAA is minimally elevated or normal, other urinary metabolites of tryptophan such as 5HTP or 5HT should be measured (Fig. 329-1).

Flushing occurs in a number of other diseases including systemic mastocytosis or chronic myeloid leukemia with increased histamine release; in menopause; as a reaction to alcohol or glutamate; or as side effects of chlorpropamide, calcium channel blockers, and nicotinic acid. None of these conditions cause an increase in urinary 5-HIAA.

The diagnosis of carcinoid tumor can be suggested by the carcinoid syndrome, by recurrent abdominal symptoms in a healthy-appearing individual, or by discovering hepatomegaly or hepatic metastases associated with minimal symptoms. Ileal carcinoids, which make up 25% of all clinically detected carcinoids, should be suspected in patients with bowel obstruction, abdominal pain, flushing, or diarrhea.

Serum chromogranin A levels are elevated in 56 to 100% of patients with carcinoid tumors, and the level correlates with tumor bulk. Serum chromogranin A levels are not specific for carcinoid tumors because they are also elevated in patients with PETs and other NETs. Plasma neuron-specific enolase levels are also used as a marker of carcinoid tumors but are less sensitive than chromogranin A, being increased in only 17 to 47% of patients.

TREATMENT

Carcinoid Syndrome Treatment includes avoiding conditions that precipitate flushing, dietary supplementation with nicotinamide, treatment of heart failure with diuretics, treatment of wheezing with oral bronchodilators, and controlling the diarrhea with antidiarrheal agents such as loperamide or diphenoxylate. If patients still have symptoms, serotonin receptor antagonists or somatostatin analogues (Fig. 329-2) are the drugs of choice.

There are 14 subclasses of serotonin (5HT) receptors; antagonists for most are not available. The $5HT_1$ and $5HT_2$ receptor antagonists methysergide, cyproheptadine, and ketanserin have all been used to control diarrhea but usually do not decrease flushing. The use of methysergide is limited because it can cause or enhance retroperitoneal fibrosis. Ketanserin diminishes diarrhea in 30 to 100% of patients. $5HT_3$ receptor antagonists (ondansetron, tropisetron, alosetron) can control diarrhea and nausea in up to 100% of patients and occasionally ameliorate the flushing. A combination of histamine H_1 and H_2 receptor antagonists (i.e., diphenhydramine and cimetidine or ranitidine) may control flushing in patients with foregut carcinoids.

Synthetic analogues of somatostatin (octreotide, lanreotide) are now the most widely used agents to control the symptoms of patients with carcinoid syndrome (Fig. 329-2). These drugs are effective at

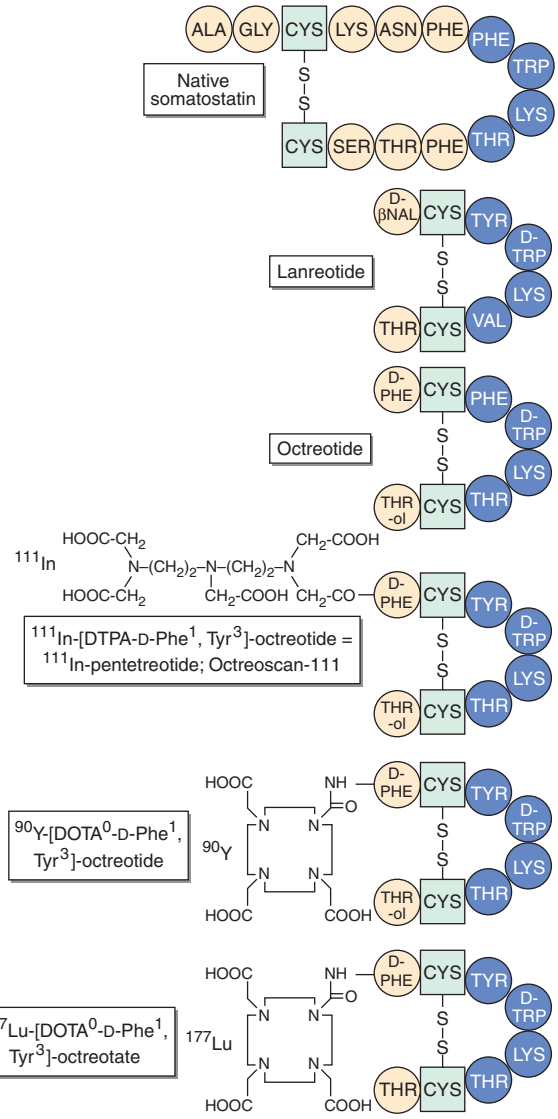

FIGURE 329-2 Structure of somatostatin and synthetic analogues used for diagnostic or therapeutic indications.

relieving symptoms and decreasing urinary 5-HIAA levels in patients with carcinoid syndrome. Octreotide controls symptoms in >80% of patients, including the diarrhea and flushing, and produces a >50% decrease in urinary 5-HIAA excretion in 70% of patients. Patients with mild to moderate symptoms should initially be treated with 100 μg subcutaneously every 8 h. Individual responses vary; doses as high as 3000 μg/d have been given. About 40% of patients escape control after a median 4 months, and the dose may need to be increased. Similar results are reported with lanreotide.

In patients with carcinoid crises, somatostatin analogues are effective at both treating the condition as well as preventing its development during known precipitating events such as surgery, anesthesia, chemotherapy, or stress. Octreotide, 150 to 250 μg subcutaneously every 6 to 8 h, should be used 24 to 48 h before anesthesia and then continued throughout the procedure.

Sustained-release preparations of both octreotide [octreotide-LAR, (long-acting release)] and lanreotide [lanreotide-PR (prolonged release)] have been developed. Octreotide-LAR (30 mg/month) gives a plasma level $\geq$ 1 ng/mL for 25 days, whereas the non-sustained-release form would need to be injected three to six times a day to achieve this level. Lanreotide-PR is given intramuscularly every 10 to 14 days. Both sustained-release forms are highly effective at controlling the symptoms of the carcinoid syndrome (61 to 85% of patients).

Short-term side effects occur in 40 to 60% of patients receiving subcutaneous somatostatin analogues. Pain at the injection site and side effects related to the GI tract (59% discomfort, 15% nausea, diarrhea) are the most common. They are usually short-lived and do not interrupt treatment. Important long-term side effects include gallstone formation, steatorrhea, and deterioration in glucose tolerance. The overall incidence of gallstones/biliary sludge is 52%, with 7% having symptomatic disease requiring surgical treatment.

Interferon-α controls symptoms of the carcinoid syndrome either alone or combined with hepatic artery embolization. The response rate to interferon-α alone is 42%, and when combined with hepatic artery embolization, diarrhea was controlled for 1 year in 43% and flushing in 86%.

Hepatic artery embolization alone or with chemotherapy (chemoembolization) has been used to control the symptoms of carcinoid syndrome. Embolization alone is reported to control symptoms in up to 76% of patients, and chemoembolization (5-fluorouracil, adriamycin, cisplatin, mitomycin) in 60 to 75% of patients. Hepatic artery embolization can have major side effects including nausea, vomiting, pain, and fever. The mortality rate is 5 to 7%.

Other drugs have been used successfully in small numbers of patients to control the symptoms of carcinoid syndrome. Parachlorophenylanine can inhibit tryptophan hydroxylase and therefore the conversion of tryptophan to 5HTP (Fig. 329-1). However, its severe side effects, including psychiatric disturbances, make it intolerable for long-term use. α-Methyldopa inhibits the conversion of 5HTP to 5HT; however, its effects are only partial.

Carcinoid Tumors (Nonmetastatic) Surgery is the only potentially curative therapy. Because the probability of metastatic disease increases with increasing primary tumor size, the extent of surgical resection is determined accordingly. With appendiceal carcinoids, simple appendectomy was curative in 103 patients followed for up to 35 years. With rectal carcinoids <1 cm, local resection is curative. With small-intestinal carcinoids <1 cm, consensus has not been reached. Because 15 to 69% of small-intestinal carcinoids this size have metastases in different studies, some recommend a wide resection with en bloc resection of the adjacent lymph-bearing mesentery. If the carcinoid tumor is >2 cm in rectal, appendiceal, or small-intestinal sites, a full cancer operation should be done. This includes a right hemicolectomy for appendiceal carcinoid, an abdominoperineal resection or low anterior resection for rectal carcinoids, and an en bloc resection of adjacent lymph nodes for small-intestinal carcinoids. For carcinoids 1 to 2 cm in the appendix, a simple appendectomy is proposed by some, whereas others favor a formal right hemicolectomy. For rectal carcinoids of 1 to 2 cm, a wide local full-thickness excision is recommended.

With type I or II gastric carcinoids, which are usually <1 cm, endoscopic removal is recommended. For type I or II gastric carcinoids >2 cm or locally invasive, some recommend total gastrectomy; others recommend antrectomy in type 1. For types I and III gastric carcinoids of 1 to 2 cm, some recommend endoscopic treatment, others surgical treatment. With type III gastric carcinoids >2 cm, excision and regional lymph node clearance are recommended. Most tumors <1 cm are treated endoscopically.

Resection of isolated or limited hepatic metastases may be beneficial (see below).

PANCREATIC ENDOCRINE TUMORS

Functional PETs usually present with symptoms due to hormone excess. Only late in the course of the disease does the tumor per se cause prominent symptoms such as abdominal pain. In contrast, all of the symptoms due to nonfunctional PETs are due to the tumor per se. The overall result is that some functional PETs may present with severe symptoms with a small or undetectable primary tumor, whereas nonfunctional tumors almost always present late in their disease course with large tumors that are usually metastatic. The mean delay between

onset of continuous symptoms and diagnosis of a functional PET syndrome is 4 to 7 years. Therefore, the diagnoses are frequently missed for extended periods of time.

Treatment of PETs requires two different strategies. Treatment must be directed at the hormone excess state such as the gastric acid hypersecretion in gastrinomas or hypoglycemia in insulinomas. Ectopic hormone secretion usually causes the presenting symptoms and can cause life-threatening complications. Second, with all of the tumors except insulinomas, >50% are malignant (Table 329-2); therefore, treatment must also be directed against the tumor per se. Because these tumors are not frequently surgically curable due to the extent of disease, in many cases surgical resection for cure, which addresses both treatment aspects, is not possible.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME) A gastrinoma is a NET that secretes gastrin. The chronic hypergastrinemia results in marked gastric acid hypersecretion (ZES) and growth of the gastric mucosa, with increased numbers of parietal cells and proliferation of gastric ECL cells. The gastric acid hypersecretion characteristically causes peptic ulcer disease (PUD), often refractory and severe, as well as diarrhea. The most common presenting symptoms are abdominal pain (70 to 100%), diarrhea (37 to 73%), and gastroesophageal reflux disease (GERD) (30 to 35%), though 10 to 20% have diarrhea only. Although peptic ulcers may occur in unusual locations, most patients have a typical duodenal ulcer. Important observations that should suggest this diagnosis include PUD with diarrhea; PUD in an unusual location or with multiple lesions; and PUD that is refractory to treatment or persistent, associated with prominent gastric folds, associated with findings suggestive of MEN-1 (endocrinopathy, family history of ulcer or endocrinopathy, nephrolithiasis), or without *Helicobacter pylori* present. *H. pylori* is present in >90% of idiopathic peptic ulcers but is present in <50% of patients with gastrinomas. Chronic unexplained diarrhea should also suggest gastrinoma.

About 20 to 25% of patients have MEN-1, and in most cases the hyperparathyroidism is present before the gastrinoma. These patients are treated differently from those without MEN-1; therefore, MEN-1 should be sought in all patients by family history, by measuring plasma ionized calcium and prolactin levels and plasma hormone levels (parathormone, growth hormone).

Most gastrinomas (50 to 70%) are present in the duodenum, followed by the pancreas (20 to 40%) and other intraabdominal sites (mesentery, lymph nodes, biliary tract, liver, stomach, ovary). Rare cases may originate outside the abdominal cavity. In MEN-1 the gastrinomas are also usually in the duodenum (70 to 90%) or the pancreas (10 to 30%), and they are almost always multiple. Between 60 and 90% of gastrinomas are malignant (Table 329-2), with metastatic spread to lymph nodes and liver. Distant metastases to bone occur in 12 to 30% of patients with liver metastases.

Diagnosis The diagnosis of gastrinoma requires the demonstration of fasting hypergastrinemia and an increased basal gastric acid output (BAO) (hyperchlorhydria). Nearly all patients with gastrinomas have fasting hypergastrinemia, although in 40 to 60% the level may be elevated by less than a factor of 10. Therefore, when the diagnosis is suspected a fasting gastrin level should be determined first. Potent gastric acid–suppressant drugs such as proton pump inhibitors (omeprazole, pantoprazole, lansoprazole, rabeprazole) can suppress acid secretion sufficiently to cause hypergastrinemia; because of their prolonged duration of action, these drugs need to be discontinued for a week before the gastrin determination. If the gastrin level is elevated, gastric pH should be measured. If gastric pH < 2.0, the hypergastrinemia is not a physiologic response to achlorhydria (atrophic gastritis, pernicious anemia), another common cause of hypergastrinemia. If the fasting gastrin > 1000 μg/L (10 times increased) and the pH < 2.0, which occurs in 40 to 60% of patients with gastrinoma, the diagnosis is established after ruling out the possibility of retained antrum syndrome by history. In patients with hypergastrinemia with fasting gastrin < 1000 μg/L and gastric pH < 2.0, other conditions such as *H. pylori* infections, antral G cell hyperplasia/hyperfunction, gastric outlet obstruction, or, rarely, renal failure can masquerade as a gastrinoma. To establish the diagnosis in this group, a determination of BAO and a secretin provocative test should be done. In patients with gastrinomas, BAO is usually (>80%) elevated (i.e., >15 meq/h) and the secretin provocative test is positive (i.e., >200 μg/L increase in serum gastrin level) (Chap. 274).

TREATMENT

The gastric acid hypersecretion in patients with gastrinomas can be controlled in almost every case by oral gastric antisecretory drugs. Because of their long duration of action and potency, allowing once or twice a day dosing, the proton pump inhibitors (H^+, K^+-ATPase inhibitors) are the drugs of choice. Histamine H_2-receptor antagonists are also effective, although more frequent (every 4 to 8 h) and high doses are usually required. In patients with MEN-1 with hyperparathyroidism, correction of the hyperparathyroidism increases the sensitivity to gastric antisecretory drugs and decreases the BAO.

Although gastric acid secretion can be controlled, more than half the patients who are not cured (>60%) will die from tumor-related causes. Careful imaging studies are essential to localize the extent of the tumor (see below). About one-third of patients present with hepatic metastases; in <15% of those with hepatic metastases, the disease is limited so that surgical resection may be possible. Surgical cure is possible in 30 to 60% of all patients without MEN-1 or liver metastases (40% of all patients). In patients with MEN-1, surgical cure is rare because the tumors are multiple, frequently with lymph node metastases.

INSULINOMAS An insulinoma is an endocrine tumor of the pancreas derived from β cells that ectopically secrete insulin, which results in hypoglycemia. The average age of occurrence is in persons 40 to 50 years old. The most common clinical symptoms are due to the effect of the hypoglycemia on the central nervous system (neuroglycemic symptoms) and include confusion, headache, disorientation, visual difficulties, irrational behavior, or even coma. Also, most patients have symptoms due to excess catecholamine release secondary to the hypoglycemia including sweating, tremor, and palpitations. Characteristically these attacks are associated with fasting.

Insulinomas are generally small (>90% are <2 cm), usually not multiple (90%), and only 5 to 15% are malignant. They almost invariably occur only in the pancreas, distributed equally in the pancreatic head, body, and tail. Insulinomas should be suspected in all patients with hypoglycemia, especially those with attacks provoked by fasting or with a family history of MEN-1. Insulin is synthesized as proinsulin which consists of a 21-amino-acid α chain and a 30-amino-acid β chain connected by a 33-amino-acid connecting peptide (C peptide). In insulinomas, in addition to elevated plasma insulin levels, elevated plasma proinsulin levels are found and C-peptide levels can be elevated.

Diagnosis The diagnosis of insulinoma requires the demonstration of an elevated plasma insulin level at the time of hypoglycemia. Other causes of fasting hypoglycemia include the inadvertent or surreptitious use of insulin or oral hypoglycemic agents, severe liver disease, alcoholism, poor nutrition, or other extrapancreatic tumors. The most reliable test to diagnose insulinoma is a fast up to 72 h with serum glucose, C-peptide, and insulin measurements every 4 to 8 h. If at any point the patient becomes symptomatic or glucose levels are persistently <2.2 mmol/L (<40 mg/dL), the test should be terminated and repeat samples for the above studies obtained before glucose is given. Between 70 and 80% of patients with insulinoma will develop hypoglycemia during the first 24 h and 98% by 48 h. In nonobese normal subjects serum insulin levels should decrease to <43 pmol/L (<6 μU/mL) when blood glucose decreases to ≤2.2 mmol/L (<40 mg/dL) and the ratio of insulin to glucose is <0.3 (in mg/dL). In addition to having an insulin level > 6 μU/mL when blood glucose ≤ 40 mg/dL, some

investigators also require an elevated C-peptide and serum proinsulin level and/or insulin:glucose ratio >0.3 for the diagnosis of insulinoma. Surreptitious use of insulin or hypoglycemic agents may be difficult to distinguish from the symptoms of insulinomas. The combination of proinsulin levels (normal in exogenous insulin/hypoglycemic agent users), C-peptide levels (low in exogenous insulin users), antibodies to insulin (positive in exogenous insulin users), and sulfonylurea levels in serum or plasma will allow the correct diagnosis to be made.

TREATMENT

Only 5 to 15% of insulinomas are malignant; therefore, after appropriate imaging (see below), surgery should be performed. Some 75 to 95% of patients are cured by surgery. Before surgery, the hypoglycemia can be controlled by frequent small meals and the use of diazoxide (150 to 800 mg/d). Diazoxide is a benzothiadiazide whose hyperglycemic effect is attributed to inhibition of insulin release; 50 to 60% of patients respond to diazoxide. Its side effects are sodium retention and GI symptoms such as nausea. Other agents effective in some patients include verapamil and diphenylhydantoin. Long-acting somatostatin analogues such as octreotide are acutely effective in 40% of patients. However, octreotide needs to be used with care because it inhibits growth hormone secretion and can alter plasma glucagon levels and so worsen the hypoglycemia in some patients.

For the 5 to 15% of patients with malignant insulinomas, the above drugs or somatostatin analogues are used initially. If they are not effective, various antitumor treatments such as hepatic arterial embolization, chemoembolization, or chemotherapy have been used. These will be discussed below.

GLUCAGONOMAS A glucagonoma is an endocrine tumor of the pancreas that secretes excessive amounts of glucagon, which causes a distinct syndrome characterized by dermatitis, glucose intolerance or diabetes, and weight loss. Glucagonomas occur in persons between 45 and 70 years of age and are clinically heralded by a characteristic dermatitis (migratory necrolytic erythema) (67 to 90%), accompanied by glucose intolerance (40 to 90%), weight loss (66 to 96%), anemia (33 to 85%), diarrhea (15 to 29%), and thromboembolism (11 to 24%). The characteristic rash usually starts as an annular erythema at intertriginous and periorificial sites, especially in the groin or buttock. It subsequently becomes raised, and bullae form and leave erosions when the bullae rupture. The lesions can wax and wane. A characteristic laboratory finding is hypoaminoacidemia, which occurs in 26 to 100% of patients.

Glucagonomas are generally large tumors at diagnosis, with average size of 5 to 10 cm. From 50 to 80% occur in the pancreatic tail, and from 50 to 82% have metastatic spread at presentation, usually to the liver. Glucagonomas are rarely extrapancreatic and usually occur singly.

Diagnosis The diagnosis is confirmed by demonstrating an increased plasma glucagon level (normal is <150 μg/L). Plasma glucagon levels are >1000 μg/mL in 90%, are between 500 and 1000 μg/mL in 7%, and <500 μg/mL in 3%. A plasma glucagon level > 1000 μg/L is considered diagnostic of glucagonoma. Other diseases causing increased plasma glucagon levels include renal insufficiency, acute pancreatitis, hypercorticism, hepatic insufficiency, prolonged fasting, or familial hyperglucagonomia. These disorders do not increase plasma glucagon to >500 μg/L except cirrhosis.

TREATMENT

In 50 to 80% of patients metastases are present at presentation, so curative surgical resection is not possible. Surgical debulking in patients with advanced disease or other antitumor treatments may be beneficial and will be discussed below. Long-acting somatostatin analogues such as octreotide or lanreotide improve the skin rash in 75% of patients and may improve the weight loss, pain, and diarrhea, but usually do not improve the glucose intolerance.

SOMATOSTATINOMA SYNDROME The somatostatinoma syndrome is due to a NET that secretes excessive amounts of somatostatin, which causes a distinct syndrome characterized by diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea. Usually no distinction is made between a tumor that contains somatostatin-like immunoreactivity (somatostatinoma) and that does or does not produce a clinical syndrome (somatostatinoma syndrome) by secreting somatostatin (11 to 45% and 55 to 89%, respectively). In one review of 173 cases of somatostatinomas, only 11% were associated with the somatostatinoma syndrome. The mean age of patients is 51 years. Somatostatinomas occur primarily in the pancreas and small intestine, and the frequency of the symptoms differs in each. Each of the usual symptoms is more frequent in pancreatic than intestinal somatostatinomas: diabetes mellitus (95% vs. 21%), gallbladder disease (94% vs. 43%), diarrhea (92% vs. 38%), steatorrhea (83% vs. 12%), hypochlorhydria (86% vs. 12%), and weight loss (90% vs. 69%). Somatostatinomas occur in the pancreas in 56 to 74% of cases, with the primary location being in the pancreatic head. The tumors are usually solitary (90%) and large, with a mean size of 4.5 cm. Liver metastases are frequent (69 to 84% of patients).

Somatostatin is a tetradecapeptide (Fig. 329-2) that is widely distributed in the central nervous system and gastrointestinal tract, where it functions as a neurotransmitter or has paracrine and autocrine actions. It is a potent inhibitor of many processes, including release of almost all hormones, acid secretion, intestinal and pancreatic secretion, and intestinal absorption. Most of the clinical manifestations are directly related to these inhibitory actions.

Diagnosis In most cases somatostatinomas have been found by accident either at the time of cholecystectomy or during endoscopy. The presence of psammoma bodies in a duodenal tumor should particularly raise suspicion. Duodenal somatostatin-containing tumors are increasingly associated with von Recklinghausen's disease. Most of these do not cause the somatostatinoma syndrome. The diagnosis of the somatostatinoma syndrome requires elevated plasma somatostatin levels.

TREATMENT

Pancreatic tumors are frequently metastatic at presentation (70 to 92%), whereas 30 to 69% of small-intestinal somatostatinomas have metastases. Surgery is the treatment of choice for those without widespread hepatic metastases. Symptoms in patients with the somatostatinoma syndrome are also improved by octreotide treatment.

VIPOMAS VIPomas are endocrine tumors that secrete excessive amounts of VIP, which causes a distinct syndrome characterized by large-volume watery diarrhea, hypokalemia, and dehydration. This syndrome is also called Verner-Morrison syndrome, pancreatic cholera, or WDHA syndrome for *w*atery *d*iarrhea, *h*ypokalemia, and *a*chlorhydria, which some patients develop. The mean age of patients is 49 years; however, it can occur in children, and when it does is usually caused by a ganglioneuroma or ganglioneuroblastoma.

The principal symptoms are large-volume diarrhea (100%) severe enough to cause hypokalemia (80 to 100%), dehydration (83%), hypochlorhydria (54 to 76%), and flushing (20%). The diarrhea is secretory in nature, persists during fasting, and is almost always >1 L/d and >3 L/d in 70%. Most patients do not have accompanying steatorrhea (16%), and the increased stool volume is due to increased excretion of sodium and potassium, which, with the anions, account for the osmolality of the stool. Patients frequently have hyperglycemia (25 to 50%) and hypercalcemia (25 to 50%).

VIP is a 28-amino-acid peptide that is an important neurotransmitter ubiquitously present in the central nervous system and GI tract. Its known actions include stimulation of small-intestinal chloride secretion and effects on smooth-muscle contractility, inhibition of acid secretion, and vasodilatory effects which explain most features of the clinical syndrome.

In adults 80 to 90% of VIPomas are pancreatic in location, with the rest due to VIP-secreting pheochromocytomas, intestinal carcinoids, and rarely ganglioneuromas. These tumors are usually not multiple, 50 to 75% are in the pancreatic tail, and 37 to 68% have hepatic metastases at diagnosis. In children <10 years, the syndrome is usually due to ganglioneuromas or ganglioblastomas, which are less malignant and account for 10% of VIPomas in adults.

Diagnosis The diagnosis requires the demonstration of an elevated plasma VIP level and the presence of large-volume diarrhea. A stool volume of <700 mL/d excludes the diagnosis of VIPoma. By fasting the patient, a number of causes can be excluded that can cause marked diarrhea. Other diseases that can give a secretory large-volume diarrhea include gastrinomas, chronic laxative abuse, carcinoid syndrome, systemic mastocytosis, rarely medullary thyroid cancer, diabetic diarrhea, and AIDS. Of these conditions, only VIPomas caused a marked increase in plasma VIP.

TREATMENT

The most important initial treatment is to correct their dehydration, hypokalemia, and electrolyte losses with fluid and electrolyte replacement. These patients may require 5 L/d of fluid and >350 meq/d of potassium. Because 37 to 68% of adults with VIPomas have metastatic disease in the liver at presentation, a significant number of patients cannot be cured surgically. In these patients, long-acting somatostatin analogues such as octreotide or lanreotide are the drugs of choice.

Octreotide will control the diarrhea in 87% of patients. In nonresponsive patients, the combination of glucocorticoids and octreotide has proved helpful in a small number of patients. Other drugs reported to be helpful in small numbers of patients include prednisone (60 to 100 mg/d), clonidine, indomethacin, phenothiazines, loperamide, lidamidine, lithium, propranolol, and metochlorpramide.

Treatment of advanced disease with embolization, chemoembolization, and chemotherapy may also be helpful (see below).

NONFUNCTIONAL PANCREATIC ENDOCRINE TUMORS Nonfunctional PETs are endocrine tumors that originate in the pancreas and either secrete no products or their secreted products do not cause a specific clinical syndrome. The symptoms are due entirely to the tumor per se. Nonfunctional PETs almost always secrete chromogranin A (90 to 100%), chromogranin B (90 to 100%), PP (58%), α-human chorionic gonadotropin (hCG) (40%), and β-hCG (20%), but none cause a specific syndrome. Because the symptoms are due to the tumor per se, patients with nonfunctional PETs usually present late in their disease course with invasive tumors and hepatic metastases (64 to 92%), and the tumors are usually large (72% are >5 cm). These tumors are usually solitary except in patients with MEN-1, where they are multiple, and occur primarily in the pancreatic head. Even though these tumors do not cause a functional syndrome, immunocytochemical studies show that they synthesize numerous peptides and cannot be distinguished from functional tumors by immunocytochemistry.

The most common symptoms are abdominal pain (30 to 80%); jaundice (20 to 35%); and weight loss, fatigue, or bleeding; 10 to 15% are found incidentally. The average time from the beginning of symptoms to diagnosis is 5 years.

Diagnosis The diagnosis is established by histologic confirmation in a patient with a PET without either clinical symptoms or elevated plasma hormone levels of one of the established syndromes. Even though chromogranin A levels are elevated in almost every patient, this is not specific for this disease as it can be found in functional PETs, carcinoids, and other neuroendocrine disorders. Plasma PP is increased in 22 to 71% of patients and should strongly suggest the diagnosis in a patient with a pancreatic mass because it is usually normal in patients with pancreatic adenocarcinomas. Elevated plasma PP is not diagnostic of this tumor because it is elevated in a number of other conditions such as chronic renal failure, old age, inflammatory conditions, and diabetes.

TREATMENT

Unfortunately, surgical curative resection can be considered only in the minority of patients because of the high frequency of metastatic disease. Treatment needs to be directed against the tumor per se (see below).

GRFOMAS GRFomas are endocrine tumors that secrete excessive amounts of GRF, which causes acromegaly. The true frequency of this syndrome is not known. GRF is a 44-amino-acid peptide, and 25 to 44% of PETs have GRF immunoreactivity, although it is uncommonly secreted. GRFomas are lung tumors in 47 to 54% of cases, PETs in 29 to 30%, and small-intestinal carcinoids in 8 to 10%, and up to 12% occur at other sites. Patients have a mean age of 38 years, and the symptoms are usually due to either acromegaly or the tumor per se. The acromegaly caused by GRFomas is indistinguishable from classic acromegaly. The pancreatic tumors are usually large (>6 cm) and liver metastases are present in 39%. They should be suspected in any patient with acromegaly and an abdominal tumor, in a patient with MEN-1 with acromegaly, or in a patient without a pituitary adenoma with acromegaly or associated with hyperprolactinemia, which occurs in 70% of GRFomas. GRFomas are an uncommon cause of acromegaly. The diagnosis is established by performing plasma assays for GRF and growth hormone. The normal level for GRF is <5 μg/L in men and <10 μg/L in women. Most GRFomas have a plasma GRF level ≥300 μg/L. Patients with GRFomas also have increased plasma insulin-like growth factor 1 levels similar to those in classic acromegaly. Surgery is the treatment of choice if diffuse metastases are not present. Long-acting somatostatin analogues such as octreotide or lanreotide are the agents of choice, with 75 to 100% of patients responding.

OTHER RARE PANCREATIC ENDOCRINE TUMOR SYNDROMES Cushing's (ACTHoma) due to a PET occurs in 4 to 16% of all ectopic Cushing's syndrome cases. It occurs in 5% of cases of sporadic gastrinomas, almost invariably in patients with hepatic metastases, and is an independent, poor prognostic factor. Paraneoplastic hypercalcemia due to PETs releasing parathyroid hormone–related peptide (PTHrP), a parathyroid hormone–like material, or unknown factor is rarely reported. The tumors are usually large, and liver metastases are usually present. Most (88%) appear to be due to release of PTHrP. PETs can occasionally cause the carcinoid syndrome. PETs secreting calcitonin appear to have a specific clinical syndrome. Half the patients have diarrhea, which disappears with resection of the tumor. That this could be a discrete syndrome is supported by finding that 25 to 42% of patients with medullary thyroid cancer with hypercalcitonemia develop diarrhea, likely secondary to a motility disorder. This is classified in Table 329-2 as a possible specific disorder because so few cases have been described. A renin-producing PET has been described in a patient presenting with hypertension (Table 329-2). Ghrelin is a 28-amino-acid peptide with growth hormone–releasing effect and a strong influence on appetite, among other functions. Even though it is detectable immunohistochemically in most PETs, only 1 in 24 patients (4%) with a PET had elevated plasma ghrelin levels and the patient was asymptomatic, suggesting that no specific syndrome is associated with release of ghrelin by a PET.

TUMOR LOCALIZATION

Localization of the primary tumor and determination of the extent of disease are essential to the proper management of all carcinoids and PETs. Without proper localization studies it is not possible (1) to determine whether the patient is a candidate for curative resection or cytoreductive surgery or requires antitumor treatment (2) or to predict the patient's prognosis.

Numerous tumor localization methods are used in both types of NETs including conventional imaging studies [CT scanning, magnetic resonance imaging (MRI), transabdominal ultrasound, selective angi-

ography] and somatostatin receptor scintigraphy (SRS). In PETs, endoscopic ultrasound (EUS) and functional localization by measuring venous hormonal gradients are also useful. Bronchial carcinoids are usually detected by a standard chest radiograph and assessed by CT. Rectal, duodenal, colonic, and gastric carcinoids are usually detected by GI endoscopy.

PETs and carcinoid tumors frequently overexpress high-affinity somatostatin receptors in both their primary and their metastatic tumors. Of the five types of somatostatin receptors (sst_{1-5}), radiolabeled octreotide binds with high affinity to sst_2 and sst_5, lower for sst_3, and has a very low affinity for sst_1 and sst_4. Nearly all carcinoid tumors and PETs express sst_2, and many also have the other four sst subtypes. Interaction with these receptors can be used to localize NETs using [^{111}In-DTPA-D-Phe^1]octreotide (Fig. 329-2) and radionuclide scanning (SRS) as well as for treatment of the hormone excess state with octreotide or lanreotide. Because of its sensitivity and ability to localize tumor throughout the body at one time, SRS is now the initial imaging modality of choice for localizing both primary NETs and metastases. SRS localizes tumor in 73 to 89% of patients with carcinoids and in 56 to 100% of patients with PETs, except for insulinomas. Insulinomas are usually small and have low densities of sst receptors, resulting in SRS being positive in only 12 to 50% of insulinomas. SRS has greater sensitivity than conventional imaging studies in localizing both the primary tumor and metastases. Figure 329-3 shows an example of the increased sensitivity of SRS in a patient with a gastrinoma. The CT scan (Fig. 329-3, *top*) did not show any disease after resection of the primary tumor; however, hypergastrinemia remained and the SRS demonstrated a metastasis in the liver (Fig. 329-3, *bottom*). Occasional false-positive responses with SRS can occur (12% in one study) because numerous other normal tissues and diseases can have high densities of sst receptors including granulomas (sarcoid, tuberculosis, etc.), thyroid diseases (goiter, thyroiditis), and activated lymphocytes (lymphomas, wound infections). For PETs located in the pancreas, EUS is highly sensitive localizing 77 to 93% of insulinomas, which occur almost exclusively within the pancreas. EUS is less sensitive for extrapancreatic tumors. If liver metastases are identified by SRS, either a CT scan or MRI is then recommended to assess the size and exact location of the metastases because SRS does not give information on tumor size. Functional localization measuring hormone gradients after intraarterial calcium injections in insulinomas (insulin) or gastrin gradients after secretin injections in gastrinoma is a sensitive method, being positive in 80 to 100% of patients. However, this method gives only regional localization and is reserved for cases where the other imaging modalities are negative.

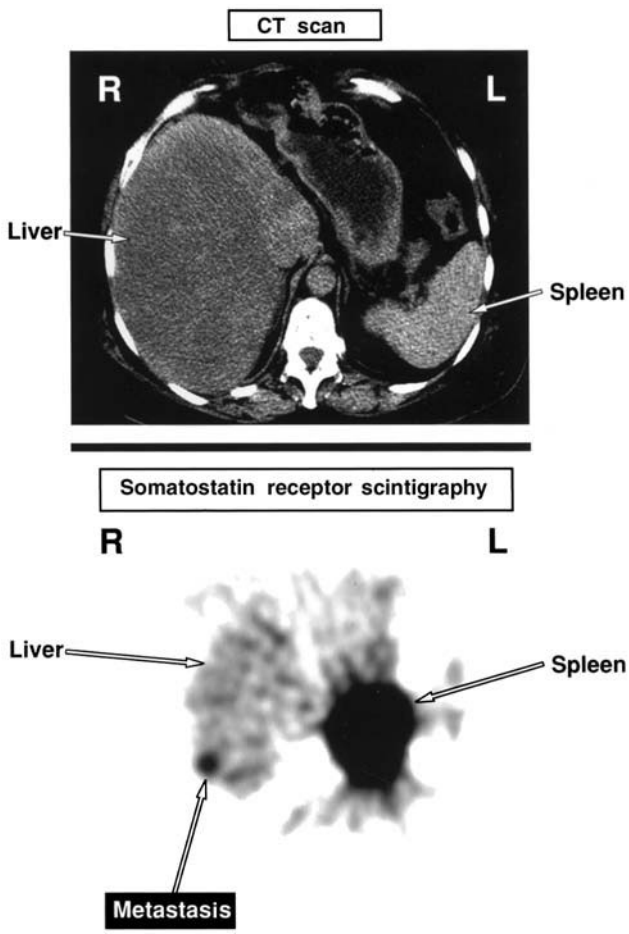

FIGURE 329-3 Ability of computed tomography (*top*) or somatostatin receptor scintigraphy (*bottom*) to localize metastatic gastrinoma in the liver in a patient with Zollinger-Ellison syndrome.

TREATMENT

Advanced Disease (Diffuse Metastatic Disease) The single most important prognostic factor for survival is the presence of liver metastases (Fig. 329-4). For patients with foregut carcinoids without hepatic metastases, the 5-year survival is 95% and with distant metastases is 20% (Fig. 329-4, *bottom*). With gastrinomas the 5-year survival without liver metastases is 98%, with limited metastases in one hepatic lobe it is 78%, and with diffuse metastases it is 16% (Fig. 329-4, *top*). Therefore, treatment for advanced metastatic disease is important. A number of different modalities are effective, including cytoreductive surgery

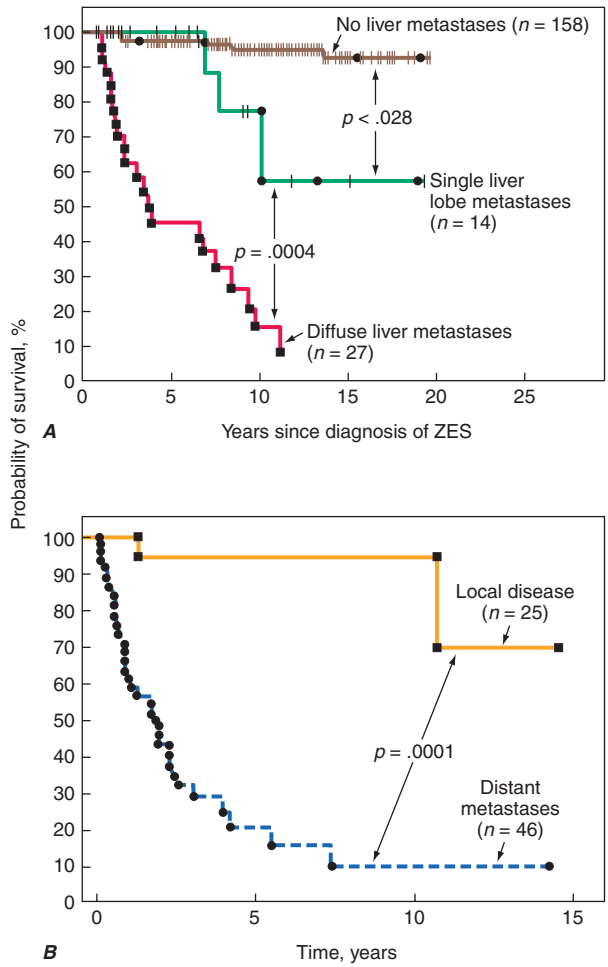

FIGURE 329-4 Effect of the presence and extent of liver metastases on survival in patients with gastrinomas (*top*) or carcinoid tumors (*bottom*). (*Top panel is drawn from data from 199 patients with gastrinomas modified from F Yu et al: J Clin Oncol 17:615, 1999. Bottom panel is drawn from data from 71 patients with foregut carcinoid tumors from EW McDermott et al: Br J Surg 81:1007, 1994; with permission.*)

(removal of all visible tumor), treatment with chemotherapy, somatostatin analogues, interferon α, hepatic embolization alone or with chemotherapy (chemoembolization), radiotherapy, and liver transplantation.

Specific Antitumor Treatments Cytoreductive surgery, unfortunately, is only possible in 9 to 22% of patients who present with limited hepatic metastases. Although no randomized studies have proven it extends life, results from a number of studies suggest it likely increases survival, and therefore it is recommended if possible.

Chemotherapy for metastatic carcinoid tumors has generally been disappointing, with response rates of 0 to 40% with various two- or three-drug combinations. Chemotherapy for PETs has been more successful with tumor shrinkage reported in 30 to 70% of patients. The current regimen of choice is streptozocin and doxorubicin.

Long-acting somatostatin analogues, such as octreotide and lanreotide, and interferon α rarely decrease tumor size (i.e., 0 to 17%); however, these drugs have tumoristatic effects, stopping additional growth in 26 to 95% of patients with NETs. How long tumor stabilization lasts or whether it prolongs survival has not been established. Somatostatin analogues can induce apoptosis in carcinoid tumors.

Hepatic embolization and chemoembolization (with dacarbazine, cisplatin, doxorubicin, 5-fluorouracil, or streptozocin) may decrease tumor bulk and help control the symptoms of the hormone-excess state. These modalities are generally reserved for cases in which treatment with somatostatin analogues, interferon (carcinoids), or chemotherapy (PETs) fails. Embolization, when combined with treatment with octreotide and interferon α, significantly reduces tumor progression compared to treatment with embolization and octreotide alone in patients with advanced midgut carcinoids.

Radiotherapy with radiolabeled somatostatin analogues (Fig. 329-2) that are internalized by the tumors is an approach being investigated. Three different radionuclides are being used. High doses of [^{111}In-DTPA-D-Phe^1]octreotide (emits γ rays, internal conversion, and Auger electrons) and yttrium-90 (emits high energy β-particles) coupled by a DOTA-chelating group (Fig. 329-2) to octreotide or octreotate are being used as well as ^{177}Lu-coupled analogues (emit β- and γ-rays). In one study, treatment with the ^{111}In or ^{177}Lu compounds caused tumor stabilization in 41% and 40%, respectively, and a decrease in tumor size in 30% and 38%, respectively, in patients with advanced metastatic NETs. Hormone-directed radiation therapy may be helpful in patients with advanced, widespread metastatic disease.

The use of liver transplantation has been abandoned for treatment of most metastatic tumors to the liver. However, for metastatic NETs it is still a consideration. In a recent review of 103 cases of malignant NETs (48 PETs, 43 carcinoids) the 2- and 5-year survival rates were 60% and 47%, respectively. However, recurrence-free survival was low (<24%). For younger patients with metastatic NETs limited to the liver, liver transplantation may be justified.

330 DISORDERS AFFECTING MULTIPLE ENDOCRINE SYSTEMS

Steven I. Sherman, Robert F. Gagel

NEOPLASTIC DISORDERS AFFECTING MULTIPLE ENDOCRINE ORGANS

Several distinct genetic disorders predispose to endocrine gland neoplasia and cause hormone excess syndromes (Table 330-1). DNA-based genetic testing is now available for these disorders, but effective management requires an understanding of endocrine neoplasia and the range of clinical features that may be manifest in an individual patient.

TABLE 330-1 Disease Associations in the Multiple Endocrine Neoplasia (MEN) Syndromes

MEN1	*MEN2*	*Mixed Syndromes*
Parathyroid hyperplasia or adenoma	MEN2A	von Hippel–Lindau syndrome, pheochromocytoma, islet cell tumor, renal cell carcinoma, hemangioblastoma of central nervous system, retinal angiomas
Islet cell hyperplasia, adenoma, or carcinoma	MTC	Neurofibromatosis with features of MEN1 or 2
Pituitary hyperplasia or adenoma	Pheochromocytoma	Carney complex
Other less common manifestations: foregut carcinoid, pheochromocytoma, subcutaneous or visceral lipomas	Parathyroid hyperplasia or adenoma	Myxomas of heart, skin, and breast
	Cutaneous lichen amyloidosis	Spotty cutaneous pigmentation
	Hirschsprung disease	Testicular, adrenal, and GH-producing pituitary tumors
	Familial MTC	Peripheral nerve schwannomas
	MEN2B	
	MTC	
	Pheochromocytoma	
	Mucosal and gastrointestinal neuromas	
	Marfanoid features	

Note: MTC, medullary thyroid carcinoma.

MULTIPLE ENDOCRINE NEOPLASIA (MEN) TYPE 1 ■ Clinical Manifestations

MEN1, or Wermer's syndrome, is an autosomal dominant genetic syndrome characterized by neoplasia of parathyroid, pituitary, pancreatic islet, and other neuroendocrine cell types (Table 330-1). Each child born to an affected parent has a 50% probability of inheriting the gene. The variable penetrance of the several neoplastic components can make the differential diagnosis challenging.

Hyperparathyroidism is the most common manifestation of MEN1. Hypercalcemia may develop during the teenage years, and most individuals are affected by age 40 (Fig. 330-1). The neoplastic changes in hyperparathyroidism exemplify one of the cardinal features of endocrine tumors in MEN1—multicentricity. The neoplastic changes inevitably affect multiple parathyroid glands, making surgical cure difficult. Screening for hyperparathyroidism involves measurement of either an albumin-adjusted or ionized serum calcium level. The diagnosis is established by demonstrating elevated levels of serum calcium and inappropriately normal or high intact parathyroid hormone. Manifestations of hyperparathyroidism in MEN1 do not differ substantially from those in sporadic hyperparathyroidism and include calcium-containing kidney stones, bone abnormalities, and gastrointestinal and musculoskeletal complaints (Chap. 332).

Other familial disorders associated with hypercalcemia include familial isolated hyperparathyroidism, a broad categorization that includes at least two types, HRPT1 and HRPT2. The first type, HRPT1, includes familial parathyroid hyperplasia and adenomatosis. The second type, HRPT2, is associated with multiple cystic parathyroid ade-

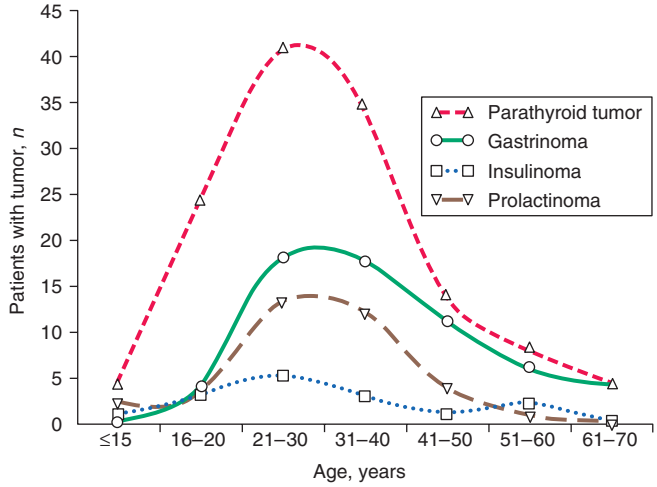

FIGURE 330-1 Age at onset of endocrine tumor expression in multiple endocrine neoplasia type 1 (MEN1). Data derived from retrospective analysis for each endocrine organ hyperfunction in 130 cases of MEN1. Age at onset is the age at first symptom or, with tumors not causing symptoms, age at the time of the first abnormal finding on a screening test. The rate of diagnosis of hyperparathyroidism increased sharply between ages 16 and 20 years. (*Reprinted with permission from S Marx et al: Ann Intern Med 129:484, 1998.*)

nomas and ossifying jaw fibromas. Inactivating mutations of the gene that encodes parafibromin were recently identified in nearly all families with HRPT2. Subsequent analysis of this gene in families with HRPT1 indicates that some patients with HRPT1 have mutations of the HRPT2 gene. Inactivating mutations of HRPT2 are also found commonly in sporadic parathyroid cancers. MEN2 (to be discussed below) should also be considered in the differential diagnosis. Another cause of familial hypercalcemia is familial hypercalcemic hypocalciuria (FHH), an autosomal dominant form of hypercalcemia caused by inactivating mutations of the calcium sensor, a transmembrane G protein–coupled receptor found in parathyroid tissue and kidney (Chap. 332). Hypercalcemia associated with MEN1, MEN2, HRPT1, and HRPT2 is characterized by increased urine calcium excretion (calcium/creatinine clearance ratio > 0.01) whereas in FHH it is associated with low urine calcium excretion (calcium/creatinine clearance ratio < 0.01). Another distinguishing feature is that the serum calcium level is rarely elevated at birth in patients with MEN1 but is frequently elevated in newborns with FHH.

Differentiation of hyperparathyroidism of MEN1 from other forms of familial primary hyperparathyroidism is usually based on family history, histologic features of resected parathyroid tissue, and, sometimes, long-term observation to determine whether other manifestations of MEN1 develop. Parathyroid hyperplasia is the most common cause of hyperparathyroidism in MEN1, although single and multiple adenomas have been described. Hyperplasia of one or more parathyroid glands is common in younger patients; adenomas are usually found in older patients or those with long-standing disease.

Neoplasia of the pancreatic islets is the second most common manifestation of MEN1 and tends to occur in parallel with hyperparathyroidism (Fig. 330-1). Increased pancreatic islet cell hormones include pancreatic polypeptide (75 to 85%), gastrin [60%; Zollinger-Ellison syndrome (ZES)], insulin (25 to 35%), vasoactive intestinal peptide (VIP) (3 to 5%; Verner-Morrison, or watery diarrhea, syndrome), glucagon (5 to 10%), and somatostatin (1 to 5%). The tumors rarely produce adrenocorticotropin (ACTH), corticotropin-releasing hormone (CRH), growth hormone–releasing hormone (GHRH), calcitonin gene products, neurotensin, gastric inhibitory peptide, and others. Many of the tumors produce more than one peptide. The pancreatic neoplasms differ from the other components of MEN1 in that approximately one-third of the tumors display malignant features, including hepatic metastases (Chap. 329).

Pancreatic islet cell tumors are diagnosed by identification of a characteristic clinical syndrome, hormonal assays with or without provocative stimuli, or radiographic techniques. One approach involves annual screening of individuals at risk with measurement of basal and meal-stimulated levels of pancreatic polypeptide to identify the tumors as early as possible; the rationale of this screening strategy is that surgical removal of islet cell tumors at an early stage will be curative. Other approaches to screening include measurement of serum gastrin and pancreatic polypeptide levels every 2 to 3 years, with the rationale that pancreatic neoplasms will be detected at a later stage but can be managed medically, if possible, or by surgery. High-resolution, early-phase computed tomography (CT) scanning or endoscopic ultrasound provides the best preoperative technique for identification of these tumors; intraoperative ultrasonography is the most sensitive method for detection of small tumors.

ZES is caused by excessive gastrin production and occurs in more than half of MEN1 patients with pancreatic islet cell tumors or small carcinoid-like tumors in the duodenal wall (Fig. 330-1) (Chap. 329). Approximately one-fourth of all ZES occurs in the context of MEN1. Clinical features include increased gastric acid production, recurrent peptic ulcers, diarrhea, and esophagitis. The ulcer diathesis is refractory to conservative therapy such as antacids. The diagnosis is made by finding increased gastric acid secretion, elevated basal gastrin levels in serum [generally >115 pmol/L (200 pg/mL)], and an exaggerated response of serum gastrin to either secretin or calcium. Other causes of elevated serum gastrin levels, such as achlorhydria, treatment with H_2 receptor antagonists or omeprazole, retained gastric antrum, small-bowel resection, gastric outlet obstruction, and hypercalcemia, should be excluded.

Insulinoma causes hypoglycemia in about one-third of MEN1 patients with pancreatic islet cell tumors (Fig. 330-1). The tumors may be benign or malignant (25%). The diagnosis can be established by documenting hypoglycemia during a short fast with simultaneous inappropriate elevation of serum insulin and C-peptide levels. More commonly, it is necessary to subject the patient to a supervised 12- to 72-h fast to provoke hypoglycemia (Chap. 324). Large insulinomas may be identified by CT scanning; small tumors not detected by radiographic techniques may be localized by selective arteriographic injection of calcium into each of the arteries that supply the pancreas and timed sampling of the hepatic vein for insulin to determine the anatomic region containing the tumor. Intraoperative ultrasonography can also be used to localize these tumors, but preoperative calcium injection data are helpful in guiding the appropriate pancreatic surgical procedure if multiple or no abnormalities are detected by intraoperative ultrasonography.

Glucagonoma in occasional MEN1 patients causes a syndrome of hyperglycemia, skin rash (necrolytic migratory erythema), anorexia, glossitis, anemia, depression, diarrhea, and venous thrombosis. In about half of these patients the plasma glucagon level is high, leading to its designation as the *glucagonoma syndrome*, although elevation of plasma glucagon level in MEN1 patients is not necessarily associated with these symptoms. Some patients with this syndrome also have elevated plasma ghrelin levels. The glucagonoma syndrome may represent a complex interaction between glucagon and ghrelin overproduction and the nutritional status of the patient.

The *Verner-Morrison syndrome*, or *watery diarrhea syndrome*, consists of watery diarrhea, hypokalemia, hypochlorhydria, and metabolic acidosis. The diarrhea can be voluminous and is almost always found in association with an islet cell tumor, prompting use of the term *pancreatic cholera*. However, the syndrome is not restricted to pancreatic islet tumors and has been observed with carcinoids or other tumors. This syndrome is believed to be due to overproduction of VIP, although plasma VIP levels are not always elevated. Hypercalcemia may be induced by the effects of VIP on bone as well as by hyperparathyroidism. The differential diagnosis includes other causes of chronic diarrhea, infectious or parasitic diseases, inflammatory bowel disease, or sprue or other endocrine causes such as ZES, carcinoid syndrome, or medullary thyroid carcinoma.

Pituitary tumors occur in more than half of patients with MEN1 and tend to be multicentric, making them difficult to resect (Chap. 318). Prolactinomas are most common (Fig. 330-1) and are diagnosed by finding serum prolactin levels >200 μg/L, with or without a pituitary mass evident by magnetic resonance imaging (MRI). Values <200 μg/L may be due to a prolactin-secreting neoplasm or to compression of the pituitary stalk by a different type of pituitary tumor. Acromegaly due to excessive growth hormone (GH) production is the second most common syndrome caused by pituitary tumors in MEN1 (Chap. 318) but is rarely caused by production of GHRH by an islet cell tumor (see above). Cushing's disease can be caused by ACTH-producing pituitary tumors or by ectopic production of ACTH or CRH by other components of MEN1 syndrome including islet cell or carcinoid tumors. Diagnosis of pituitary Cushing's disease is generally best accomplished by a high-dose dexamethasone suppression test or by petrosal venous sinus sampling for ACTH after intravenous injection of CRH (Chap. 318). Differentiation of a primary pituitary tumor from an ectopic CRH-producing tumor may be difficult because the pituitary is the source of ACTH in both disorders; documentation of CRH production by a pancreatic islet or carcinoid tumor may be the only method of proving ectopic CRH production. Adrenal cortical tumors are found in almost one-half of gene carriers but are rarely functional; malignancy in the cortical adenomas is uncommon.

Carcinoid tumors in MEN1 are of the foregut type and are derived from thymus, lung, stomach, or duodenum; they may metastasize or be locally invasive. These tumors usually produce serotonin, calcitonin, or CRH. The typical carcinoid syndrome with flushing, diarrhea, and bronchospasm is rare (Chap. 329). Mediastinal carcinoid tumors (an upper mediastinal mass) are more common in men; bronchial carcinoid tumors are more common in women. Carcinoid tumors are a late manifestation of MEN1; screening regularly for mediastinal carcinoid tumors by chest CT scans has been recommended because of the high rate of malignant transformation.

UNUSUAL MANIFESTATIONS OF MEN1 Subcutaneous or visceral lipomas and cutaneous leiomyomas may also be present but rarely undergo malignant transformation. Skin angiofibromas or collagenomas are seen in most patients with MEN1 when carefully sought.

GENETIC CONSIDERATIONS

MEN1 is transmitted as an autosomal dominant trait, reflecting the fact that the gene that causes MEN1, located on chromosome 11q13, encodes a tumor-suppressor protein termed *menin* (Fig. 330-2). Affected individuals typically harbor a germline mutation in *MEN1* and acquire a "second hit" in the normal gene as a result of another mutation or, more commonly, loss of the portion of chromosome 11 that contains the MEN1 locus (Chap. 68). Though the function of menin is not well understood, it is a nuclear protein that interacts with at least two transcriptional factors, SMAD 3 and Jun D, suggesting a regulatory role in cell growth.

MEN1 gene mutations are found in >90% of families with the syndrome (Fig. 330-2). Genetic testing can be performed in individuals at risk for the development of MEN1 and is now commercially available in the United States and Europe. The major value of genetic testing in a kindred with an identifiable mutation is the assignment or exclusion of gene carrier status. In those identified as carrying the mutant gene, routine screening for individual manifestations of MEN1 should be performed as outlined above. Those with negative genetic test results (in a kindred with an identified mutation) can be excluded from further screening for MEN1. A significant percentage of sporadic parathyroid, islet cell, and carcinoid tumors also have loss or mutation of *MEN1*. It is presumed that these mutations are somatic and occur in a single cell, leading to subsequent transformation.

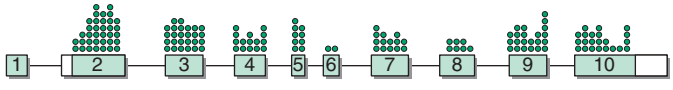

FIGURE 330-2 Schematic depiction of the MEN1 gene and the distribution of mutations. The shaded areas show coding sequence. The closed circles show the relative distribution of mutations, mostly inactivating, in each exon. Mutation data are derived from the Human Gene Mutation Database from which more detailed information can be obtained (*www.uwcm.ac.uk/uwcm/mg/hgmd0.html*). (*From M Krawczak, DN Cooper: Trends Genet 13:1321, 1998, with permission.*)

TREATMENT

Almost everyone who inherits a mutant *MEN1* gene develops at least one clinical manifestation of the syndrome. Most develop hyperparathyroidism, 80% develop pancreatic islet cell tumors, and more than half develop pituitary tumors. For most of these tumors, initial surgery is not curative and patients frequently require multiple surgical procedures on two or more endocrine glands during a lifetime. For this reason, it is essential to establish clear goals for management of these patients rather than to recommend surgery casually each time a tumor is discovered. Ranges for acceptable management are discussed below.

Hyperparathyroidism Individuals with serum calcium levels >3.0 mmol/L (12 mg/dL), evidence of calcium nephrolithiasis or renal dysfunction, neuropathic or muscular symptoms, or bone involvement (including osteopenia) should undergo parathyroid exploration. There is less agreement regarding the necessity for parathyroid exploration in individuals who do not meet these criteria, and observation may be appropriate in the MEN1 patient with asymptomatic hyperparathyroidism.

When parathyroid surgery is indicated in MEN1, all parathyroid tissue should be identified and removed at the time of primary operation, and parathyroid tissue should be implanted in the nondominant forearm. Thymectomy should also be performed because of the potential for later development of malignant carcinoid tumors. If reoperation for hyperparathyroidism is necessary at a later date, transplanted parathyroid tissue can be resected from the forearm under local anesthesia with titration of tissue removal to lower the intact parathyroid hormone (PTH) to <50% of basal.

A less desirable approach is to remove 3 to 3.5 parathyroid glands from the neck (leaving ~50 mg of parathyroid tissue), carefully marking the location of residual tissue so that the remaining tissue can be located easily during subsequent surgery. If this approach is utilized, intraoperative PTH measurements should be utilized to monitor adequacy of removal of parathyroid tissue with a goal of reducing postoperative serum intact PTH to ≤50% of basal values.

Pancreatic Islet Tumors (See Chap. 329 for discussion of pancreatic islet tumors not associated with MEN1.) Two features of pancreatic islet cell tumors in MEN1 complicate the management. First, the pancreatic islet cell tumors are multicentric, malignant about a third of the time, and cause death in 10 to 20% of patients. Second, removal of all pancreatic islets to prevent malignancy causes diabetes mellitus, a disease with significant long-term complications that include neuropathy, retinopathy, and nephropathy. These features make it difficult to formulate clear-cut guidelines, but some general concepts appear to be valid. First, islet cell tumors producing insulin, glucagon, VIP, GHRH, or CRH should be resected because medical therapy for the hormonal effects of these tumors is generally ineffective. Second, gastrin-producing islet cell tumors that cause ZES are frequently multicentric. Recent experience suggests that a high percentage of ZES in MEN1 is caused by duodenal wall tumors and that resection of these tumors improves the cure rate. Treatment with H_2 receptor antagonists (cimetidine or ranitidine) and the H^+,K^+-ATPase inhibitors (omeprazole or lansoprazole) provides an alternative, and some think preferable, therapy to surgery for control of ulcer disease in patients with multicentric tumors or with hepatic metastases. Third, total pancreatectomy at an early age may be justified to prevent malignancy for families who have a high incidence of malignant cell tumors that cause death.

Management of metastatic islet cell carcinoma is unsatisfactory. Hormonal abnormalities can sometimes be controlled. For example, ZES can be treated with H_2 receptor antagonists or H^+,K^+-ATPase inhibitors; the somatostatin analogues, octreotide or lanreotide, are

useful in the management of carcinoid and the watery diarrhea syndrome. Bilateral adrenalectomy may be required for ectopic ACTH syndrome if medical therapy is ineffective (Chap. 321). Islet cell carcinomas frequently metastasize to the liver but may grow slowly. Hepatic artery embolization or chemotherapy (5-fluorouracil, streptozocin, chlorozotocin, doxorubicin, or dacarbazine) may reduce tumor mass, control symptoms of hormone excess, and prolong life; however, these treatments are never curative.

Pituitary Tumors Treatment of prolactinomas with dopamine agonists (bromocriptine, cabergoline, or quinagolide) usually returns the serum prolactin level to normal and prevents further tumor growth (Chap. 318). Surgical resection of a prolactinoma is rarely curative but may relieve mass effects. Transsphenoidal resection is appropriate for neoplasms that secrete ACTH, GH, or the α-subunit of the pituitary glycoprotein hormones. Octreotide reduces tumor mass in one-third of GH-secreting tumors and reduces GH and insulin-like growth factor I levels in >75% of patients. Pegvisomant, a GH receptor antagonist, rapidly lowers insulin-like growth factor levels 1/(IGF-1) and is now approved for treatment of acromegaly. Radiation therapy may be useful for large or recurrent tumors.

Advances in the management of MEN1, particularly islet cell and pituitary tumors, have improved outcome in these patients substantially. As a result, other neoplastic manifestations that develop later in the course of this disorder, such as carcinoid syndrome, are now seen with increased frequency.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 ■ Clinical Manifestations Medullary thyroid carcinoma (MTC) and pheochromocytoma are associated in two major syndromes: MEN type 2A and MEN type 2B (Table 330-1). MEN2A is the combination of MTC, hyperparathyroidism, and pheochromocytoma. Three subvariants of MEN2A are familial medullary thyroid carcinoma (FMTC), MEN2A with cutaneous lichen amyloidosis, and MEN2A with Hirschsprung disease. MEN2B is the combination of MTC, pheochromocytoma, mucosal neuromas, intestinal ganglioneuromatosis, and marfanoid features.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2A MTC is the most common manifestation. This tumor usually develops in childhood, beginning as hyperplasia of the calcitonin-producing cells (C cells) of the thyroid. MTC is typically located at the junction of the upper one-third and lower two-thirds of each lobe of the thyroid, reflecting the high density of C cells in this location; tumors >1 cm in size are frequently associated with local or distant metastases. Measurement of the serum calcitonin level after calcium or pentagastrin injection makes it possible to diagnose this disorder at an early stage in its development (see below).

Pheochromocytoma occurs in ~50% of patients with MEN2A and causes hypertension with palpitations, nervousness, headaches, and sometimes sweating (Chap. 322). About half the tumors are bilateral. After unilateral adrenalectomy, >50% of patients develop a pheochromocytoma in the contralateral gland within a decade. A second feature of these tumors is a disproportionate increase in the secretion of epinephrine relative to norepinephrine. This characteristic differentiates the MEN2 pheochromocytomas from sporadic pheochromocytoma and those associated with von Hippel–Lindau (VHL) syndrome, hereditary paraganglioma, or neurofibromatosis. Capsular invasion is common, but metastasis is uncommon. Finally, the pheochromocytomas are almost always found in the adrenal gland, differentiating the pheochromocytomas in MEN2 from the extraadrenal tumors found in hereditary paraganglioma syndromes.

Hyperparathyroidism occurs in 15 to 20% of patients, with the peak incidence in the third or fourth decade. The manifestations of hyperparathyroidism do not differ from those in other forms of primary hyperparathyroidism (Chap. 332). Diagnosis is established by finding hypercalcemia, hypophosphatemia, hypercalciuria, and an inappropriately high serum level of intact PTH. Multiglandular parathyroid hyperplasia is the most common histologic finding, although with long-standing disease, adenomatous changes may be superimposed on hyperplasia.

The most common subvariant of MEN2A is familial MTC, an autosomal dominant syndrome in which MTC is the only manifestation (Table 330-1). The clinical diagnosis of FMTC is established by the identification of MTC in multiple generations without a pheochromocytoma. Since the penetrance of pheochromocytoma is 50% in MEN2A, it is possible that MEN2A could masquerade as FMTC in small kindreds. It is important to consider this possibility carefully before classifying a kindred as having FMTC; failure to do so could lead to death or serious morbidity from pheochromocytoma in an affected kindred member.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2B The association of MTC, pheochromocytoma, mucosal neuromas, and a marfanoid habitus is designated MEN2B. MTC in MEN2B develops earlier and is more aggressive than in MEN2A. Metastatic disease has been described prior to 1 year of age, and death commonly occurs in the second or third decade of life. However, the prognosis is not invariably bad even in patients with metastatic disease, as evidenced by a number of multigenerational families with this disease.

Pheochromocytoma occurs in more than half of MEN2B patients and does not differ from that in MEN2A. Hypercalcemia is rare in MEN2B, and there are no well-documented examples of hyperparathyroidism.

The mucosal neuromas and marfanoid body habitus are the most distinctive features and are recognizable in childhood. Neuromas are present on the tip of the tongue, under the eyelids, and throughout the gastrointestinal tract and are true neuromas, distinct from neurofibromas. The most common presentation in children relates to gastrointestinal symptomatology, including intermittent colic, pseudoobstruction, and diarrhea.

GENETIC CONSIDERATIONS Mutations of the *RET* proto-oncogene have been identified in most patients with MEN2 (Fig. 330-3). *RET* encodes a tyrosine kinase receptor that, in combination with a co-receptor, GDNF family-receptor alpha (GFRα), is normally activated by glial cell–derived neurotropic factor or other members of this transforming growth factor–like family of peptides including artemin, persephin, and neurturin. In the C cell there is evidence that persephin normally activates the RET/GFRα-4 receptor complex and is partially responsible for migration of the C cells into the thyroid gland, whereas in the gastrointestinal tract, glial cell–derived neurotrophic factor activates a RET/GFRα-1 complex. *RET* mutations induce constitutive activity of the receptor, explaining the autosomal dominant transmission of the disorder.

Naturally occurring mutations localize to two regions of the RET tyrosine kinase receptor. The first is a cysteine-rich extracellular domain; point mutations in the coding sequence for one of six cysteines (codons 609, 611, 618, 620, 630, or 634) cause amino acid substitutions that induce receptor dimerization and activation in the absence of its ligand. Codon 634 mutations occur in 80% of MEN2A kindreds and are most commonly associated with classic MEN2A features (Figs. 330-3 and 330-2); an arginine substitution at this codon accounts for half of all MEN2A mutations. All reported families with MEN2A and cutaneous lichen amyloidosis have a codon 634 mutation. Mutations of codons 609, 611, 618, or 620 occur in 10 to 15% of MEN2A kindreds and are more commonly associated with FMTC (Fig. 330-3). Mutations in codons 609, 618, and 620 have also been identified in a variant of MEN2A that includes Hirschsprung disease (Fig. 330-3).

The second region of the RET tyrosine kinase that is mutated in MEN2 is in the substrate recognition pocket at codon 918 (Fig. 330-3). This activating mutation is present in ~95% of patients with MEN2B and accounts for 5% of all *RET* proto-oncogene mutations in MEN2. Mutations of codons 883 and 922 have also been identified in a few patients with MEN2B.

Uncommon mutations (initially <5% of the total) include those of codons 533 (exon 8), 768, 790, 791, 804, 891, and 912. Mutations associated with only FMTC include codons 533, 768, V804M, and 912. A cautionary note is that rare mutations that were once associated with FMTC only (791, V804L, and 891) have been found in families with MEN2A as there are occasional reports of pheochromocytoma. At present it is reasonable to conclude that only kindreds with codon 533, 768, V804M, or 912 mutations are consistently associated with FMTC; in kindreds with all other *RET* mutations, pheochromocytoma is a possibility. Germline mutations occur in at least 6% of patients with apparently sporadic MTC, leading to the recommendation that all patients with MTC should be screened for these mutations. These findings mirror results in other malignancies where germline mutations of cancer-causing genes contribute to a greater percentage of apparently sporadic cancer than previously considered. The recognition of new mutations of *RET* almost 10 years following the initial discovery of *RET* mutations suggests that more will be identified in the future.

Somatic mutations (found only in the tumor and not transmitted in the germline) of the *RET* proto-oncogene have been identified in sporadic MTC; 25 to 35% of sporadic tumors have codon 918 mutations, and somatic mutations in codons 630, 768, and 804 have also been identified (Fig. 330-3).

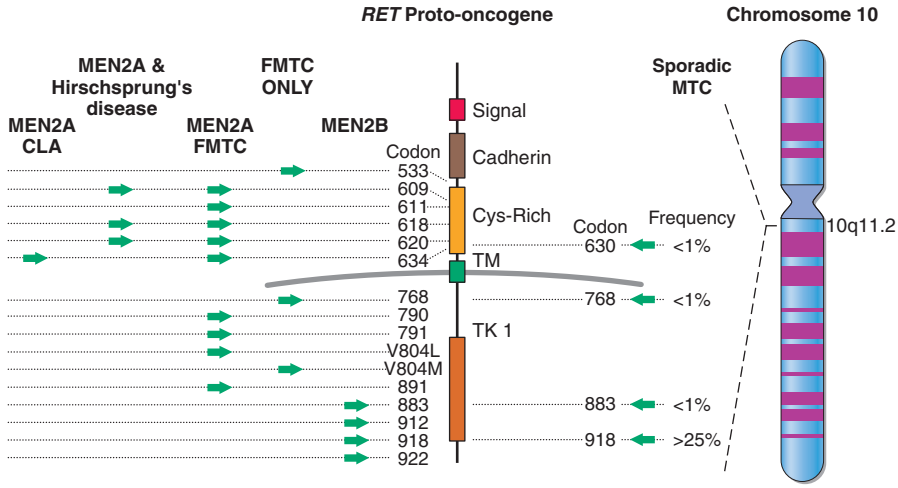

FIGURE 330-3 Schematic diagram of the *RET* proto-oncogene showing mutations found in MEN type 2 and sporadic medullary thyroid carcinoma (MTC). The *RET* proto-oncogene is located on the proximal arm of chromosome 10q (10q11.2). Activating mutations of two functional domains of the RET tyrosine kinase receptor have been identified. The first affects a cysteine-rich (Cys-Rich) region in the extracellular portion of the receptor. Each germline mutation changes a cysteine at codons 609, 611, 618, 620, or 634 to another amino acid. The second region is the intracellular tyrosine kinase (TK) domain. Codon 634 mutations account for ~80% of all germline mutations. Mutations of codons 630, 768, 883, and 918 have been identified as somatic (nongermline) mutations that occur in a single parafollicular or C cell within the thyroid gland in sporadic MTC. A codon 918 mutation is the most common somatic mutation. Abbreviations: MEN2, multiple endocrine neoplasia type 2; CLA cutaneous lichen amyloidosis; FMTC, familial medullary thyroid carcinoma; Signal, the signal peptide; Cadherin, a cadherin-like region in the extracellular domain; TM, transmembrane domain; TK, tyrosine kinase domain.

TREATMENT

Screening for Multiple Endocrine Neoplasia Type 2 Death from MTC can be prevented by early thyroidectomy. The identification of *RET* proto-oncogene mutations and the application of DNA-based molecular diagnostic techniques to identify these mutations has simplified the screening process. During the initial evaluation of a kindred, a *RET* proto-oncogene analysis should be performed on an individual with proven MEN2A. Establishment of the specific germline mutation facilitates the subsequent analysis of other family members. Each family member at risk should be tested twice for the presence of the specific mutation; the second analysis should be performed on a new DNA sample and, ideally, in a second laboratory to exclude sample mix-up or technical error (see *www.genetests.org* for an up-to-date list of laboratory testing sites). Both false-positive and false-negative analyses have been described; a false-negative test result is of the greatest concern because calcitonin testing is now rarely performed as a diagnostic backup study; if there is a genetic test error, a child may present in the second or third decade with metastatic MTC. Individuals in a kindred with a known mutation who have two normal analyses can be excluded from further screening.

There is general consensus that children with codon 883, 918, and 922 mutations, those associated with MEN2B, should have a total thyroidectomy and central lymph node dissection (level VI) performed during the first months of life or soon after identification of the syndrome. If local metastasis is discovered, a more extensive lymph node dissection (levels II to V) is generally indicated. In children with codon 611, 618, 620, 630, 634, and 891 mutations, thyroidectomy should be performed before age 6 because of reports of local metastatic disease in children this age. Finally, there are kindreds with codon 609, 768, 790, 791, 804, and 912 mutations where the phenotype of MTC appears to be less aggressive. In kindreds with these mutations, two management approaches have been suggested: (1) perform a total thyroidectomy, with or without central node dissection, at some arbitrary age (perhaps 6 to 10 years of age); or (2) continue annual or biannual calcitonin provocative testing with performance of total thyroidectomy, with or without central neck dissection, when the test becomes abnormal. The pentagastrin test involves measurement of serum calcitonin basally and at 2, 5, 10, and 15 min after a bolus injection of 5 μg pentagastrin per kilogram body weight. Before injection, patients should be warned of epigastric tightness, nausea, warmth, and tingling of extremities and reassured that the symptoms will last ~2 min. The recent unavailability of pentagastrin in the United States has led to use of a short calcium infusion, performed by obtaining a baseline serum calcitonin and then infusing 150 mg calcium salt intravenously over 10 min with measurement of serum calcium and calcitonin at 5, 10, 15, and 30 min after initiation of the infusion.

The *RET* proto-oncogene analysis should be performed in patients with suspected MEN2B to detect codon 883, 918, and 922 mutations, especially in newborn children where the diagnosis is suspected but the clinical phenotype is not fully developed. Other family members at risk for MEN2B should also be tested because the mucosal neuromas can be subtle and not always identified. Most MEN2B mutations represent de novo germline mutations derived from the paternal allele. In the rare families with proven germline transmission of MTC but no identifiable *RET* proto-oncogene mutation, annual pentagastrin or calcium-pentagastrin testing should be performed on members at risk.

Annual screening for pheochromocytoma in subjects with germline *RET* mutations should be performed by measuring basal plasma or 24-h urine catecholamines and metanephrines. The goal is to identify a pheochromocytoma before it causes significant symptoms or is likely to cause sudden death, an event most commonly associated with large tumors. Radiographic studies, such as MRI or CT scans, are generally reserved for individuals with abnormal screening tests or with symptoms suggestive of pheochromocytoma (Chap. 322). Women should be tested during pregnancy because undetected pheochromocytoma can cause maternal death during childbirth.

Measurement of serum calcium and parathyroid hormone levels every 2 to 3 years provides an adequate screen for hyperparathyroidism, except in those families in which hyperparathyroidism is a prominent component.

Medullary Thyroid Carcinoma Hereditary MTC is a multicentric disorder. Total thyroidectomy with a central lymph node dissection should be performed in children who carry the mutant gene. Incomplete thyroid-

ectomy leaves the possibility of later transformation of residual C cells. The goal of early therapy is to cure, and a strategy that does not accomplish this goal is short-sighted. Long-term follow-up studies indicate an excellent outcome with ~90% of children free of disease 15 to 20 years after surgery. In contrast, 15 to 25% of patients whose diagnosis is based on a palpable thyroid nodule die from the disease within 15 to 20 years.

In adults with MTC >1 cm in size, metastases to regional lymph nodes are common (>75%). Total thyroidectomy with central lymph node dissection and selective dissection of other regional chains provide the best chance for cure. In patients with extensive local metastatic disease in the neck, external radiation may prevent local recurrence or reduce tumor mass but is not curative. Chemotherapy with combinations of adriamycin, vincristine, cyclophosphamide, and dacarbazine may provide palliation. The recent success of gleevec for treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors has prompted efforts to develop inhibitors that target the RET tyrosine kinase. Preliminary in vitro studies have identified several promising agents, and human trials are forthcoming.

Pheochromocytoma The long-term goal for management of pheochromocytoma is to prevent death and cardiovascular complications. Improvements in radiographic imaging of the adrenals make direct examination of the apparently normal contralateral gland during surgery less important, and the rapid evolution of laparoscopic surgery has simplified management of early pheochromocytoma. The major question is whether to remove both adrenal glands or to remove only the affected adrenal at the time of primary surgery. Issues to be considered in this decision include the possibility of malignancy (<15 reported cases), the high probability of developing pheochromocytoma in the apparently unaffected gland over an 8- to 10-year period, and the risks of adrenal insufficiency caused by removal of both glands (at least two deaths related to adrenal insufficiency in MEN2 patients). Most clinicians recommend removing only the affected gland. If both adrenals are removed, glucocorticoid and mineralocorticoid replacement are mandatory. An alternative approach is to perform a cortical-sparing adrenalectomy, removing the pheochromocytoma and adrenal medulla, leaving the adrenal cortex behind. This approach is usually successful and eliminates the necessity for steroid hormone replacement in most patients, although the pheochromocytoma recurs in a small percentage.

Hyperparathyroidism Hyperparathyroidism has been managed by one of two approaches. Removal of 3.5 glands with maintenance of the remaining half gland in the neck is the usual procedure. In families in whom hyperparathyroidism is a prominent manifestation (almost always associated with a codon 634 *RET* mutation) and recurrence is common, total parathyroidectomy with transplantation of parathyroid tissue into the nondominant forearm is preferred. This approach is discussed above in the context of hyperparathyroidism associated with MEN1.

OTHER GENETIC ENDOCRINE TUMOR SYNDROMES A number of mixed syndromes exist in which the neoplastic associations differ from those in MEN1 or 2 (Table 330-1).

The cause of VHL syndrome, the association of central nervous system tumors, renal cell carcinoma, pheochromocytoma, and islet cell neoplasms, is a mutation in the *VHL* tumor-suppressor gene. Germline-inactivating mutations of the *VHL* gene cause tumor formation when there is additional loss or somatic mutation of the normal *VHL* allele in brain, kidney, pancreatic islet, or adrenal medullary cells. Missense mutations have been identified in >40% of VHL families with pheochromocytoma, suggesting that families with this type of mutation should be surveyed routinely for pheochromocytoma. A point that may be useful in differentiating VHL from MEN1 (overlapping features include islet cell tumor and rare pheochromocytoma) or MEN2 (overlapping feature is pheochromocytoma) is that hyperparathyroidism rarely occurs in VHL.

The molecular defect in type 1 neurofibromatosis inactivates neurofibromin, a cell membrane–associated protein that normally activates a GTPase. Inactivation of this protein impairs GTPase and causes continuous activation of p21 Ras and its downstream tyrosine kinase pathway. Endocrine tumors also form in less common neoplastic genetic syndromes. These include Cowden's disease, Carney complex, familial acromegaly, and familial carcinoid syndrome. Carney complex comprises myxomas of the heart, skin, and breast; peripheral nerve schwannomas; spotty skin pigmentation; and testicular, adrenal, and GH-secreting pituitary tumors. Linkage analysis has identified two loci: chromosome 2p in half of families and 17q in the others. The 17q gene has been identified as the regulatory subunit (type IA) of protein kinase A (PRKA1A).

IMMUNOLOGIC SYNDROMES AFFECTING MULTIPLE ENDOCRINE ORGANS

When immune dysfunction affects two or more endocrine glands and other nonendocrine immune disorders are present, the polyglandular autoimmune (PGA) syndromes should be considered. The PGA syndromes are classified as two main types: the type I syndrome starts in childhood and is characterized by mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency; the type II, or Schmidt syndrome, is more likely to present in adults and most commonly comprises adrenal insufficiency, thyroiditis, and type 1 diabetes mellitus (Table 330-2).

POLYGLANDULAR AUTOIMMUNE SYNDROME TYPE I PGA type I is usually recognized in the first decade of life and requires two of three components for diagnosis: mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency. Mineralocorticoids and glucocorticoids may be lost simultaneously or sequentially. This disorder is also called *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED). Other endocrine defects can include gonadal failure, hypothyroidism, anterior hypophysitis, and, less commonly, destruction of the β cells of the pancreatic islets and development of insulin-dependent (type 1) diabetes mellitus. Additional features include hypoplasia of the dental enamel, ungual dystrophy, tympanic membrane sclerosis, vitiligo, keratopathy, and gastric parietal cell dysfunction resulting in pernicious anemia. Some patients develop autoimmune hepatitis, malabsorption (variably attributed to intestinal lymphangiectasia, IgA deficiency, bacterial overgrowth, or hypoparathyroidism), asplenism, achalasia, and cholelithiasis (Table 330-2). At the outset, only one organ may be involved, but the number increases with time so that patients eventually manifest two to five components of the syndrome.

Most patients initially present with oral candidiasis in childhood; it is poorly responsive to treatment and relapses frequently. Chronic hypoparathyroidism usually occurs before adrenal insufficiency de-

TABLE 330-2 *Features of Polyglandular Autoimmune (PGA) Syndromes*

PGA I	PGA II
EPIDEMIOLOGY	
Autosomal recessive	Polygenic inheritance
Mutations in APECED gene	HLA-DR3 and HLA-DR4 associated
Childhood onset	Adult onset
Equal male:female ratio	Female predominance
DISEASE ASSOCIATIONS	
Mucocutaneous candidiasis	Adrenal insufficiency
Hypoparathyroidism	Hypothyroidism
Adrenal insufficiency	Graves' disease
Hypogonadism	Type 1 diabetes
Alopecia	Hypogonadism
Hypothyroidism	Hypophysitis
Dental enamel hypoplasia	Myasthenia gravis
Malabsorption	Vitiligo
Chronic active hepatitis	Alopecia
Vitiligo	Pernicious anemia
Pernicious anemia	Celiac disease

Note: APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy.

velops. More than 60% of postpubertal women develop premature hypogonadism. The endocrine components, including adrenal insufficiency and hypoparathyroidism, may not develop until the fourth decade, making continued surveillance necessary.

Type I PGA syndrome is usually inherited as an autosomal recessive trait. The responsible gene, designated as either *APECED* or *AIRE*, encodes a transcription factor that is expressed in thymus and lymph nodes; a variety of different mutations have been reported.

POLYGLANDULAR AUTOIMMUNE SYNDROME TYPE II PGA type II is characterized by two or more of the endocrinopathies listed in Table 330-2. Most often these include primary adrenal insufficiency, Graves' disease or autoimmune hypothyroidism, type 1 diabetes mellitus, and primary hypogonadism. Because adrenal insufficiency is relatively rare, it is frequently used to define the presence of the syndrome. Among patients with adrenal insufficiency, type 1 diabetes mellitus coexists in 52% and autoimmune thyroid disease occurs in 69%. However, many patients with antimicrosomal and antithyroglobulin antibodies never develop abnormalities of thyroid function. Thus, increased antibody titers alone are poor predictors of future disease. Other associated conditions include hypophysitis, celiac disease, atrophic gastritis, and pernicious anemia. Vitiligo, caused by antibodies against the melanocyte (see Fig. 46-12), and alopecia are less common than in the type I syndrome. Mucocutaneous candidiasis does not occur. A few patients develop a late-onset, usually transient hypoparathyroidism caused by antibodies that compete with parathyroid hormone for binding to the PTH receptor. Up to 25% of patients with myasthenia gravis, and an even higher percentage who have myasthenia and a thymoma, have PGA type II (Chap. 366).

The type II syndrome is familial in nature, often transmitted as an autosomal dominant trait with incomplete penetrance. Like many of the individual autoimmune endocrinopathies, certain HLA-DR3 and HLA-DR4 alleles increase disease susceptibility; several different genes probably contribute to the expression of this syndrome.

A variety of autoantibodies are seen in PGA type II, including antibodies directed against: (1) thyroid antigens such as thyroid peroxidase, thyroglobulin, or the thyroid-stimulating hormone (TSH) receptor; (2) adrenal side chain cleavage enzyme, steroid 21-hydroxylase, or ACTH receptor; and (3) pancreatic islet glutamic acid decarboxylase or the insulin receptor, among others.

DIAGNOSIS The clinical manifestations of adrenal insufficiency often develop slowly, may be difficult to detect, and can be fatal if not diagnosed and treated appropriately. Thus, prospective screening should be performed routinely in all patients and family members at risk for PGA types I and II. The most effective screening test for adrenal disease is a cosyntropin stimulation test (Chap. 321). A fasting blood glucose level can be obtained to screen for hyperglycemia. Additional screening tests should include measurements of TSH, luteinizing hormone, follicle-stimulating hormone, and, in men, testosterone levels. In families with suspected type I PGA syndrome, calcium and phosphorus levels should be measured. These screening studies should be performed every 1 to 2 years up to about age 50 in families with PGA type II syndrome and until about age 40 in patients with type I syndrome. Screening measurements of autoantibodies against potentially affected endocrine organs are of uncertain prognostic value. The differential diagnosis of PGA syndrome should include the DiGeorge syndrome (hypoparathyroidism due to glandular agenesis and mucocutaneous candidiasis), Kearns-Sayre syndrome (hypoparathyroidism, primary hypogonadism, type 1 diabetes mellitus, and panhypopituitarism), Wolfram's syndrome (congenital diabetes insipidus and diabetes mellitus), IPEX syndrome (*i*mmunodysregulation, *p*olyendocrinopathy, and *e*nteropathy, *X*-linked), and congenital rubella (type 1 diabetes mellitus and hypothyroidism).

℞ TREATMENT

With the exception of Graves' disease, the management of each of the endocrine components of the disease involves hormone replacement and is covered in detail in the chapters on adrenal, thyroid, gonadal, and parathyroid disease (Chaps. 320, 321, 325, 326, and 332). One aspect of therapy deserves special emphasis. Namely, primary hypothyroidism can mask adrenal insufficiency by prolonging the half-life of cortisol; consequently, administration of thyroid hormone to a patient with unsuspected adrenal insufficiency can precipitate adrenal crisis. Thus, all patients with hypothyroidism in the context of PGA syndrome should be screened for adrenal disease and, if it is present, be treated with glucocorticoids prior to or concurrently with thyroid hormone therapy.

OTHER AUTOIMMUNE ENDOCRINE SYNDROMES ■ Insulin Receptor Antibodies Rare insulin-resistance syndromes occur in patients who develop antibodies that block the interaction of insulin with its receptor. Conversely, other classes of anti-insulin receptor antibodies can activate the receptor and can cause hypoglycemia; this disorder should be considered in the differential diagnosis of fasting hypoglycemia (Chap. 324).

Patients with insulin receptor antibodies and acanthosis nigricans are often middle-aged women who acquire insulin resistance in association with other autoimmune disorders such as systemic lupus erythematosus or Sjögren's syndrome. Vitiligo, alopecia, Raynaud's phenomenon, and arthritis may also be seen. Other autoimmune endocrine disorders, including thyrotoxicosis, hypothyroidism, and hypogonadism, occur rarely. Acanthosis nigricans, a velvety, hyperpigmented, thickened skin lesion, is prominent on the dorsum of the neck and other skin fold areas in the axillae or groin and often heralds the diagnosis in these patients. However, acanthosis nigricans also occurs in patients with obesity or polycystic ovarian syndrome, in which insulin resistance appears to be due to a postreceptor defect; thus acanthosis nigricans itself is not diagnostic of the immunologic form of insulin resistance.

Ataxia telangiectasia is an autosomal recessive disorder caused by mutations in *ATM*, a gene involved in cellular responses to ionizing radiation and oxidative damage (Chap. 352). This disorder is characterized by ataxia, telangiectasia, immune abnormalities, and an increased incidence of malignancies. Insulin-resistant diabetes mellitus occurs and is associated with anti-insulin antibodies.

Autoimmune Insulin Syndrome with Hypoglycemia This disorder typically occurs in patients with other autoimmune disorders and is caused by polyclonal insulin-binding autoantibodies that bind to endogenously synthesized insulin. If the insulin dissociates from the antibodies several hours or more after a meal, hypoglycemia can result. Most cases of the syndrome have been described in Japan, and there may be a genetic component. In plasma cell dyscrasias such as multiple myeloma, the plasma cells may produce monoclonal antibodies against insulin and cause hypoglycemia by a similar mechanism.

Antithyroxine Antibodies and Hypothyroidism Circulating autoantibodies against thyroid hormones in patients with both immune thyroid disease and plasma cell dyscrasias such as Waldenström's macroglobulinemia can bind thyroid hormones, decrease their biologic activity, and result in primary hypothyroidism. In other patients the antibodies simply interfere with thyroid hormone immunoassays and cause false elevations or decreases in measured hormone levels.

Crow-Fukase Syndrome The features of this syndrome are highlighted by an acronym that emphasizes its important features: *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-proteins, and *s*kin changes (POEMS). The most important feature is a severe, progressive sensorimotor polyneuropathy associated with a plasma cell dyscrasia. Localized collections of plasma cells (plasmacytomas) can cause sclerotic bone lesions and produce monoclonal IgG or IgA proteins. Endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men, hypogonadism, hyperprolactinemia, type 2 diabetes mellitus, primary hypothyroidism, adrenal insufficiency, and hyperparathyroidism. Skin changes include hyperpigmentation, thickening of the dermis, hirsutism, and hyperhidrosis. Hepatomegaly and

lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in about one-third. Other manifestations include increased cerebrospinal fluid pressure with papilledema, peripheral edema, ascites, pleural effusions, glomerulonephritis, and fever. Median survival may be >10 years, though shorter in patients with extravascular volume overload or clubbing.

The systemic nature of the disorder may cause confusion with other connective tissue diseases. The endocrine manifestations suggest an autoimmune basis of the disorder, but circulating antibodies against endocrine cells have not been demonstrated. Increased serum and tissue levels of interleukin 6, interleukin 1β, vascular endothelial growth factor, matrix metalloproteins, and tumor necrosis factor α are present, but the pathophysiologic basis for the POEMS syndrome is uncertain. Therapy directed against the plasma cell dyscrasia such as local radiation of bony lesions, chemotherapy, thalidomide, plasmapheresis, bone marrow or stem cell transplantation, and treatment with all-*trans* retinoic acid may result in endocrine improvement.

Section 2 Disorders of Bone and Mineral Metabolism

331 BONE AND MINERAL METABOLISM IN HEALTH AND DISEASE

F. Richard Bringhurst, Marie B. Demay, Stephen M. Krane, Henry M. Kronenberg

BONE STRUCTURE AND METABOLISM

Bone is a dynamic tissue that is remodeled constantly throughout life. The arrangement of compact and cancellous bone provides a strength and density suitable for mobility and protection. In addition, bone provides a reservoir for calcium, magnesium, phosphorus, sodium, and other ions necessary for homeostatic functions. The skeleton is highly vascular and receives about 10% of the cardiac output. Remodeling of bone is accomplished by two distinct cell types: osteoblasts produce bone matrix and osteoclasts resorb the matrix.

The extracellular components of bone consist of a solid mineral phase in close association with an organic matrix, of which 90 to 95% is type I collagen (Chap. 342). The noncollagenous portion of the organic matrix is heterogeneous and contains serum proteins, such as albumin, as well as many locally produced proteins, whose functions are incompletely understood. These proteins include cell attachment/signaling proteins, such as thrombospondin, osteopontin, and fibronectin; calcium-binding proteins such as matrix gla protein and osteocalcin; and proteoglycans such as biglycan and decorin. Some of these proteins organize collagen fibrils; others initiate mineralization and binding of the mineral phase to the matrix.

The mineral phase is made up of calcium and phosphate and is best characterized as a poorly crystalline hydroxyapatite. The mineral phase of bone is deposited initially in intimate relation to the collagen fibrils and is found in specific locations in the "holes" between the collagen fibrils. This architectural arrangement of mineral and matrix results in a two-phase material well suited to withstand mechanical stresses. The organization of collagen influences the amount and type of mineral phase formed in bone. Although the primary structures of type I collagen in skin and bone tissues are similar, there are differences in posttranslational modifications and distribution of intermolecular cross-links. The holes in the packing structure of the collagen are larger in mineralized collagen of bone and dentin than in unmineralized collagens such as tendon. Single amino-acid substitutions in the helical portion of either the α1 (*COL1A1*) or α2 (*COL1A2*) chains of type I collagen disrupt the organization of bone in osteogenesis imperfecta. The severe skeletal fragility associated with these disorders highlights the importance of the fibrillar matrix in the structure of bone (Chap. 342).

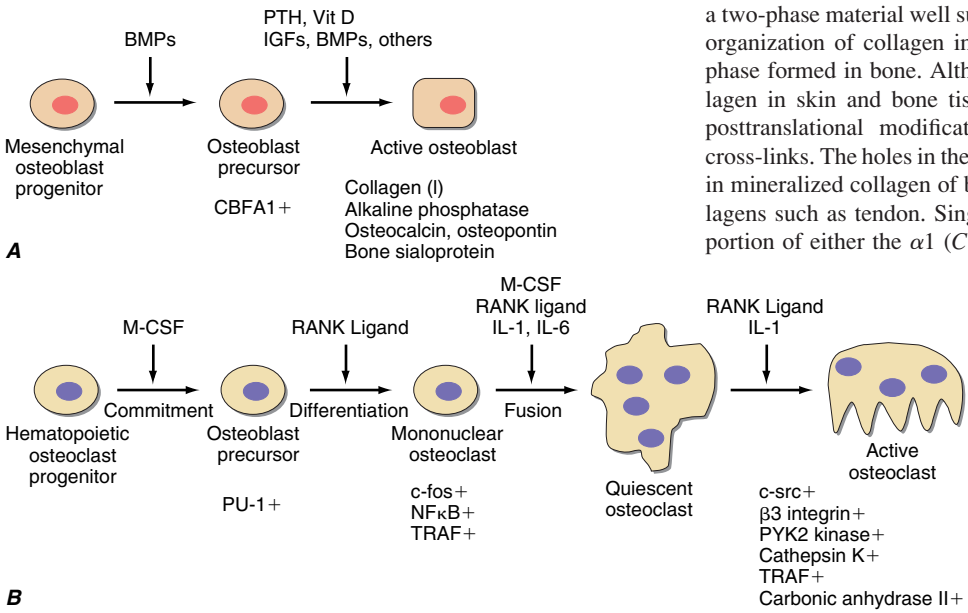

FIGURE 331-1 Pathways regulating development of (*A*) osteoblasts and (*B*) osteoclasts. Hormones, cytokines, and growth factors that control cell proliferation and differentiation are shown above the arrows. Transcription factors and other markers specific for various stages of development are depicted below the arrows. BMPs, bone morphogenic proteins; PTH, parathyroid hormone; Vit D, vitamin D; IGFs, insulin-like growth factors; CBFA1, core binding factor A1; M-CSF, macrophage colony-stimulating factor; PU-1, a monocyte- and B lymphocyte–specific ets family transcription factor; NFκB, nuclear factor κB; TRAF, tumor necrosis factor receptor–associated factors; RANK ligand, receptor activator of NFκB ligand; IL-1, interleukin-1; IL-6, interleukin-6. *(Modified from Suda et al, with permission.)*

Osteoblasts synthesize and secrete the organic matrix. They are derived from cells of mesenchymal origin (Fig. 331-1*A*). Active osteoblasts are found on the surface of newly forming bone. As an osteoblast secretes matrix, which is then mineralized, the cell becomes an *osteocyte*, still connected with its blood supply through a series of canaliculi. Osteocytes represent the vast majority of the cells in bone. They are thought to be the mechanosensors in bone that communicate signals to surface osteo-

blasts and their progenitors through the canalicular network. Mineralization of the matrix, both in trabecular bone and in osteones of compact cortical bone (*haversian systems*), begins soon after the matrix is secreted (primary mineralization) but is not completed for several weeks or even longer (secondary mineralization). While this mineralization takes advantage of the high concentrations of calcium and phosphate already near saturation in serum, mineralization is a carefully regulated process dependent on the activity of osteoblast-derived alkaline phosphatase, which probably works by hydrolyzing inhibitors of mineralization.

Genetic studies in humans and mice have identified several key genes that control osteoblast development. Core-binding factor A1 (*CBFA1*, also called *RUNX2*), is a transcription factor expressed specifically in chondrocyte (cartilage cells) and osteoblast progenitors, as well as in mature osteoblasts. *CBFA1* regulates the expression of several important osteoblast proteins including osterix (another transcription factor needed for osteoblast maturation), osteopontin, bone sialoprotein, type I collagen, osteocalcin, and receptor-activator of NFκB (RANK) ligand. *CBFA1* expression is regulated, in part, by bone morphogenic proteins (BMPs). *CBFA1*-deficient mice are devoid of osteoblasts, whereas mice with a deletion of only one allele (*CBFA1* +/−) exhibit a delay in formation of the clavicles and some cranial bones. The latter abnormalities are similar to those in the human disorder *cleidocranial dysplasia*, which is also caused by heterozygous inactivating mutations in *CBFA1*.

The paracrine signaling molecule, Indian hedgehog (Ihh), also plays a critical role in osteoblast development, as evidenced by Ihh-deficient mice that lack osteoblasts in bone formed on a cartilage mold (endochondral ossification). Signals originating from members of the wnt (wingless-type mouse mammary tumor virus integration site) family of paracrine factors are also important. Humans and mice missing a wnt-family co-receptor, LRP5 (lipoprotein receptor–related protein 5), have osteoporosis. Remarkably, humans with an overactive form of LPR5 have increased bone mass. Numerous other growth-regulatory factors affect osteoblast function, including the three closely related transforming growth factor βs, fibroblast growth factors (FGFs) 2 and 18, platelet-derived growth factor, and insulin-like growth factors (IGFs) I and II. Hormones, such as parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] activate receptors expressed by osteoblasts to assure mineral homeostasis and to influence a variety of bone cell functions.

Resorption of bone is carried out mainly by *osteoclasts*, multinucleated cells that are formed by fusion of cells derived from the common precursor of macrophages and osteoclasts. Multiple factors regulating osteoclast development have been identified (Fig. 331-1*B*). Factors produced by osteoblasts or marrow stromal cells allow osteoblasts to control osteoclast development and activity. Macrophage colony-stimulating factor (M-CSF) plays a critical role during several steps in the pathway and ultimately leads to fusion of osteoclast progenitor cells to form multinucleated, active osteoclasts. RANK ligand, a member of the tumor necrosis factor (TNF) family, is expressed on the surface of osteoblast progenitors and stromal fibroblasts. In a process involving cell-cell interactions, RANK ligand binds to the RANK receptor on osteoclast progenitors, stimulating osteoclast differentiation and activation. Alternatively, a soluble decoy receptor, referred to as osteoprotegerin, can bind RANK ligand and inhibit osteoclast differentiation. Several growth factors and cytokines (including interleukins 1, 6, and 11; TNF; and interferon γ) modulate osteoclast differentiation and function. Most hormones that influence osteoclast function do not directly target this cell but instead influence M-CSF and RANK ligand signaling by osteoblasts. Both PTH and 1,25$(OH)_2$D increase osteoclast number and activity, whereas estrogen decreases osteoclast number and activity by this indirect mechanism. Calcitonin, in contrast, binds to its receptor on the basal surface of osteoclasts and directly inhibits osteoclast function.

Osteoclast-mediated resorption of bone takes place in scalloped spaces (*Howship's lacunae*) where the osteoclasts are attached through a specific $\alpha_v\beta_3$ integrin to components of the bone matrix such as osteopontin. The osteoclast forms a tight seal to the underlying matrix and secretes protons, chloride, and proteinases into a confined space likened to an extracellular lysosome. The active osteoclast surface forms a ruffled border that contains a specialized proton-pump ATPase, which secretes acid and solubilizes the mineral phase. Carbonic anhydrase (type II isoenzyme) within the osteoclast generates the needed protons. The bone matrix is resorbed in the acid environment adjacent to the ruffled border by proteases that act at low pH, such as cathepsin K.

In the embryo and in the growing child, bone develops by remodeling and replacing previously calcified cartilage (endochondral bone formation) or is formed without a cartilage matrix (intramembranous bone formation). Chondrocytes proliferate, secrete and mineralize a matrix, enlarge (hypertrophy), and then die, thereby enlarging bone and providing the matrix and factors that stimulate endochondral bone formation. This program is regulated by both local factors, such as IGF-I and -II, parathyroid hormone–related peptide (PTHrP), and FGFs, and by systemic hormones such as growth hormone, glucocorticoids, and estrogen.

New bone, whether formed in infants or in adults during repair, has a relatively high ratio of cells to matrix and is characterized by coarse fiber bundles of collagen that are interlaced and randomly dispersed (woven bone). In adults, the more mature bone is organized with fiber bundles regularly arranged in parallel or concentric sheets (lamellar bone). In long bones, deposition of lamellar bone in a concentric arrangement around blood vessels forms the haversian systems. Growth in length of bones is dependent on proliferation of cartilage cells and on the endochondral sequence at the growth plate. Growth in width and thickness is accomplished by formation of bone at the periosteal surface and by resorption at the endosteal surface, with the rate of formation exceeding that of resorption. In adults, after the growth plates close, growth in length and endochondral bone formation cease, except for some activity in the cartilage cells beneath the articular surface. Even in adults, however, remodeling of bone (within haversian systems as well as trabecular bone) continues throughout life. In adults, ~4% of the surface of trabecular bone (such as iliac crest) is involved in active resorption, whereas 10 to 15% of trabecular surfaces is covered with osteoid. Radioisotope studies indicate that as much as 18% of the total skeletal calcium is deposited and removed each year. Thus, bone is an active metabolizing tissue that requires an intact blood supply. The cycle of bone resorption and formation is a highly orchestrated process carried out by the basic multicellular unit, composed of a group of osteoclasts and osteoblasts (Fig. 331-2).

The response of bone to fractures, infection, and interruption of blood supply and to expanding lesions is relatively limited. Dead bone must be resorbed, and new bone must be formed, a process carried out in association with growth of new blood vessels into the involved area. In injuries that disrupt the organization of the tissue, such as a fracture in which apposition of fragments is poor or when motion exists at the fracture site, the progenitor stromal cells differentiate into cells with functional capacities different from those of osteoblasts, and varying amounts of fibrous tissue and cartilage are formed. When there is good apposition with fixation and little motion at the fracture site, repair occurs predominantly by formation of new bone without other scar tissue.

Remodeling of bone occurs along lines of force generated by mechanical stress. The signals from these mechanical stresses are sensed by osteocytes, which transmit signals to osteoclasts or osteoblasts, or their precursors. A bowing deformity increases new bone formation at the concave surface and resorption at the convex surface, seemingly designed to produce the strongest mechanical structure. Expanding lesions in bone, such as tumors, induce resorption at the surface in contact with the tumor, by producing ligands, such as PTHrP, that stimulate osteoclast differentiation and function. Even in a disorder as architecturally disruptive as Paget's disease, remodeling is dictated by mechanical forces. Thus, bone plasticity reflects the interaction of cells with each other and with the environment.

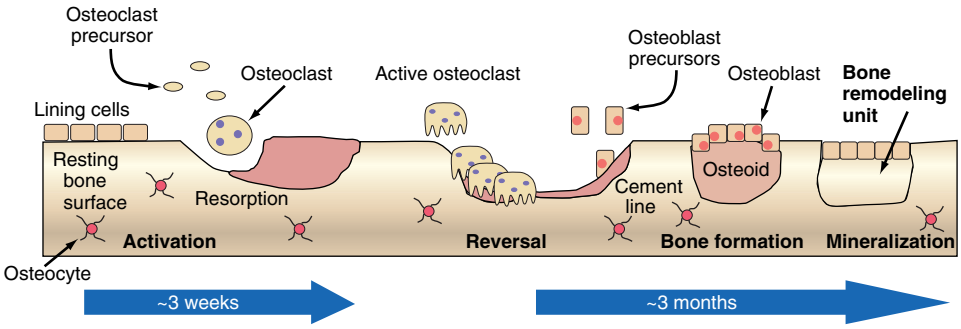

FIGURE 331-2 Schematic representation of bone remodeling. The cycle of bone remodeling is carried out by the basic multicellular unit (BMU), comprising a group of osteoclasts and osteoblasts. In cortical bone, the BMUs tunnel through the tissue, whereas in cancellous bone, they move across the trabecular surface. The process of bone remodeling is initiated by contraction of the lining cells and the recruitment of osteoclast precursors. These precursors fuse to form multinucleated, active osteoclasts that mediate bone resorption. Osteoclasts adhere to bone and subsequently remove it by acidification and proteolytic digestion. As the BMU advances, osteoclasts leave the resorption site and osteoblasts move in to cover the excavated area and begin the process of new bone formation by secreting osteoid, which is eventually mineralized into new bone. After osteoid mineralization, osteoblasts flatten and form a layer of lining cells over new bone.

The products of osteoblast and osteoclast activity can assist in the diagnosis and management of bone diseases. Osteoblast activity can be assessed by measuring serum bone-specific alkaline phosphatase. Similarly, osteocalcin, a protein secreted from osteoblasts, is made virtually only by osteoblasts. Osteoclast activity can be assessed by measurement of products of collagen degradation. Collagen molecules are covalently linked to each other in the extracellular matrix through the formation of hydroxypyridinium crosslinks (Chap. 342). These cross-linked peptides can be measured both in urine and in blood.

CALCIUM METABOLISM

Over 99% of the 1 to 2 kg of calcium present normally in the adult human body resides in the skeleton, where it provides mechanical stability and serves as a reservoir sometimes needed to maintain extracellular fluid (ECF) calcium concentration (Fig. 331-3). Skeletal calcium accretion first becomes significant during the third trimester of fetal life, accelerates throughout childhood and adolescence, reaches a peak in early adulthood, and gradually declines thereafter at rates that rarely exceed 1 to 2% per year. These slow changes in total skeletal calcium content contrast with relatively high daily rates of closely matched fluxes of calcium into and out of bone (approximately 250 to 500 mg each), a process mediated by coupled osteoblastic and osteoclastic activity. Another 0.5 to 1% of skeletal calcium is freely exchangeable (e.g., in chemical equilibrium) with that in the ECF.

The concentration of ionized calcium in the ECF must be maintained within a narrow range because of the critical role it plays in a wide array of cellular functions, especially those involved in neuromuscular activity, secretion, and signal transduction. Intracellular cytosolic free calcium levels are approximately 100 nmol/L and are 10,000-fold lower than ionized calcium concentration in the blood and ECF (1.1 to 1.3 mmol/L). This steep chemical gradient promotes rapid calcium influx through various membrane calcium channels that can be activated by hormones, metabolites, or neurotransmitters, swiftly changing cellular function. In blood, total calcium concentration is normally 2.2 to 2.6 mM (8.5 to 10.5 mg/dL), of which approximately 50% is ionized. The remainder is bound ionically to negatively charged proteins (predominantly albumin and immunoglobulins) or loosely complexed with phosphate, citrate, sulfate, or other anions. Alterations in serum protein concentrations directly affect the total blood calcium concentration, even if the ionized calcium concentration remains normal. An algorithm to correct for protein changes adjusts the total serum calcium (in mg/dL) upward by 0.8 times the deficit in serum albumin (g/dL) or by 0.5 times the deficit in serum immunoglobulin (in g/dL). Such corrections provide only rough approximations of actual free calcium concentrations, however, and may be misleading. Acidosis also alters ionized calcium by reducing its association with proteins. The best practice is to measure blood ionized calcium directly by a method that employs calcium-selective electrodes.

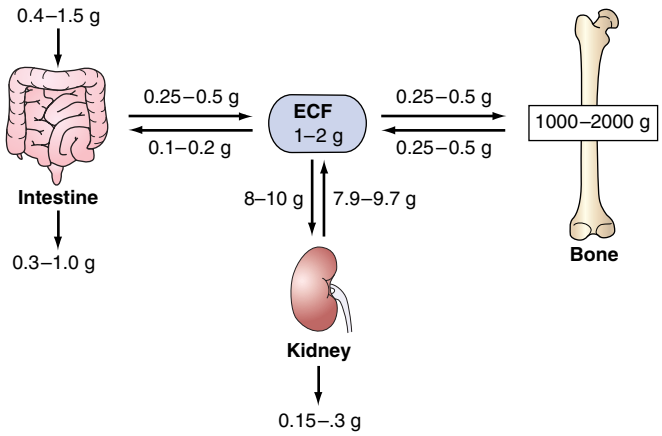

FIGURE 331-3 Calcium homeostasis. Schematic illustration of calcium content of extracellular fluid (ECF) and bone as well as of diet and feces; magnitude of calcium flux per day as calculated by various methods is shown at sites of transport in intestine, kidney, and bone. Ranges of values shown are approximate and chosen to illustrate certain points discussed in text. In conditions of calcium balance, rates of calcium release from and uptake into bone are equal.

Control of the ionized calcium concentration in the ECF ordinarily is accomplished by adjusting the rates of calcium movement across intestinal and renal epithelia. These adjustments are mediated mainly via changes in blood levels of the hormones PTH and $1,25(OH)_2D$. Blood ionized calcium directly suppresses PTH secretion by activating parathyroid calcium-sensing receptors (CaSRs). Also, ionized calcium indirectly affects PTH secretion via effects on $1,25(OH)_2D$ production. This active vitamin D metabolite inhibits PTH production by an incompletely understood mechanism of negative feedback (Chap. 332).

Normal dietary calcium intake in the United States varies widely, ranging from 10 to 37 mmol/d (400 to 1500 mg/d). Many individuals, in an effort to prevent osteoporosis, routinely supplement this further with oral calcium salts to a total intake of 37 to 50 mmol/d (1500 to 2000 mg/d). Intestinal absorption of ingested calcium involves both active (transcellular) and passive (paracellular) mechanisms. Passive calcium absorption is nonsaturable and approximates 5% of daily calcium intake, whereas the active mechanism, controlled principally by $1,25(OH)_2D$, normally ranges from 20 to 70%. Active calcium transport occurs mainly in the proximal small bowel (duodenum and proximal jejunum), although some active calcium absorption occurs in most segments of the small intestine. Optimal rates of calcium absorption require gastric acid. This is especially true for weakly dissociable calcium supplements such as calcium carbonate. In fact, large boluses of calcium carbonate are poorly absorbed because of their neutralizing effect upon gastric acid. In achlorhydric subjects or for those taking drugs that inhibit gastric acid secretion, supplements should be taken with meals to optimize their absorption. Use of calcium citrate may be preferable in these circumstances. Calcium absorption may also be blunted in disease states such as pancreatic or biliary insufficiency, where ingested calcium remains bound to unabsorbed fatty acids or other food constituents. At high levels of calcium intake, synthesis of $1,25(OH)_2D$ is reduced, which decreases the rate of active intestinal calcium absorption. The opposite occurs with dietary calcium restriction. Some calcium, approximately 2.5 to 5.0 mmol/d (100 to 200 mg/d), is excreted as an obligate component of intestinal secretions and is not regulated by calciotropic hormones.

The feedback-controlled hormonal regulation of intestinal absorp-

tive efficiency results in a relatively constant daily net calcium absorption of approximately 5 to 7.5 mmol/d (200 to 400 mg/d), despite large changes in daily dietary calcium intake. This daily load of absorbed calcium is excreted by the kidneys in a manner that is also tightly regulated by the concentration of ionized calcium in the blood. Approximately 8 to 10 g/d of calcium are filtered by the glomeruli, of which only 2 to 3% appears in the urine. Most filtered calcium (65%) is reabsorbed in the proximal tubules via a passive, paracellular route that is coupled to concomitant NaCl reabsorption and not specifically regulated. The cortical thick ascending limb of Henle's loop (cTAL) reabsorbs roughly another 20% of filtered calcium, also via a paracellular mechanism. Calcium reabsorption in the cTAL requires a tight-junctional protein called paracellin-1 and is inhibited by increased blood concentrations of calcium or magnesium, acting via the CaSR, which is highly expressed on basolateral membranes in this nephron segment. Operation of the renal CaSR provides a mechanism, independent of those engaged directly by PTH or $1,25(OH)_2D$, whereby serum ionized calcium can control renal calcium reabsorption. Finally, ~10% of filtered calcium is reabsorbed in the distal convoluted tubules (DCT) by a transcellular mechanism. Calcium enters the luminal surface of the cell through specific apical calcium channels, whose number is regulated. It then moves across the cell in association with a specific calcium-binding protein (calbindin-D28k) that buffers cytosolic calcium concentrations from the large mass of transported calcium. Ca^{2+}-ATPases and Na/ Ca^{2+} exchangers actively extrude calcium across the basolateral surface and thereby maintain the transcellular calcium gradient. All of these steps are increased, directly or indirectly, by PTH. The DCT is also the site of action of thiazide diuretics, which lower urinary calcium excretion by blocking a NaCl transporter expressed on the apical surface of these cells. Conversely, dietary sodium loads, or increased distal sodium delivery caused by loop diuretics or saline infusion, reduce DCT calcium reabsorption by an action opposite to that of thiazides.

The homeostatic mechanisms that normally maintain a constant serum ionized calcium concentration may fail at extremes of calcium intake or when the hormonal systems or organs involved are compromised. Thus, even with maximal activity of the vitamin D–dependent intestinal active transport system, sustained calcium intakes <5 mmol/d (<200 mg/d) cannot provide enough net calcium absorption to replace obligate losses via the intestine, kidney, sweat, or other secretions. In this case, increased blood levels of PTH and $1,25(OH)_2D$ activate osteoclastic bone resorption to obtain needed calcium from bone, which leads to progressive bone loss and negative calcium balance. Increased PTH and $1,25(OH)_2D$ also enhance renal calcium reabsorption, and $1,25(OH)_2D$ enhances calcium absorption in the gut. At very high calcium intakes [> 100 mmol/d; > 4 g/d], passive intestinal absorption continues to deliver calcium into the ECF, despite maximally downregulated intestinal active transport and renal tubular calcium reabsorption. This can cause severe hypercalciuria, nephrocalcinosis, progressive renal failure, and hypercalcemia (e.g., "milk alkali syndrome"). Deficiency or excess of PTH or vitamin D, intestinal disease, and renal failure represent other commonly encountered challenges to normal calcium homeostasis (Chap. 332).

PHOSPHORUS METABOLISM

Although 85% of the ~600 g of body phosphorus is present in bone mineral, phosphorus is also a major intracellular constituent, both as the free anion(s) and as a component of numerous organophosphate compounds including structural proteins, enzymes, transcription factors, carbohydrate and lipid intermediates, high-energy stores (ATP, creatine phosphate), and nucleic acids. Unlike calcium, phosphorus exists intracellularly at concentrations close to those present in ECF (e.g., 1 to 2 mmol/L). In cells and in the ECF, phosphorus exists in several forms, predominantly as $H_2PO_4^-$ or $NaHPO_4^-$, with perhaps 10% as HPO_4^{2-}. This mixture of anions will be referred to here as "phosphate." In serum, about 12% of phosphorus is bound to proteins. Concentrations of phosphates in blood and ECF are generally expressed in terms of elemental phosphorus, the normal range in adults being 0.75 to 1.45 mmol/L (2.5 to 4.5 mg/dL). Because the volume of the intracellular fluid compartment is twice that of the ECF, measurements of ECF phosphate may not accurately reflect phosphate availability within cells that follows even modest shifts of phosphate from one compartment to the other.

Phosphate is widely available in foods and is efficiently absorbed (65%) by the small intestine, even in the absence of vitamin D. On the other hand, phosphate absorptive efficiency may be further enhanced (to 85 to 90%) via active transport mechanisms that are stimulated by $1,25(OH)_2D$. These involve activation of Na^+/PO_4^{2-} cotransporters that move phosphate into intestinal cells against an unfavorable electrochemical gradient. Daily net intestinal phosphate absorption varies widely according to the composition of the diet but is generally in the range of 500 to 1000 mg/d. Phosphate absorption can be inhibited by large doses of calcium salts or by sevelamer hydrochloride (Renagel), strategies commonly used to control levels of serum phosphate in renal failure. Aluminum hydroxide antacids also reduce phosphate absorption but are less commonly used because of the potential for aluminum toxicity. Low serum phosphate directly stimulates renal proximal tubular synthesis of $1,25(OH)_2D$.

Serum phosphate levels vary by as much as 50% on a normal day. This reflects the effect of food intake but also an underlying circadian rhythm that produces a nadir between 7 and 10 A.M. Carbohydrate administration, especially as intravenous dextrose solutions in fasting subjects, can decrease serum phosphate by >0.7 mmol/L (2 mg/dL) due to rapid uptake into, and utilization by, cells. A similar response is observed in the treatment of diabetic ketoacidosis and during metabolic or respiratory alkalosis. Because of this wide variation in serum phosphate, it is best to perform measurements in the basal, fasting state.

Control of serum phosphate is determined mainly by the rate of renal tubular reabsorption of the filtered load, which approximates 4 to 6 g/d. Because intestinal phosphate absorption is highly efficient, urinary excretion is not constant but varies directly with dietary intake. The fractional excretion of phosphate (ratio of phosphate to creatinine clearance) is generally in the range of 10 to 15%. The proximal tubule is the principal site at which renal phosphate reabsorption is regulated. This is accomplished by changes in the apical expression and activity of a specific Na^+/PO_4^{2-} co-transporter (NaPi-2) in the proximal tubule. Apical expression of NaPi-2 is rapidly reduced by PTH, the major known hormonal regulator of renal phosphate excretion. FGF23 can dramatically impair phosphate reabsorption. Activating *FGF23* mutations cause the rare disorder autosomal dominant hypophosphatemic rickets. In contrast to PTH, this molecule also leads to reduced synthesis of $1,25(OH)_2D$, which may worsen the resulting hypophosphatemia by lowering intestinal phosphate absorption. Renal reabsorption of phosphate is responsive to changes in dietary intake, such that experimental dietary phosphate restriction leads to a dramatic lowering of urinary phosphate within hours, preceding any decline in serum phosphate (e.g., filtered load). This physiologic renal adaptation to changes in dietary phosphate availability occurs independently of PTH. Findings in *FGF23*-knockout mice suggest that FGF23 normally acts to lower blood phosphate and $1,25(OH)_2D$ levels.

Renal phosphate reabsorption is impaired by hypocalcemia, hypomagnesemia, and severe hypophosphatemia. Phosphate clearance is enhanced by ECF volume expansion and impaired by dehydration. Phosphate retention is an important pathophysiologic feature of renal insufficiency (Chap. 261).

HYPOPHOSPHATEMIA ■ Causes Hypophosphatemia can occur by one or more of three primary mechanisms: (1) inadequate intestinal phosphate absorption, (2) excessive renal phosphate excretion, or (3) rapid redistribution of phosphate from the ECF into bone or soft tissue (Table 331-1). Because phosphate is so abundant in foods, inadequate intestinal absorption is almost never observed now that aluminum hydroxide antacids, which bind phosphate in the gut, are no longer commonly

TABLE 331-1 Causes of Hypophosphatemia

I. Reduced renal tubular phosphate reabsorption
  A. PTH/PTHrP-dependent
    1. Primary hyperparathyroidism
    2. Secondary hyperparathyroidism
      a. Vitamin D deficiency/resistance
      b. Calcium starvation/malabsorption
      c. Bartter syndrome
      d. Autosomal recessive renal hypercalciuria with hypomagnesemia
    3. PTHrP-dependent hypercalcemia of malignancy
    4. Familial hypocalciuric hypercalcemia
  B. PTH/PTHrP-independent
    1. Genetic hypophosphatemia
      a. X-linked hypophosphatemic rickets
      b. Dent disease
      c. Autosomal dominant hypophosphatemic rickets
      d. Fanconi syndrome(s)
      e. Cystinosis
      f. Wilson disease
      g. McCune-Albright syndrome (fibrous dysplasia)
      h. Idiopathic hypercalciuria (absorptive subtype)
      i. Hereditary hypophosphatemia with hypercalciuria (Bedouins)
    2. Tumor-induced osteomalacia
    3. Other systemic disorders
      a. Poorly controlled diabetes mellitus
      b. Alcoholism
      c. Hyperaldosteronism
      d. Hypomagnesemia
      e. Amyloidosis
      f. Hemolytic uremic syndrome
      g. Renal transplantation or partial liver resection
      h. Rewarming or induced hyperthermia
    4. Drugs or toxins
      a. Ethanol
      b. Acetazolamide, other diuretics
      c. High-dose estrogens or glucocorticoids
      d. Heavy metals (lead, cadmium)
      e. Toluene, *N*-methyl formamide
      f. Cisplatin, ifosfamide, foscarnet, rapamycin
      g. Calcitonin, pamidronate
II. Impaired intestinal phosphate absorption
  A. Aluminum-containing antacids
  B. Sevalamer
III. Shifts of extracellular phosphate into cells
  A. Intravenous glucose
  B. Insulin therapy of prolonged hyperglycemia or diabetic ketoacidosis
  C. Catecholamines (epinephrine, dopamine, albuterol)
  D. Acute respiratory alkalosis
  E. Gram-negative sepsis, toxic shock syndrome
  F. Recovery from starvation or acidosis
  G. Rapid cellular proliferation
    1. Leukemic blast crisis
    2. Intensive erythropoetin, other CSF therapy
IV. Accelerated net bone formation
  A. Following parathyroidectomy
  B. Treatment of vitamin D deficiency, Paget disease
  C. Osteoblastic metastases

Note: CSF, cerebrospinal fluid.

used. Fasting or starvation, however, may result in depletion of body phosphate and predispose to subsequent hypophosphatemia during refeeding, especially if this is accomplished with intravenous glucose alone.

Chronic hypophosphatemia usually signifies a persistent renal tubular phosphate-wasting disorder. Excessive activation of PTH/PTHrP receptors in the proximal tubule, because of primary or secondary hyperparathyroidism or because of the PTHrP-mediated hypercalcemia syndrome in malignancy (Chap. 332), is among the more common causes of renal hypophosphatemia, especially because of the high prevalence of vitamin D deficiency in older Americans. Familial hypocalciuric hypercalcemia and Jansen's chondrodystrophy are rare examples of genetic disorders in this category (Chap. 332). Several genetic diseases cause PTH/PTHrP-independent tubular phosphate wasting, with associated rickets and osteomalacia. The most common of these is X-linked hypophosphatemic rickets (XLHR), which results from inactivating mutations in an endopeptidase termed *PHEX* (*p*hosphate-regulating gene with *h*omologies to *e*ndopeptidases on the *X* chromosome) that is most abundantly expressed on the surface of mature osteoblasts. It is believed that PHEX normally inactivates a phosphaturic hormone (phosphatonin) that impairs both renal tubular phosphate reabsorption and $1,25(OH)_2D$ synthesis in the proximal renal tubules. Disorders likely to share a related pathophysiology with XLHR are autosomal dominant hypophosphatemic rickets (ADHR) and tumor-induced osteomalacia (TIO). All of these manifest severe hypophosphatemia; renal phosphate wasting, sometimes accompanied by aminoaciduria; low blood levels of $1,25(OH)_2D$; low or low-normal serum levels of calcium; and evidence of impaired cartilage or bone mineralization. ADHR results from activating mutations in the gene encoding FGF23, which is phosphaturic when administered to mice. TIO is an acquired disorder in which tumors, usually of mesenchymal origin and generally histologically benign, secrete a phosphatonin-like molecule (Chap. 87). The hypophosphatemic syndrome resolves completely within hours to days following successful resection of the responsible tumor. Such tumors express large amounts of FGF23 mRNA, raising the possibility that FGF23 may be a phosphatonin. It is not yet clear if FGF23 is a physiologic substrate for PHEX, however. Dent's disease is an X-linked recessive disorder caused by inactivating mutations in CLCN5, a chloride transporter expressed in endosomes of the proximal tubule; features include hypercalciuria, hypophosphatemia, and recurrent kidney stones. Renal phosphate wasting is common among poorly controlled diabetics and alcoholics, who therefore are at risk for iatrogenic hypophosphatemia when treated with insulin or intravenous glucose, respectively. Diuretics and certain other drugs and toxins can cause defective renal tubular phosphate reabsorption (Table 331-1).

In hospitalized patients, hypophosphatemia is often attributable to massive redistribution of phosphate from the ECF into cells. Insulin therapy of diabetic ketoacidosis is a paradigm for this phenomenon, in which the severity of the hypophosphatemia is related to the extent of antecedent depletion of phosphate and other electrolytes (Chap. 323). The hypophosphatemia is usually greatest at a point many hours after initiation of insulin therapy and is difficult to predict from baseline measurements of serum phosphate at the time of presentation, when prerenal azotemia can obscure significant phosphate depletion. Other factors that may contribute to such acute redistributive hypophosphatemia include antecedent starvation or malnutrition, administration of intravenous glucose without other nutrients, elevated blood catecholamines (endogenous or exogenous), respiratory alkalosis, and recovery from metabolic acidosis.

Hypophosphatemia can also occur transiently (over weeks to months) during the phase of accelerated net bone formation following parathyroidectomy for severe primary hyperparathyroidism or during treatment of vitamin D deficiency or lytic Paget's disease. This is usually most prominent in patients who preoperatively have evidence of high bone turnover (e.g., high serum levels of alkaline phosphatase). Osteoblastic metastases can also lead to this syndrome.

Clinical and Laboratory Findings The clinical manifestations of severe hypophosphatemia reflect a generalized defect in cellular energy metabolism because of ATP depletion, a shift from oxidative phosphorylation toward glycolysis, and associated tissue or organ dysfunction. Acute, severe hypophosphatemia occurs mainly or exclusively in hospitalized patients with underlying serious medical or surgical illness and preexisting phosphate depletion due to excessive urinary losses, severe malabsorption, or malnutrition. Chronic hypophosphatemia tends to be less severe, with a clinical presentation dominated by musculoskeletal complaints such as bone pain, pseudofractures, and proximal muscle weakness or, in children, rickets and short stature.

Neuromuscular manifestations of severe hypophosphatemia are

variable but may include muscle weakness, lethargy, confusion, disorientation, hallucinations, dysarthria, dysphagia, oculomotor palsies, anisocoria, nystagmus, ataxia, cerebellar tremor, ballismus, hyporeflexia, impaired sphincter control, distal sensory deficits, paresthesia, hyperesthesia, generalized or Guillain Barré–like ascending paralysis, seizures, coma, and death. Serious sequelae such as paralysis, confusion, and seizures are likely only at phosphate concentrations <0.25 mmol/L (< 0.8 mg/dL). Rhabdomyolysis may develop during rapidly progressive hypophosphatemia. The diagnosis of hypophosphatemia-induced rhabdomyolysis may be overlooked, as up to 30% of patients with acute hypophosphatemia (< 0.7 m*M*) have creatine phosphokinase elevations that peak 1 to 2 days after the nadir in serum phosphate, when the release of phosphate from injured myocytes may have led to a near-normalization of circulating levels of phosphate.

Respiratory failure and cardiac dysfunction, reversible with phosphate treatment, may occur at serum phosphate levels of 0.5 to 0.8 mmol/L (1.5 to 2.5 mg/dL). Renal tubular defects, including tubular acidosis, glycosuria, and impaired reabsorption of sodium and calcium, may occur. Hematologic abnormalities correlate with reductions in intracellular ATP and 2,3-diphosphoglycerate and may include erythrocyte microspherocytosis and hemolysis; impaired oxyhemoglobin dissociation; defective leukocyte chemotaxis, phagocytosis, and bacterial killing; and platelet dysfunction with spontaneous gastrointestinal hemorrhage.

TREATMENT

Severe hypophosphatemia [< 0.75 mmol/L (< 2 mg/dL)], particularly in the setting of underlying phosphate depletion, constitutes a dangerous electrolyte abnormality that should be corrected promptly. Unfortunately, the cumulative deficit in body phosphate cannot be easily predicted from knowledge of the circulating level of phosphate, and therapy must be approached empirically. The threshold for intravenous phosphate therapy and the dose administered should reflect consideration of renal function, the likely severity and duration of the underlying phosphate depletion, and the presence and severity of symptoms consistent with those of hypophosphatemia. In adults, phosphate may be safely administered intravenously as neutral mixtures of sodium and potassium phosphate salts at initial doses of 0.2 to 0.8 mmol/kg of elemental phosphorus over 6 h (e.g., 10 to 50 mmol over 6 h), with doses >20 mmol/6 h reserved for those who have serum levels <0.5 mmol/L (1.5 mg/dL) and normal renal function. A suggested approach is presented in Table 331-2. Serum levels of phosphate and calcium must be monitored closely (every 6 to 12 h) throughout treatment. It is necessary to avoid a serum calcium-phosphorus product >50 to reduce the risk of heterotopic calcification. Hypocalcemia, if present, should be corrected before administering intravenous phosphate. Less severe hypophosphatemia, in the range of 0.5 to 0.8 mmol/L (1.5 to 2.5 mg/dL), can usually be treated with oral phosphate in divided doses of 750 to 2000 mg/d, as elemental phosphorus; higher doses can cause bloating and diarrhea.

Management of chronic hypophosphatemia requires knowing the cause(s) of the disorder. Hypophosphatemia related to the secondary hyperparathyroidism of vitamin D deficiency usually responds to treatment with vitamin D and calcium alone. XLHR, ADHR, TIO, and related renal tubular disorders are usually managed with divided oral doses of phosphate, often with calcium and $1,25(OH)_2D$ supplements to bypass the block in renal $1,25(OH)_2D$ synthesis and prevent secondary hyperparathyroidism caused by suppression of ECF calcium levels. Thiazide diuretics may be used to prevent nephrocalcinosis in patients who are managed this way. Complete normalization of hypophosphatemia is generally not possible in these conditions. Optimal therapy of TIO is extirpation of the responsible tumor, which may be localized by radiographic skeletal survey or bone scan (many are located in bone) or by radionuclide scanning using sestamibi or labeled octreotide. Successful treatment of TIO-induced hypophosphatemia with octreotide has been reported in a small number of patients.

TABLE 331-2 Intravenous Therapy of Hypophosphatemia

Consider

Likely severity of underlying phosphate depletion
Concurrent parenteral glucose administration
Presence of neuromuscular, cardiopulmonary, or hematologic complications of hypophosphatemia
Renal function [reduce dose by 50% if serum creatinine >220 μmol/L (>2.5 mg/dL)]
Serum calcium level (correct hypocalcemia first; reduce dose by 50% in hypercalcemia)

Guidelines

Serum Phosphorus, mM(mg/dL)	Rate of Infusion, mmol/h	Duration, h	Total Administered, mmol
<0.8 (<2.5)	2.0	6	12
<0.5 (<1.5)	4.0	6	24
<0.3 (<1.0)	8.0	6	48

Rates shown are calculated for a 70-kg person; levels of serum calcium and phosphorus must be measured every 6 to 12 h during therapy; infusions can be repeated to achieve stable serum phosphorus levels > 0.8 mmol/L (>2.5 mg/dL); most formulations available in the United States provide 3 mmol/mL of sodium or potassium phosphate.

HYPERPHOSPHATEMIA ■ Causes When the filtered load of phosphate and glomerular filtration rate (GFR) are normal, control of serum phosphate levels is achieved by adjusting the rate at which phosphate is reabsorbed by the proximal tubular NaPi-2 co-transporter. The principal hormonal regulator of NaPi-2 activity is PTH. Hyperphosphatemia, defined in adults as a fasting serum phosphate concentration >1.8 mmol/L (5.5 mg/dL), usually results from impaired glomerular filtration, hypoparathyroidism, excessive delivery of phosphate into the ECF (from bone, gut, or parenteral phosphate therapy), or some combination of these factors (Table 331-3). The upper limit of normal serum phosphate concentrations is higher in children and neonates [2.4 mmol/L (7 mg/dL)]. It is useful to distinguish hyperphosphatemia caused by impaired renal phosphate excretion from that which results from excessive delivery of phosphate into the ECF (Table 331-3).

TABLE 331-3 Causes of Hyperphosphatemia

I. Impaired renal phosphate excretion
  A. Renal insufficiency
  B. Hypoparathyroidism
    1. Developmental
    2. Autoimmune
    3. After neck surgery or radiation
    4. Activating mutations of the calcium-sensing receptor
  C. Parathyroid suppression
    1. Parathyroid-independent hypercalcemia
      a. Vitamin D or vitamin A intoxication
      b. Sarcoidosis, other granulomatous diseases
      c. Immobilization, osteolytic metastases
      d. Milk-alkali syndrome
    2. Severe hypermagnesemia or hypomagnesemia
  D. Pseudohypoparathyroidism
  E. Acromegaly
  F. Tumoral calcinosis
  G. Heparin therapy
II. Massive extracellular fluid phosphate loads
  A. Rapid administration of exogenous phosphate (intravenous, oral, rectal)
  B. Extensive cellular injury or necrosis
    1. Crush injuries
    2. Rhabdomyolysis
    3. Hyperthermia
    4. Fulminant hepatitis
    5. Cytotoxic therapy
    6. Severe hemolytic anemia
  C. Transcellular phosphate shifts
    1. Metabolic acidosis
    2. Respiratory acidosis

In chronic renal insufficiency, reduced GFR leads to phosphate retention. Hyperphosphatemia, in turn, further impairs renal synthesis of $1,25(OH)_2D$ and stimulates PTH secretion and hypertrophy, both directly and indirectly (by lowering blood ionized calcium levels). Thus, hyperphosphatemia is a major cause of the secondary hyperparathyroidism of renal failure and must be addressed early in the course of the disease (Chaps. 261 and 332).

Hypoparathyroidism leads to hyperphosphatemia via increased expression of NaPi-2 co-transporters in the proximal tubule. Hypoparathyroidism, or parathyroid suppression, has multiple potential causes including autoimmune disease; developmental, surgical, or radiation-induced absence of functional parathyroid tissue; vitamin D intoxication or other causes of PTH-independent hypercalcemia; cellular PTH resistance (pseudohypoparathyroidism or hypomagnesemia); infiltrative disorders such as Wilson disease and hemochromatosis; and impaired PTH secretion caused by hypermagnesemia, severe hypomagnesemia, or activating mutations in the CaSR. Hypocalcemia may also contribute directly to impaired phosphate clearance, as calcium infusion can induce hyperphosphaturia in hypoparathyroid subjects. Increased tubular phosphate reabsorption also occurs in acromegaly, during heparin administration, and in tumoral calcinosis. Tumoral calcinosis is a rare genetic disorder in which elevated serum $1,25(OH)_2D$, parathyroid suppression, increased intestinal calcium absorption, and focal hyperostosis with large, lobulated periarticular heterotopic ossifications (especially at shoulders or hips) are accompanied by hyperphosphatemia. In some forms of tumoral calcinosis serum phosphorus levels are normal.

When large amounts of phosphate are rapidly delivered into the ECF, hyperphosphatemia can occur despite normal renal function. Examples include overzealous intravenous phosphate therapy, oral or rectal administration of large amounts of phosphate-containing laxatives or enemas (especially in children), extensive soft tissue injury or necrosis (crush injuries, rhabdomyolysis, hyperthermia, fulminant hepatitis, cytotoxic chemotherapy), extensive hemolytic anemia, or transcellular phosphate shifts induced by severe metabolic or respiratory acidosis.

Clinical Findings The clinical consequences of acute, severe hyperphosphatemia are due mainly to the formation of widespread calcium phosphate precipitates and resulting hypocalcemia. Thus, tetany, seizures, accelerated nephrocalcinosis (with renal failure, hyperkalemia, hyperuricemia, and metabolic acidosis), and pulmonary or cardiac calcifications (including development of acute heart block) may occur. The severity of these complications relates to the elevation of serum phosphate levels, which can reach concentrations as high as 7 mmol/L (20 mg/dL) in instances of massive soft tissue injury or tumor lysis syndrome.

℞ TREATMENT

Therapeutic options for management of severe hyperphosphatemia are limited. Volume expansion may enhance renal phosphate clearance. Aluminum hydroxide antacids or sevalamer may be helpful in chelating and limiting absorption of offending phosphate salts present in the intestine. Hemodialysis is the most effective therapeutic strategy and should be considered early in the course of severe hyperphosphatemia, especially in the setting of renal failure and symptomatic hypocalcemia.

MAGNESIUM METABOLISM

Magnesium is the major intracellular divalent cation. Normal concentrations of extracellular magnesium and calcium are crucial for normal neuromuscular activity. Intracellular magnesium forms a key complex with ATP and is an important cofactor for a wide range of enzymes, transporters, and nucleic acids required for normal cellular function, replication, and energy metabolism. The concentration of magnesium in serum is closely regulated within the range of 0.7 to 1.0 mmol/L (1.5 to 2.0 meq/L; 1.7 to 2.4 mg/dL), of which 30% is protein-bound and another 15% is loosely complexed to phosphate and other anions. Half of the 25 g (1000 mmol) of total body magnesium is located in bone, only half of which is insoluble in the mineral phase. Almost all extraskeletal magnesium is present within cells, where the total concentration is 5 mM, 95% of which is bound to proteins and other macromolecules. Because only 1% of body magnesium resides in the ECF, measurements of serum magnesium levels may not accurately reflect the level of total body magnesium stores.

Dietary magnesium content normally ranges from 6 to 15 mmol/d (140 to 360 mg/d), of which 30 to 40% is absorbed, mainly in the jejunum and ileum. Intestinal magnesium absorptive efficiency is stimulated by $1,25(OH)_2D$ and can reach 70% during magnesium deprivation. Urinary magnesium excretion normally matches net intestinal absorption and is approximately 4 mmol/d (100 mg/d). Regulation of serum magnesium concentrations is achieved mainly by control of renal magnesium reabsorption. Only 20% of filtered magnesium is reabsorbed in the proximal tubule, whereas 60% is reclaimed in the cTAL and another 5 to 10% in the DCT. Magnesium reabsorption in the cTAL occurs via a paracellular route that requires both a lumen-negative potential, created by NaCl reabsorption, and the tight-junction protein, paracellin-1. Magnesium reabsorption in the cTAL is increased by PTH but inhibited by hypercalcemia or hypermagnesemia, both of which activate the CaSR in this nephron segment.

HYPOMAGNESIA ■ Causes Hypomagnesemia usually signifies substantial depletion of body magnesium stores (0.5 to 1 mmol/kg). Hypomagnesemia can result from intestinal malabsorption; protracted vomiting, diarrhea, or intestinal drainage; defective renal tubular magnesium reabsorption; or rapid shifts of magnesium from the ECF into cells, bone, or third spaces (Table 331-4). Dietary magnesium deficiency is unlikely except possibly in the setting of alcoholism. A rare genetic disorder causing selective intestinal magnesium malabsorption has been described (primary infantile hypomagnesemia). Mal-

Note: ATN, acute tubular necrosis; SIADH, syndrome of inappropriate anti-diuretic hormone.

absorptive states, often compounded by vitamin D deficiency, can critically limit magnesium absorption and produce hypomagnesemia, despite the compensatory effects of secondary hyperparathyroidism and of hypocalcemia and hypomagnesemia to enhance cTAL magnesium reabsorption. Diarrhea or surgical drainage fluid may contain ≥5 mmol/L of magnesium.

Several genetic magnesium-wasting syndromes are described, including inactivating mutations of genes encoding the DCT NaCl cotransporter (Gitelman syndrome), proteins required for cTAL Na-K-Cl_2 transport (Bartter syndrome), paracellin-1 (autosomal recessive renal hypomagnesemia with hypercalciuria), and a DCT Na-K-ATPase γ-subunit (autosomal dominant renal hypomagnesemia with hypocalciuria). ECF expansion, hypercalcemia, and severe phosphate depletion may impair magnesium reabsorption, as can various forms of renal injury, including those caused by drugs such as cisplatin, cyclosporine, aminoglycosides, and pentamidine (Table 331-4). A rising blood concentration of ethanol directly impairs tubular magnesium reabsorption, and persistent glycosuria with osmotic diuresis leads to magnesium wasting and likely contributes to the high frequency of hypomagnesemia in poorly controlled diabetics. Magnesium depletion is aggravated by metabolic acidosis, which causes intracellular losses as well.

Hypomagnesemia due to rapid shifts of magnesium from ECF into the intracellular compartment can occur during recovery from diabetic ketoacidosis, from starvation, or from respiratory acidosis. Less acute shifts may be seen during rapid bone formation after parathyroidectomy, with treatment of vitamin D deficiency, or with osteoblastic metastases. Large amounts of magnesium may be lost with acute pancreatitis, extensive burns, protracted and severe sweating, and during pregnancy and lactation.

Clinical and Laboratory Findings Hypomagnesemia may cause generalized alterations in neuromuscular function, including tetany, tremor, seizures, muscle weakness, ataxia, nystagmus, vertigo, apathy, depression, irritability, delirium, and psychosis. Patients are usually asymptomatic when serum magnesium concentrations are >0.5 mmol/L (1 meq/L; 1.2 mg/dL), although the severity of symptoms may not correlate with serum magnesium levels. Cardiac arrhythmias may occur, including sinus tachycardia, other supraventricular tachycardias, and ventricular arrhythmias. Electrocardiographic abnormalities may include prolonged PR or QT intervals, T-wave flattening or inversion, and ST straightening. Sensitivity to digitalis toxicity may be enhanced.

Other electrolyte abnormalities often seen with hypomagnesemia, including hypocalcemia (with hypocalciuria) and hypokalemia, may not be easily corrected unless magnesium is administered as well. The hypocalcemia may be a result of concurrent vitamin D deficiency, although hypomagnesemia can cause impaired synthesis of $1,25(OH)_2D$, cellular resistance to PTH and, at very low serum magnesium [< 0.4 mmol/L (<0.8 meq/L; < 1 mg/dL)], a defect in PTH secretion; these abnormalities are reversible with therapy.

Rx TREATMENT

Mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts [$MgCl_2$, MgO, $Mg(OH)_2$] in divided doses totaling 20 to 30 mmol/d (40 to 60 meq/d). Diarrhea may occur with larger doses. More severe hypomagnesemia should be treated parenterally, preferably with intravenous $MgCl_2$, which can be administered safely as a continuous infusion of 50 mmol/d (100 meq Mg^{2+}/d) if renal function is normal. If GFR is reduced, the infusion rate should be lowered by 50 to 75%. Use of intramuscular $MgSO_4$ is discouraged; the injections are painful and provide relatively little magnesium (2 mL of 50% $MgSO_4$ supplies only 4 mmol). $MgSO_4$ may be given intravenously instead of $MgCl_2$, although the sulfate anions may bind calcium in serum and urine and aggravate hypocalcemia. Serum magnesium should be monitored at intervals of 12 to 24 h during therapy, which may continue for several days because of impaired renal conservation of magnesium (only 50 to 70% of the daily intravenous magnesium dose is retained) and delayed repletion of intracellular deficits, which may be as high as 1 to 1.5 mmol/kg (2 to 3 meq/kg).

It is important to consider the need for calcium, potassium, and phosphate supplementation in patients with hypomagnesemia. Vitamin D deficiency frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH)D [but not $1,25(OH)_2D$, which may impair tubular magnesium reabsorption, possibly via PTH suppression]. In severely hypomagnesemic patients with concomitant hypocalcemia and hypophosphatemia, administration of intravenous magnesium alone may worsen hypophosphatemia, provoking neuromuscular symptoms or rhabdomyolysis, due to rapid stimulation of PTH secretion. This is avoided by administering both calcium and magnesium.

HYPERMAGNESEMIA ■ Causes

Hypermagnesemia is rarely seen in the absence of renal insufficiency, as normal kidneys can excrete large amounts (250 mmol/d) of magnesium. Mild hypermagnesemia due to excessive reabsorption in the cTAL occurs with calcium-sensing receptor mutations in familial hypocalciuric hypercalcemia and has been described in some patients with adrenal insufficiency, hypothyroidism, or hypothermia. Massive exogenous magnesium exposures, usually via the gastrointestinal tract, can overwhelm renal excretory capacity and cause life-threatening hypermagnesemia (Table 331-5). A notable example of this is prolonged retention of even normal amounts of magnesium-containing cathartics in patients with intestinal ileus, obstruction, or perforation. Extensive soft tissue injury or necrosis can also deliver large amounts of magnesium into the ECF in patients who have suffered trauma, shock, sepsis, cardiac arrest, or severe burns.

Clinical and Laboratory Findings The most prominent clinical manifestations of hypermagnesemia are vasodilation and neuromuscular blockade, which may appear at serum magnesium concentrations >2 mmol/L (> 4 meq/L; > 4.8 mg/dL). Hypotension, refractory to vasopressors or volume expansion, may be an early sign. Nausea, lethargy, and weakness may progress to respiratory failure, paralysis, and coma, with hypoactive tendon reflexes, at serum magnesium levels >4 mmol/L. Other findings may include gastrointestinal hypomotility or ileus; facial flushing; pupillary dilation; paradoxical bradycardia; prolongation of PR, QRS, and QT intervals, heart block; and, at serum magnesium levels approaching 10 mmol/L, asystole.

Hypermagnesemia, acting via the CaSR, causes hypocalcemia and hypercalciuria due to both parathyroid suppression and impaired cTAL calcium reabsorption.

Rx TREATMENT

Successful treatment of hypermagnesemia generally involves identifying and interrupting the source of magnesium and employing measures to increase magnesium clearance from the ECF. Use of magnesium-free cathartics or enemas may be helpful in clearing ingested magnesium from the gastrointestinal tract. Vigorous intravenous hydration should be attempted, if appropriate. Hemodialysis is effective and may be required in patients with significant renal insufficiency. Calcium, administered intravenously in doses of 100 to 200 mg over 1 to 2 h, has been reported to provide temporary improvement in signs and symptoms of hypermagnesemia.

TABLE 331-5 Causes of Hypermagnesemia

Impaired Mg excretion	Rapid Mg mobilization from soft tissues
Renal failure	Trauma
Familial hypocalciuric hypercalcemia	Extensive burns
Excessive Mg intake	Shock, sepsis
Cathartics	Post cardiac arrest
Intestinal obstruction/perforation following magnesium ingestion	Other disorders
Parenteral magnesium administration	Adrenal insufficiency
Magnesium-rich urologic irrigants	Hypothyroidism
	Hypothermia

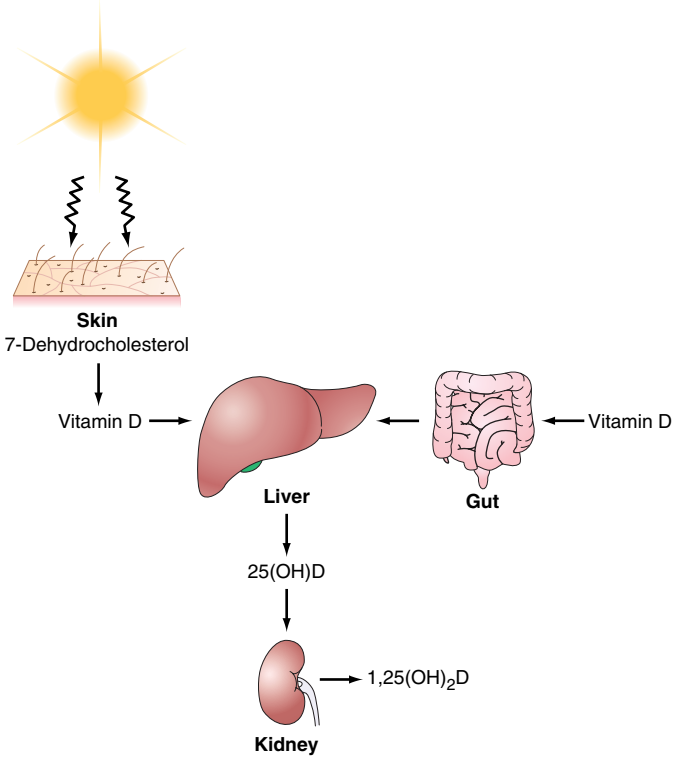

FIGURE 331-4 Vitamin D synthesis and activation. Vitamin D is synthesized in the skin in response to ultraviolet radiation and is also absorbed from the diet. It is then transported to the liver, where it undergoes 25-hydroxylation. This metabolite is the major circulating form of vitamin D. The final step in hormone activation, 1α-hydroxylation, occurs in the kidney.

VITAMIN D

SYNTHESIS AND METABOLISM 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] is the major steroid hormone involved in mineral ion homeostasis regulation. Vitamin D and its metabolites are hormones and hormone precursors rather than vitamins, since in the proper biologic setting, they can be synthesized endogenously (Fig. 331-4). In response to ultraviolet radiation of the skin, a photochemical cleavage results in the formation of vitamin D from 7-dehydrocholesterol. Cutaneous production of vitamin D is decreased by melanin and high solar protection factor sunblocks, which effectively impair skin penetration of ultraviolet light. The increased use of sunblocks in North America and Western Europe and a reduction in the magnitude of solar exposure of the general population over the past several decades has led to an increased reliance on dietary sources of vitamin D. In the United States and Canada, these sources largely consist of fortified cereals and dairy products, in addition to fish oils and egg yolks. Vitamin D from plant sources is in the form of vitamin D_2, whereas that from animal sources is vitamin D_3. These two forms have equivalent biologic activity and are activated equally well by the vitamin D hydroxylases in humans. Vitamin D enters the circulation, whether absorbed from the intestine or synthesized cutaneously, bound to vitamin D–binding protein, an α-globulin synthesized in the liver. Vitamin D is subsequently 25-hydroxylated in the liver by cytochrome P450–like enzymes in the mitochondria and microsomes. The activity of this hydroxylase is not tightly regulated, and the resultant metabolite, 25-hydroxyvitamin D [25(OH)D], is the major circulating and storage form of vitamin D. Approximately 88% of 25(OH)D circulates bound to the vitamin D–binding protein, 0.03% is free, and the rest circulates bound to albumin. The half-life of 25(OH)D is approximately 2 to 3 weeks; however, it is dramatically shortened when vitamin D–binding protein levels are reduced, as can occur with increased urinary losses in the nephrotic syndrome.

The final hydroxylation required for mature hormone formation occurs in the kidney (Fig. 331-5). The 25(OH)D-1α-hydroxylase is a tightly regulated cytochrome P450–like mixed function oxidase expressed in proximal convoluted tubule cells. PTH stimulates this microsomal enzyme, whereas calcium and the product of the enzyme's action, 1,25$(OH)_2$D, repress it. The 25(OH)D-1α-hydroxylase is also present in epidermal keratinocytes, but keratinocyte production of 1,25$(OH)_2$D is not thought to contribute to circulating levels of this hormone. The 1α-hydroxylase is present in the trophoblastic layer of the placenta and is produced in the granulomas of sarcoidosis, tuberculosis, and berylliosis as well as in lymphomas. In these latter pathologic states, the activity of the enzyme is induced by interferon γ and TNF but is not regulated by calcium or 1,25$(OH)_2$D; therefore, hypercalcemia may occur because of elevated levels of 1,25$(OH)_2$D. Treatment of sarcoidosis-associated hypercalcemia with glucocorticoids, ketoconazole, or chloroquine has been shown to lower serum 1,25$(OH)_2$D levels.

The major pathway for inactivation of vitamin D metabolites is an additional hydroxylation step by vitamin D–24-hydroxylase, an enzyme that is expressed in most tissues. 1,25$(OH)_2$D, the major inducer of vitamin D–24-hydroxylase, thus promotes its own inactivation, thereby limiting its biologic effects. Polar metabolites of 1,25$(OH)_2$D are secreted into the bile and reabsorbed via the enterohepatic circulation. Impairment of this circulation, seen with diseases of the terminal ileum, leads to accelerated losses of vitamin D metabolites.

ACTIONS OF 1,25$(OH)_2$D 1,25$(OH)_2$D mediates its biologic effects by binding to a member of the nuclear receptor superfamily, the vitamin D receptor (VDR). This receptor belongs to the subfamily that includes the thyroid hormone receptors, the retinoid receptors, and the peroxisome proliferator–activated receptors (Chap. 317). In contrast to the

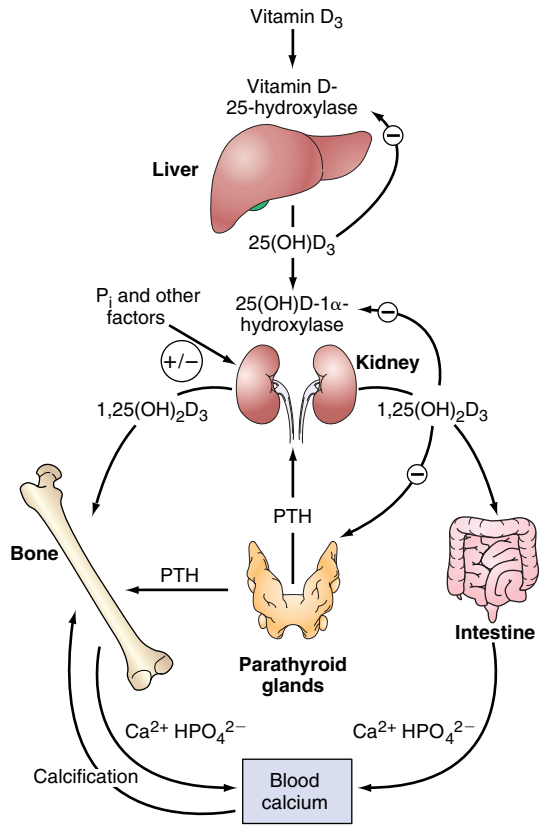

FIGURE 331-5 Schematic representation of the hormonal control loop for vitamin D metabolism and function. A reduction in the serum calcium below approximately 2.2 mmol/L (8.8 mg/dL) prompts a proportional increase in the secretion of parathyroid hormone (PTH) and so mobilizes additional calcium from the bone. PTH promotes the synthesis of 1,25$(OH)_2$D in the kidney, which, in turn, stimulates the mobilization of calcium from bone and intestine and regulates the synthesis of PTH by negative feedback.

other members of this subfamily, however, only one VDR isoform has been isolated. The VDR binds to target DNA sequences as a heterodimer with the retinoid X receptor, recruiting a series of coactivators that result in the induction of target gene expression. When the VDR causes repression of target gene expression, it either interferes with the action of activating transcription factors or recruits novel proteins to the VDR complex that cause transcriptional repression.

The affinity of the VDR for $1,25(OH)_2D$ is approximately three orders of magnitude higher than for the other vitamin D metabolites. Under normal physiologic circumstances, these other metabolites do not stimulate receptor-dependent actions. However, in states of vitamin D toxicity, the markedly elevated levels of 25(OH)D may lead to hypercalcemia by interacting directly with the VDR and by displacing $1,25(OH)_2D$ from serum vitamin D–binding protein, resulting in increased bioavailability of the active hormone.

The VDR is expressed in a wide range of cells and tissues. The molecular actions of $1,25(OH)_2D$ have been most extensively studied in tissues involved in the regulation of mineral ion homeostasis. This hormone is a major inducer of calbindin 9K, a calcium-binding protein expressed in the intestine, which is thought to play an important role in the active transport of calcium across the enterocyte. The two major calcium transporters expressed by intestinal epithelia, ECaC and ICaC, are also vitamin D responsive. By inducing the expression of these and other genes in the small intestine, $1,25(OH)_2D$ increases the efficiency of intestinal calcium absorption.

The VDR regulates the expression of several genes in osteoblasts. Target genes include the bone matrix proteins, osteocalcin and osteopontin, which are upregulated by $1,25(OH)_2D$, in addition to type I collagen, which is transcriptionally repressed by $1,25(OH)_2D$. $1,25(OH)_2D$, as well as PTH, induces the expression of RANK ligand, which promotes osteoclast differentiation and increases osteoclast activity.

In the parathyroid gland, the VDR exerts antiproliferative effects on parathyroid cells and suppresses the transcription of the PTH gene. These effects of $1,25(OH)_2D$ on the parathyroid gland provide part of the rationale for current therapies directed at preventing and treating hyperparathyroidism associated with renal insufficiency.

The VDR is also expressed in tissues and organs that do not play a role in mineral ion homeostasis. Notable in this respect is the observation that $1,25(OH)_2D$ has an antiproliferative effect on several cell types, including keratinocytes, breast cancer cells, and prostate cancer cells. Alopecia is seen in humans and mice with mutant VDRs, but alopecia is not a feature of vitamin D deficiency, suggesting hormone-independent effects of the receptor.

VITAMIN D DEFICIENCY The mounting concern about the relationship between solar exposure and the development of skin cancer has led to increased reliance on dietary sources of vitamin D. Although the prevalence of vitamin D deficiency varies, the third National Health and Nutrition Examination Survey (NHANES III) revealed that vitamin D deficiency is common throughout the United States. The clinical syndrome of vitamin D deficiency can result from deficient production of vitamin D in the skin, lack of dietary intake, accelerated losses of vitamin D, impaired vitamin D activation, or resistance to the biologic effects of $1,25(OH)_2D$ (Table 331-6). The elderly and nursing home residents are particularly at risk for vitamin D deficiency, since both the efficiency of vitamin D synthesis in the skin and the absorption of vitamin D from the intestine decline with age.

Intestinal malabsorption of dietary fats can also lead to vitamin D deficiency. This is further exacerbated in the presence of terminal ileal disease, which results in impaired enterohepatic circulation of vitamin D metabolites. In addition to intestinal diseases, accelerated inactivation of vitamin D metabolites can be seen with drugs such as barbiturates, phenytoin, and rifampin, which induce hepatic cytochrome P450 mixed function oxidases. Impaired 25-hydroxylation, associated with severe liver disease or isoniazid, is an infrequent cause of vitamin D deficiency. Impaired 1α-hydroxylation is prevalent in the population with profound renal dysfunction, and therapeutic interventions should be considered in patients whose creatinine clearance is <0.5 mL/s (30 mL/min).

Mutations in the renal 1α-hydroxylase are the basis for the genetic disorder, pseudo-vitamin D–deficiency rickets. This autosomal recessive disorder presents with the syndrome of vitamin D deficiency in the first year of life. Affected children manifest growth retardation, rickets, and hypocalcemic seizures. Serum $1,25(OH)_2D$ levels are low, despite normal 25(OH)D levels and elevated PTH levels. Treatment with vitamin D metabolites that do not require 1α-hydroxylation corrects this disorder and must be continued throughout life. A second autosomal recessive disorder, hereditary vitamin D–resistant rickets, is caused by VDR mutations. Affected children present in a similar fashion during the first year of life, but alopecia often accompanies the disorder, demonstrating a functional role of the VDR in postnatal hair regeneration. Serum levels of $1,25(OH)_2D$ are dramatically elevated in these individuals, both because of increased production due to stimulation of 1α-hydroxylase activity as a consequence of secondary hyperparathyroidism and because of impaired inactivation, since induction of the 24-hydroxylase by $1,25(OH)_2D$ requires an intact VDR. Since the receptor mutation results in hormone resistance, daily calcium and phosphorus infusions may be required to bypass the defect in intestinal mineral ion absorption.

Regardless of the cause, the clinical manifestations of vitamin D deficiency are largely a consequence of impaired intestinal calcium absorption. Mild to moderate vitamin D deficiency is asymptomatic, whereas long-standing vitamin D deficiency results in hypocalcemia accompanied by secondary hyperparathyroidism, impaired mineralization of the skeleton (osteopenia on x-ray or decreased bone mineral density), and proximal myopathy. In the absence of an intercurrent illness, the hypocalcemia associated with long-standing vitamin D deficiency rarely presents with acute symptoms of hypocalcemia, such as numbness, tingling, or seizures. The concurrent development of hypomagnesemia, however, which impairs parathyroid gland function, or the administration of potent bisphosphonates, which impairs bone resorption, can lead to acute symptomatic hypocalcemia in vitamin D–deficient individuals.

RICKETS AND OSTEOMALACIA In children, prior to epiphyseal fusion, vitamin D deficiency results in growth retardation associated with an expansion of the growth plate known as *rickets*. Three layers of chondrocytes are present in the normal growth plate: the reserve zone, the proliferating zone, and the hypertrophic zone. Rickets, associated with impaired vitamin D action, is characterized by expansion of the hypertrophic chondrocyte layer. The expansion of the growth plate is thought to be a result of impaired apoptosis of the late hypertrophic chondrocytes, an event that precedes replacement of these cells by osteoblasts during endochondral bone formation. Investigations in mice lacking the VDR have demonstrated that maintenance of normal mineral ion homeostasis prevents the development of rickets. The observation that phosphate promotes chondrocyte apoptosis, combined with the presence of rickets in syndromes associated with renal phosphate wasting, suggests that hypophosphatemia, which in vitamin D deficiency is a consequence of secondary hyperparathyroidism, is a key etiologic factor in the development of the rachitic growth plate.

TABLE 331-6 Causes of Impaired Vitamin D Action

Vitamin D deficiency	Impaired 1α-hydroxylation
Impaired cutaneous production	Hypoparathyroidism
Dietary absence	Renal failure
Malabsorption	Ketoconazole
Accelerated loss of vitamin D	1α-hydroxylase mutation
Increased metabolism (barbiturates, phenytoin, rifampin)	Oncogenic osteomalacia
Impaired enterohepatic circulation	X-linked hypophosphatemic rickets
Impaired 25-hydroxylation	Target organ resistance
Liver disease	Vitamin D receptor mutation
Isoniazid	Phenytoin

The hypocalcemia and hypophosphatemia that accompany vitamin D deficiency result in impaired mineralization of bone matrix, a condition known as *osteomalacia*. Osteomalacia is also a feature of long-standing hypophosphatemia, which may be a consequence of renal phosphate wasting or chronic use of etidronate or phosphate-binding antacids. This hypomineralized matrix is biomechanically inferior to normal bone and, as a result, patients with vitamin D deficiency are prone to bowing of weight-bearing extremities because of abnormal remodeling and to skeletal fractures. Vitamin D and calcium supplementation have been shown to decrease the incidence of hip fracture among ambulatory nursing home residents in France, suggesting that undermineralization of bone contributes significantly to morbidity in the elderly. Proximal myopathy is a striking feature of severe vitamin D deficiency, both in children and in adults. Rapid resolution of the myopathy is observed after vitamin D repletion.

Though vitamin D deficiency is the most common cause of rickets and osteomalacia, many disorders lead to inadequate mineralization of the growth plate and bone. Calcium deficiency without vitamin D deficiency, the disorders of vitamin D metabolism previously discussed, and hypophosphatemia can all lead to inefficient mineralization. Even in the presence of normal calcium and phosphate levels, chronic acidosis and drugs such as bisphosphonates can lead to osteomalacia. The inorganic calcium/phosphate mineral phase of bone cannot form at low pH, and bisphosphonates bind to and prevent mineral crystal growth. Since alkaline phosphatase is necessary for normal mineral deposition, probably because the enzyme can hydrolyze inhibitors of mineralization such as inorganic pyrophosphate, genetic inactivation of the alkaline phosphatase gene (hereditary hypophosphatasia) can also lead to rickets and osteomalacia in the setting of normal calcium and phosphate levels.

DIAGNOSIS OF VITAMIN D DEFICIENCY, RICKETS, AND OSTEOMALACIA The most specific screening test for vitamin D deficiency in otherwise healthy individuals is a serum 25(OH)D level. While the normal ranges vary, levels of 25(OH)D $<$37 nmol/L ($<$15 ng/mL) are associated with increasing PTH levels and lower bone density, suggesting the need to revise normative values. Vitamin D deficiency leads to impaired intestinal absorption of calcium, resulting in decreased serum total and ionized calcium levels. Hypocalcemia results in secondary hyperparathyroidism, a homeostatic response that initially maintains serum calcium levels at the expense of the skeleton. Alkaline phosphatase levels are often increased because of the PTH-induced increase in bone turnover. In addition to increasing bone resorption, PTH decreases urinary calcium excretion, while promoting phosphaturia. This results in hypophosphatemia, which exacerbates the mineralization defect in the skeleton. With prolonged vitamin D deficiency resulting in osteomalacia, calcium stores in the skeleton become relatively inaccessible, since osteoclasts cannot resorb unmineralized osteoid, and frank hypocalcemia ensues. Since PTH is a major stimulus for the renal 1α-hydroxylase, there is increased synthesis of the active hormone, 1,25$(OH)_2$D. Paradoxically, levels of this hormone may be normal in vitamin D deficiency. Measurements of 1,25$(OH)_2$D, therefore, do not provide an accurate index of vitamin D stores and should not be used to diagnose vitamin D deficiency in patients with normal renal function.

Radiologic features of vitamin D deficiency in children include a widened, expanded growth plate, characteristic of rickets. These findings are apparent not only in the long bones, but also at the costochondral junctions, where the expansion of the growth plate leads to swellings known as "rachitic rosaries." Impairment of intramembranous bone mineralization leads to delayed fusion of the calvarial sutures and a decrease in the radio-opacity of cortical bone in the long bones. If vitamin D deficiency occurs after epiphyseal fusion, the main radiologic finding is a decrease in cortical thickness and relative radiolucency of the skeleton. A specific radiologic feature of osteomalacia, whether associated with phosphate wasting or vitamin D deficiency, is pseudofractures or Looser's zones (Fig. 331-6). These are radiolucent lines that occur where large arteries are in contact with the underlying skeletal elements; it is believed that the arterial pulsations lead to the radiolucencies. As a result, these pseudofractures are usually a few millimeters wide, several centimeters long, and are seen particularly in the scapula, the pelvis, and the femoral neck.

Rx TREATMENT

Daily intake of a multivitamin preparation that contains 400 IU of vitamin D is often insufficient to prevent vitamin D deficiency. Based on the observation that 800 IU of vitamin D, with calcium supplementation, decreases the risk of hip fractures in elderly women, 800 IU is considered to be a more appropriate daily dosage for prevention of vitamin D deficiency. The safety margin for vitamin D is large, and vitamin D toxicity is usually observed only in patients taking doses $>$40,000 IU daily. Treatment of vitamin D deficiency should be directed at the underlying disorder, if possible, and tailored to the severity of the condition. Vitamin D should always be repleted in conjunction with calcium supplementation since most, if not all, of the consequences of vitamin D deficiency are a result of impaired mineral ion homeostasis.

In patients whose 1α-hydroxylation is impaired, vitamin D analogues not requiring this activation step are preferred. These include dihydrotachysterol (DHT, 0.2 to 1.0 mg daily), 1,25$(OH)_2D_3$ [calcitriol (Rocaltrol), 0.25 to 0.5 μg daily], and 1α-hydroxyvitamin D_2 [doxercalciferol (Hectorol), 2.5 to 5 μg daily). If the pathway required for activation of vitamin D is intact, severe vitamin D deficiency can be treated with pharmacologic repletion initially (50,000 IU weekly for 3 to 12 weeks), followed by maintenance therapy (800 IU daily). Pharmacologic doses may be required for maintenance therapy in patients who are taking drugs such as barbiturates or phenytoin that accelerate the metabolism of, or cause resistance to, 1,25-dihydroxyvitamin D. If intestinal malabsorption is a contributing factor, up to tenfold higher doses of vitamin D may be needed, or repletion can be performed with intramuscular vitamin D (250,000 IU biannually). Calcium supplementation should include 1.5 to 2.0 g of elemental calcium daily. Normocalcemia is usually observed within 1 week of institution of therapy, although increases in PTH and alkaline phosphatase levels may persist for 3 to 6 months.

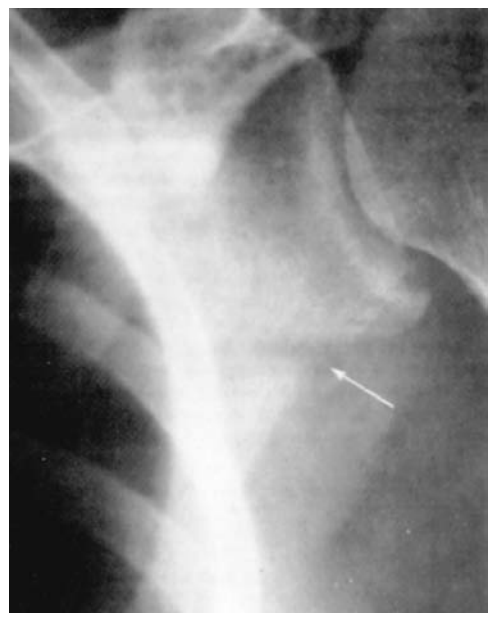

FIGURE 331-6 Radiograph of the scapula of a 58-year-old woman with phosphaturia as a cause of osteomalacia. The presence of a pseudofracture or Looser's zone is indicated by an arrow.

The most efficacious methods to monitor treatment and resolution of vitamin D deficiency are serum and urinary calcium measurements. For patients who are vitamin D replete and are taking adequate calcium supplementation, the 24-h urinary calcium excretion should be in the range of 100 to 250 mg/24 h. Lower levels suggest problems with adhering to the treatment regimen or with absorption of calcium or vitamin D supplements. The 25(OH)D level can be remeasured to address the latter, although the half-life of this metabolite is long (3 weeks) and levels may continue to increase for many months on a stable regimen. Urinary calcium excretion >250 mg/24 h predisposes to nephrolithiasis and should prompt a reduction in vitamin D dosage and/or calcium supplementation.

332 DISEASES OF THE PARATHYROID GLAND AND OTHER HYPER- AND HYPOCALCEMIC DISORDERS

John T. Potts, Jr

The four parathyroid glands are located posterior to the thyroid gland. They produce parathyroid hormone (PTH), which is the primary regulator of calcium physiology. PTH acts directly on bone, where it induces calcium resorption, and on the kidney, where it stimulates calcium reabsorption and synthesis of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], a hormone that stimulates gastrointestinal calcium absorption. Serum PTH levels are tightly regulated by a negative feedback loop. Calcium, acting through the calcium-sensing receptor, and vitamin D, acting through its nuclear receptor, inhibit PTH release and synthesis. Understanding the hormone pathways that regulate calcium levels and bone metabolism is essential for effective diagnosis and management of a wide array of hyper- and hypocalcemic disorders.

Hyperparathyroidism, characterized by excess production of PTH, is a common cause of hypercalcemia and is usually the result of autonomously functioning adenomas or hyperplasia. Surgery for this disorder is highly effective and has been shown to reverse some of the deleterious effects of long-standing PTH excess on bone density. Hypercalcemia of malignancy is also common and is usually due to the overproduction of parathyroid hormone–related peptide (PTHrP) by cancer cells. The similarities in the biochemical characteristics of hyperparathyroidism and hypercalcemia of malignancy, first noted by Albright in 1941, are now known to reflect the actions of PTH and PTHrP through the same G protein–coupled PTH/PTHrP receptor.

The genetic basis of multiple endocrine neoplasia (MEN) types 1 and 2, familial hypocalciuric hypercalcemia (FHH), the different forms of pseudohypoparathyroidism (PHP), Jansen's syndrome, disorders of vitamin D synthesis and action, and the molecular events associated with parathyroid gland neoplasia have provided new insights into calcium metabolism. The advent of new drugs, including bisphosphonates and selective estrogen receptor modulators (SERMs), offers new avenues for the treatment and prevention of metabolic bone disease. PTH analogues are promising therapeutic agents for the treatment of postmenopausal or senile osteoporosis, and calcimimetic agents, which act through the calcium-sensing receptor, may provide new approaches for PTH suppression.

PARATHYROID HORMONE

PHYSIOLOGY The primary function of PTH is to maintain the extracellular fluid (ECF) calcium concentration within a narrow normal range. The hormone acts directly on bone and kidney and indirectly on intestine through its effects on synthesis of 1,25$(OH)_2$D to increase serum calcium concentrations; in turn, PTH production is closely regulated by the concentration of serum ionized calcium. This feedback system is the critical homeostatic mechanism for maintenance of ECF calcium. Any tendency toward hypocalcemia, as might be induced by calcium-deficient diets, is counteracted by an increased secretion of PTH. This in turn (1) increases the rate of dissolution of bone mineral, thereby increasing the flow of calcium from bone into blood; (2) reduces the renal clearance of calcium, returning more of the calcium filtered at the glomerulus into ECF; and (3) increases the efficiency of calcium absorption in the intestine by stimulating the production of 1,25$(OH)_2$D. Immediate control of blood calcium is due to PTH effects on bone and, to a lesser extent, on renal calcium clearance. Maintenance of steady-state calcium balance, on the other hand, probably results from the effects of 1,25$(OH)_2$D on calcium absorption (Chap. 331). The renal actions of the hormone are exerted at multiple sites and include inhibition of phosphate transport (proximal tubule), increased reabsorption of calcium (distal tubule), and stimulation of the renal 25(OH)D-1α-hydroxylase. As much as 12 mmol (500 mg) calcium is transferred between the ECF and bone each day (a large amount in relation to the total ECF calcium pool), and PTH has a major effect on this transfer. The homeostatic role of the hormone can preserve calcium concentration in blood at the cost of bone destruction.

PTH has multiple actions on bone, some direct and some indirect. PTH-mediated changes in bone calcium release can be seen within minutes. The chronic effects of PTH are to increase the number of bone cells, both osteoblasts and osteoclasts, and to increase the remodeling of bone; these effects are apparent within hours after the hormone is given and persist for hours after PTH is withdrawn. Continuous exposure to elevated PTH (as in hyperparathyroidism or long-term infusions in animals) leads to increased osteoclast-mediated bone resorption. However, the intermittent administration of PTH, elevating hormone levels for 1 to 2 h each day, leads to a net stimulation of bone formation rather than bone breakdown. Striking increases, especially in trabecular bone in the spine and hip, have been reported with the use of PTH in combination with estrogen. PTH as monotherapy caused a highly significant reduction in fracture incidence in a worldwide placebo-controlled trial.

Osteoblasts (or stromal cell precursors), which have PTH receptors, are crucial to this bone-forming effect of PTH; osteoclasts, which mediate bone breakdown, lack PTH receptors. PTH-mediated stimulation of osteoclasts is believed to be indirect, acting in part through cytokines released from osteoblasts to activate osteoclasts; in experimental studies of bone resorption in vitro, osteoblasts must be present for PTH to activate osteoclasts to resorb bone (Chap. 331).

STRUCTURE PTH is an 84-amino-acid single-chain peptide. The amino acid portion, PTH(1–34), is highly conserved and is critical for the biologic actions of the molecule. Modified synthetic fragments of the amino-terminal sequence as small as PTH(1–11) are sufficient to activate the major receptor (see below). The carboxyl-terminal region of

PTH binds to a separate receptor (cPTH-R), but it has not yet been cloned. Fragments shortened at the amino terminus bind to cPTH-R and inhibit the actions of the full-length PTH(1–84) or the PTH(1–34) active fragments.

BIOSYNTHESIS, SECRETION, AND METABOLISM ■ **Synthesis** Parathyroid cells have multiple methods of adapting to increased needs for PTH production. Most rapid (within minutes) is secretion of preformed hormone in response to hypocalcemia. Second, within hours, PTH mRNA expression is induced by sustained hypocalcemia. Finally, protracted challenge leads within days to cellular replication to increase gland mass.

PTH is initially synthesized as a larger molecule (preproparathyroid hormone, consisting of 115 amino acids), which is then reduced in size by a second cleavage (proparathyroid hormone, 90 amino acids) before secretion as the 84-amino-acid peptide. In one kindred with hypoparathyroidism, a mutation in the preprotein region of the gene interferes with hormone transport and secretion.

Transcriptional suppression of the PTH gene by calcium is nearly maximal at physiologic calcium concentrations. Hypocalcemia increases transcriptional activity within hours. $1,25(OH)_2D_3$ strongly suppresses PTH gene transcription. In patients with renal failure, intravenous administration of supraphysiologic levels of $1,25(OH)_2D_3$ or analogues of the active metabolite can dramatically suppress PTH overproduction, which is sometimes difficult to control due to severe secondary hyperparathyroidism. Regulation of proteolytic destruction of preformed hormone (posttranslational regulation of hormone production) is an important mechanism for mediating rapid (minutes) changes in hormone availability. High calcium increases and low calcium inhibits the proteolytic destruction of hormone stores.

Regulation of PTH Secretion PTH secretion increases steeply to a maximum value of five times the basal rate of secretion as calcium concentration falls from normal to the range of 1.9 to 2.0 mmol/L (7.5 to 8.0 mg/dL) (measured as total calcium). The ionized fraction of blood calcium is the important determinant of hormone secretion. Severe intracellular magnesium deficiency impairs PTH secretion (see below).

ECF calcium controls PTH secretion by interaction with a calcium sensor, a G protein–coupled receptor (GPCR) for which Ca^{2+} ions act as the ligand (see below). This receptor is a member of a distinctive subfamily of the GPCR superfamily that is characterized by a large extracellular domain suitable for "clamping" the small-molecule ligand. Stimulation of the receptor by high calcium levels suppresses PTH secretion. The receptor is present in parathyroid glands and the calcitonin-secreting cells (C cells) of the thyroid, as well as in other sites such as brain and kidney. Genetic evidence has revealed a key biologic role for the calcium-sensing receptor in parathyroid gland responsiveness to calcium and in renal calcium clearance. Point mutations associated with loss of function cause a syndrome FHH resembling hyperparathyroidism but with hypocalciuria. On the other hand, gain-of-function mutations cause a form of hypocalcemia resembling hypoparathyroidism (see below).

Metabolism The secreted form of PTH is indistinguishable by immunologic criteria and by molecular size from the 84-amino-acid peptide (PTH 1–84) extracted from glands. However, much of the immunoreactive material found in the circulation is smaller than the extracted or secreted hormone. The principal circulating fragments of immunoreactive hormone lack a portion of the critical amino-terminal sequence required for biologic activity and, hence, are biologically inactive fragments (so-called middle- and carboxyl-terminal fragments). Much of the proteolysis of hormone occurs in the liver and kidney. Peripheral metabolism of PTH does not appear to be regulated by physiologic states (high versus low calcium, etc.); hence peripheral metabolism of hormone, although responsible for rapid clearance of secreted hormone, appears to be a high-capacity, metabolically invariant catabolic process.

The rate of clearance of the secreted 84-amino-acid peptide from blood is more rapid than the rate of clearance of the biologically inactive fragment(s) corresponding to the middle- and carboxyl-terminal regions of PTH. Consequently, the interpretation of PTH immunoassays is influenced by the nature of the peptide fragments detected by the antibodies.

Although the problems inherent in PTH measurements have been largely circumvented by use of double-antibody assays that detect only the intact molecule, new evidence has revealed the existence of a hitherto unappreciated larger PTH fragment that may affect the interpretation of most currently available double-antibody assays. A large amino-terminally truncated form of PTH, possibly PTH(7–84), is present in normal and uremic individuals in addition to PTH(1–84). The concentration of the putative (7–84) fragment relative to that of intact PTH(1–84) is higher with induced hypercalcemia than in eucalcemic or hypocalcemic conditions and is higher in patients with renal failure. Growing evidence suggests that the PTH(7–84)-like amino-terminally truncated fragments can act as an inhibitor of PTH action and may be of clinical significance, particularly in renal failure. Efforts to prevent secondary hyperparathyroidism by a variety of measures (vitamin D analogues, higher calcium intake, and phosphate-lowering strategies) may have led to oversuppression of biologically active intact PTH since the amino-terminally truncated PTH reacts in many first-generation double-antibody PTH assays. The role, if any, of excessive PTH suppression due to inaccurate measurement of PTH in adynamic bone disease in renal failure (see below) is unknown. Newer assays with extreme amino-terminal epitopes that detect only full-length PTH(1–84) are being studied intensively.

PARATHYROID HORMONE–RELATED PROTEIN

The paracrine factor termed *PTHrP* is responsible for most instances of hypercalcemia of malignancy (Chap. 86), a syndrome that resembles hyperparathyroidism. Many different cell types produce PTHrP, including brain, pancreas, heart, lung, mammary tissue, placenta, endothelial cells, and smooth muscle. In fetal animals, PTHrP directs transplacental calcium transfer, and high concentrations of PTHrP are produced in mammary tissue and secreted into milk. Human and bovine milk contain very high concentrations of the hormone, the biologic significance of which is unknown. PTHrP may also play a role in uterine contraction and other biologic functions.

PTH and PTHrP, although distinctive products of different genes, exhibit considerable functional and structural homology (Fig. 332-1) and may have evolved from a shared ancestral gene. The structure of the gene for human PTHrP, however, is more complex than that of PTH, containing multiple exons and multiple sites for alternate splicing patterns during formation of the mature mRNA. Protein products of 141, 139, and 173 amino acids are produced, and other molecular forms may result from tissue-specific degradation at accessible internal cleavage sites. The biologic roles of these various molecular species and the nature of the circulating forms of PTHrP are unclear. It is uncertain whether PTHrP circulates at any significant level in adults; as a paracrine factor, PTHrP may be produced, act, and be destroyed locally within tissues. In adults PTHrP appears to have little influence on calcium homeostasis, except in disease states, when large tumors, especially of the squamous cell type, lead to massive overproduction of the hormone.

PTH AND PTHrP HORMONE ACTION Both PTH and PTHrP bind to and activate the PTH/PTHrP receptor. The 500-amino-acid PTH/PTHrP receptor (also known as the PTH-1 receptor, PTH1R) belongs to a subfamily of GPCRs that includes those for glucagon, secretin, and vasoactive intestinal peptide. The extracellular regions are involved in hormone binding, and the intracellular domains, after hormone activation, bind G protein subunits to transduce hormone signaling into cellular responses through stimulation of second messengers. A second receptor that binds PTH, termed the *PTH-2 receptor* (PTH2R), is expressed in brain, pancreas, and several other tissues. PTH1R responds equivalently to PTH and PTHrP, whereas PTH2R responds only to PTH. The endogenous ligand of this receptor is now believed to be a

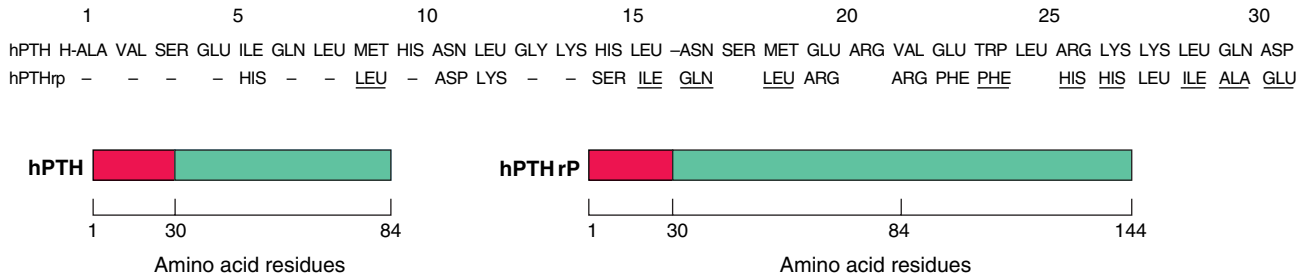

FIGURE 332-1 Schematic diagram to illustrate similarities and differences in structure of human parathyroid hormone (PTH) and human PTH-related peptide (PTHrP). Close structural (and functional) homology exists between the first 30 amino acids of hPTH and hPTHrP. The PTHrP sequence may be ≥144 amino acid residues in length. PTH is only 84 residues long; after residue 30, there is little structural homology between the two. Dashed lines in the PTHrP sequence indicate identity; underlined residues, although different from those of PTH, still represent conservative changes (charge or polarity preserved). Eleven amino acids are identical, and a total of 21 of 30 are homologues.

peptide distinct from PTH, a 39-amino-acid hypothalamic peptide (*tubular infundibular peptide*, TIP-39). PTH1R and PTH2R can be traced backward in evolutionary time to fish. Zebrafish PTH1R and PTH2R exhibit the same selective responses to PTH and PTHrP as do human PTH1R and PTH2R. The evolutionary conservation of structure and function suggests unique biologic roles for these receptors.

Studies using cloned PTH1R confirm that it can be coupled to more than one G protein and second-messenger kinase pathway, apparently explaining the multiplicity of pathways stimulated by PTH. Stimulation of protein kinases (A and C) and calcium transport channels is associated with a variety of hormone-specific tissue responses. These responses include inhibition of phosphate and bicarbonate transport, stimulation of calcium transport, and activation of renal 1α-hydroxylase in the kidney. The responses in bone include effects on collagen synthesis; increased alkaline phosphatase, ornithine decarboxylase, citrate decarboxylase, and glucose-6-phosphate dehydrogenase activities; DNA, protein, and phospholipid synthesis; and calcium and phosphate transport. Ultimately, these biochemical events lead to an integrated hormonal response in bone turnover and calcium homeostasis. PTH also activates Na^+/Ca^{2+} exchanges in renal distal tubular sites and stimulates translocation of preformed calcium transport channels, moving them from the interior to the apical surface to mediate increased tubular uptake of calcium. PTH-dependent stimulation of phosphate excretion (blocking reabsorption—the opposite effect from actions on calcium in the kidney) involves the sodium-dependent phosphate cotransporter, NPT-2, lowering its apical membrane content (and therefore function). Similar shifts may be involved in other renal tubular transport effects of PTH.

PTHrP exerts important developmental influences on fetal bone development and in adult physiology. A homozygous knockout of the PTHrP gene (or the gene for the PTH receptor) in mice causes a lethal deformity in which animals are born with severe skeletal deformities resembling chondrodysplasia (Fig. 332-2).

CALCITONIN (See also Chap. 330)

Calcitonin is a hypocalcemic peptide hormone that in several mammalian species acts as an antagonist to PTH. Calcitonin seems to be of limited physiologic significance in humans, however, at least in calcium homeostasis. It is of medical significance because of its role as a tumor marker in sporadic and hereditary cases of medullary carcinoma and its medical use as an adjunctive treatment in severe hypercalcemia and in Paget's disease of bone.

The hypocalcemic activity of calcitonin is accounted for primarily by inhibition of osteoclast-mediated bone resorption and secondarily by stimulation of renal calcium clearance. These effects are mediated by receptors on osteoclasts and renal tubular cells. Calcitonin exerts additional effects through receptors present in brain, gastrointestinal tract, and the immune system. The hormone, for example, exerts analgesic effects directly on cells in the hypothalamus and related structures, possibly by interacting with receptors for related peptide hormones, such as calcitonin gene–related peptide (CGRP) or amylin. The latter ligands have specific high-affinity receptors and can also bind to and trigger calcitonin receptors. The calcitonin receptors are homologous in structure to PTH1R.

The thyroid is the major source of the hormone, and the cells involved in calcitonin synthesis arise from neural crest tissue. During embryogenesis, these cells migrate into the ultimobranchial body, derived from the last branchial pouch. In submammalian vertebrates, the ultimobranchial body constitutes a discrete organ, anatomically separate from the thyroid gland; in mammals, the ultimobranchial gland fuses with and is incorporated into the thyroid gland.

The naturally occurring calcitonins consist of a peptide chain of 32 amino acids. There is considerable sequence variability among species. Calcitonin from salmon, which is used therapeutically, is 10 to 100 times more potent than mammalian forms in lowering serum calcium.

There are two calcitonin genes, α and β; the transcriptional control of these genes is complex. Two different mRNA molecules are transcribed from the α gene; one is translated into the precursor for calcitonin, and the other message is translated into an alternative product, CGRP. CGRP is synthesized wherever the calcitonin mRNA is expressed, e.g., in medullary carcinoma of the thyroid. The β, or CGRP-2, gene is transcribed into the mRNA for CGRP in the central nervous system (CNS); this gene does not produce calcitonin, however. CGRP has cardiovascular actions and may serve as a neurotransmitter or play a developmental role in the CNS.

The circulating level of calcitonin in humans is lower than that in many other species. In humans, even extreme variations in calcitonin production do not change calcium and phosphate metabolism; no definite effects are attributable to calcitonin deficiency (totally thyroidectomized patients receiving only replacement thyroxine) or excess (patients with medullary carcinoma of the thyroid, a calcitonin-secreting tumor) (Chap. 330). Calcitonin has been a useful pharmacologic agent to suppress bone resorption in Paget's disease (Chap. 334) and osteoporosis (Chap. 333) and in the treatment of hypercalcemia

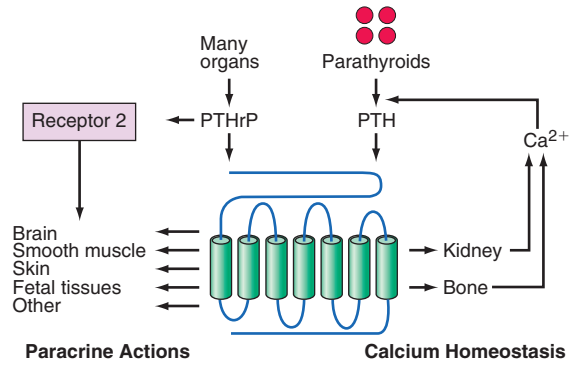

FIGURE 332-2 Dual role for the actions of the PTH/PTHrP receptor (PTH1R). Parathyroid hormone (PTH; endocrine-calcium homeostasis) and PTH-related peptide (PTHrP; paracrine–multiple tissue actions including growth plate cartilage in developing bone) use the single receptor for their disparate functions mediated by the amino-terminal 30 residues of either peptide. Other regions of both ligands interact with other receptors (not shown).

of malignancy (see below). However, the physiologic role, if any, of calcitonin in humans is uncertain.

HYPERCALCEMIA

Hypercalcemia can be a manifestation of a serious illness such as malignancy or can be detected coincidentally by laboratory testing in a patient with no obvious illness. The number of patients recognized with asymptomatic hypercalcemia, usually hyperparathyroidism, increased in the late twentieth century but is now declining somewhat, perhaps due to decreased use of routine blood calcium measurements or for other unknown reasons.

Whenever hypercalcemia is confirmed, a definitive diagnosis must be established. Although hyperparathyroidism, a frequent cause of asymptomatic hypercalcemia, is a chronic disorder in which manifestations, if any, may be expressed only after months or years, hypercalcemia can also be the earliest manifestation of malignancy, the second most common cause of hypercalcemia in the adult. The causes of hypercalcemia are numerous (Table 332-1), but hyperparathyroidism and cancer account for 90% of cases.

Before undertaking a diagnostic workup, it is essential to be sure that true hypercalcemia, not a false-positive laboratory test, is present. A false-positive diagnosis of hypercalcemia is usually the result of inadvertent hemoconcentration during blood collection or elevation in serum proteins such as albumin. Hypercalcemia is a chronic problem, and it is cost-effective to obtain several serum calcium measurements; these tests need not be in the fasting state.

Clinical features are helpful in differential diagnosis. Hypercalcemia in an adult who is asymptomatic is usually due to primary hyperparathyroidism. In malignancy-associated hypercalcemia the disease is usually not occult; rather, symptoms of malignancy bring the patient to the physician, and hypercalcemia is discovered during the evaluation. In such patients the interval between detection of hypercalcemia and death is often <6 months. Accordingly, if an asymptomatic individual has had hypercalcemia or some manifestation of hypercalcemia, such as kidney stones, for >1 or 2 years, it is unlikely that malignancy is the cause. Nevertheless, differentiating primary hyperparathyroidism from *occult* malignancy can occasionally be difficult, and careful evaluation is required, particularly when the duration of the hypercalcemia is unknown. Hypercalcemia not due to hyperparathyroidism or malignancy can result from excessive vitamin D action, high bone turnover from any of several causes, or from renal failure (Table 332-1). Dietary history and a history of ingestion of vitamins or drugs are often helpful in diagnosing some of the less frequent causes. PTH immunoassays based on double-antibody methods serve as the principal laboratory test in differential diagnosis.

TABLE 332-1 Classification of Causes of Hypercalcemia

I. Parathyroid-related
  A. Primary hyperparathyroidism
    1. Solitary adenomas
    2. Multiple endocrine neoplasia
  B. Lithium therapy
  C. Familial hypocalciuric hypercalcemia
II. Malignancy-related
  A. Solid tumor with metastases (breast)
  B. Solid tumor with humoral mediation of hypercalcemia (lung, kidney)
  C. Hematologic malignancies (multiple myeloma, lymphoma, leukemia)
III. Vitamin D–related
  A. Vitamin D intoxication
  B. ↑ $1,25(OH)_2D$; sarcoidosis and other granulomatous diseases
  C. Idiopathic hypercalcemia of infancy
IV. Associated with high bone turnover
  A. Hyperthyroidism
  B. Immobilization
  C. Thiazides
  D. Vitamin A intoxication
V. Associated with renal failure
  A. Severe secondary hyperparathyroidism
  B. Aluminum intoxication
  C. Milk-alkali syndrome

Hypercalcemia from any cause can result in fatigue, depression, mental confusion, anorexia, nausea, vomiting, constipation, reversible renal tubular defects, increased urination, a short QT interval in the electrocardiogram, and, in some patients, cardiac arrhythmias. There is a variable relation from one patient to the next between the severity of hypercalcemia and the symptoms. Generally, symptoms are more common at calcium levels >2.9 to 3 mmol/L (11.5 to 12.0 mg/dL), but some patients, even at this level, are asymptomatic. When the calcium level is >3.2 mmol/L (13 mg/dL), calcification in kidneys, skin, vessels, lungs, heart, and stomach occurs and renal insufficiency may develop, particularly if blood phosphate levels are normal or elevated due to impaired renal function. Severe hypercalcemia, usually defined as ≥3.7 to 4.5 mmol/L (15 to 18 mg/dL), can be a medical emergency; coma and cardiac arrest can occur.

Acute management of the hypercalcemia is usually successful. The type of treatment is based on the severity of the hypercalcemia and the nature of associated symptoms, as outlined below.

PRIMARY HYPERPARATHYROIDISM ■ Natural History and Incidence Primary hyperparathyroidism is a generalized disorder of calcium, phosphate, and bone metabolism due to an increased secretion of PTH. The elevation of circulating hormone usually leads to hypercalcemia and hypophosphatemia. There is great variation in the manifestations. Patients may present with multiple signs and symptoms, including recurrent nephrolithiasis, peptic ulcers, mental changes, and, less frequently, extensive bone resorption. However, with greater awareness of the disease and wider use of multiphasic screening tests, including measurements of blood calcium, the diagnosis is frequently made in patients who have no symptoms and minimal, if any, signs of the disease other than hypercalcemia and elevated levels of PTH. The manifestations may be subtle, and the disease may have a benign course for many years or a lifetime. This milder form of the disease is usually termed *asymptomatic hyperparathyroidism*. Rarely, hyperparathyroidism develops or worsens abruptly and causes severe complications, such as marked dehydration and coma, so-called hypercalcemic parathyroid crisis.

The annual incidence of the disease is calculated to be as high as 0.2% in patients >60, with an estimated prevalence, including undiscovered asymptomatic patients, of ≥1%; some reports suggest the incidence may be declining, perhaps reflecting earlier overestimates. The disease has a peak incidence between the third and fifth decades but occurs in young children and in the elderly.

Etiology ■ *SOLITARY ADENOMAS* The cause of hyperparathyroidism is one or more hyperfunctioning glands. A single abnormal gland is the cause in ~80% of patients; the abnormality in the gland is usually a benign neoplasm or adenoma and rarely a parathyroid carcinoma. Some surgeons and pathologists report that the enlargement of multiple glands is common; double adenomas are reported. In ~15% of patients, all glands are hyperfunctioning; *chief cell parathyroid hyperplasia* is usually hereditary and frequently associated with other endocrine abnormalities.

MULTIPLE ENDOCRINE NEOPLASIA Hereditary hyperparathyroidism can occur without other endocrine abnormalities but is usually part of a *multiple endocrine neoplasia* syndrome (Chap. 330). MEN 1 (Wermer's syndrome) consists of hyperparathyroidism and tumors of the pituitary and pancreas, often associated with gastric hypersecretion and peptic ulcer disease (Zollinger-Ellison syndrome). MEN 2A is characterized by pheochromocytoma and medullary carcinoma of the thyroid, as well as hyperparathyroidism; MEN 2B has additional associated features such as multiple neuromas but usually lacks hyperparathyroidism. Each of these MEN syndromes is transmitted in an apparent autosomal dominant manner, although, as noted below, the genetic basis does not always involve a dominant allele.

Pathology Adenomas are most often located in the inferior parathyroid glands, but in 6 to 10% of patients, parathyroid adenomas may be located in the thymus, the thyroid, the pericardium, or behind the esophagus. Adenomas are usually 0.5 to 5 g in size but may be as large as 10 to 20 g (normal glands weigh 25 mg on average). Chief cells are predominant in both hyperplasia and adenoma. With chief cell hyperplasia, the enlargement may be so asymmetric that some involved glands appear grossly normal. If generalized hyperplasia is present, however, histologic examination reveals a uniform pattern of chief cells and disappearance of fat even in the absence of an increase in gland weight. Thus, microscopic examination of biopsy specimens of several glands is essential to interpret findings at surgery.

Parathyroid carcinoma is usually not aggressive. Long-term survival without recurrence is common if at initial surgery the entire gland is removed without rupture of the capsule. Recurrent parathyroid carcinoma is usually slow-growing with local spread in the neck, and surgical correction of recurrent disease may be feasible. Occasionally, however, parathyroid carcinoma is more aggressive, with distant metastases (lung, liver, and bone) found at the time of initial operation. It may be difficult to appreciate initially that a primary tumor is carcinoma; increased numbers of mitotic figures and increased fibrosis of the gland stroma may precede invasion. The diagnosis of carcinoma is often made in retrospect. Hyperparathyroidism from a parathyroid carcinoma may be indistinguishable from other forms of primary hyperparathyroidism; a potential clue to the diagnosis, however, is provided by the degree of calcium elevation. Calcium values of 3.5 to 3.7 mmol/L (14 to 15 mg/dL) are frequent with carcinoma and may alert the surgeon to remove the abnormal gland with care to avoid capsular rupture.

GENETIC CONSIDERATIONS **Defects Associated with Hyperparathyroidism** As in many other types of neoplasia, two fundamental types of genetic defects have been identified in parathyroid gland tumors: (1) overactivity of protooncogenes, and (2) loss of function of tumor-suppressor genes. The former, by definition, can lead to uncontrolled cellular growth and function by activation (gain-of-function mutation) of a single allele of the responsible gene, whereas the latter requires loss of function of both allelic copies.

Mutations in the *MENIN* gene locus on chromosome 11q13 are responsible for causing MEN 1; the normal allele of this gene fits the definition of a tumor-suppressor gene. A mutation of one allele is inherited; loss of the other allele via somatic cell mutation leads to monoclonal expansion and tumor development. In ~20% of sporadic parathyroid adenomas, the *MENIN* locus on chromosome 11 is deleted, implying that the same defect responsible for MEN 1 can also cause the sporadic disease (Fig. 332-3*A*). Consistent with the Knudson hypothesis for two-step neoplasia in certain inherited cancer syndromes (Chap. 68), the earlier onset of hyperparathyroidism in the hereditary syndromes reflects the need for only one mutational event to trigger the monoclonal outgrowth. In sporadic adenomas, typically occurring later in life, two different somatic events must occur before the *MENIN* gene is silenced.

Other presumptive antioncogenes involved in hyperparathyroidism include a gene mapped to chromosome 1p seen in 40% of sporadic parathyroid adenomas and a gene mapped to chromosome Xp11 in patients with secondary hyperparathyroidism and renal failure, who progressed to "tertiary" hyperparathyroidism, now known to reflect monoclonal outgrowths within previously hyperplastic glands.

The *Rb* gene, a tumor-suppressor gene located on chromosome 13q14, was initially associated with retinoblastomas but has since been implicated in many other forms of neoplasia including parathyroid carcinoma. Allelic deletion (with a presumed point mutation in the second allele) has been identified in all parathyroid carcinomas examined; there is also an abnormal staining pattern of the protein product of the gene. Allelic deletion is also seen in 10% of parathyroid adenomas, although the abnormal staining pattern of the Rb protein is not seen. Other gene loci on chromosome 13 may be involved in addition to the *Rb* locus.

There are two rare syndromes associated with hyperparathyroidism that involve one or more genes located on chromosome 1q. The he-

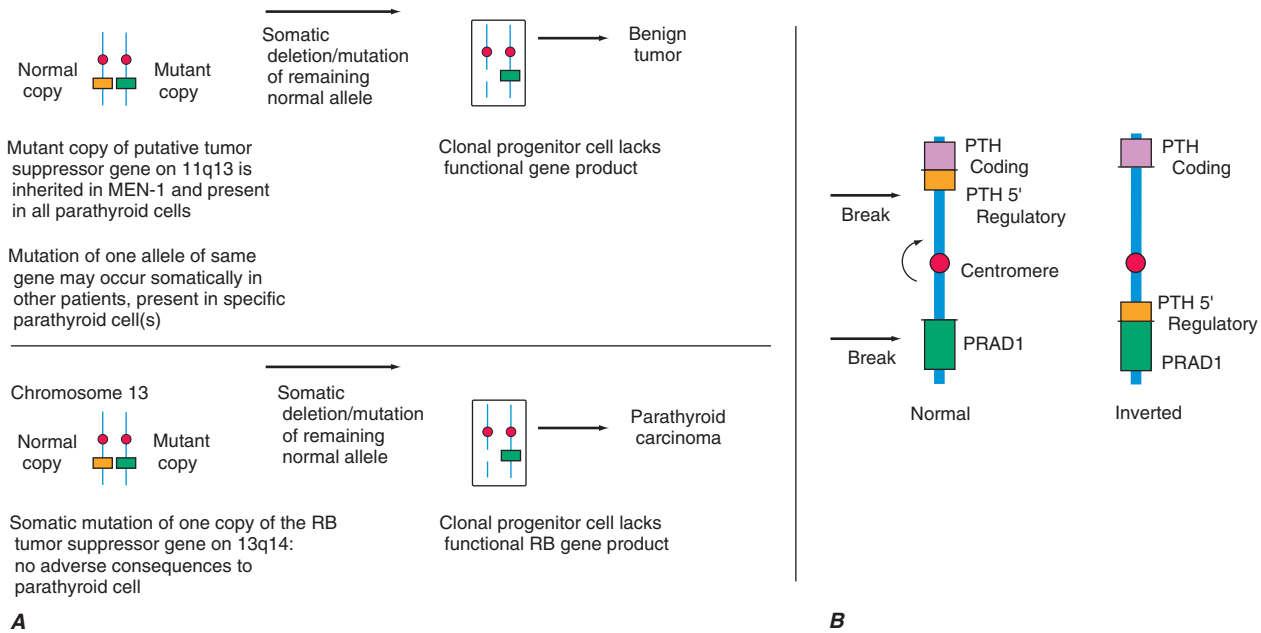

FIGURE 332-3 *A*. Schematic diagram indicating concept of autosomal recessive rather than autosomal dominant inheritance of tumor susceptibility. The patient with the hereditary abnormality (multiple endocrine neoplasia, or MEN) is envisioned as having one defective gene inherited from the affected parent on chromosome 11, but one copy of the normal gene is present from the other parent. In the monoclonal tumor (benign tumor), a somatic event, here partial chromosomal deletion, removes the remaining normal gene from a cell. In nonhereditary tumors, two successive somatic mutations must occur, a process that takes a longer time. By either pathway, the cell, deprived of growth-regulating influence from this gene, has unregulated growth and becomes a tumor. A different genetic locus also involving loss of a tumor-suppressor gene on chromosome 13 is involved in the pathogenesis of parathyroid carcinoma. *B*. Schematic illustration of the mechanism and consequences of gene rearrangement and overexpression of the PRAD 1 protooncogene (pericentromeric inversion of chromosome 11) in parathyroid adenomas. The excessive expression of PRAD 1 (a cell cycle control protein, cyclin D_1) by the highly active PTH gene promoter in the parathyroid cell contributes to excess cellular proliferation. [*From J Habener et al, in L DeGroot, JL Jameson (eds): Endocrinology, 4th ed. Philadelphia, Saunders, 2001, with permission.*]

reditary *hyperparathyroidism jaw tumor* (HPT-JT) syndrome shows an autosomal dominant inheritance pattern; the jaw tumors are benign, but the parathyroid pathology may involve carcinoma as well as adenoma. Parathyroid carcinoma may also appear in the other syndrome, *familial isolated primary hyperparathyroidism* (FIPH). Both syndromes have been mapped through linkage studies to the chromosome 1q21-q31 region. Certain findings have led to speculation that this chromosome region might contain a protooncogene rather than a tumor-suppressor gene.

In some parathyroid adenomas, activation of a protooncogene has been identified (Fig. 332-3*B*). A reciprocal translocation involving chromosome 11 has been identified that juxtaposes the PTH gene promoter upstream of a gene product termed *PRAD-1*, a cyclin D protein that plays a key role in normal cell division. This translocation is found in as many as 15% of parathyroid adenomas, usually in larger tumors. Targeted overexpression of cyclin D_1 in the parathyroid glands of transgenic mice causes the development of hyperparathyroidism, consistent with the role of this cell cycle control protein in parathyroid neoplasia.

A mutated protooncogene, *RET*, is involved in each of the clinical variants of MEN 2 (Chap. 330). *RET* encodes a tyrosine kinase–type receptor; specific mutations lead to constitutive activity of the receptor, thereby explaining the autosomal dominant mode of transmission and the relatively early onset of neoplasia.

Signs and Symptoms Half or more of patients with hyperparathyroidism are asymptomatic. In series in which patients are followed without operation, as many as 80% are classified as without symptoms. Manifestations of hyperparathyroidism involve primarily the kidneys and the skeletal system. Kidney involvement, due either to deposition of calcium in the renal parenchyma or to recurrent nephrolithiasis, was present in 60 to 70% of patients prior to 1970. With earlier detection, renal complications occur in <20% of patients in many large series. Renal stones are usually composed of either calcium oxalate or calcium phosphate. In occasional patients, repeated episodes of nephrolithiasis or the formation of large calculi may lead to urinary tract obstruction, infection, and loss of renal function. Nephrocalcinosis may also cause decreased renal function and phosphate retention.

The distinctive bone manifestation of hyperparathyroidism is *osteitis fibrosa cystica*, which occurred in 10 to 25% of patients in series reported 50 years ago. Histologically, the pathognomonic features are an increase in the giant multinucleated osteoclasts in scalloped areas on the surface of the bone (Howship's lacunae) and a replacement of the normal cellular and marrow elements by fibrous tissue. X-ray changes include resorption of the phalangeal tufts and replacement of the usually sharp cortical outline of the bone in the digits by an irregular outline (subperiosteal resorption). In recent years, osteitis fibrosa cystica is very rare in primary hyperparathyroidism, probably due to the earlier detection of the disease.

With the use of multiple markers of bone turnover, such as formation indices (bone-specific alkaline phosphatase, osteocalcin, and type I procollagen peptides) and bone resorption indices (including hydroxypyridinium collagen cross-links and telopeptides of type I collagen), increased skeletal turnover is detected in essentially all patients with established hyperparathyroidism.

Computed tomography (CT) scan and dual-energy x-ray absorptiometry (DEXA) of the spine provide reproducible quantitative estimates (within a few percent) of spinal bone density (Chap. 333). Similarly, bone density in the extremities can be quantified by densitometry of the hip or of the distal radius at a site chosen to be primarily cortical. Cortical bone density is reduced while cancellous bone density, especially in the spine, is relatively preserved. Serial studies in patients who choose to be followed without surgery have indicated that in the majority there is little further change over a number of years, consistent with laboratory data indicating relatively unchanged blood calcium and PTH levels. After an initial loss of bone mass in patients with mild asymptomatic hyperparathyroidism, a new equilibrium may be reached, with bone density and biochemical manifestations of the disease remaining relatively unchanged.

In symptomatic patients, dysfunctions of the CNS, peripheral nerve and muscle, gastrointestinal tract, and joints also occur. It has been reported that severe neuropsychiatric manifestations may be reversed by parathyroidectomy; it remains unclear, in the absence of controlled studies, whether this improvement has a defined cause-and-effect relationship. Generally, the fact that hyperparathyroidism is common in elderly patients, in whom there are often other problems, suggests the possibility that such coexisting problems as hypertension, renal deterioration, and depression may not be parathyroid-related and suggests caution in recommending parathyroid surgery as a cure for these manifestations.

When present, neuromuscular manifestations may include proximal muscle weakness, easy fatigability, and atrophy of muscles and may be so striking as to suggest a primary neuromuscular disorder. The distinguishing feature is the complete regression of neuromuscular disease after surgical correction of the hyperparathyroidism.

Gastrointestinal manifestations are sometimes subtle and include vague abdominal complaints and disorders of the stomach and pancreas. Again, cause and effect are unclear. In MEN 1 patients with hyperparathyroidism, duodenal ulcer may be the result of associated pancreatic tumors that secrete excessive quantities of gastrin (Zollinger-Ellison syndrome). Pancreatitis has been reported in association with hyperparathyroidism, but the incidence and the mechanism are not established.

DIAGNOSIS The diagnosis is typically made by detecting an elevated immunoreactive PTH level in a patient with asymptomatic hypercalcemia (see "Differential Diagnosis: Special Tests," below). Serum phosphate is usually low but may be normal, especially if renal failure has developed.

Many tests based on renal responses to excess PTH (renal calcium and phosphate clearance; blood phosphate, chloride, magnesium; urinary or nephrogenous cyclic AMP) were used in earlier decades. These tests have low specificity for hyperparathyroidism and are therefore not cost-effective; they have been replaced by PTH immunoassays.

Rx TREATMENT

Medical Surveillance versus Surgical Treatment The critical management question is whether the disease should be treated surgically. If severe hypercalcemia [3.7 to 4.5 mmol/L (15 to 18 mg/dL)] is present, surgery is mandatory as soon as the diagnosis can be confirmed by a PTH immunoassay. However, in most patients with hyperparathyroidism, hypercalcemia is mild and does not require urgent surgical or medical treatment.

The National Institutes of Health (NIH) held a Consensus Conference on Management of Asymptomatic Hyperparathyroidism in 1990. *Asymptomatic hyperparathyroidism* was defined as documented (presumptive) hyperparathyroidism without signs or symptoms attributable to the disease. The consensus was that patients <50 should undergo surgery, given the long surveillance that would be required. Other considerations that favored surgery included concern that consistent follow-up would be unlikely or that coexistent illness would complicate management. Patients >50 were deemed appropriate for medical monitoring if certain criteria were met, the patients wished to avoid surgery, or the guidelines for recommending surgery were not present (Table 332-2). Careful evaluation of patients over the subsequent dozen years has both provided reassurance that in some patients medical monitoring rather than surgery is still prudent yet has promoted new questions about the natural history of the disease with or without surgery.

Data developed since the Consensus Conference indicated that a subgroup of patients had selective vertebral osteopenia out of proportion to bone loss at other sites and responded to surgery with striking restoration of bone mass (average >20%). In addition, as much as a

5% increase in bone mineral density in the spine and hip have been reported with alendronate use in asymptomatic hyperparathyroid patients. In light of this new information, the NIH convened a Workshop on Asymptomatic Hyperparathyroidism in 2002, and an independent (non-NIH) panel offered a revised set of recommendations. The changes reflect both practical considerations (such as the difficulty in creatinine clearance measurements and therefore substituting calculations based on serum creatinine) and concerns regarding potential deleterious skeletal effects in untreated patients (Tables 332-2 and 332-3). Accordingly, indication for surgical intervention was lowered (i.e., stricter serum calcium and bone density criteria). Asymptomatic patients should be monitored regularly. Surgical correction of hyperparathyroidism can always be undertaken when indicated, since the success rate is high (>90%), mortality is low, and morbidity is minimal. The goals of monitoring are early detection of worsening hypercalcemia, deteriorating bone or renal status, or other complications of hyperparathyroidism. No specific recommendations about medical therapy were made, but the promise of the newer agents was stressed, with the prediction that they would be used in clinical practice to increase bone mass in patients not electing surgery as further experience is gained. Neither panel recommended estrogen use in patients for whom surgery was not elected because there was insufficient cumulative experience with such therapy to balance theoretical risks (breast and endometrial cancer) versus benefits. Raloxifene (Evista), the first of the SERMS, has been shown to have many of the bone-protective effects of estrogen in osteoporotic subjects yet at the same time lowers the incidence of breast cancer; preliminary use of this agent in a small series of hyperparathyroid patients led to increased bone density. Experience with calcimimetics, drugs that selectively stimulate the calcium sensor and suppress PTH secretion, indicates that these agents decrease calcium levels to normal and lower PTH levels by at least 50% for >1 year of continuous use.

TABLE 332-2 *Guidelines for Parathyroid Surgery in Asymptomatic Primary Hyperparathyroidism*[a]

Measurement	Guidelines, 1990	Guidelines, 2002
Serum calcium (above upper limit of normal)	0.3–0.4 mmol/L (1–6 mg/dL)	0.3 mmol/L (1.0 mg/dL)
24-h urinary calcium	>400 mg	>400 mg
Creatinine clearance	Reduced by 30%	Reduced by 30%
Bone mineral density	Z-score < −2.0 (forearm)	T-score < −2.5 at any site
Age	<50	<50

[a] Surgery is also indicated in patients for whom medical surveillance is neither desired nor possible.

Surgical Treatment Parathyroid exploration is challenging and should be undertaken by an experienced surgeon. Certain features help in predicting the pathology (e.g., multiple abnormal glands in familial cases). However, some critical decisions regarding management can be made only during the operation.

As discussed above, there are many unresolved issues to consider in surgery for this disease. One surgical strategy is based on the view that typically only one gland (the adenoma) is abnormal. If an enlarged gland is found, a normal gland should be sought. In this view, if a biopsy of a normal-sized second gland confirms its histologic (and presumed functional) normality, no further exploration, biopsy, or excision is needed. At the other extreme is the minority viewpoint that all four glands be sought and that most of the total parathyroid tissue mass should be removed. The concern with the former approach is that the recurrence rate of hyperparathyroidism may be high if a second abnormal gland is missed; the latter approach could involve unnecessary surgery and an unacceptable rate of hypoparathyroidism. The majority viewpoint favors conservative surgery, i.e., removal of what is usually only one enlarged gland but only after four-gland exploration to eliminate the possibility that more than one gland is abnormal. When normal glands are found in association with one enlarged gland, excision of the single adenoma usually leads to cure or at least years free of symptoms. Long-term follow-up studies are limited to establish true rates of recurrence.

Recently, there has been growing experience with new surgical strategies that feature a minimally invasive approach guided by improved preoperative localization and intraoperative monitoring by PTH assays. Preoperative ^{99m}Tc sestamibi scans with positron emission computed tomography (SPECT) are used to predict the location of an abnormal gland and intraoperative sampling of PTH before and at 5-min intervals after removal of a suspected adenoma to confirm a rapid fall (>50%) to normal levels of PTH. In several centers, a combination of preoperative sestamibi imaging, cervical block anesthesia, minimal surgical incision, and intraoperative PTH measurements has allowed successful outpatient surgical management with a clear-cut cost benefit compared to general anesthesia and more extensive neck surgery. The use of these minimally invasive approaches requires clinical judgment to select patients unlikely to have multiple gland disease (e.g., MEN or secondary hyperparathyroidism). The growing acceptance of the technique and its relative ease for the patient has lowered the threshold for surgery.

When parathyroid carcinoma is encountered, the tissue should be widely excised; care must be taken to avoid rupture of the capsule to prevent local seeding of tumor cells.

Multiple gland hyperplasia, as predicted in familial cases, poses more difficult questions of surgical management. Once a diagnosis of hyperplasia is established, all the glands must be identified. Two schemes have been proposed for surgical management. One is to totally remove three glands with partial excision of the fourth gland; care is taken to leave a good blood supply for the remaining gland. Other surgeons advocate total parathyroidectomy with immediate transplantation of a portion of a removed, minced parathyroid gland into the muscles of the forearm, with the view that surgical excision is easier from the ectopic site in the arm if there is recurrent hyperfunction.

In a minority of cases, if no abnormal parathyroid glands are found in the neck, the issue of further exploration must be decided. There are documented cases of five or six parathyroid glands and of unusual locations for adenomas, such as in the mediastinum.

When a second parathyroid exploration is indicated, the minimally invasive techniques such as ultrasound, CT scan, and isotope scanning may be combined with venous sampling and/or selective digital arteriography in one of the centers specializing in these techniques. Intraoperative monitoring of PTH levels by rapid PTH immunoassays may be useful in guiding the surgery, especially in patients who are reexplored after an initial unsuccessful operation. At one center, long-term cures have been achieved with selective embolization or injection of large amounts of contrast material into the end-arterial circulation feeding the parathyroid tumor.

A decline in serum calcium occurs within 24 h after successful surgery; usually blood calcium falls to low-normal values for 3 to 5

TABLE 332-3 *Management Guidelines for Patients with Aymptomatic Primary Hyperparathyroidism Who Do Not Undergo Parathyroid Surgery*

Measurement	Older Guidelines	New Guidelines
Serum calcium	Biannually	Biannually
24-h urinary calcium	Annually	Not recommended[a]
Creatinine clearance	Annually	Not recommended[a]
Serum creatinine	Annually	Annually[b]
Bone density	Annually (forearm)	Annually (lumbar spine, hip, forearm)
Abdominal x-ray (+/− ultrasound)	Annually	Not recommended[a]

[a] Except at the time of initial evaluation.
[b] If the serum creatinine concentration suggests a change in the creatinine clearance when the Cockroft-Gault equation is applied, further, more direct assessments of the creatinine clearance are recommended.

days until the remaining parathyroid tissue resumes hormone secretion. Severe postoperative hypocalcemia is likely only if osteitis fibrosa cystica is present or if injury to all the normal parathyroid glands occurs during surgery. In general, patients with uncomplicated disease such as a single adenoma (the clear majority) who do not have symptomatic bone disease or a large deficit in bone mineral and who have good renal and gastrointestinal function have few problems with postoperative hypocalcemia. The extent of postoperative hypocalcemia varies with the surgical approach. If all glands are biopsied, hypocalcemia may be transiently symptomatic and more prolonged. Hypocalcemia is more likely to be symptomatic after second parathyroid explorations, particularly when normal parathyroid tissue was removed at the initial operation and when the manipulation and/or biopsy of the remaining normal glands is more extensive in the search for the missing adenoma.

Patients with hyperparathyroidism have efficient intestinal calcium absorption due to the increased levels of $1,25(OH)_2D$ stimulated by PTH excess. Once hypocalcemia signifies successful surgery, patients can be put on a high-calcium intake or be given oral calcium supplements. Despite mild hypocalcemia, most patients do not require parenteral therapy. If the serum calcium falls to <2 mmol/L (8 mg/dL), *and if the phosphate level rises simultaneously*, the possibility that surgery has caused hypoparathyroidism must be considered. With unexpected hypocalcemia, coexistent hypomagnesemia should be considered, as it interferes with PTH secretion and causes functional hypoparathyroidism (see below). Signs of hypocalcemia include symptoms such as muscle twitching, a general sense of anxiety, and positive Chvostek and Trousseau signs coupled with serum calcium consistently <2 mmol/L (8 mg/dL). Parenteral calcium replacement at a low level should be instituted when hypocalcemia is symptomatic. The rate and duration of intravenous therapy are determined by the severity of the symptoms and the response of the serum calcium to treatment. An infusion of 0.5 to 2 (mg/kg)/h or 30 to 100 mL/h of a 1-mg/mL solution usually suffices to relieve symptoms. Usually, parenteral therapy is required for only a few days. If symptoms worsen or if parenteral calcium is needed for >2 to 3 days, therapy with a vitamin D analogue and/or oral calcium (2 to 4 g/d) should be started (see below). It is cost-effective to use calcitriol (doses of 0.5 to 1.0 μg/d) because of the rapidity of onset of effect and prompt cessation of action when stopped, in comparison to other forms of vitamin D (see below). A rise in blood calcium after several months of vitamin D replacement may indicate restoration of parathyroid function to normal. It is also appropriate to monitor serum PTH serially to estimate gland function in such patients.

Magnesium deficiency may also complicate the postoperative course. Magnesium deficiency impairs the secretion of PTH, and so hypomagnesemia should be corrected whenever detected. Magnesium chloride is effective by mouth, but this compound is not widely available. Repletion is usually parenteral. Because the depressant effect of magnesium on central and peripheral nerve functions does not occur at levels <2 mmol/L (normal range 0.8 to 1.2 mmol/L), parenteral replacement can be given rapidly. A cumulative dose as great as 0.5 to 1 mmol/kg of body weight can be administered if severe hypomagnesemia is present; often, however, total doses of 20 to 40 mmol are sufficient. The magnesium is given either as an intravenous infusion over 8 to 12 h or in divided doses intramuscularly (magnesium sulfate, USP).

OTHER PARATHYROID-RELATED CAUSES OF HYPERCALCEMIA ■ Lithium Therapy Lithium, used in the management of bipolar depression and other psychiatric disorders, causes hypercalcemia in ~10% of treated patients. The hypercalcemia is dependent on continued lithium treatment, remitting and recurring when lithium is stopped and restarted. The parathyroid adenomas reported in some hypercalcemic patients with lithium therapy may reflect the presence of an independently occurring parathyroid tumor; a permanent effect of lithium on parathyroid gland growth need not be implicated as most patients have complete reversal of hypercalcemia when lithium is stopped. However, long-standing stimulation of parathyroid cell replication by lithium may predispose to development of adenomas (as is documented in secondary hyperparathyroidism and renal failure).

At the levels achieved in blood in treated patients, lithium can be shown in vitro to shift the PTH secretion curve to the right in response to calcium; i.e., higher calcium levels are required to lower PTH secretion, probably acting at the calcium sensor (see below); this effect can cause elevated PTH levels and consequent hypercalcemia in otherwise normal individuals. Fortunately, there are alternative medications for the underlying psychiatric illness. Parathyroid surgery should not be recommended unless hypercalcemia and elevated PTH levels persist after lithium is discontinued.

GENETIC DISORDERS CAUSING HYPERPARATHYROID-LIKE SYNDROMES ■ Familial Hypocalciuric Hypercalcemia FHH (also called *familial benign hypercalcemia*) is inherited as an autosomal dominant trait. Affected individuals are discovered because of asymptomatic hypercalcemia. This disorder and Jansen's disease (discussed below) are variants of hyperparathyroidism. FHH involves excessive secretion of PTH, whereas Jansen's disease is caused by excessive biologic activity of the PTH receptor in target tissues. Neither disorder, however, involves a primary growth disorder of the parathyroids.

The pathophysiology of FHH is now understood. The primary defect is abnormal sensing of the blood calcium by the parathyroid gland and renal tubule, causing inappropriate secretion of PTH and excessive renal reabsorption of calcium. The calcium sensor is a member of the third family of GPCRs (type C, or III). The receptor responds to the ECF calcium concentration, suppressing PTH secretion through second messenger signaling, thereby providing negative-feedback regulation of PTH secretion. Many different mutations in the calcium-sensing receptor have been identified in patients with FHH (Fig. 332-4). These mutations lower the capacity of the sensor to bind calcium, and the mutant receptors function as though blood calcium levels were low; excessive secretion of PTH occurs from an otherwise normal gland. Approximately two-thirds of patients with FHH have mutations within the protein-coding region of the gene. The remaining one-third of kindreds may have mutations in the gene promoter or may involve still unknown mechanisms in other regions of the genome identified through mapping studies (e.g., chromosome 19).

Even before elucidation of the pathophysiology of FHH, abundant clinical evidence served to separate the disorder from primary hyperparathyroidism. Patients with primary hyperparathyroidism have <99% renal calcium reabsorption, whereas most patients with FHH have >99% reabsorption. The hypercalcemia in FHH is often detectable in affected members of the kindreds in the first decade of life, whereas hypercalcemia rarely occurs in patients with primary hyperparathyroidism or the MEN syndromes who are <10. PTH may be elevated in FHH, but the values are usually normal or lower for the same degree of calcium elevation than in patients with primary hyperparathyroidism. Parathyroid surgery in a few patients with FHH led to permanent hypoparathyroidism, but hypocalciuria persisted nevertheless, establishing that hypocalciuria, therefore, is not PTH-dependent (now known to be due to the abnormal calcium sensor in the kidney).

Few clinical signs or symptoms are present in patients with FHH, and other endocrine abnormalities are not present. Most patients are detected as a result of family screening after hypercalcemia is detected in a proband. In those patients inadvertently operated upon, the parathyroids appeared normal or moderately hyperplastic. Parathyroid surgery is not appropriate, nor, in view of the lack of symptoms, does medical treatment seem needed to lower the calcium. Calcimimetic agents that bind to the calcium sensor and elevate the set point are under investigation.

One striking exception to the rule against parathyroid surgery in this syndrome is the occurrence, usually in consanguineous marriages (due to the rarity of the gene mutation), of a homozygous or compound

heterozygote state, resulting in complete loss of the calcium sensor function. In this condition, neonatal severe hypercalcemia, total parathyroidectomy is mandatory.

Jansen's Disease Mutations in the PTH1R have been identified as responsible for this rare autosomal dominant syndrome (Fig. 332-4). Because the mutations lead to constitutive receptor function, one abnormal copy of the mutant receptor is sufficient to cause the disease, thereby accounting for its dominant mode of transmission. The disorder leads to short-limbed dwarfism due to abnormal regulation of the bone growth plate. In adult life, there are numerous abnormalities in bone, including multiple cystic resorptive areas resembling those seen in severe hyperparathyroidism. Hypercalcemia and hypophosphatemia with undetectable or low PTH levels are typically seen. The pathogenesis of the disease has been confirmed by transgenic experiments in which targeted expression of the mutant receptor to the growth plate emulated several features of the disorder.

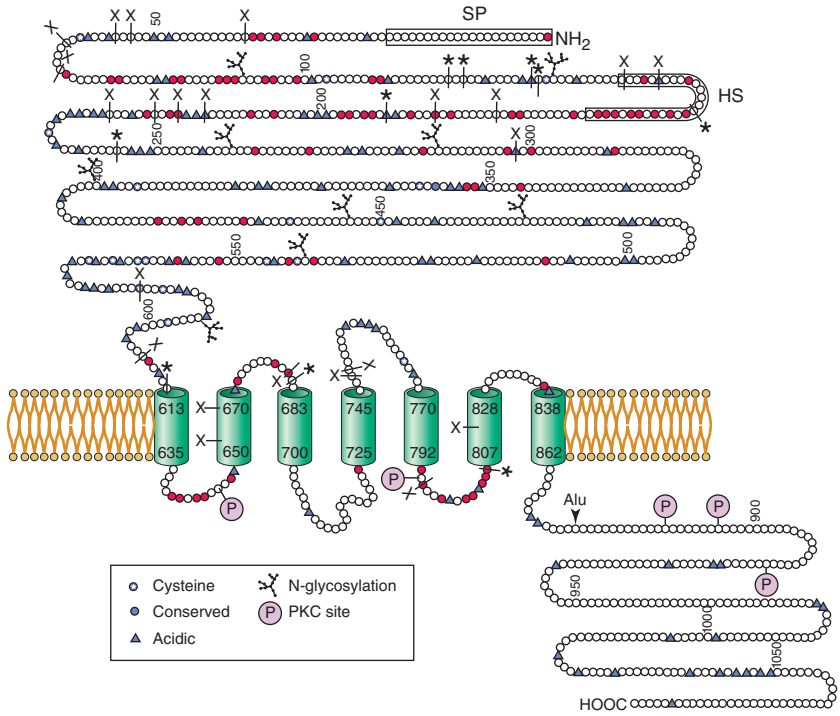

FIGURE 332-4 Mutations in the calcium sensor receptor. The extracellular domain binds calcium, leading to conformational changes that stimulate Gq-coupled activation of the phospholipase C and suppression of PTH. The identified sequence alterations (X) cause loss of function and lead to inadequate suppression of parathyroid hormone release and, therefore, mild hypercalcemia (FHH); *, a gain-of-function mutation that causes hypocalcemia; •, conserved residues; ▲, acidic residues. (*From EM Brown et al: J Nutr 125:19655, 1995, with permission.*)

MALIGNANCY-RELATED HYPERCALCEMIA ■ Clinical Syndromes and Mechanisms of Hypercalcemia Hypercalcemia due to malignancy is common (occurring with 10 to 15% of certain types of tumor, such as lung carcinoma), often severe and difficult to manage, and occasionally difficult to distinguish from primary hyperparathyroidism. Although malignancy is often clinically obvious or readily detectable by medical history, hypercalcemia can occasionally be due to an occult tumor. Previously, hypercalcemia associated with malignancy was thought to be due to local invasion and destruction of bone by tumor cells; many cases are now known to result from the elaboration by the malignant cells of humoral mediators of hypercalcemia. PTHrP is the responsible humoral agent in most solid tumors that cause hypercalcemia.

The histologic character of the tumor is more important than the extent of skeletal metastases in predicting hypercalcemia. Small-cell carcinoma (oat cell) and adenocarcinoma of the lung, although the most common lung tumors associated with skeletal metastases, rarely cause hypercalcemia. By contrast, as many as 10% of patients with squamous cell carcinoma of the lung develop hypercalcemia. Histologic studies of bone in patients with squamous cell or epidermoid carcinoma of the lung, in sites invaded by tumor as well as areas remote from tumor invasion, reveal increased bone remodeling, including osteoclastic and osteoblastic activity.

Two main mechanisms of hypercalcemia are operative in cancer hypercalcemia. Many solid tumors associated with hypercalcemia, particularly squamous cell and renal tumors, produce and secrete PTHrP that causes increased bone resorption and mediate the hypercalcemia through systemic actions on the skeleton. Alternatively, direct bone marrow invasion occurs with hematologic malignancies such as leukemia, lymphoma, and multiple myeloma. Lymphokines and cytokines produced by cells involved in the marrow response to the tumors promote resorption of bone through local destruction. Several hormones, hormone analogues, cytokines, and growth factors have been implicated as the result of clinical assays, in vitro tests, or chemical isolation. The etiologic factor produced by activated normal lymphocytes and by myeloma and lymphoma cells, termed *osteoclast activation factor*, now appears to represent the biologic action of several different cytokines, probably interleukin 1 and lymphotoxin or tumor necrosis factor. In some lymphomas, typically B cell lymphomas, there is a third mechanism, caused by an increased blood level of $1,25(OH)_2D$, which is probably produced by lymphocytes.

The more common mechanism, usually termed *humoral hypercalcemia of malignancy*, solid tumors (cancers of the lung and kidney, in particular), in which bone metastases are absent, minimal, or not detectable clinically, secrete PTHrP measurable by immunoassay. Secretion by the tumors of the PTH-like factor, PTHrP, activates the PTH1R, resulting in a pathophysiology closely resembling hyperparathyroidism. The clinical picture resembles primary hyperparathyroidism (hypophosphatemia accompanies hypercalcemia), and elimination or regression of the primary tumor leads to disappearance of the hypercalcemia.

As in hyperparathyroidism, patients with the humoral hypercalcemia of malignancy have elevated urinary nephrogenous cyclic AMP excretion, hypophosphatemia, and increased urinary phosphate clearance. However, in humoral hypercalcemia of malignancy, immunoreactive PTH is undetectable or suppressed, making the differential diagnosis easier. Other features of the disorder differ from those of true hyperparathyroidism. Patients may have high, rather than low, renal calcium clearance (relative to serum calcium when compared to true hyperparathyroidism, unlike the expected elevation) and low to normal levels of $1,25(OH)_2D$. The reason that the humoral syndrome differs from hyperparathyroidism in these parameters is unclear since the biologic actions of PTH and PTHrP are presumably exerted through the same receptor. Other cytokines elaborated by the malignancy may be responsible for these variations from hyperparathyroidism. In some patients with the humoral hypercalcemia of malignancy, osteoclastic resorption is unaccompanied by an osteoblastic or bone-forming response, implying inhibition of the normal coupling of bone formation and resorption. Thus the interaction of more than one substance may determine whether hypercalcemia develops in a particular patient.

Several different assays (single- or double-antibody, different epitopes) have been developed to detect PTHrP. Most data indicate that circulating PTHrP levels are undetectable (or low) in normal individuals, elevated in most cancer patients with the humoral syndrome, and high in human milk. The etiologic mechanisms in cancer hypercalcemia may be multiple in the same patient. For example, in breast carcinoma (metastatic to bone) and in a distinctive type of T cell lymphoma/leukemia initiated by human T cell lymphotropic virus I, hypercalcemia is caused by direct local lysis of bone as well as by a humoral mechanism involving excess production of PTHrP.

Diagnostic Issues Levels of PTH measured by the double-antibody technique are undetectable or extremely low in tumor hypercalcemia, as would be expected with the mediation of the hypercalcemia by a factor other than PTH (the hypercalcemia suppresses the normal parathyroid glands). In a patient with minimal symptoms referred for hypercalcemia, low or undetectable PTH levels would focus attention on a possible occult malignancy.

Ordinarily, the diagnosis of cancer hypercalcemia is not difficult because tumor symptoms are prominent when hypercalcemia is detected. Indeed, hypercalcemia may be noted incidentally during the workup of a patient with known or suspected malignancy. Clinical suspicion that malignancy is the cause of the hypercalcemia is heightened when there are other paraneoplastic signs or symptoms, such as weight loss, fatigue, muscle weakness, or unexplained skin rash, or when symptoms specific for a particular tumor are present. Squamous cell tumors are most frequently associated with hypercalcemia, particularly tumors of the lung, kidney, head and neck, and urogenital tract. Radiologic examinations can focus on these areas when clinical evidence is unclear. Bone scans with technetium-labeled bisphosphonate are useful for detection of osteolytic metastases; the sensitivity is high, but specificity is low; results must be confirmed by conventional x-rays to be certain that areas of increased uptake are due to osteolytic metastases per se. Bone marrow biopsies are helpful in patients with anemia or abnormal peripheral blood smears.

Rx TREATMENT

Treatment of the hypercalcemia of malignancy is first directed to control of tumor; reduction of tumor mass usually corrects hypercalcemia. If a patient has severe hypercalcemia yet has a good chance for effective tumor therapy, treatment of the hypercalcemia should be vigorous while awaiting the results of definitive therapy. If hypercalcemia occurs in the late stages of a tumor that is resistant to anti-tumor therapy, the treatment of the hypercalcemia should be judicious as high calcium levels can have a mild sedating effect. Standard therapies for hypercalcemia (discussed below) are applicable to patients with malignancy.

VITAMIN D–RELATED HYPERCALCEMIA Hypercalcemia caused by vitamin D can be due to excessive ingestion or abnormal metabolism of the vitamin. Abnormal metabolism of the vitamin is usually acquired in association with a widespread granulomatous disorder. Vitamin D metabolism is carefully regulated, particularly the activity of renal 1α-hydroxylase, the enzyme responsible for the production of $1,25(OH)_2D$ (Chap. 331). The regulation of 1α-hydroxylase and the normal feedback suppression by $1,25(OH)_2D$ seem to work less well in infants than in adults and to operate poorly, if at all, in sites other than the renal tubule; these phenomena explain the occurrence of hypercalcemia secondary to excessive $1,25(OH)_2D_3$ production in infants with Williams' syndrome (see below) and in adults with sarcoidosis or lymphoma.

Vitamin D Intoxication Chronic ingestion of 50 to 100 times the normal physiologic requirement of vitamin D (amounts >50,000 to 100,000 U/d) is usually required to produce significant hypercalcemia in normal individuals. An upper limit of dietary intake of 2000 U/d (50 μg/d) in adults is now recommended because of concerns about potential toxic effects of cumulative supraphysiologic doses. Vitamin D excess increases intestinal calcium absorption and, if severe, also increases bone resorption.

Hypercalcemia in vitamin D intoxication is due to an excessive biologic action of the vitamin, perhaps the consequence of increased levels of 25(OH)D rather than merely increased levels of the active metabolite $1,25(OH)_2D$ (the latter may not be elevated in vitamin D intoxication). 25(OH)D has definite, if low, biologic activity in intestine and bone. The production of 25(OH)D is less tightly regulated than is the production of $1,25(OH)_2D$. Hence concentrations of 25(OH)D are elevated several-fold in patients with excess vitamin D intake.

The diagnosis is substantiated by documenting elevated levels of 25(OH)D >100 ng/mL. Hypercalcemia is usually controlled by restriction of dietary calcium intake and appropriate attention to hydration. These measures, plus discontinuation of vitamin D, usually lead to resolution of hypercalcemia. However, vitamin D stores in fat may be substantial, and vitamin D intoxication may persist for weeks after vitamin D ingestion is terminated. Such patients are responsive to glucocorticoids, which in doses of 100 mg/d of hydrocortisone or its equivalent, usually return serum calcium levels to normal over several days; severe intoxication may require intensive therapy.

Sarcoidosis and Other Granulomatous Diseases In patients with sarcoidosis and other granulomatous diseases, such as tuberculosis and fungal infections, excess $1,25(OH)_2D$ is synthesized in macrophages or other cells in the granulomas. Indeed, increased $1,25(OH)_2D$ levels have been reported in anephric patients with sarcoidosis and hypercalcemia. Macrophages obtained from granulomatous tissue convert 25(OH)D to $1,25(OH)_2D$ at an increased rate. There is a positive correlation in patients with sarcoidosis between 25(OH)D levels (reflecting vitamin D intake) and the circulating concentrations of $1,25(OH)_2D$, whereas normally there is no increase in $1,25(OH)_2D$ with increasing 25(OH)D levels due to multiple feedback controls on renal 1α-hydroxylase (Chap. 331). The usual regulation of active metabolite production by calcium or PTH does not operate in these patients; hypercalcemia does not lead to a reduction in the blood levels of $1,25(OH)_2D$ in patients with sarcoidosis. Clearance of $1,25(OH)_2D$ from blood may be decreased in sarcoidosis as well. PTH levels are usually low and $1,25(OH)_2D$ levels are elevated, but primary hyperparathyroidism and sarcoidosis may coexist in some patients.

Management of the hypercalcemia can often be accomplished by avoiding excessive sunlight exposure and limiting vitamin D and calcium intake. Presumably, however, the abnormal sensitivity to vitamin D and abnormal regulation of $1,25(OH)_2D$ synthesis will persist as long as the disease is active. Alternatively, glucocorticoids in the equivalent of ≤100 mg/d of hydrocortisone control hypercalcemia. Glucocorticoids appear to act by blocking excessive production of $1,25(OH)_2D$ as well as the response to it in target organs.

Idiopathic Hypercalcemia of Infancy This rare disorder, usually referred to as *Williams' syndrome*, is an autosomal dominant disorder characterized by multiple congenital development defects, including supravalvular aortic stenosis, mental retardation, and an elfin facies, in association with hypercalcemia due to abnormal sensitivity to vitamin D. The syndrome was first recognized in England after the fortification of milk with vitamin D. Levels of $1,25(OH)_2D$ are elevated, ranging from 46 to 120 nmol/L (150 to 500 pg/mL). The mechanism of the abnormal sensitivity to vitamin D and of the increased circulating levels of $1,25(OH)_2D$ is still unclear. Studies suggest that mutations involving the elastin locus and perhaps other genes on chromosome 7 may play a role in the pathogenesis.

HYPERCALCEMIA ASSOCIATED WITH HIGH BONE TURNOVER ■ Hyperthyroidism As many as 20% of hyperthyroid patients have high-normal or mildly elevated serum calcium concentrations; hypercalciuria is even more common. The hypercalcemia is due to increased bone turnover, with bone resorption exceeding bone formation. Severe calcium elevations are not typical, and the presence of such suggests a concomitant disease such as hyperparathyroidism. Usually, the diagnosis is obvious, but signs of hyperthyroidism may occasionally be occult, particularly in the elderly (Chap. 320). Hypercalcemia is managed by treatment of the hyperthyroidism.

Immobilization Immobilization is a rare cause of hypercalcemia in adults in the absence of an associated disease but may cause hypercalcemia in children and adolescents, particularly after spinal cord injury and paraplegia or quadriplegia. With resumption of ambulation, the hypercalcemia in children usually returns to normal.

The mechanism appears to involve a disproportion between bone

formation and bone resorption. Hypercalciuria and increased mobilization of skeletal calcium can develop in normal volunteers subjected to extensive bed rest, although hypercalcemia is unusual. Immobilization of an adult with a disease associated with high bone turnover, however, such as Paget's disease, may cause hypercalcemia.

Thiazides Administration of benzothiadiazines (thiazides) can cause hypercalcemia in patients with high rates of bone turnover, such as patients with hypoparathyroidism treated with high doses of vitamin D. Traditionally, thiazides are associated with aggravation of hypercalcemia in primary hyperparathyroidism, but this effect can be seen in other high-bone-turnover states as well. The mechanism of thiazide action is complex. Chronic thiazide administration leads to reduction in urinary calcium; the hypocalciuric effect appears to reflect the enhancement of proximal tubular resorption of sodium and calcium in response to sodium depletion. Some of this renal effect is due to augmentation of PTH action and is more pronounced in individuals with intact PTH secretion. However, thiazides cause hypocalciuria in hypoparathyroid patients on high-dose vitamin D and oral calcium replacement if sodium intake is restricted. This finding is the rationale for the use of thiazides as an adjunct to therapy in hypoparathyroid patients, as discussed below. Thiazide administration to normal individuals causes a transient increase in blood calcium (usually within the high-normal range) that reverts to preexisting levels after a week or more of continued administration. If hormonal function and calcium and bone metabolism are normal, homeostatic controls are reset to counteract the calcium-elevating effect of the thiazides. In the presence of hyperparathyroidism or increased bone turnover from another cause, homeostatic mechanisms are ineffective. The abnormal effects of the thiazide on calcium metabolism disappear within days of cessation of the drug.

Vitamin A Intoxication Vitamin A intoxication is a rare cause of hypercalcemia and is most commonly a side effect of dietary faddism (Chap. 61). Calcium levels can be elevated into the 3 to 3.5 mmol/L (12 to 14 mg/dL) range after the ingestion of 50,000 to 100,000 units of vitamin A daily (10 to 20 times the minimum daily requirement). Typical features of severe hypercalcemia include fatigue, anorexia, and, in some, severe muscle and bone pain. Excess vitamin A intake is presumed to increase bone resorption.

The diagnosis can be established by history and by measurement of vitamin A levels in serum. Occasionally, skeletal x-rays reveal periosteal calcifications, particularly in the hands. Withdrawal of the vitamin is usually associated with prompt disappearance of the hypercalcemia and reversal of the skeletal changes. As in vitamin D intoxication, administration of 100 mg/d hydrocortisone or its equivalent leads to a rapid return of the serum calcium to normal.

HYPERCALCEMIA ASSOCIATED WITH RENAL FAILURE ■ Severe Secondary Hyperparathyroidism Secondary hyperparathyroidism occurs when partial resistance to the metabolic actions of PTH leads to excessive production of the hormone. Parathyroid gland hyperplasia occurs because resistance to the normal level of PTH leads to hypocalcemia, which, in turn, is a stimulus to parathyroid gland enlargement.

Secondary hyperparathyroidism occurs not only in patients with renal failure but also in those with osteomalacia due to multiple causes (Chap. 331), including deficiency of vitamin D action, and PHP (deficient response to PTH at the level of the receptor). Hypocalcemia seems to be the common denominator in initiating secondary hyperparathyroidism. Primary and secondary hyperparathyroidism can be distinguished conceptually by the autonomous growth of the parathyroid glands in primary hyperparathyroidism (presumably irreversible) and the adaptive response of the parathyroids in secondary hyperparathyroidism (typically reversible). In fact, reversal over weeks from an abnormal pattern of secretion, presumably accompanied by involution of parathyroid gland mass to normal, occurs in patients who have been treated effectively to reverse the resistance to PTH (such as with calcium and vitamin D in osteomalacia).

Patients with secondary hyperparathyroidism may develop bone pain, ectopic calcification, and pruritus. The bone disease seen in patients with secondary hyperparathyroidism and renal failure is termed *renal osteodystrophy*. Osteomalacia (predominantly due to vitamin D and calcium deficiency) and/or osteitis fibrosa cystica (excessive PTH action on bone) may occur.

Two other skeletal disorders are associated with long-term dialysis in patients with renal failure. Aluminum deposition (see below) is associated with an osteomalacia-like picture. The other entity is a low-bone-turnover state termed "aplastic" or "adynamic" bone disease; PTH levels are lower than in typical secondary hyperparathyroidism. It is believed that the condition is caused, at least in part, by excessive PTH suppression, which may be even greater than previously appreciated in light of evidence that some of the immunoreactive PTH detected by most commercially available PTH assays is not the full-length biologically active molecule (as discussed above).

Rx TREATMENT

Medical therapy to reverse secondary hyperparathyroidism includes reduction of excessive blood phosphate by restriction of dietary phosphate, the use of nonabsorbable antacids, and careful, selective addition of calcitriol (0.25 to 2.0 μg/d); calcium carbonate is preferred over aluminum-containing antacids to prevent aluminum toxicity. Intravenous calcitriol, administered as several pulses each week, helps control secondary hyperparathyroidism. Aggressive but carefully administered medical therapy can often, but not always, reverse hyperparathyroidism and its symptoms and manifestations.

Occasional patients develop severe manifestations of secondary hyperparathyroidism, including hypercalcemia, pruritus, extraskeletal calcifications, and painful bones, despite aggressive medical efforts to suppress the hyperparathyroidism. PTH hypersecretion no longer responsive to medical therapy, a state of severe hyperparathyroidism in patients with renal failure that requires surgery, has been referred to as *tertiary hyperparathyroidism*. Parathyroid surgery is necessary to control this condition. Based on genetic evidence from examination of tumor samples in these patients, the emergence of autonomous parathyroid function is due to a monoclonal outgrowth of one or more previously hyperplastic parathyroid glands. The adaptive response has become an independent contributor to disease; this finding seems to emphasize the importance of optimal medical management to reduce the proliferative response of the parathyroid cells that enables the irreversible genetic change.

Aluminum Intoxication Aluminum intoxication (and often hypercalcemia as a complication of medical treatment) may occur in patients on chronic dialysis; manifestations include acute dementia and unresponsive and severe osteomalacia. Bone pain, multiple nonhealing fractures, particularly of the ribs and pelvis, and a proximal myopathy may occur. Hypercalcemia develops when these patients are treated with vitamin D or calcitriol because of impaired skeletal responsiveness. Aluminum is present at the site of osteoid mineralization, osteoblastic activity is minimal, and calcium incorporation into the skeleton is impaired. Prevention is accomplished by avoidance of aluminum excess in the dialysis regimen; treatment of established disease involves mobilizing aluminum through the use of the chelating agent deferoxamine (Chap. 339).

Milk-Alkali Syndrome The milk-alkali syndrome is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate. It is much less frequent since nonabsorbable antacids and other treatments became available for peptic ulcer disease. However, the increased use of calcium carbonate in the management of osteoporosis has led to reappearance of the syndrome. Several clinical presentations—acute, subacute, and chronic—have been described, all of which feature hypercalcemia, alkalosis, and renal failure. The chronic form of the disease, termed *Burnett's syndrome*, is associated with irreversible renal damage. The acute syndromes reverse if the excess calcium and absorbable alkali are stopped.

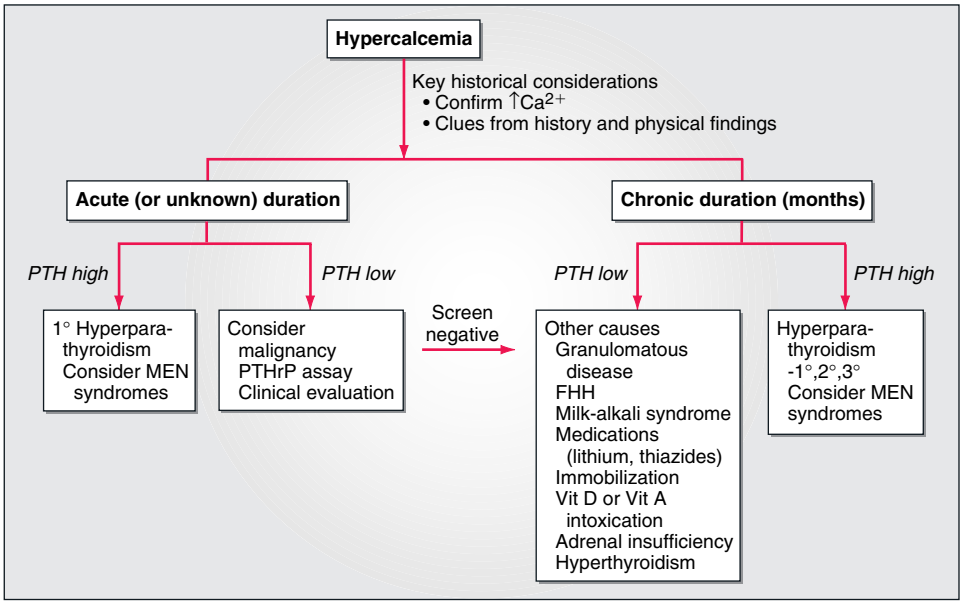

FIGURE 332-5 Algorithm for the evaluation of patients with hypercalcemia. See text for details. FHH, familial hypocalciuric hypercalcemia; MEN, multiple endocrine neoplasia; PTH, parathyroid hormone; PTHrP, parathyroid hormone–related peptide.

Individual susceptibility is important in the pathogenesis, as many patients are treated with calcium carbonate alkali regimens without developing the syndrome. One variable is the fractional calcium absorption as a function of calcium intake. Some individuals absorb a high fraction of calcium, even with intakes as high as 2 g or more of elemental calcium per day, instead of reducing calcium absorption with high intake, as occurs in most normal individuals. Resultant mild hypercalcemia after meals in such patients is postulated to contribute to the generation of alkalosis. Development of hypercalcemia causes increased sodium excretion and some depletion of total-body water. These phenomena and perhaps some suppression of endogenous PTH secretion due to mild hypercalcemia lead to increased bicarbonate resorption and to alkalosis in the face of continued calcium carbonate ingestion. Alkalosis per se selectively enhances calcium resorption in the distal nephron, thus aggravating the hypercalcemia. The cycle of mild hypercalcemia → bicarbonate retention → alkalosis → renal calcium retention → severe hypercalcemia perpetuates and aggravates hypercalcemia and alkalosis as long as calcium and absorbable alkali are ingested.

DIFFERENTIAL DIAGNOSIS: SPECIAL TESTS Differential diagnosis of hypercalcemia is best achieved by using clinical criteria, but the immunoassay for PTH is especially useful in distinguishing among major causes (Fig. 332-5). The clinical features that deserve emphasis are the presence or absence of symptoms or signs of disease and evidence of chronicity. If one discounts fatigue or depression, >90% of patients with primary hyperparathyroidism have *asymptomatic hypercalcemia*; symptoms of malignancy are usually present in cancer-associated hypercalcemia. Disorders other than hyperparathyroidism and malignancy cause <10% of cases of hypercalcemia, and some of the nonparathyroid causes are associated with clear-cut manifestations such as renal failure.

Hyperparathyroidism is the likely diagnosis in patients with *chronic hypercalcemia*. If hypercalcemia has been manifest for >1 year, malignancy can usually be excluded as the cause. A striking feature of malignancy-associated hypercalcemia is the rapidity of the course, whereby signs and symptoms of the underlying malignancy are evident within months of the detection of hypercalcemia. Although clinical considerations are helpful in arriving at the correct diagnosis of the cause of hypercalcemia, appropriate laboratory testing is essential for definitive diagnosis. The immunoassay for PTH should separate hyperparathyroidism from all other causes of hypercalcemia. Patients with hyperparathyroidism have elevated PTH levels despite hypercalcemia, whereas patients with malignancy and the other causes of hypercalcemia (except for disorders mediated by PTH such as lithium-induced hypercalcemia) have levels of hormone below normal or undetectable. Assays based on the double-antibody method for PTH exhibit very high sensitivity (especially if serum calcium is simultaneously evaluated) and specificity for the diagnosis of primary hyperparathyroidism (Fig. 332-6).

In summary, PTH values are elevated in >90% of parathyroid-related causes of hypercalcemia, undetectable or low in malignancy-related hypercalcemia, and undetectable or normal in vitamin D–related and high-bone-turnover causes of hypercalcemia. In view of the specificity of the PTH immunoassay and the high frequency of hyperparathyroidism in hypercalcemic patients, it is cost-effective to measure the PTH level in all hypercalcemic patients unless malignancy or a specific nonparathyroid disease is obvious. False-positive PTH assay results are rare. There are very rare reports of ectopic production of excess PTH by nonparathyroid tumors. Immunoassays for PTHrP are helpful in diagnosing certain types of malignancy-associated hypercalcemia. Although FHH is parathyroid-related, the disease should be managed distinctively from hyperparathyroidism. Clinical features and the low urinary calcium excretion can help make the distinction. Because the

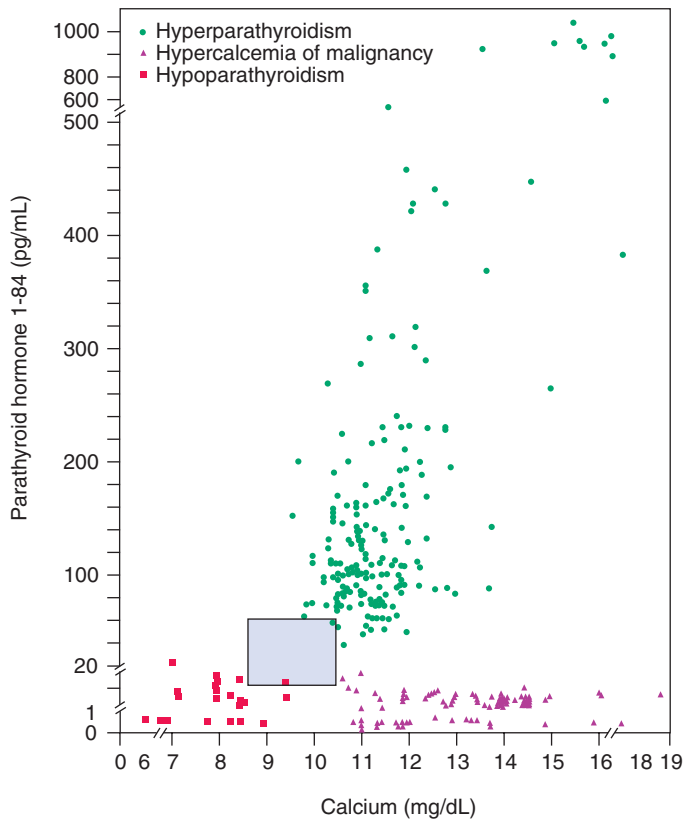

FIGURE 332-6 Levels of immunoreactive parathyroid hormone (PTH) detected in patients with primary hyperparathyroidism, hypercalcemia of malignancy, and hypoparathyroidism. Boxed area represents the upper and normal limits of blood calcium and/or immunoreactive PTH. [*From SR Nussbaum, JT Potts, Jr, in L DeGroot, JL Jameson (eds): Endocrinology, 4th ed. Philadelphia, Saunders, 2001, with permission.*]

incidence of malignancy and hyperparathyroidism both increase with age, they can coexist as two independent causes of hypercalcemia.

$1,25(OH)_2D$ levels are elevated in many (but not all) patients with primary hyperparathyroidism. In other disorders associated with hypercalcemia, concentrations of $1,25(OH)_2D$ are low or, at the most, normal. However, this test is of low specificity and is not cost-effective, as not all patients with hyperparathyroidism have elevated $1,25(OH)_2D$ levels, and not all nonparathyroid hypercalcemic patients have suppressed $1,25(OH)_2D$. Measurement of $1,25(OH)_2D$ is, however, critically valuable in establishing the cause of hypercalcemia in sarcoidosis and certain B cell lymphomas.

A useful general approach is outlined in Fig. 332-5. If the patient is *asymptomatic* and there is evidence of *chronicity* to the hypercalcemia, hyperparathyroidism is almost certainly the cause. If PTH levels (usually measured at least twice) are elevated, the clinical impression is confirmed and little additional evaluation is necessary. If there is only a short history or no data as to the duration of the hypercalcemia, *occult malignancy* must be considered; if the PTH levels are not elevated, then a thorough workup must be undertaken for malignancy, including chest x-ray, CT of chest and abdomen, and bone scan. Immunoassays for PTHrP may be especially useful in such situations. Attention should also be paid to clues for underlying hematologic disorders such as anemia, increased plasma globulin, and abnormal serum immunoelectrophoresis; bone scans can be negative in some patients with metastases, such as in multiple myeloma. Finally, if a patient with chronic hypercalcemia is asymptomatic and malignancy therefore seems unlikely on clinical grounds, but PTH values are not elevated, it is useful to search for other chronic causes of hypercalcemia, such as occult sarcoidosis. A careful history of dietary supplements and drug use may suggest intoxication with vitamin D or vitamin A or the use of thiazides.

TABLE 332-4 *Therapies for Severe Hypercalcemia*

Treatment	Onset of Action	Duration of Action	Advantages	Disadvantages
MOST USEFUL THERAPIES				
Hydration with saline	Hours	During infusion	Rehydration invariably needed	Volume overload, cardiac decompensation, intensive monitoring, electrolyte disturbance, inconvenience
Forced diuresis; saline plus loop diuretic	Hours	During treatment	Rapid action	
Bisphosphonates				
1st generation: etidronate	1–2 days	5–7 days in doses used	First available bisphosphonate; intermediate onset of action	Less effective than other bisphosphonates
2d generation: pamidronate	1–2 days	10–14 days to weeks	High potency; intermediate onset of action	Fever in 20% hypophosphatemia, hypocalcemia, hypomagnesemia
3d generation: zolendronate	1–2 days	>3 weeks	High potency; rapid infusion; prolonged duration of action	Minor; fever, rarely hypocalcemia or hypophosphatemia
Calcitonin	Hours	1–2 days	Rapid onset of action; useful as adjunct in severe hypercalcemia	Rapid tachyphylaxis
SPECIAL USE THERAPIES				
Phosphate				
Oral	24 h	During use	Chronic management (with hypophosphatemia); low toxicity if P < 4 mg/dL	Limited use except as adjuvant or chronic therapy
Intravenous	Hours	During use and 24–48 h afterward	Rapid action, highly potent but *rarely used* except with severe hypercalcemia and cardiac and renal decompensation present	Ectopic calcification; renal damage, fatal hypocalcemia
Glucocorticoids	Days	Days, weeks	Oral therapy, antitumor agent	Active only in certain malignancies; glucocorticoid side effects
Dialysis	Hours	During use and 24–48 h afterward	Useful in renal failure; onset of effect in hours; can immediately reverse life-threatening hypercalcemia	Complex procedure, reserved for extreme or special circumstances

TREATMENT

Hypercalcemic States The approach to medical treatment of hypercalcemia varies with its severity (Table 332-4). Mild hypercalcemia, <3.0 mmol/L (12 mg/dL), can be managed by hydration. More severe hypercalcemia [levels of 3.2 to 3.7 mmol/L (13 to 15 mg/dL)] must be managed aggressively; above that level, hypercalcemia can be life-threatening and requires emergency measures. By using a combination of approaches in severe hypercalcemia, the serum calcium concentration can be decreased by 0.7 to 2.2 mmol/L (3 to 9 mg/dL) within 24 to 48 h in most patients, enough to relieve acute symptoms, prevent death from hypercalcemic crisis, and permit diagnostic evaluation. Therapy can then be directed at the underlying disorder—the second priority.

Hypercalcemia develops because of excessive skeletal calcium release, increased intestinal calcium absorption, or inadequate renal calcium excretion. Understanding the particular pathogenesis helps guide therapy. For example, hypercalcemia in patients with malignancy is primarily due to excessive skeletal calcium release and is, therefore, minimally improved by restriction of dietary calcium. On the other hand, patients with vitamin D hypersensitivity or vitamin D intoxication have excessive intestinal calcium absorption, and restriction of dietary calcium is beneficial. Decreased renal function or ECF depletion decreases urinary calcium excretion. In such situations, rehydration may rapidly reduce or reverse the hypercalcemia, even though increased bone resorption persists. As outlined below, the more severe the hypercalcemia, the greater the number of combined therapies that should be used. Rapid acting (hours) approaches—rehydration, forced diuresis, and calcitonin—can be used with the most effective antiresorptive agents, such as bisphosphonates (since severe hypercalcemia usually involves excessive bone resorption).

HYDRATION, INCREASED SALT INTAKE, MILD AND FORCED DIURESIS The first principle of treatment is to restore normal hydration. Many hypercalcemic patients are dehydrated because of vomiting, inanition, and/or hypercalcemia-induced defects in urinary concentrating ability. The resultant drop in glomerular filtration rate is accompanied by an additional decrease in renal tubular sodium and calcium clearance. Restoring a normal ECF volume corrects these abnormalities and increases urine calcium excretion by 2.5 to 7.5 mmol/d (100 to 300

mg/d). Increasing urinary sodium excretion to 400 to 500 mmol/d increases urinary calcium excretion even further than simple rehydration. After rehydration has been achieved, saline can be administered or furosemide or ethacrynic acid can be given twice daily to depress the tubular reabsorptive mechanism for calcium (care must be taken to prevent dehydration). The combined use of these therapies can increase urinary calcium excretion to ≥12.5 mmol/d (500 mg/d) in most hypercalcemic patients. Since this is a substantial percentage of the exchangeable calcium pool, the serum calcium concentration usually falls 0.25 to 0.75 mmol/L (1 to 3 mg/dL) within 24 h. Precautions should be taken to prevent potassium and magnesium depletion; calcium-containing renal calculi are a potential complication.

Under life-threatening circumstances, the preceding approach can be pursued more aggressively, giving as much as 6 L isotonic saline (900 mmol sodium) daily plus furosemide or equivalent in doses up to 100 mg every 1 to 2 h or ethacrynic acid in doses to 40 mg every 1 to 2 h. Urinary calcium excretion may exceed 25 mmol/d (1000 mg/d), and the serum calcium may decrease by ≥1 mmol/L (4 mg/dL) within 24 h. Depletion of potassium and magnesium is inevitable unless replacements are given; pulmonary edema can be precipitated. The potential complications can be reduced by careful monitoring of central venous pressure and plasma or urine electrolytes; catheterization of the bladder may be necessary. This treatment approach should be supplemented with agents to block bone resorption. Though these agents do not become effective for several days, forced diuresis is difficult to sustain even in patients with good cardiopulmonary and renal function.

BISPHOSPHONATES The bisphosphonates are analogues of pyrophosphate, with high affinity for bone, especially in areas of increased bone turnover, where they are powerful inhibitors of bone resorption. These bone-seeking compounds are stable in vivo because phosphatase enzymes cannot hydrolyze the central carbon-phosphorus-carbon bond. The bisphosphonates are concentrated in areas of high bone turnover and are taken up by and inhibit osteoclast action; the mechanism of action is complex. Bisphosphonates alter osteoclast proton pump function or impair the release of acid hydrolases into the extracellular lysosomes contiguous with mineralized bone. They may also inhibit the differentiation of monocyte-macrophage precursors into osteoclasts and possibly have effects on osteoblasts as well. The bisphosphonate molecules that contain amino groups in the side chain structure (see below) interfere with prenylation of proteins and can lead to cellular apoptosis. The highly active non-amino group–containing bisphosphonates are also metabolized to cytotoxic products.

The initial bisphosphonate widely used in clinical practice, etidronate, was effective but had several disadvantages, including the capacity to inhibit bone formation as well as blocking resorption. Subsequently, a number of second-generation compounds have become the mainstays of antiresorptive therapy for treatment of hypercalcemia and osteoporosis. The newer bisphosphonates have a highly favorable ratio of blocking resorption versus inhibiting bone formation; they inhibit osteoclast-mediated skeletal resorption yet do not cause mineralization defects at ordinary doses. Though the bisphosphonates have similar structures, the routes of administration, efficacy, toxicity, and side effects vary. The potency of the compounds for inhibition of bone resorption varies a thousandfold, increasing in the order of etidronate, tiludronate, pamidronate, alendronate, and risedronate. Oral alendronate and risedronate are approved for the therapy of osteoporosis in the United States, but in Europe only for the chronic treatment of hypercalcemia. Only the intravenous use of pamidronate is approved for the treatment of hypercalcemia in the United States; between 30 and 90 mg pamidronate, given as a single intravenous dose over a few hours, returns serum calcium to normal within 24 to 48 h with an effect that lasts for weeks in 80 to 100% of patients.

Even more potent third-generation bisphosphonates have been recently introduced into clinical practice. Zolendronate, said to be several-fold more potent than second-generation compounds, is reported in preliminary trials to be superior in treatment of hypercalcemia, normalizing calcium faster and for longer periods of time after infusion. Doses of 1 to 4 mg can be given over a few minutes intravenously.

CALCITONIN Calcitonin acts within a few hours of its administration, through receptors on osteoclasts, to block bone resorption and, in addition, to increase urinary calcium excretion by inhibition of renal tubular calcium reabsorption. Results with calcitonin, particularly after 24 h of use, are variable, with minimal lowering of calcium. Tachyphylaxis, a known phenomenon with this drug, may explain the results. However, in life-threatening hypercalcemia, calcitonin can be used effectively within the first 24 h in combination with rehydration and saline diuresis while waiting for more sustained effects from a simultaneously administered bisphosphonate such as pamidronate. Usual doses of calcitonin are 2 to 8 U/kg of body weight intravenously, subcutaneously, or intramuscularly every 6 to 12 h.

OTHER THERAPIES *Plicamycin* (formerly mithramycin), which inhibits bone resorption, has been a useful therapeutic agent but is now seldom used because of its toxicity and the effectiveness of bisphosphonates. Plicamycin must be given intravenously, either as a bolus or by slow infusion; the usual dose is 25 μg/kg body weight. *Gallium nitrate* exerts a hypocalcemic action by inhibiting bone resorption and altering the structure of bone crystals. It is not often used now because of superior alternatives.

Glucocorticoids have utility, especially in hypercalcemia complicating certain malginancies. They increase urinary calcium excretion and decrease intestinal calcium absorption when given in pharmacologic doses, but they also cause negative skeletal calcium balance. In normal individuals and in patients with primary hyperparathyroidism, glucocorticoids neither increase nor decrease the serum calcium concentration. In patients with hypercalcemia due to certain osteolytic malignancies, however, glucocorticoids may be effective as a result of antitumor effects. The malignancies in which hypercalcemia responds to glucocorticoids include multiple myeloma, leukemia, Hodgkin's disease, other lymphomas, and carcinoma of the breast, at least early in the course of the disease. Glucocorticoids are also effective in treating hypercalcemia due to vitamin D intoxication and sarcoidosis. In all the preceding situations, the hypocalcemic effect develops over several days, and the usual glucocorticoid dosage is 40 to 100 mg prednisone (or its equivalent) daily in four divided doses. The side effects of chronic glucocorticoid therapy may be acceptable in some circumstances.

Dialysis is often the treatment of choice for severe hypercalcemia complicated by renal failure, which is difficult to manage medically. Peritoneal dialysis with calcium-free dialysis fluid can remove 5 to 12.5 mmol (200 to 500 mg) of calcium in 24 to 48 h and lower the serum calcium concentration by 0.7 to 3 mmol/L (3 to 12 mg/dL). Large quantities of phosphate are lost during dialysis, and serum inorganic phosphate concentrations usually fall, thus aggravating hypercalcemia. Therefore, the serum inorganic phosphate concentration should be measured after dialysis, and phosphate supplements should be added to the diet or to dialysis fluids if necessary.

Phosphate therapy, oral or intravenous, has a limited role in certain circumstances. Correcting hypophosphatemia lowers the serum calcium concentration by several mechanisms, including bone/calcium exchange. The usual oral treatment is 1 to 1.5 g phosphorus per day for several days, given in divided doses. It is generally believed, but not established, that toxicity does not occur if therapy is limited to restoring serum inorganic phosphate concentrations to normal.

Raising the serum inorganic phosphate concentration above normal decreases serum calcium levels, sometimes strikingly. Intravenous phosphate is one of the most dramatically effective treatments available for severe hypercalcemia but is toxic and even dangerous (fatal hypocalcemia). For these reasons, it is used rarely and only in severely hypercalcemic patients with cardiac or renal failure. A phosphate phosphorus dose of ≥1500 mg intravenously over 6 to 8 h leads to a prompt decrease in serum calcium of as much as 1.2 to 2.5 mmol/L (5 to 10

mg/dL) in patients with initially normal serum inorganic phosphate concentrations. This therapy should be employed only in extreme emergencies. Inorganic phosphate is commercially available for oral use in liquid, powder, and capsule form and as a liquid for intravenous use. If used, it is important to calculate doses in terms of phosphate phosphorus.

Summary The various therapies for hypercalcemia are listed in Table 332-4. The choice depends on the underlying disease, the severity of the hypercalcemia, the serum inorganic phosphate level, and the renal, hepatic, and bone marrow function. Mild hypercalcemia [≤3 mmol/L (12 mg/dL)] can usually be managed by hydration. Severe hypercalcemia [≥3.7 mmol/L (15 mg/dL)] requires rapid correction. Calcitonin should be given for its rapid, albeit short-lived, blockade of bone resorption, and intravenous pamidronate or zolendronate should be administered, although its onset of action is delayed for 1 to 2 days. In addition, for the first 24 to 48 h, aggressive sodium-calcium diuresis with intravenous saline and large doses of furosemide or ethacrynic acid following initial hydration should be initiated, but only if appropriate monitoring is available and cardiac and renal function are adequate. Otherwise, dialysis may be necessary. Intermediate degrees of hypercalcemia between 3.0 and 3.7 mmol/L (12 and 15 mg/dL) should be approached with vigorous hydration and then the most appropriate selection for the patient of the combinations used with severe hypercalcemia.

HYPOCALCEMIA

PATHOPHYSIOLOGY OF HYPOCALCEMIA: CLASSIFICATION BASED ON MECHANISM

Chronic hypocalcemia is less common than hypercalcemia; causes include chronic renal failure, hereditary and acquired hypoparathyroidism, vitamin D deficiency, PHP, and hypomagnesemia.

Acute rather than chronic hypocalcemia is seen in critically ill patients or as a consequence of certain medications and often does not require specific treatment. Transient hypocalcemia is seen with severe sepsis, burns, acute renal failure, and extensive transfusions with citrated blood. Although as many as half of patients in an intensive care setting are reported to have calcium concentrations <2.1 mmol/L (8.5 mg/dL), most do not have a reduction in ionized calcium. Patients with severe sepsis may have a decrease in ionized calcium (true hypocalcemia), but in other severely ill individuals, hypoalbuminemia is the primary cause of the reduced total calcium concentration. Alkalosis increases calcium binding to proteins, and in this setting direct measurements of ionized calcium should be made.

Medications such as protamine, heparin, and glucagon may cause transient hypocalcemia. These forms of hypocalcemia are usually not associated with tetany and resolve with improvement in the overall medical condition. The hypocalcemia after repeated transfusions of citrated blood usually resolves quickly.

Patients with *acute pancreatitis* have hypocalcemia that persists during the acute inflammation and varies in degree with the severity of the pancreatitis. The cause of hypocalcemia remains unclear. PTH values are reported to be low, normal, or elevated, and both resistance to PTH and impaired PTH secretion have been postulated. Occasionally, a chronic low total calcium and low ionized calcium concentration are detected in an elderly patient without obvious cause and with a paucity of symptoms; the pathogenesis is unclear.

Chronic hypocalcemia, however, is usually symptomatic and requires treatment. Neuromuscular and neurologic manifestations of chronic hypocalcemia include muscle spasms, carpopedal spasm, facial grimacing, and, in extreme cases, laryngeal spasm and convulsions. Respiratory arrest may occur. Increased intracranial pressure occurs in some patients with long-standing hypocalcemia, often in association with papilledema. Mental changes include irritability, depression, and psychosis. The QT interval on the electrocardiogram is prolonged, in contrast to its shortening with hypercalcemia. Arrhythmias occur, and digitalis effectiveness may be reduced. Intestinal cramps and chronic malabsorption may occur. Chvostek's or Trousseau's sign can be used to confirm latent tetany.

The classification of hypocalcemia shown in Table 332-5 is based on an organizationally useful premise that PTH is responsible for minute-to-minute regulation of plasma calcium concentration and, therefore, that the occurrence of hypocalcemia must mean a failure of the homeostatic action of PTH. Failure of the PTH response can occur if there is hereditary or acquired parathyroid gland failure, if PTH is ineffective in target organs, or if the action of the hormone is overwhelmed by the loss of calcium from the ECF at a rate faster than it can be replaced.

PTH ABSENT Whether hereditary or acquired, hypoparathyroidism has a number of common components. Symptoms of untreated hypocalcemia are shared by both types of hypoparathyroidism, although the onset of hereditary hypoparathyroidism is more gradual and is often associated with other developmental defects. Basal ganglia calcification and extrapyramidal syndromes are more common and earlier in onset in hereditary hypoparathyroidism. In earlier decades, acquired hypoparathyroidism secondary to surgery in the neck was more common than hereditary hypoparathyroidism, but the frequency of surgically induced parathyroid failure has diminished as a result of improved surgical techniques that spare the parathyroid glands and increased use of nonsurgical therapy for hyperthyroidism. PHP, an example of ineffective PTH action rather than a failure of parathyroid gland production, may share several features with hypoparathyroidism, including extraosseous calcification and extrapyramidal manifestations such as choreoathetotic movements and dystonia.

Papilledema and raised intracranial pressure may occur in both hereditary and acquired hypoparathyroidism, as do chronic changes in fingernails and hair and lenticular cataracts, the latter usually reversible with treatment of hypocalcemia. Certain skin manifestations, including alopecia and candidiasis, are characteristic of hereditary hypoparathyroidism associated with autoimmune polyglandular failure (Chap. 330).

Hypocalcemia associated with hypomagnesemia is associated with both deficient PTH release and impaired responsiveness to the hormone. Patients with hypocalcemia secondary to hypomagnesemia have absent or low levels of circulating PTH, indicative of diminished hormone release despite maximum physiologic stimulus by hypocalcemia. Plasma PTH levels return to normal with correction of the hypomagnesemia. Thus hypoparathyroidism with low levels of PTH in blood can be due to hereditary gland failure, acquired gland failure, or acute but reversible gland dysfunction (hypomagnesemia).

Genetic Abnormalities and Hereditary Hypoparathyroidism Hereditary hypoparathyroidism can occur as an isolated entity without other endocrine or dermatologic manifestations (idiopathic hypoparathyroidism).

TABLE 332-5 *Functional Classification of Hypocalcemia (Excluding Neonatal Conditions)*

PTH ABSENT	
Hereditary hypoparathyroidism Acquired hypoparathyroidism	Hypomagnesemia
PTH INEFFECTIVE	
Chronic renal failure Active vitamin D lacking ↓ Dietary intake or sunlight Defective metabolism: Anticonvulsant therapy Vitamin D–dependent rickets type I	Active vitamin D ineffective Intestinal malabsorption Vitamin D–dependent rickets type II Pseudohypoparathyroidism
PTH OVERWHELMED	
Severe, acute hyperphosphatemia Tumor lysis Acute renal failure Rhabdomyolysis	Osteitis fibrosa after parathyroidectomy

Note: PTH, parathyroid hormone.

More typically, it occurs in association with other abnormalities such as defective development of the thymus or failure of other endocrine organs such as the adrenal, thyroid, or ovary (Chap. 330). Idiopathic and hereditary hypoparathyroidism are often manifest within the first decade but may appear later.

A rare form of hypoparathyroidism associated with defective development of both the thymus and the parathyroid glands is termed the *DiGeorge syndrome*, or the *velocardiofacial syndrome*. Congenital cardiovascular, facial, and other developmental defects are present, and most patients die in early childhood with severe infections, hypocalcemia and seizures, or cardiovascular complications. Some survive into adulthood, and milder, incomplete forms occur. Most cases are sporadic, but an autosomal dominant form involving microdeletions of chromosome 22q11.2 has been described. Smaller deletions in this region are seen in incomplete forms of the DiGeorge syndrome, appearing in childhood or adolescence, that are manifest primarily by parathyroid gland failure.

Hypoparathyroidism can occur in association with a complex hereditary autoimmune syndrome involving failure of the adrenals, the ovaries, the immune system, and the parathyroids in association with recurrent mucocutaneous candidiasis, alopecia, vitiligo, and pernicious anemia (Chap. 330). The responsible gene on chromosome 21q22.3 has been identified. The protein product, which resembles a transcription factor, has been termed the *autoimmune regulator*, or AIRE. A stop codon mutation occurs in many Finnish families with the disorder, commonly referred to as *polyglandular autoimmune type 1 deficiency*.

Gain-of-function mutations in the calcium-sensing receptor cause *autosomal dominant hypocalcemia*. These mutations induce constitutive receptor functions that lead to features that are the inverse of FHH. The activated receptor suppresses PTH secretion, leading to hypocalcemia; receptor activation in the kidney results in excessive renal calcium excretion. Recognition of the syndrome is important because efforts to treat the hypocalcemia of these patients with vitamin D analogues and increased oral calcium exacerbate the already excessive urinary calcium secretion (several grams or more per 24 h), leading to irreversible renal damage from stones and ectopic calcification.

Hypoparathyroidism is seen in two disorders associated with mitochondrial dysfunction and myopathy, one termed the *Kearns-Sayre syndrome* (KSS), with ophthalmaplegia and pigmentary retinopathy, and the other termed the *MELAS syndrome*, *m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and *s*troke-like episodes. Mutations or deletions in mitochondrial genes have been identified.

The two other rare forms of hypoparathyroidism with other multisystem developmental abnormalities follow either an autosomal dominant pattern, with deafness and/or renal dysplasia, or an autosomal recessive pattern, with growth retardation and dysmorphic features.

Hereditary hypoparathyroidism occurs also as an isolated entity without any other defects. The pattern of inheritance varies and includes autosomal dominant, autosomal recessive, and X-linked inheritance patterns. In one family in which the disorder is transmitted as an autosomal dominant trait, a structural abnormality in the PTH gene has been identified. A defect in the signal sequence needed for processing of the hormone impairs PTH secretion. In another kindred with autosomal recessive inheritance, the mutant allele in the first intron of the PTH gene causes a splicing defect in mRNA production. An X-linked recessive form of hypoparathyroidism has been described in males and the defect has been localized to chromosome Xq26-q27.

Acquired Hypoparathyroidism *Acquired chronic hypoparathyroidism* is usually the result of inadvertent surgical removal of all the parathyroid glands; in some instances, not all the tissue is removed, but the remainder undergoes vascular supply compromise secondary to fibrotic changes in the neck after surgery. In the past, the most frequent cause of acquired hypoparathyroidism was surgery for hyperthyroidism. Hypoparathyroidism now usually occurs after surgery for hyperparathyroidism when the surgeon, facing the dilemma of removing too little tissue and thus not curing the hyperparathyroidism, removes too much. Parathyroid function may not be totally absent in all patients with postoperative hypoparathyroidism.

Even rarer causes of acquired chronic hypoparathyroidism include radiation-induced damage subsequent to radioiodine therapy of hyperthyroidism and glandular damage in patients with hemochromatosis or hemosiderosis after repeated blood transfusions. Infection may involve one or more of the parathyroids but usually does not cause hypoparathyroidism because all four glands are rarely involved.

Transient hypoparathyroidism is frequent following surgery for hyperparathyroidism. After a variable period of hypoparathyroidism, normal parathyroid function may return due to hyperplasia or recovery of remaining tissue. Occasionally, recovery occurs months after surgery.

TREATMENT

Treatment of acquired and hereditary hypoparathyroidism involves replacement with vitamin D or $1,25(OH)_2D_3$ (calcitriol) combined with a high oral calcium intake. In most patients, blood calcium and phosphate levels are satisfactorily regulated, but some patients show resistance and a brittleness, with a tendency to alternate between hypocalcemia and hypercalcemia. For many patients, vitamin D in doses of 40,000 to 120,000 U/d (1 to 3 mg/d) combined with $\geq$1 g elemental calcium is satisfactory. The wide dosage range reflects the variation encountered from patient to patient; precise regulation of each patient is required. Compared to typical daily requirements in euparathyroid patients of 200 U/d, the high dose of vitamin D reflects the reduced conversion of vitamin D to $1,25(OH)_2D$. Many physicians now use 0.5 to 1.0 μg of calcitriol in management of such patients, especially if they are difficult to control. Because of its storage in fat, when vitamin D is withdrawn, weeks are required for the disappearance of the biologic effects, compared with a few days for calcitriol, which has a rapid turnover.

Oral calcium and vitamin D restore the overall calcium-phosphate balance but do not reverse the lowered urinary calcium reabsorption typical of hypoparathyroidism. Therefore, care must be taken to avoid excessive urinary calcium excretion after vitamin D and calcium replacement therapy; otherwise, kidney stones can develop. Thiazide diuretics lower urine calcium by as much as 100 mg/d in hypoparathyroid patients on vitamin D, provided they are maintained on a low-sodium diet. Use of thiazides seems to be of benefit in mitigating hypercalciuria and easing the daily management of these patients.

Hypomagnesemia Severe hypomagnesemia (<0.4 mmol/L; <0.8 meq/L) is associated with hypocalcemia (Chap. 331). Restoration of the total-body magnesium deficit leads to rapid reversal of hypocalcemia. There are at least two causes of the hypocalcemia—impaired PTH secretion and reduced responsiveness to PTH. →***For discussion of causes and treatment of hypomagnesemia, see Chap. 331.***

The effects of magnesium on PTH secretion are similar to those of calcium; hypermagnesemia suppresses and hypomagnesemia stimulates PTH secretion. The effects of magnesium on PTH secretion are normally of little significance, however, because the calcium effects dominate. Greater change in magnesium than in calcium is needed to influence hormone secretion. Nonetheless, hypomagnesemia might be expected to increase hormone secretion. It is therefore surprising to find that severe hypomagnesemia is associated with blunted secretion of PTH. The explanation for the paradox is that severe, chronic hypomagnesemia leads to intracellular magnesium deficiency, which interferes with secretion and peripheral responses to PTH. The mechanism of the cellular abnormalities caused by hypomagnesemia is unknown, although effects on adenylate cyclase (for which magnesium is a cofactor) have been proposed.

PTH levels are undetectable or inappropriately low in severe hypomagnesemia despite the stimulus of severe hypocalcemia, and acute repletion of magnesium leads to a rapid increase in PTH level. Serum phosphate levels are often not elevated, in contrast to the situation with acquired or idiopathic hypoparathyroidism, probably because

phosphate deficiency is a frequent accompaniment of hypomagnesemia.

Diminished peripheral responsiveness to PTH also occurs in some patients, as documented by subnormal response in urinary phosphorus and urinary cyclic AMP excretion after administration of exogenous PTH to patients who are hypocalcemic and hypomagnesemic. Both blunted PTH secretion and lack of renal response to administered PTH can occur in the same patient. When acute magnesium repletion is undertaken, the restoration of PTH levels to normal or supranormal may precede restoration of normal serum calcium by several days.

Rx TREATMENT

Repletion of magnesium cures the condition. Repletion should be parenteral. Attention must be given to restoring the intracellular deficit, which may be considerable. After intravenous magnesium administration, serum magnesium may return transiently to the normal range, but unless replacement therapy is adequate serum magnesium will again fall. If the cause of the hypomagnesemia is renal magnesium wasting, magnesium may have to be given chronically to prevent recurrence (Chap. 331).

PTH INEFFECTIVE PTH is ineffective when the hormone receptor–guanyl nucleotide–binding protein complex is defective (PHP, discussed below), when PTH action to promote calcium absorption from the diet is impaired because of vitamin D deficiency or because vitamin D is ineffective (receptor or synthesis defects), or in chronic renal failure in which the calcium-elevating action of PTH is impaired.

Typically, hypophosphatemia is more severe than hypocalcemia in vitamin D deficiency states because of the increased secretion of PTH, which, although only partly effective in elevating blood calcium, is capable of promoting phosphaturia.

PHP, on the other hand, has a pathophysiology different from the other disorders of ineffective PTH action. PHP resembles hypoparathyroidism (in which PTH synthesis is deficient) and is manifested by hypocalcemia and hyperphosphatemia. The cause of the disorder is defective hormone activation of guanyl nucleotide–binding proteins, resulting in failure of PTH to increase intracellular cyclic AMP (see below).

Chronic Renal Failure Improved medical management of chronic renal failure now allows many patients to survive for years and hence time enough to develop features of renal osteodystrophy, which must be controlled to avoid its morbidity. Phosphate retention and impaired production of $1,25(OH)_2D$ are the principal factors that cause calcium deficiency, secondary hyperparathyroidism, and bone disease. Low levels of $1,25(OH)_2D$ due to hyperphosphatemia and destruction of renal tissue are critical in the development of hypocalcemia. The uremic state also causes impairment of intestinal absorption by mechanisms other than defects in vitamin D metabolism. Nonetheless, treatment with supraphysiologic amounts of vitamin D or calcitriol corrects the impaired calcium absorption.

Hyperphosphatemia in renal failure lowers blood calcium levels by several mechanisms, including extraosseous deposition of calcium and phosphate, impairment of the bone-resorbing action of PTH, and reduction in $1,25(OH)_2D$ production by remaining renal tissue.

Rx TREATMENT

Therapy of chronic renal failure (Chap. 261) involves appropriate management of patients prior to dialysis and adjustment of regimens once dialysis is initiated. Attention should be paid to restriction of phosphate in the diet; avoidance of aluminum-containing phosphate-binding antacids to prevent the problem of aluminum intoxication; provision of an adequate calcium intake by mouth, usually 1 to 2 g/d; and supplementation with 0.25 to 1.0 μg/d calcitriol. Each patient must be monitored closely. The aim of therapy is to restore normal calcium balance to prevent osteomalacia and secondary hyperparathyroidism and, in light of evidence of genetic changes and monoclonal outgrowths of parathyroid glands in renal failure patients, to prevent secondary from becoming autonomous hyperparathyroidism. Reduction of hyperphosphatemia and restoration of normal intestinal calcium absorption by calcitriol can improve blood calcium levels and reduce the manifestations of secondary hyperparathyroidism. Since adynamic bone disease can occur in association with low PTH levels, it is important to avoid excessive suppression of the parathyroid glands while recognizing the beneficial effects of controlling the secondary hyperparathyroidism. These patients should probably be closely monitored with PTH assays that detect only the full-length PTH(1–84) to ensure that biologically active PTH and not inactive, inhibitory PTH fragments are measured.

Vitamin D Deficiency Due to Inadequate Diet and/or Sunlight Vitamin D deficiency due to inadequate intake of dairy products enriched with vitamin D, lack of vitamin supplementation, and reduced sunlight exposure in the elderly, particularly during winter in northern latitudes, is more common in the United States than previously recognized. Biopsies of bone in elderly patients with hip fracture (documenting osteomalacia) and abnormal levels of vitamin D metabolites, PTH, calcium, and phosphate indicate that vitamin D deficiency may occur in as many as 25% of elderly patients, particularly in northern latitudes in the United States. Concentrations of 25(OH)D are low or low-normal in these patients. Quantitative histomorphometry of bone biopsy specimens reveals widened osteoid seams consistent with osteomalacia (Chap. 331). PTH hypersecretion compensates for the tendency for the blood calcium to fall but also induces renal phosphate wasting and results in osteomalacia.

Treatment involves adequate replacement with vitamin D and calcium until the deficiencies are corrected. Severe hypocalcemia rarely occurs in moderately severe vitamin D deficiency of the elderly, but vitamin D deficiency must be considered in the differential diagnosis of mild hypocalcemia.

Defective Vitamin D Metabolism ■ *ANTICONVULSANT THERAPY* Anticonvulsant therapy with any of several agents induces acquired vitamin D deficiency by increasing the conversion of vitamin D to inactive compounds. The more marginal the vitamin D intake in the diet, the more likely that anticonvulsant therapy will lead to abnormal mineral and bone metabolism →***For discussion of treatment, see Chap. 331.***

VITAMIN D–DEPENDENT RICKETS TYPE I Rickets can be due to *resistance to the action* of vitamin D as well as to vitamin D deficiency. Vitamin D–dependent rickets type I, previously termed *pseudo-vitamin D–resistant rickets*, differs from true vitamin D–resistant rickets (vitamin D-dependent rickets type II, see below) in that it is less severe and the biochemical and radiographic abnormalities can be reversed with appropriate doses of the vitamin or the active metabolite, $1,25(OH)_2D_3$. Physiologic amounts of calcitriol cure the disease (Chap. 331). This finding fits with the pathophysiology of the disorder, which is autosomal recessive, and is now known to be caused by mutations in the gene encoding 25(OH)D-1α-hydroxylase. Both alleles are inactivated in all patients, and compound heterozygotes, harboring distinct mutations, are common.

Clinical features include hypocalcemia, often with tetany or convulsions, hypophosphatemia, secondary hyperparathyroidism, and osteomalacia, often associated with skeletal deformities and increased alkaline phosphatase. Treatment involves physiologic replacement doses of $1,25(OH)_2D_3$ (Chap. 331).

Vitamin D Ineffective ■ *INTESTINAL MALABSORPTION* Mild hypocalcemia, secondary hyperparathyroidism, severe hypophosphatemia, and a variety of nutritional deficiencies occur with gastrointestinal diseases. Hepatocellular dysfunction can lead to reduction in 25(OH)D levels, as in portal or biliary cirrhosis of the liver, and malabsorption of vitamin D and its metabolites, including $1,25(OH)_2D$, may occur in a variety of bowel diseases, hereditary or acquired. Hypocalcemia itself can lead to steatorrhea, due to deficient production of pancreatic enzymes and bile salts. Depending on the disorder, vitamin D or its

TABLE 332-6 *Classification of Pseudohypoparathyroidism (PHP) and Pseudopseudohypoparathyroidism (PPHP)*

Type	Hypocalcemia, Hyperphosphatemia	Response of Urinary cAMP to PTH	Serum PTH	$G_{s\alpha}$ Subunit Deficiency	AHO	Resistance to Hormones in Addition to PTH
PHP-Ia	Yes	↓	↑	Yes	Yes	Yes
PHP-Ib	Yes	↓	↑	No	No	No
PHP-II	Yes	Normal	↑	No	No	No
PPHP	No	Normal	Normal	Yes	Yes	±

Note: ↓, decreased; ↑, increased; AHO, Albright's hereditary osteodystrophy; PTH, parathyroid hormone.

metabolites can be given parenterally, guaranteeing adequate blood levels of active metabolites.

VITAMIN D–DEPENDENT RICKETS TYPE II Vitamin D–dependent rickets type II results from end-organ resistance to the active metabolite $1,25(OH)_2D_3$. The clinical features resemble those of the type I disorder and include hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and rickets but also partial or total alopecia. Plasma levels of $1,25(OH)_2D$ are at least three times normal, in keeping with the refractoriness of the end organs. All of the genetically characterized phenotypes have mutations in the gene for the vitamin D receptor. Treatment is difficult, given the receptor defect (Chap. 331).

Pseudohypoparathyroidism PHP is a hereditary disorder characterized by symptoms and signs of hypoparathyroidism, typically in association with distinctive skeletal and developmental defects. The hypoparathyroidism is due to a deficient end-organ response to PTH. Hyperplasia of the parathyroids, a response to hormone resistance, causes elevation of PTH levels. Studies, both clinical and basic, have clarified some aspects of this syndrome, including the variable clinical spectrum, the pathophysiology, the genetic defects, and the inheritance.

A working classification of the various forms of PHP is given in Table 332-6. The classification scheme is based on the signs of ineffective PTH action (low calcium and high phosphate), urinary cyclic AMP response to exogenous PTH, the presence or absence of *Albright's hereditary osteodystrophy* (AHO), and assays of the concentration of the $G_s\alpha$ subunit of the adenylate cyclase enzyme. Using these criteria, there are four types: PHP type I, subdivided into a and b categories; PHP-II; and pseudopseudohypoparathyroidism (PPHP).

PHP-IA AND PHP-IB Individuals with PHP-I, the most common of the disorders, show a deficient urinary cyclic AMP response to administration of exogenous PTH. Patients with PHP-I are divided into type a, who have reduced amounts of $G_s\alpha$ in vitro assays with erythrocytes, and type b, with normal amounts of $G_s\alpha$ in erythrocytes. There is a third type (PHP-Ic, reported in a few patients) that differs from PHP-Ia only in having normal erythroycte levels of $G_s\alpha$ despite having AHO, hypocalcemia, and decreased urinary cyclic AMP responses to PTH (presumably with a post-$G_s\alpha$ defect in adenyl cyclase stimulation).

Most patients show characteristic features of AHO, consisting of short stature, round face, skeletal anomalies (brachydactyly), and heterotopic calcification. Patients have low calcium and high phosphate levels, as with true hypoparathyroidism. PTH levels, however, are elevated, reflecting resistance to hormone action.

Amorphous deposits of calcium and phosphate are found in the basal ganglia in about half of patients. The defects in metacarpal and metatarsal bones are sometimes accompanied by short phalanges as well, possibly reflecting premature closing of the epiphyses. The typical findings are short fourth and fifth metacarpals and metatarsals. The defects are usually bilateral. Exostoses and radius curvus are frequent. Impairments in olfaction and taste and unusual dermatoglyphic abnormalities have been reported.

PPHP Multiple defects have now been identified in the *GNAS-1* gene in PHP-Ia and PPHP patients. This gene, which is located on chromosome 20q13, encodes the stimulatory G protein subunit $G_s\alpha$, among other products (see below). Mutations include abnormalities in splice junctions associated with deficient mRNA production and point mutations that result in a protein with defective function as well as a 50% reduction in $G_s\alpha$ levels in erythrocytes.

Detailed analyses of disease transmission in affected kindreds have clarified many features of PHP-Ia, PPHP, and PHP-Ib (Fig. 332-7). The former two entities, traced through multiple kindreds, have an inheritance pattern consistent with gene imprinting—only females, not males, can transmit the full disease with hypocalcemia—and PHP and PPHP do not coexist in the same generation. The phenomenon of gene imprinting involves selective inactivation of either the maternal or the paternal allele (Chap. 56). In the case of the $G_s\alpha$ gene, it is paternally imprinted (silenced) so that the disease PHP-Ia is never inherited from the father carrying the defective allele but only from the mother. On the other hand, the defective allele is not imprinted or silenced in all tissues. It seems possible, therefore, that the AHO phenotype recognized in PPHP as well as PHP-Ia reflects haplotype insufficiency during embryonic development. In the renal cortex, however, it is postulated that only the maternal allele is normally active, such that lack of activity from a defective paternal allele is not of consequence. This explains the occurrence in PHP-Ia of hypocalcemia, hyperphosphatemia, and other stigmata such as variable resistance to other hormones (if similar tissue-specific imprinting occurs in other organs). Strong evidence favoring this overall hypothesis comes from gene knockout studies in the mouse (ablating exon 2 of the gene). Mice inheriting the mutant allele from the female had undetectable $G_s\alpha$ protein in renal cortex and were hypocalcemic and resistant to renal actions of PTH. Offspring inheriting the mutant allele from the male showed no evidence of PTH resistance or hypercalcemia.

The complex mechanisms that control the *GNAS-1* gene also contribute to challenges involved in unraveling the pathogenesis of these disorders. Alternative splicing patterns produce three different transcripts that encode distinct proteins. In addition to $G_s\alpha$, this gene encodes a second protein product with a unique NH_2-terminus (the XL exon); $XL_\alpha s$ includes exons 2–13. It is unknown whether this protein can function as a stimulatory G protein, but the mRNA encoding it is

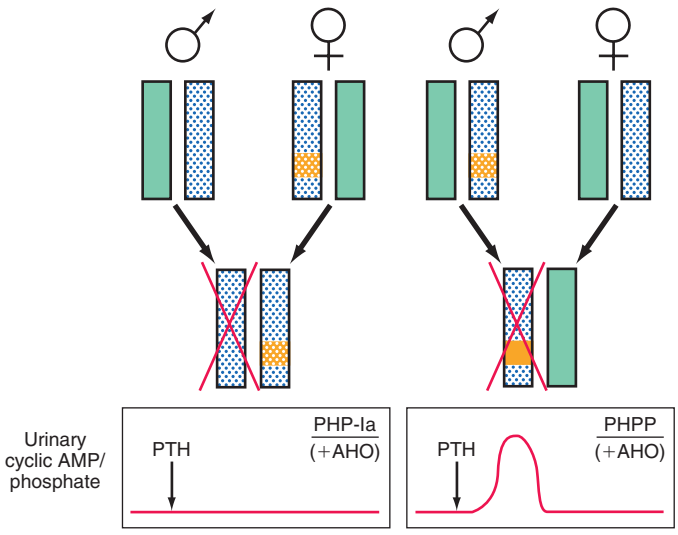

FIGURE 332-7 Paternal imprinting of renal parathyroid hormone (PTH) resistance (*GNAS-1* gene for $G_s\alpha$ subunit) in pseudohypoparathyroidism (PHP). An impaired excretion of urinary cyclic AMP and phosphate is observed in patients with PHP. In the renal cortex, there is selective silencing of the paternal $G_s\alpha$ gene mRNA. The disease becomes manifest only in patients who inherit the defective gene from an obligate female carrier (*left*). If the genetic defect is inherited from an obligate male gene carrier, there is no biochemical abnormality; administration of PTH causes an appropriate increase in the urinary cyclic AMP and phosphate concentration [pseudo-PHP (PPHP); *right*]. Both patterns of inheritance lead to Albright's hereditary osteodystrophy (AHO), perhaps because of haplotype insufficiency—i.e., both copies of $G_s\alpha$ must be active in the fetus for normal bone development.

expressed in numerous endocrine tissues and is transcribed from only the paternal allele. A third transcript is transcribed from only the maternal allele and encodes the protein product, NESP55, which contains no homology with $XL_{\alpha}s$ or $G_s\alpha$.

PHP-Ib, lacking the AHO phenotype, shares with PHP-Ia the resistance to PTH action and a blunted urinary cyclic AMP response to administered PTH, a standard test for hormone resistance (Table 332-6). PHP-Ib patients, however, show normal levels of $G_s\alpha$ in erythrocytes. Bone responsiveness may be excessive rather than blunted in PHP-Ib compared to PHP-Ia patients, based on case reports that have emphasized an osteitis fibrosa–like pattern in some PHP patients who lack the AHO phenotype. The inheritance patterns in PHP-Ib kindreds are clearly consistent with paternal imprinting and lack male transmission of symptomatic disease; gene cloning studies have narrowed the responsible region to chromosome 20, close to—if not within—the *GNAS-1* gene locus. Elucidation of the responsible genetic and pathogenetic mechanisms in this disorder may further illuminate the function of the complex *GNAS-1* gene and the role of its products in hormonal signaling.

PHP-II refers to patients with hypocalcemia and hyperphosphatemia who have a normal urinary cyclic AMP response to PTH. These patients are assumed to have a defect in the response to PTH at a locus distal to cyclic AMP production, although at least some patients may instead have occult vitamin D deficiency.

The diagnosis of these hormone-resistant states can usually be made without difficulty when there is a positive family history for developmental defects and/or the presence of developmental anomalies, including brachydactyly, in association with the signs and symptoms of hypoparathyroidism. In all categories—PHP-Ia, -Ib, and -II—serum PTH levels are elevated, particularly when patients are hypocalcemic. However, patients with PHP-Ib or PHP-II do not have phenotypic abnormalities, only hypocalcemia with high PTH levels, confirming hormone resistance. In PHP-Ib, the response of urinary cyclic AMP to the administration of exogenous PTH is blunted. Levels of $G_s\alpha$ subunits in erythrocyte membranes are, however, normal in those with PHP-Ib. The diagnosis of PHP-II is more complex, in that cyclic AMP responses in urine are, by definition, normal. Since vitamin D deficiency itself can dissociate phosphaturic and urinary cyclic AMP responses to exogenous PTH, vitamin D deficiency must be excluded before the diagnosis of PHP-II can be entertained.

TREATMENT

Treatment of PHP is similar to that of hypoparathyroidism, except that the doses of vitamin D and calcium are usually lower than those required in true hypoparathyroidism, presumably because the defect in PHP is only partial because of imprinting in specific tissues (renal cortex vs. renal medulla). Variability in response makes it necessary to establish the optimal regimen for each patient, based on maintaining the appropriate blood calcium level and urinary calcium excretion.

PTH Overwhelmed Occasionally, loss of calcium from the ECF is so severe that PTH cannot compensate. Such situations include acute pancreatitis and severe, acute hyperphosphatemia, often in association with renal failure, conditions in which there is rapid efflux of calcium from the ECF. Severe hypocalcemia can occur quickly; PTH rises in response to hypocalcemia but does not return blood calcium to normal.

Severe, Acute Hyperphosphatemia Severe hyperphosphatemia is associated with extensive tissue damage or cell destruction (Chap. 331). The combination of increased release of phosphate from muscle and impaired ability to excrete phosphorus because of renal failure causes moderate to severe hyperphosphatemia, the latter causing calcium loss from the blood and mild to moderate hypocalcemia. Hypocalcemia is usually reversed with tissue repair and restoration of renal function as phosphorus and creatinine values return to normal. There may even be a mild hypercalcemic period in the oliguric phase of renal function recovery. This sequence, severe hypocalcemia followed by mild hypercalcemia, reflects widespread deposition of calcium in muscle and subsequent redistribution of some of the calcium to the ECF after phosphate levels return to normal.

Other causes of hyperphosphatemia include hypothermia, massive hepatic failure, and hematologic malignancies, either because of high cell turnover of malignancy or because of cell destruction by chemotherapy.

TREATMENT

Treatment is directed toward lowering of blood phosphate by the administration of phosphate-binding antacids or dialysis, often needed for the management of renal failure. Although calcium replacement may be necessary if hypocalcemia is severe and symptomatic, calcium administration during the hyperphosphatemic period tends to increase extraosseous calcium deposition and aggravate tissue damage. The levels of $1,25(OH)_2D$ may be low during the hyperphosphatemic phase and return to normal during the oliguric phase of recovery.

Osteitis Fibrosis after Parathyroidectomy Severe hypocalcemia after parathyroid surgery is rare now that osteitis fibrosa cystica is an infrequent manifestation of hyperparathyroidism. When osteitis fibrosa cystica is severe, however, bone mineral deficits can be large. After parathyroidectomy, hypocalcemia can persist for days if calcium replacement is inadequate. Treatment may require parenteral administration of calcium; addition of calcitriol and oral calcium supplementation is sometimes needed for weeks to a month or two until bone defects are filled (which, of course, is of therapeutic benefit in the skeleton), making it possible to discontinue parenteral calcium and/or reduce the amount.

DIFFERENTIAL DIAGNOSIS OF HYPOCALCEMIA Care must be taken to ensure that true hypocalcemia is present; in addition, acute transient hypocalcemia can be a manifestation of a variety of severe, acute illnesses, as discussed above. *Chronic hypocalcemia*, however, can usually be ascribed to a few disorders associated with absent or ineffective PTH. Important clinical criteria include the duration of the illness, signs or symptoms of associated disorders, and the presence of features that suggest a hereditary abnormality. A nutritional history can be helpful in recognizing a low intake of vitamin D and calcium in the elderly, and a history of excessive alcohol intake may suggest magnesium deficiency.

Hypoparathyroidism and PHP are typically lifelong illnesses, usually (but not always) appearing by adolescence; hence a recent onset of hypocalcemia in an adult is more likely due to nutritional deficiencies, renal failure, or intestinal disorders that result in deficient or ineffective vitamin D. Neck surgery, even long past, however, can be associated with a delayed onset of postoperative hypoparathyroidism. A history of seizure disorder raises the issue of anticonvulsive medication. Developmental defects may point to the diagnosis of PHP. Rickets and a variety of neuromuscular syndromes and deformities may indicate ineffective vitamin D action, either due to defects in vitamin D metabolism or to vitamin D deficiency.

A pattern of *low calcium with high phosphorus* in the absence of renal failure or massive tissue destruction almost invariably means hypoparathyroidism or PHP. A *low calcium and low phosphorus* points to absent or ineffective vitamin D, thereby impairing the action of PTH on calcium metabolism (but not phosphate clearance). The relative ineffectiveness of PTH in calcium homeostasis in vitamin D deficiency, anticonvulsant therapy, gastrointestinal disorders, and hereditary defects in vitamin D metabolism leads to secondary hyperparathyroidism as a compensation. The excess PTH on renal tubule phosphate transport accounts for renal phosphate wasting and hypophosphatemia.

Exceptions to these patterns may occur. Most forms of hypomagnesemia are due to long-standing nutritional deficiency as seen in chronic alcoholics. Despite the fact that the hypocalcemia is principally due to an acute absence of PTH, phosphate levels are usually low, rather than elevated as in hypoparathyroidism. Chronic renal fail-

ure is often associated with hypocalcemia and hyperphosphatemia, despite secondary hyperparathyroidism.

Diagnosis is usually established by application of the PTH immunoassay, tests for vitamin D metabolites, and measurements of the urinary cyclic AMP response to exogenous PTH. In hereditary and acquired hypoparathyroidism and in severe hypomagnesemia, PTH is either undetectable or in the normal range. This finding in a hypocalcemic patient is supportive of hypoparathyroidism, as distinct from ineffective PTH action, in which even mild hypocalcemia is associated with elevated PTH levels. Hence a failure to detect elevated PTH levels establishes the diagnosis of hypoparathyroidism; elevated levels suggest the presence of secondary hyperparathyroidism, as found in many of the situations in which the hormone is ineffective due to associated abnormalities in vitamin D action. Assays for 25(OH)D and $1,25(OH)_2D$ can be helpful. Low or low normal 25(OH)D indicates vitamin D deficiency due to lack of sunlight, inadequate vitamin D intake, or intestinal malabsorption. A low level of $1,25(OH)_2D$ in the presence of elevated concentrations of PTH suggests ineffective PTH action in disorders such as chronic renal failure, severe vitamin D deficiency, vitamin D–dependent rickets type I, and PHP. Recognition that mild hypocalcemia, rickets, and hypophosphatemia are due to anticonvulsant therapy is made by history.

TREATMENT

Hypocalcemic States The management of hypoparathyroidism, PHP, chronic renal failure, and hereditary defects in vitamin D metabolism involves the use of vitamin D or vitamin D metabolites and calcium supplementation. Vitamin D itself is the least expensive form of vitamin D replacement and is frequently used in the management of uncomplicated hypoparathyroidism and some disorders associated with ineffective vitamin D action. When vitamin D is used prophylactically, as in the elderly or in those with chronic anticonvulsant therapy, there is a wider margin of safety than with the more potent metabolites. However, most of the conditions in which vitamin D is administered chronically for hypocalcemia require amounts 50 to 100 times the daily replacement dose because the formation of $1,25(OH)_2D$ is deficient. In such situations, vitamin D is no safer than the active metabolite because intoxication can occur with high-dose therapy (because of storage in fat). Calcitriol is more rapid in onset of action and also has a short biologic half-life.

Vitamin D [200 U (5 μg/d)] or calcifediol and lower doses of calcitriol (0.25 to 1.0 μg/d) are required to prevent rickets in normal individuals. In contrast, 40,000 to 12,000 U (1 to 3 mg) of vitamin D_2 or D_3 is typically required in hypoparathyroidism; doses of calcifediol are also high (several hundred micrograms per day). The dose of calcitriol is unchanged in hypoparathyroidism, since the defect is in hydroxylation by the 25(OH)D-1α-hydroxylase.

Patients with hypoparathyroidism should be given 2 to 3 g elemental calcium by mouth each day. The two agents, vitamin D or calcitriol and oral calcium, can be varied independently. If hypocalcemia alternates with episodes of hypercalcemia in more brittle patients with hypoparathyroidism, administration of calcitriol and use of thiazides, as discussed above, may make management easier.

333 OSTEOPOROSIS

Robert Lindsay, Felicia Cosman

Osteoporosis, a condition characterized by decreased bone strength, is prevalent among postmenopausal women but also occurs in men and women with underlying conditions or major risk factors associated with bone demineralization. Its chief clinical manifestations are vertebral and hip fractures, although fractures can occur at any skeletal site. Osteoporosis affects >10 million individuals in the United States, but only a small proportion are diagnosed and treated.

DEFINITION *Osteoporosis* is defined as a reduction of bone mass (or density) or the presence of a fragility fracture. Loss of bone tissue causes deterioration in the architecture of the skeleton, the combination leading to a markedly increased risk of fracture. Based on recommendation of a WHO committee, osteoporosis is defined operationally as a bone density that falls 2.5 standard deviations (SD) below the mean for young healthy adults of the same race and gender—also referred to as a *T-score* of −2.5. Those who fall at the lower end of the young normal range (a T-score of >1 SD below the mean) are defined as having low bone density and are considered to be at increased risk of osteoporosis.

EPIDEMIOLOGY In the United States, as many as 8 million women and 2 million men have osteoporosis (T-score < −2.5), and an additional 18 million individuals have bone mass levels that put them at increased risk of developing osteoporosis (e.g., bone mass T-score < −1.0). Osteoporosis occurs more frequently with increasing age as bone tissue is progressively lost. In women, the loss of ovarian function at menopause (typically about age 50) precipitates rapid bone loss such that most women meet the diagnostic criteria for osteoporosis by age 70 to 80.

The epidemiology of fractures follows similar trends as bone density loss. Fractures of the distal radius increase in frequency before age 50 and plateau by age 60, with only a modest age-related increase thereafter. In contrast, incidence rates for hip fractures double every 5 years after age 70 (Fig. 333-1). This distinct epidemiology may be related to the way people fall as they age, with fewer falls on an outstretched hand and more directly on the hip. At least 1.5 million fractures occur each year in the United States as a consequence of osteoporosis. As the population continues to age, the total number of fractures will continue to escalate.

About 300,000 hip fractures occur each year in the United States, most of which require hospital admission and surgical intervention. The probability that a 50-year-old white individual will have a hip fracture during his or her lifetime is 14% for women and 5% for men; the risk for African Americans is lower (about half these rates). Hip fractures are associated with a high incidence of deep vein thrombosis and pulmonary embolism (20 to 50%) and a mortality rate between 5 and 20% during the year after surgery.

There are about 700,000 vertebral crush fractures per year in the United States. Only a fraction of these are recognized clinically, since many are relatively asymptomatic and are identified incidentally during radiography for other purposes (Fig. 333-2). Vertebral fractures rarely require hospitalization but are associated with long-term morbidity and a slight increase in mortality. Multiple fractures lead to height loss (often of several inches), kyphosis, and secondary pain and discomfort related to altered biomechanics of the back. Thoracic frac-

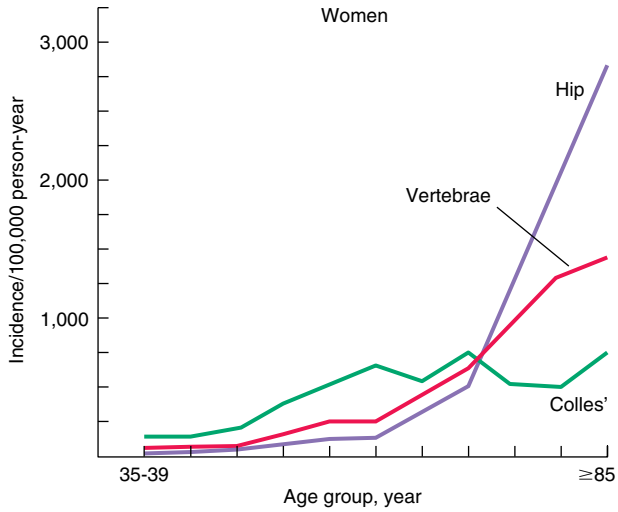

FIGURE 333-1 Epidemiology of vertebral, hip, and Colles' fractures with age. [*Adapted from LJ Melton III, in BL Riggs, LJ Melton II (eds): Osteoporosis: Etiology, Diagnosis and Management, 2d ed. Rochester, MN, Mayo Foundation, 1995.*]

tures can be associated with restrictive lung disease, whereas lumbar fractures are associated with abdominal symptoms including distention, early satiety, and constipation.

Approximately 250,000 wrist fractures occur in the United States each year. Fractures of other bones (estimated to be about 300,000 per year) also occur with osteoporosis, which is not surprising given that bone loss is a systemic phenomenon. Fractures of the pelvis and proximal humerus are clearly associated with osteoporosis. Although some fractures are the result of major trauma, the threshold for fracture is reduced for an osteoporotic bone (Fig. 333-3). A list of common risk factors for osteoporotic fractures is summarized in Table 333-1. Prior fractures, a family history of osteoporotic fractures, and low body weight are each independent predictors of fracture. Chronic diseases that increase the risk of falling or frailty, including dementia, Parkinson's disease, and multiple sclerosis, also increase fracture risk.

In the United States and Europe, osteoporosis-related fractures are more common among women than men, presumably due to a lower peak bone mass as well as postmenopausal bone loss in women. However, this gender difference in bone density and age-related increase in hip fractures is not as apparent in some other cultures, possibly due to genetics, physical activity level, or diet.

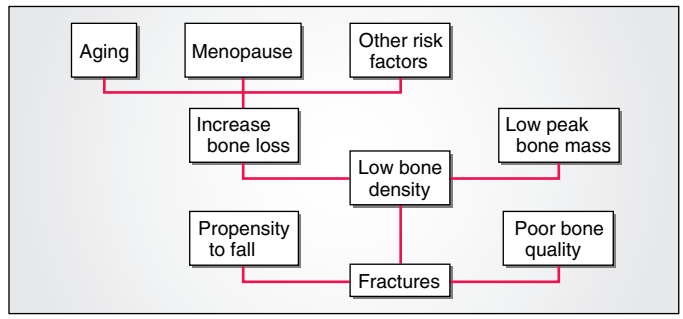

FIGURE 333-3 Factors leading to osteoporotic fractures.

PATHOPHYSIOLOGY ■ Bone Remodeling Osteoporosis results from bone loss due to normal age-related changes in bone remodeling as well as extrinsic and intrinsic factors that exaggerate this process. These changes may be superimposed on a low peak bone mass. Consequently, understanding the bone remodeling process is fundamental to understanding the pathophysiology of osteoporosis (Chap. 331). The skeleton increases in size by linear growth and by apposition of new bone tissue on the outer surfaces of the cortex (Fig. 333-4). This latter process is called *modeling*, a process that also allows the long bones to adapt in shape to the stresses placed upon them. Increased sex hormone production at puberty is required for skeletal maturation, which reaches maximum mass and density in early adulthood. Nutrition and life-style also play an important role in growth, though genetic factors are the major determinants of peak skeletal mass and density. Numerous genes control skeletal growth, peak bone mass, and body size, but it is likely that separate genes control skeletal structure and density. Heritability estimates of 50 to 80% for bone density and size have been derived based on twin studies. Though peak bone mass is often lower among individuals with a family history of osteoporosis, association studies of candidate genes [vitamin D receptor; type I collagen, the estrogen receptor (ER), interleukin (IL) 6; and insulin-like growth factor (IGF) I] and bone mass, bone turnover, and fracture prevalence have been inconsistent. Linkage studies suggest that a genetic locus on chromosome 11 is associated with high bone mass. Recently, a family with extremely high bone mass was identified with a point mutation in LRP 5, a low-density lipoprotein receptor–related protein.

Bone remodeling has two primary functions: (1) to repair microdamage within the skeleton to maintain skeletal strength, and (2) to supply calcium from the skeleton to maintain serum calcium. Remodeling may be activated by microdamage to bone as a result of excessive or accumulated stress. Acute demands for calcium involve osteoclast-mediated resorption as well as calcium transport by osteocytes.

Bone remodeling is also regulated by several circulating hormones, including estrogens, androgens, vitamin D, and parathyroid hormone (PTH), as well as locally produced growth factors such as IGF-I and -II, transforming growth factor (TGF) β, parathyroid hormone–related peptide (PTHrP), ILs, prostaglandins, and tumor necrosis factor

TABLE 333-1 Risk Factors for Osteoporosis Fracture

Nonmodifiable	Estrogen deficiency
Personal history of fracture as an adult	Early menopause (<45 years) or bilateral ovariectomy
History of fracture in first-degree relative	Prolonged premenstrual amenorrhea (>1 year)
Female sex	Low calcium intake
Advanced age	Alcoholism
Caucasian race	Impaired eyesight despite adequate correction
Dementia	Recurrent falls
Potentially modifiable	Inadequate physical activity
Current cigarette smoking	Poor health/frailty
Low body weight [<58 kg (127 lb)]	

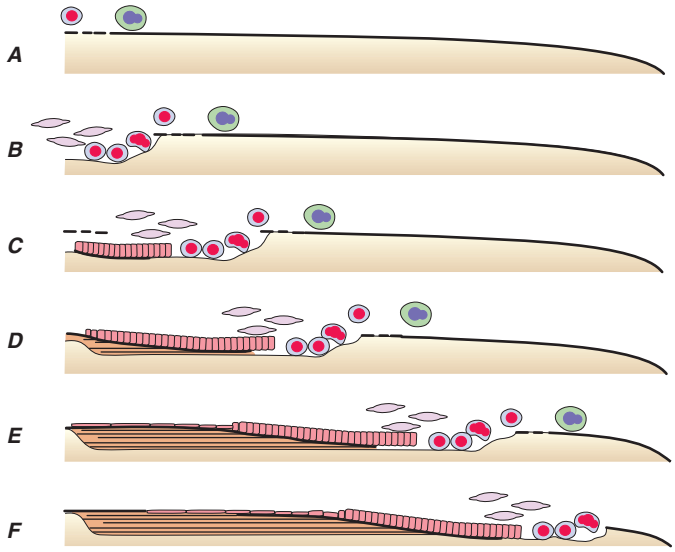

FIGURE 333-4 Mechanism of bone remodeling. The basic molecular unit (BMU) moves along the trabecular surface at a rate of about 10 μm/d. The figure depicts remodeling over ~120 days. *A*. Origination of BMU-lining cells contract to expose collagen and attract preosteoclasts. *B*. Osteoclasts fuse into multinucleated cells that resorb a cavity. Mononuclear cells continue resorption and preosteoblasts are stimulated to proliferate. *C*. Osteoblasts align at bottom of cavity and start forming osteoid (black). *D*. Osteoblasts continue formation and mineralization. Previous osteoid starts to mineralize (horizontal lines). *E*. Osteoblasts begin to flatten. *F*. Osteoblasts turn into lining cells; bone remodeling at initial surface (left of drawing) is now complete, but BMU is still advancing (to the right). [*Adapted from: SM Ott, in JP Bilezikian et al (eds): Principles of Bone Biology, vol. 18. San Diego, Academic Press, 1996, pp 231–241.*]

(TNF). The cytokine responsible for communication between the osteoblast and osteoclast has been identified as RANK or osteoprotegerin ligand (Chap. 331). The osteoclast receptor for this protein is referred to as RANK. A humoral decoy for RANK ligand is referred to as osteoprotegerin (Fig. 333-5). Modulation of osteoclast recruitment and activity appears to be related to the interplay among these three factors.

Additional influences include nutrition (particularly calcium intake) and physical activity level. The end result of this remodeling process is that the resorbed bone is replaced by an equal amount of new bone tissue. Thus, the mass of the skeleton remains constant after peak bone mass is achieved in adulthood. After age 30 to 45, however, the resorption and formation processes become imbalanced, and resorption exceeds formation. This imbalance may begin at different ages and varies at different skeletal sites; it becomes exaggerated in women after menopause. Excessive bone loss can be due to an increase in osteoclastic activity and/or a decrease in osteoblastic activity. In addition, an increase in remodeling activation frequency can magnify the small imbalance seen at each remodeling unit.

In trabecular bone, if the osteoclasts penetrate trabeculae, they leave no template for new bone formation to occur and, consequently, may cause rapid bone loss. In cortical bone, increased activation of remodeling creates more porous bone. The effect of this increased porosity on cortical bone strength may be modest if the overall diameter of the bone is not changed. However, decreased apposition of new bone on the periosteal surface coupled with increased endocortical resorption of bone decreases the biomechanical strength of long bones. Even a slight exaggeration in normal bone loss increases the risk of osteoporotic fracture.

Calcium Nutrition Peak bone mass may be impaired by inadequate calcium intake during growth among other nutritional factors (calories, protein, and other minerals), thereby leading to increased risk of osteoporosis later in life. During the adult phase of life, insufficient calcium intake induces secondary hyperparathyroidism and an increase in the rate of remodeling to maintain normal serum calcium levels. PTH stimulates the hydroxylation of vitamin D in the kidney, leading to increased levels of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] and enhanced gastrointestinal calcium absorption. PTH also reduces renal calcium loss. Although these are appropriate short-term homeostatic responses for adjusting calcium economy, the long-term effects are detrimental to the skeleton because of the ongoing imbalance at remodeling sites.

Total daily calcium intakes of <400 mg are likely to be detrimental to the skeleton, but there are fewer data about intakes in the 600- to 800-mg range, which is the average intake among adults in the United States. The recommended daily required intake of 1000 to 1200 mg for adults accommodates population heterogeneity in controlling calcium balance (Chap. 60).

Vitamin D (See also Chap. 331) Severe vitamin D deficiency causes rickets in children or osteomalacia in adults. There is accumulating evidence that vitamin D deficiency may be more prevalent than previously thought, particularly among individuals at increased risk, such as the elderly; those living in northern latitudes; and in individuals with poor nutrition, malabsorption, or chronic liver or renal disease. Modest vitamin D deficiency [25-hydroxyvitamin D levels ≤50 nmol/L (20 ng/mL)] leads to compensatory secondary hyperparathyroidism and is an important risk factor for osteoporosis and fractures. Some studies have shown that >50% of inpatients on a general medical service exhibit biochemical features of vitamin D deficiency, including increased levels of PTH and alkaline phosphatase and lower levels of ionized calcium. In women living in northern latitudes, it has been shown that vitamin D levels decline during the winter months. This is associated with a striking seasonal bone loss, reflecting increased bone turnover. Even among healthy ambulatory individuals, mild vitamin D deficiency is increasing in prevalence. Treatment with vitamin D can return vitamin D levels to normal [>50 μmol/L (20 ng/mL)] and prevent the associated increase in bone remodeling, bone loss, and fractures. Reduced fracture rates have also been documented among individuals in northern latitudes who have greater vitamin D intake and have higher 25-hydroxyvitamin D [25(OH)D] levels (see below).

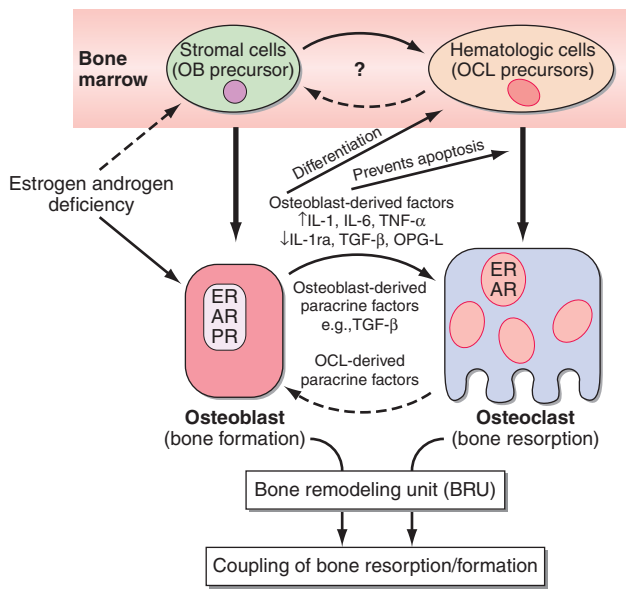

FIGURE 333-5 Steroid actions and interactions with growth factors/cytokines in bone cells at bone resorption and formation sites. Estrogen inhibits osteoclasts (OCL), cells that mediate bone resorption; estrogen stimulates osteoblasts (OB), cells that mediate bone formation. OBs produce many growth factors and cytokines that mediate estrogen action, some of which regulate the OCL indirectly. Estrogen deficiency stimulates OB production of IL-1, IL-6, and TNF-α (and inhibits apoptosis and extends the life span of OCLs). Estrogen deficiency decreases IL-1ra leading to enhanced OCL sensitivity to IL-1. Estrogen deficiency also decreases production of TGF-β and OPG-L, factors that mediate osteoclast apoptosis. Solid lines indicate well-documented pathways. Dashed lines indicate less well defined pathways. ER, estrogen receptor; AR, androgen receptor; OPG, osteoprotegerin; OPG-L, osteoprotegerin-ligand; IL, interleukin; IL-1ra, interleukin 1 receptor antagonist; TGF-β, transforming growth factor β; TNF-α, tumor necrosis factor α. (*Adapted from TC Spelsberg et al: Mol Endocrinol 13:819, 1999.*)

Estrogen Status Estrogen deficiency probably causes bone loss by two distinct but interrelated mechanisms: (1) activation of new bone remodeling sites, and (2) exaggeration of the imbalance between bone formation and resorption. The change in activation frequency causes a transient bone loss until a new steady state between resorption and formation is achieved. The remodeling imbalance, however, results in a permanent decrement in mass that can only be corrected by a remodeling event during which bone formation exceeds resorption. In addition, the very presence of more remodeling sites in the skeleton increases the probability that trabeculae will be penetrated, thereby eliminating the template upon which new bone can be formed and accelerating the loss of bony tissue.

The most frequent estrogen-deficient state is the cessation of ovarian function at the time of menopause, which occurs on average at the age of 51. Thus, with current life expectancy, an average woman will spend about 30 years without ovarian supply of estrogen. The mechanism by which estrogen deficiency causes bone loss is summarized in Fig. 333-5. Marrow cells (macrophages, monocytes, osteoclast precursors, mast cells) as well as bone cells (osteoblasts, osteocytes, osteoclasts) express ERs α and β. The net effect of estrogen deficiency is increased osteoclast recruitment and perhaps activity. Estrogen may also play an important role in determining the life span of bone cells by controlling the rate of apoptosis. Thus, in situations of estrogen deprivation, the life span of osteoblasts may be decreased whereas the longevity of osteoclasts is increased.

Since remodeling is initiated at the surface of bone, it follows that trabecular bone—which has a considerably larger surface area (80% of the total) than cortical bone—will be preferentially affected by estrogen deficiency. Fractures occur earliest at sites where trabecular bone contributes most to bone strength; consequently, vertebral fractures are the most common early consequence of estrogen deficiency.

Physical Activity Inactivity, such as prolonged bed rest or paralysis, results in significant bone loss. Concordantly, athletes have higher bone mass than the general population. These changes in skeletal mass are most marked when the stimulus begins during growth and before the age of puberty. Adults are less capable than children of increasing bone mass following restoration of physical activity. Epidemiologic data support the beneficial effects on the skeleton of chronic high levels of physical activity. Fracture risk is lower in rural communities and in countries where physical activity is maintained into old age. However, when exercise is initiated during adult life, the effects of moderate exercise are modest, with a bone mass increase of 1 to 2% in short-term studies of <2 years duration. It is argued that more active individuals are less likely to fall and are more capable of protecting themselves upon falling, thereby reducing fracture risk.

Chronic Disease Various genetic and acquired diseases are associated with an increase in the risk of osteoporosis (Table 333-2). Mechanisms that contribute to bone loss are unique for each disease and typically result from multiple factors including nutrition, reduced physical activity levels, and factors that affect bone-remodeling rates.

Medications A large number of medications used in clinical practice have potentially detrimental effects on the skeleton (Table 333-3). *Glucocorticoids* are the most common cause of medication-induced osteoporosis. It is often not possible to determine the extent to which osteoporosis is related to the glucocorticoid or to other factors, as treatment is superimposed on the effects of the primary disease, which may in itself be associated with bone loss (e.g., rheumatoid arthritis). Excessive doses of thyroid hormone can accelerate bone remodeling and result in bone loss.

Other medications have less detrimental effects upon the skeleton than pharmacologic doses of glucocorticoids. *Anticonvulsants* are thought to increase the risk of osteoporosis, although many affected individuals have concomitant vitamin D insufficiency, as some anticonvulsants induce the cytochrome P450 system and vitamin D metabolism. Patients undergoing transplantation are at high risk for rapid bone loss and fracture not only from glucocorticoids but also from treatment with other *immunosuppressants*, such as cyclosporine and tacrolimus (FK506). In addition, these patients often have underlying metabolic abnormalities, such as hepatic or renal failure, that predispose to bone loss.

TABLE 333-2 Diseases Associated with an Increased Risk of Generalized Osteoporosis in Adults

Hypogonadal states	Hematologic disorders/malignancy
Turner syndrome	Multiple myeloma
Klinefelter syndrome	Lymphoma and leukemia
Anorexia nervosa	Malignancy-associated parathyroid hormone (PTHrP) production
Hypothalamic amenorrhea	Mastocytosis
Hyperprolactinemia	Hemophilia
Other primary or secondary hypogonadal states	Thalassemia
Endocrine disorders	Selected inherited disorders
Cushing's syndrome	Osteogenesis imperfecta
Hyperparathyroidism	Marfan syndrome
Thyrotoxicosis	Hemochromatosis
Type 1 diabetes mellitus	Hypophosphatasia
Acromegaly	Glycogen storage diseases
Adrenal insufficiency	Homocystinuria
Nutritional and gastrointestinal disorders	Ehlers-Danlos syndrome
Malnutrition	Porphyria
Parenteral nutrition	Menkes' syndrome
Malabsorption syndromes	Epidermolysis bullosa
Gastrectomy	Other disorders
Severe liver disease, especially biliary cirrhosis	Immobilization
Pernicious anemia	Chronic obstructive pulmonary disease
Rheumatologic disorders	Pregnancy and lactation
Rheumatoid arthritis	Scoliosis
Ankylosing spondylitis	Multiple sclerosis
	Sarcoidosis
	Amyloidosis

Cigarette Consumption The use of cigarettes over a long period has detrimental effects on bone mass. These effects may be mediated directly, by toxic effects on osteoblasts, or indirectly by modifying estrogen metabolism. On average, cigarette smokers reach menopause 1 to 2 years earlier than the general population. Cigarette smoking also produces secondary effects that can modulate skeletal status, including intercurrent respiratory and other illnesses, frailty, decreased exercise, poor nutrition, and the need for additional medications (e.g., glucocorticoids for lung disease).

MEASUREMENT OF BONE MASS

Several noninvasive techniques are now available for estimating skeletal mass or density. These include dual-energy x-ray absorptiometry (DXA), single-energy x-ray absorptiometry (SXA), quantitative computed tomography (CT), and ultrasound.

DXA is a highly accurate x-ray technique that has become the standard for measuring bone density in most centers. Though it can be used for measurements of any skeletal site, clinical determinations are usually made of the lumbar spine and hip. Portable DXA machines have been developed that measure the heel (calcaneus), forearm (radius and ulna), or finger (phalanges). DXA can also be used to measure body composition. In the DXA technique, two x-ray energies are used to estimate the area of mineralized tissue, and the mineral content is divided by the area, which partially corrects for body size. However, this correction is only partial since DXA is a two-dimensional scanning technique and cannot estimate the depths or posteroanterior length of the bone. Thus, small people tend to have lower-than-average bone

TABLE 333-3 Drugs Associated with an Increased Risk of Generalized Osteoporosis in Adults

Excessive alcohol	Lithium

mineral density (BMD). Bone spurs, which are frequent in osteoarthritis, tend to falsely increase bone density of the spine. Because DXA instrumentation is provided by several different manufacturers, the output varies in absolute terms. Consequently, it has become standard practice to relate the results to "normal" values using T-scores, which compare individual results to those in a young population that is matched for race and gender. Z-scores compare individual results to those of an age-matched population that is also matched for race and gender. Thus, a 60-year-old woman with a Z-score of −1 (1 SD below mean for age) has a T-score of −2.5 (2.5 SD below mean for a young control group) (Fig. 333-6).

CT is used primarily to measure the spine, and peripheral CT is used to measure bone in the forearm or tibia. Research into the use of CT for measurement of the hip is ongoing. The results obtained from CT are different from all others currently available since this technique specifically analyzes trabecular bone in vertebrae, eliminating posterior cortical elements of the spine, and can provide a true density (mass of bone per unit volume) measurement. However, CT remains expensive, involves greater radiation exposure, and is less reproducible.

Ultrasound is used to measure bone mass by calculating the attenuation of the signal as it passes through bone or the speed with which it traverses the bone. It is unclear whether ultrasound assesses bone quality, but this may be an advantage of the technique. Because of its relatively low cost and mobility, ultrasound is amenable for use as a screening procedure.

All of these techniques for measuring BMD have been approved by the U.S. Food and Drug Administration (FDA) based upon their capacity to predict fracture risk. The hip is the preferred site of measurement in most individuals, since it predicts the risk of hip fracture, the most important consequence of osteoporosis, better than any other bone density measurement site. When hip measurements are performed by DXA, the spine can be measured at the same time. In younger individuals, such as perimenopausal or early postmenopausal women, spine measurements may be the most sensitive indicator of bone loss.

When to Measure Bone Mass Clinical guidelines developed by the National Osteoporosis Foundation recommend bone mass measurements in postmenopausal women, assuming they have risk factors for osteoporosis in addition to age, gender, and estrogen deficiency. The guidelines further recommend that bone mass measurement be considered in *all* women by age 65, a position ratified by the U.S. Preventive Health Services Task Force. Criteria approved for Medicare reimbursement of BMD are summarized in Table 333-4.

When to Treat Based Upon Bone Mass Results Several guidelines suggest that patients be considered for treatment when BMD is >2.5 SD below the mean value for young adults (T-score ≤ −2.5). Treatment should also be considered in postmenopausal women with risk factors if BMD of the hip is <−2.0. Because the fracture risk increases continuously as T-scores decline, there is no critical threshold and treatment decisions must be individualized. Clearly clinical status must be evaluated carefully, considering age, prior fracture history, weight, and family history of osteoporosis. Moreover, high bone turnover, particularly in older individuals, should be considered an independent risk factor for fracture and should prompt treatment at a higher BMD level.

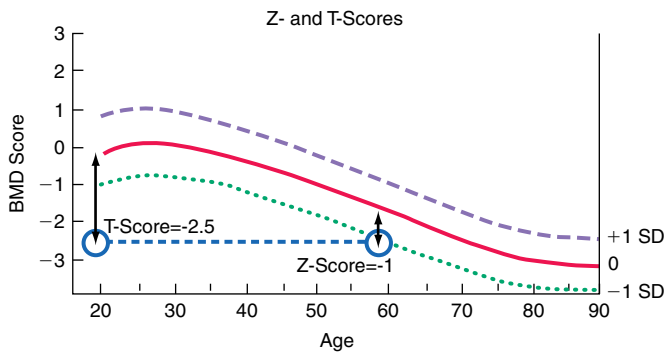

FIGURE 333-6 Relationship between Z-scores and T-scores in a 60-year-old woman (BMD, bone mineral density; SD, standard deviation).

TABLE 333-4 FDA-Approved Indications for BMD Tests[a]

Estrogen-deficient women at clinical risk of osteoporosis
Vertebral abnormalities on x-ray suggestive of osteoporosis (osteopenia, vertebral fracture)
Glucocorticoid treatment equivalent to ≥7.5 mg of prednisone, or duration of therapy >3 months
Primary hyperparathyroidism
Monitoring response to an FDA-approved medication for osteoporosis
Repeat BMD evaluations at >23-month intervals, or more frequently, if medically justified

[a] Criteria adapted from the 1998 Bone Mass Measurement Act.
Note: FDA, U.S. Food and Drug Administration; BMD, bone mineral density.

APPROACH TO THE PATIENT

The perimenopausal transition is a good opportunity to initiate discussion about risk factors for osteoporosis and to consider indications for a BMD test. A careful history and physical examination should be performed to identify risk factors for osteoporosis. A low Z-score increases the suspicion of a secondary disease. Height loss >2.5 to 3.8 cm (>1 to 1.5 in.) is an indication for radiography to rule out asymptomatic vertebral fractures, as is the presence of significant kyphosis or back pain, particularly if it began after menopause. For patients who present with fractures, it is important to ensure that the fractures are not caused by an underlying malignancy. Usually this is clear on routine radiography, but on occasion, CT, magnetic resonance imaging, or radionuclide scans may be necessary.

Routine Laboratory Evaluation There is no established algorithm for the evaluation of women presenting with osteoporosis. A general evaluation that includes complete blood count, serum calcium, and perhaps urine calcium is helpful for identifying selected secondary causes of low bone mass, particularly for women with fractures or very low Z-scores. An elevated serum calcium level suggests hyperparathyroidism or malignancy, whereas a reduced serum calcium level may reflect malnutrition and osteomalacia. In the presence of hypercalcemia, a serum PTH level differentiates between hyperparathyroidism (PTH↑) and malignancy (PTH↓), and a high PTHrP level can help document the presence of humoral hypercalcemia of malignancy (Chap. 332). A low urine calcium (<50 mg/24 h) suggests osteomalacia, malnutrition, or malabsorption; a high urine calcium (>300 mg/24 h) is indicative of hypercalciuria and must be investigated further. Hypercalciuria occurs primarily in three situations: (1) a renal calcium leak, which is more frequent in males with osteoporosis; (2) absorptive hypercalciuria, which can be idiopathic or associated with increased $1,25(OH)_2D$ in granulomatous disease; or (3) hematologic malignancies or conditions associated with excessive bone turnover such as Paget's disease, hyperparathyroidism, and hyperthyroidism.

Possible hyperthyroidism can be evaluated by measuring thyroid-stimulating hormone (TSH). When there is clinical suspicion of Cushing's syndrome, urinary free cortisol levels or a fasting serum cortisol should be measured after overnight dexamethasone. When bowel disease, malabsorption, or malnutrition is suspected, serum albumin, cholesterol, and a complete blood count should be checked. Asymptomatic malabsorption might be heralded by anemia (macrocytic-vitamin B_{12} or folate deficiency; or microcytic-iron deficiency) or low serum cholesterol or urinary calcium levels. If these or other features suggest malabsorption, further evaluation is required. Asymptomatic celiac disease with selective malabsorption is being found with increasing prevalence; the diagnosis can be made by testing for antigliadin, antiendomysial, or transglutam-

inase antibodies but may require endoscopic biopsy. A trial of a gluten-free diet can be confirmatory (Chap. 275). When osteoporosis is found associated with symptoms of rash, multiple allergies, diarrhea, or flushing, mastocytosis should be excluded using 24-h urine histamine collection or serum tryptase.

Myeloma can masquerade as generalized osteoporosis, although it more commonly presents with bone pain and characteristic "punched-out" lesions on radiography. Serum and urine electrophoresis and evaluation for light chains in urine are required to exclude this diagnosis. A bone marrow biopsy may be required to rule out myeloma (in patients with equivocal electrophoretic results) and can also be used to exclude mastocytosis, leukemia, and other marrow infiltrative disorders, such as Gaucher's disease.

Bone Biopsy Tetracycline labeling of the skeleton allows determination of the rate of remodeling as well as evaluation for other metabolic bone diseases. The current use of BMD tests, in combination with hormonal evaluation and biochemical markers of bone remodeling, has largely replaced bone biopsy.

Biochemical Markers Several biochemical tests are now available that provide an index of the overall rate of bone remodeling (Table 333-5). Biochemical markers are usually characterized as those related primarily to *bone formation* or *bone resorption*. These tests measure the overall state of bone remodeling at a single point in time. Clinical use of these tests has been hampered by biologic variability (in part related to circadian rhythm) as well as to analytical variability.

For the most part, remodeling markers do not predict rates of bone loss well enough to use this information clinically. However, markers of bone resorption may help in the prediction of fracture risk, particularly in older individuals. In women ≥65 years, when bone density results are greater than the usual treatment thresholds noted above, a high level of bone resorption should prompt consideration of treatment. The primary use of biochemical markers is for monitoring the response to treatment. With the introduction of antiresorptive therapeutic agents, bone remodeling declines rapidly, with the fall in resorption occurring earlier than the fall in formation. Inhibition of bone resorption is maximal within 3 to 6 months. Thus, measurement of bone resorption prior to initiating therapy and 4 to 6 months after starting therapy provides an earlier estimate of patient response than does bone densitometry. A decline in resorptive markers can be ascertained after treatment with bisphosphonates or estrogen; this effect is less marked after treatment with either raloxifene or intranasal calcitonin. A biochemical marker response to therapy is particularly useful for asymptomatic patients and might help to ensure long-term compliance. Bone turnover markers are also useful in monitoring the effects of PTH, or teriparatide, which rapidly increases bone formation and later bone resorption.

TREATMENT

Management of Osteoporotic Fractures Treatment of the patient with osteoporosis frequently involves management of acute fractures as well as treatment of the underlying disease. Hip fractures almost always require surgical repair if the patient is to become ambulatory again. Depending on the location and severity of the fracture, condition of the neighboring joint, and general status of the patient, procedures may include open reduction and internal fixation with pins and plates, hemiarthroplasties, and total arthroplasties. These surgical procedures are followed by intense rehabilitation in an attempt to return patients to their prefracture functional level. Long bone fractures often require either external or internal fixation. Other fractures (e.g., vertebral, rib, and pelvic fractures) are usually managed with only supportive care, requiring no specific orthopedic treatment.

Only ~25 to 30% of vertebral compression fractures present with sudden-onset back pain. For acutely symptomatic fractures, treatment with analgesics is required, including nonsteroidal anti-inflammatory agents and/or acetaminophen, sometimes with the addition of a narcotic agent (codeine or oxycodone). A few small, randomized clinical trials suggest that calcitonin may reduce pain related to acute vertebral compression fracture. A recently developed technique involves percutaneous injection of artificial cement (polymethylmethacrylate) into the vertebral body (vertebroplasty or kyphoplasty); this has been reported to offer significant immediate pain relief in the majority of patients. Long-term effects are unknown, and conclusions are based on observational studies in patients with severe persistent back pain from acute or subacute vertebral fractures. There have been no randomized controlled trials of either vertebroplasty or kyphoplasty to date. Short periods of bed rest may be helpful for pain management, but, in general, early mobilization is recommended as it helps prevent further bone loss associated with immobilization. Occasionally, use of a soft elastic-style brace may facilitate earlier mobilization. Muscle spasms often occur with acute compression fractures and can be treated with muscle relaxants and heat treatments.

Severe pain usually resolves within 6 to 10 weeks. Chronic pain is probably not bony in origin; instead, it is related to abnormal strain on muscles, ligaments, and tendons and to secondary facet-joint arthritis associated with alterations in thoracic and/or abdominal shape. Chronic pain is difficult to treat effectively and may require analgesics, sometimes including narcotic analgesics. Frequent intermittent rest in a supine or semireclining position is often required to allow the soft tissues, which are under tension, to relax. Back-strengthening exercises (paraspinal) may be beneficial. Heat treatments help relax muscles and reduce the muscular component of discomfort. Various physical modalities, such as ultrasound and transcutaneous nerve stimulation, may be beneficial in some patients. Pain also occurs in the neck region, not as a result of compression fractures (which almost never occur in the cervical spine as a result of osteoporosis) but because of chronic strain associated from trying to elevate the head in a person with a severe thoracic kyphosis.

Multiple vertebral fractures are often associated with psychological symptoms, not always commonly appreciated. The changes in body configuration and back pain can lead to marked loss of self-image and a secondary depression. Altered balance, precipitated by the kyphosis and the anterior movement of the body's center of gravity, leads to a fear of falling, a consequent tendency to remain indoors, and the onset of social isolation. These symptoms can sometimes be alleviated by family support and/or psychotherapy. Medication may be necessary when depressive features are present.

Management of the Underlying Disease ■ *RISK FACTOR REDUCTION* Patients should be thoroughly educated to reduce the likelihood of risk factors associated with bone loss and falling. Medications should be reviewed to ensure that any glucocorticoid medication is truly indicated and is being given in doses as low as possible. For those on thyroid hormone replacement, TSH testing should be performed to determine that an excessive dose is not being used, as thyrotoxicosis can be associated with increased bone loss. In patients who smoke, efforts should be made to facilitate smoking cessation. Reducing risk factors for falling

also includes alcohol abuse treatment and a review of the medical regimen for any drugs that might be associated with orthostatic hypotension and/or sedation, including hypnotics and anxiolytics. If nocturia occurs, the frequency should be reduced, if possible (e.g., by decreasing or modifying diuretic use), as arising in the middle of sleep is a common precipitant of a fall. Patients should be instructed about environmental safety with regard to eliminating exposed wires, curtain strings, slippery rugs, and mobile tables. Avoiding stocking feet on wood floors, checking carpet condition (particularly on stairs), and providing good light in paths to bathrooms and outside the home are important preventive measures. Treatment for impaired vision is recommended, particularly a problem with depth perception, which is specifically associated with increased falling risk. Elderly patients with neurologic impairment (e.g., stroke, Parkinson's disease, Alzheimer's disease) are particularly at risk of falling and require specialized supervision and care.

NUTRITIONAL RECOMMENDATIONS ■ *Calcium* A large body of data indicates that optimal calcium intake reduces bone loss and suppresses bone turnover. Recommended intakes from a recent report from the Institute of Medicine are shown in Table 333-6. The National Health and Nutritional Evaluation Studies (NHANES) have consistently documented that average calcium intakes fall considerably short of these recommendations. The preferred source of calcium is from dairy products and other foods, but many patients require calcium supplementation. Food sources of calcium are dairy products (milk, yogurt, and cheese) and fortified foods such as certain cereals, waffles, snacks, juices, and crackers. Some of these fortified foods contain as much calcium per serving as milk.

If a calcium supplement is required, it should be taken in doses ≤600 mg at a time, as the calcium absorption fraction decreases at higher doses. Calcium supplements should be calculated based on the elemental calcium content of the supplement, not the weight of the calcium salt (Table 333-7). Calcium supplements containing carbonate are best taken with food since they require acid for solubility. Calcium citrate supplements can be taken at any time.

Several controlled clinical trials of calcium plus vitamin D have confirmed reductions in clinical fractures, including fractures of the hip (~20 to 30% risk reduction). All recent studies of pharmacologic agents have been conducted in the context of calcium replacement (± vitamin D). Thus, it is standard practice to ensure an adequate calcium and vitamin D intake in patients with osteoporosis, whether they are receiving additional pharmacologic therapy or not.

Although side effects from supplemental calcium are minimal, individuals with a history of kidney stones should have a 24-h urine calcium determination before starting increased calcium to avoid hypercalciuria.

Vitamin D Vitamin D is synthesized in skin under the influence of heat and ultraviolet light (Chap. 331). However, large segments of the population do not obtain sufficient vitamin D to maintain what is now considered an adequate supply [serum 25(OH)D consistently >50 μmol/L (20 ng/mL)]. Since vitamin D supplementation at doses that would achieve these serum levels is safe and inexpensive, the Institute of Medicine recommends daily intakes of 200 IU for adults <50 years of age, 400 IU for those from 50 to 70 years, and 600 IU for those >70 years. Multivitamin tablets usually contain 400 IU, and many calcium supplements also contain vitamin D. Some data suggest that higher doses may be required in the elderly and chronically ill.

TABLE 333-6 *Adequate Calcium Intake*

Life Stage Group	Estimated Adequate Daily Calcium Intake, mg/d
Young children (1–3 years)	500
Older children (4–8 years)	800
Adolescents and young adults (9–18 years)	1300
Men and women (19–50 years)	1000
Men and women (51 and older)	1200

Note: Pregnancy and lactation needs are the same as for nonpregnant women (e.g., 1300 mg/d for adolescents/young adult and 1000 mg/d for ≥19 years.)

Other Nutrients Other nutrients such as salt and caffeine may have modest effects on calcium excretion or absorption. Adequate vitamin K status is required for optimal carboxylation of osteocalcin. States in which vitamin K nutrition or metabolism is impaired, such as with long-term warfarin therapy, have been associated with reduced bone mass.

Magnesium is abundant in foods, and magnesium deficiency is quite rare in the absence of a serious chronic disease. Magnesium supplementation may be warranted in patients with inflammatory bowel disease, celiac disease, chemotherapy, severe diarrhea, malnutrition, or alcoholism. Dietary phytoestrogens, which are derived primarily from soy products and legumes (e.g., garbanzo beans, chickpeas, and lentils), exert some estrogenic activity but are insufficiently potent to justify their use in place of a pharmacologic agent in the treatment of osteoporosis.

Patients with hip fracture are often frail and relatively malnourished. Some data suggest an improved outcome in such patients when they are provided calorie and protein supplementation. Excessive protein intake can increase renal calcium excretion but this can be corrected by an adequate calcium intake.

EXERCISE Exercise in young individuals increases the likelihood that they will attain the maximal genetically determined peak bone mass. Meta-analyses of studies performed in postmenopausal women indicate that weight-bearing exercise prevents bone loss but does not appear to result in substantial gain of bone mass. This beneficial effect wanes if exercise is discontinued. Exercise also has beneficial effects on neuromuscular function, and it improves coordination, balance, and strength, thereby reducing the risk of falling. A walking program is a practical way to start. Other activities such as dancing, racquet sports, cross-country skiing, and use of gym equipment are also recommended, depending on the patient's personal preference. Even women who cannot walk benefit from swimming or water exercises, not so much for the effects on bone, which are quite minimal, but because of effects on muscle. Exercise habits should be consistent, optimally at least three times a week.

Pharmacologic Therapies Until fairly recently, estrogen treatment, either by itself or in concert with a progestin, was the primary therapeutic agent for prevention or treatment of osteoporosis. Over the past 10 years, a number of new drugs have appeared, and more are expected in the near future. Some are agents that specifically treat osteoporosis (bisphosphonates, calcitonin, PTH); others, such as selective estrogen response modulators (SERMs), have broader effects. The availability of these drugs allows therapy to be tailored to the needs of an individual patient.

ESTROGENS A large body of clinical trial data indicates that various types of estrogens (conjugated equine estrogens, estradiol, estrone, esterified estrogens, ethinyl estradiol, and mestranol) reduce bone turn-

over, prevent bone loss, and induce small increases in bone mass of the spine, hip, and total body. The effects of estrogen are seen in women with natural or surgical menopause and in late postmenopausal women with or without established osteoporosis. Estrogens are efficacious when administered orally or transdermally. For both oral and transdermal routes of administration, combined estrogen/progestin preparations are now available in many countries, obviating the problem of taking two tablets or using a patch and oral progestin. One large study, referred to as PEPI (Postmenopausal Estrogen/Progestin Intervention Trial), indicated that C-21 progestins alone do not augment the effect of standard estrogen doses on bone mass (Fig. 333-7).

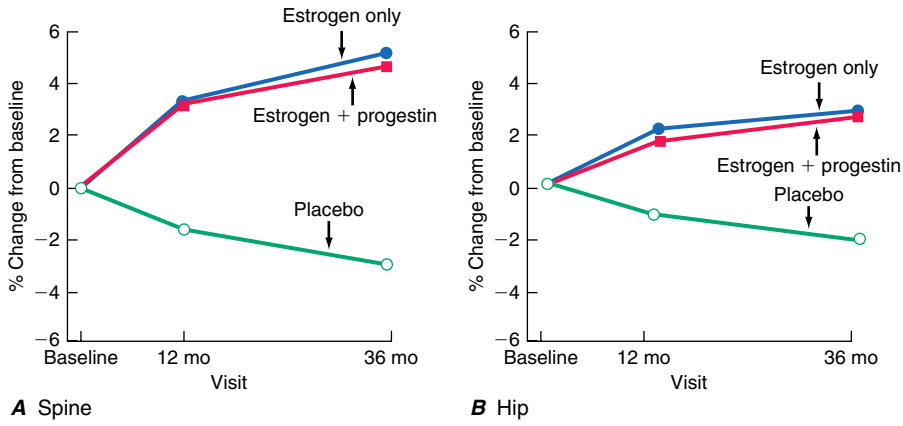

FIGURE 333-7 Results of hormone therapy regimens on bone mineral density (BMD) of the spine (*A*) and hip (*B*). Unadjusted mean percent change in BMD in the hip by treatment assignment and visit: adherent PEPI participants only. Results From the Postmenopausal Estrogen/Progestin Interventions (PEPI) Trial. Estrogen, conjugated equine estrogen 0.625 mg/d; progestin, medroxyprogesterone acetate 10 mg/d. (*Adapted from TL Bush et al: JAMA 276: 1389, 1996.*)

Dose of Estrogen For oral estrogens, the standard recommended doses are 0.3 mg/d for esterified estrogens, 0.625 mg/d for conjugated equine estrogens, and 5μg/d for ethinyl estradiol. For transdermal estrogen, the commonly used dose supplies 50 μg estradiol per day, but a lower dose may be appropriate for some individuals. Dose response data for conjugated equine estrogens indicate that lower doses are effective.

Fracture Data Epidemiologic databases indicate that women who take estrogen replacement have a 50% reduction, on average, of osteoporotic fractures, including hip fractures. The beneficial effect of estrogen is greatest among those who start replacement early and continue the treatment; the benefit declines after discontinuation such that there is no residual protective effect against fracture by 10 years after discontinuation. The first clinical trial evaluating fractures as secondary outcomes, the Heart and Estrogen-Progestin Replacement Study (HERS) trial, showed no effect of hormone therapy against hip or other clinical fractures in women with established coronary artery disease. These data made the results of the Women's Health Initiative (WHI) exceedingly important (Chap. 327). The estrogen-progestin arm of the WHI in >16,000 postmenopausal healthy women indicated that hormone therapy reduces the risk of hip fracture by 34% and all clinical fractures by 24%.

A few clinical trials have evaluated spine fracture occurrence as an outcome with estrogen therapy. One that used high doses of estrogen (2.5 mg/d conjugated equine estrogen) indicated marked vertebral fracture reduction in estrogen-treated women. Several other small studies, using lower estrogen doses, have consistently shown that estrogen treatment reduces the incidence of vertebral compression fracture.

The WHI has now provided a vast amount of data on the multisystemic effects of hormone therapy. Although earlier observational studies suggested that estrogen replacement might reduce heart disease, the WHI showed that combined estrogen-progestin treatment increased risk of fatal and nonfatal myocardial infarction by about 29%, confirming data from the HERS study. Other important relative risks included a 40% increase in stroke, 100% increase in venous thromboembolic disease, and a 26% increase in risk of breast cancer. Subsequent analyses have confirmed the increased risk of stroke and shown a twofold increase in dementia. Benefits other than the fracture reductions noted above included a 37% reduction in risk of colon cancer. These relative risks have to be interpreted in light of absolute risk (Fig. 333-8). For example, out of 10,000 women treated with estrogen-progestin for 1 year, there will be 8 excess heart attacks, 8 excess breast cancers, 18 excess venous thromboembolic events, 5 fewer hip fractures, 44 fewer clinical fractures, and 6 fewer colorectal cancers. These numbers must be multiplied by years of hormone treatment. There was no effect of hormone treatment on risk of uterine cancer or total mortality.

It is important to note that the WHI findings apply specifically to hormone treatment in the form of conjugated equine estrogen plus medroxyprogesterone acetate. Furthermore the relative benefits and risks of unopposed estrogen in women who had hysterectomy are still being evaluated in the estrogen-only arm of the WHI.

Mode of Action Two subtypes of ERs, α and β, have been identified in bone and other tissues. Cells of monocyte lineage express both ERα and -β, as do osteoblasts. Estrogen-mediated effects vary depending on the receptor type. Using ER knockout mouse models, elimination of ERα produces a modest reduction in bone mass, whereas mutation of ERβ has less effect on bone. A male patient with a homozygous mutation of ERα had markedly decreased bone density as well as abnormalities in epiphyseal closure, confirming the important role of ERα in bone biology. The mechanism of estrogen action in bone is an area of active investigation (Fig. 333-5). Although data are conflicting, estrogens may inhibit osteoclasts directly. However, the majority of estrogen (and androgen) effects on bone resorption are mediated indirectly through paracrine factors produced by osteoblasts. These actions include: (1) increasing IGF-I and TGF-β, and (2) suppressing IL-1 (α and β), IL-6, TNF-α, and osteocalcin synthesis. The indirect estrogen actions primarily decrease bone resorption.

PROGESTINS In women with a uterus, daily progestin or cyclical progestins at least 12 days per month are prescribed in combination with estrogens to reduce the risk of uterine cancer. Medroxyprogesterone acetate and norethindrone acetate blunt the high-density lipoprotein response to estrogen, but micronized progesterone does not. Neither medroxyprogesterone acetate nor micronized progesterone appears to have an independent effect on bone; at lower doses, norethindrone acetate might have an additive benefit. On breast tissue, progestins may increase the risk of breast cancer.

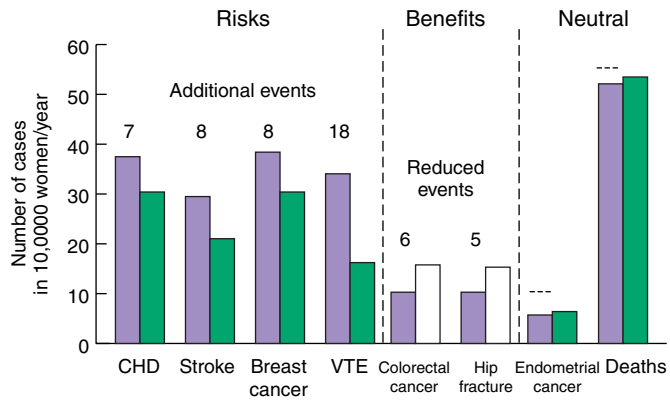

FIGURE 333-8 Effects of hormone therapy on event rates (CHD, coronary heart disease; VTE, venous thromboembolic events). (*Adapted from: Women's Health Initiative. WHI HRT Update. Available at http://www.nhlbi.nih.gov/whi/hrtupd/upd20002.htm.2002.*)

SERMS Two SERMs are currently being used in postmenopausal women: raloxifene, which is approved for prevention and treatment of osteoporosis, and tamoxifen, which is approved for the prevention and treatment of breast cancer.

Tamoxifen reduces bone turnover and bone loss in postmenopausal women compared to placebo groups. These findings support the concept that tamoxifen acts as an estrogenic agent in bone. There are limited data on the effect of tamoxifen on fracture risk, but the Breast Cancer Prevention study indicated a possible reduction in clinical vertebral, hip, and Colles' fractures. The major benefit of tamoxifen is on breast cancer occurrence. The breast cancer prevention trial indicated that tamoxifen administration over 4 to 5 years reduced the incidence of new invasive and noninvasive breast cancer by ~45% in women at increased risk of breast cancer. The incidence of ER-positive breast cancers was reduced by 65%.

Raloxifene (60 mg/d) has effects on bone turnover and bone mass that are very similar to those of tamoxifen, indicating that this agent is also estrogenic on the skeleton. The effect of raloxifene on bone density (+1.4 to 2.8% versus placebo in the spine, hip, and total body) is somewhat less than that seen with standard doses of estrogens. Raloxifene reduces the occurrence of vertebral fracture by 30 to 50%, depending on the subpopulation; however, there are no data confirming that raloxifene can reduce the risk of nonvertebral fractures.

Raloxifene, like tamoxifen and estrogen, has effects in other organ systems. The most beneficial effect appears to be a reduction in invasive breast cancer (mainly decreased ER-positive) occurrence of about 65% in women who take raloxifene compared to placebo. In contrast to tamoxifen, raloxifene is not associated with an increase in the risk of uterine cancer or benign uterine disease. Raloxifene increases the occurrence of hot flashes but reduces serum total and low-density lipoprotein cholesterol, lipoprotein(a), and fibrinogen. In women at high risk of heart disease, preliminary data suggest that raloxifene may reduce the occurrence of heart disease and stroke outcomes by about 40%. A large ongoing pivotal study, called Raloxifene Use for the Heart (RUTH), will further evaluate vascular disease and breast cancer outcomes.

Mode of Action of SERMs All SERMs bind to the ER, but each agent produces a unique receptor conformation. As a result, specific coactivator or co-repressor proteins are bound to the receptor (Chap. 317), resulting in differential effects on gene transcription that vary depending on other transcription factors present in the cell. Another aspect of selectivity is the affinity of each SERM for the different ERα and -β subtypes, which are expressed differentially in various tissues. These tissue-selective effects of SERMs offer the possibility of tailoring estrogen therapy to best meet the needs and risk factor profile of an individual patient.

BISPHOSPHONATES Both alendronate and risedronate are approved for the prevention and treatment of postmenopausal osteoporosis and treatment of steroid-induced osteoporosis. Risedronate is also approved for the prevention of steroid-induced osteoporosis. Alendronate is approved for treatment of osteoporosis in men.

Alendronate has been shown to decrease bone turnover and increase bone mass in the spine by up to 8% versus placebo and by 6% versus placebo in the hip. Multiple trials have evaluated its effect on fracture occurrence. The Fracture Intervention Trial provided evidence in >2000 women with prevalent vertebral fractures that daily alendronate treatment (5 mg/d for 2 years and 10 mg/d for 9 months afterwards) reduces vertebral fracture risk by about 50%, multiple vertebral fractures by up to 90%, and hip fractures by up to 50% (Fig. 333-9). Several subsequent trials have confirmed these findings. For example, in a study of >1900 women with low bone mass treated with alendronate (10 mg/d) versus placebo, the incidence of all nonvertebral fractures was reduced by ~47% after only 1 year.

Trials comparing once-weekly alendronate, 70 mg, with daily 10-mg dosing have shown equivalence with regard to bone mass and bone turnover responses. Consequently, once-weekly therapy is generally preferred because of low incidence of gastrointestinal side effects and ease of administration. Alendronate should be given with a full glass of water before breakfast, as bisphosphonates are poorly absorbed. Because of the potential for esophageal irritation, alendronate is contraindicated in patients who have stricture or inadequate emptying of the esophagus. It is recommended that patients remain upright for at least 30 min after taking the medication to avoid esophageal irritation. Cases of esophagitis, esophageal ulcer, and esophageal stricture have been described, but the incidence appears to be low. In clinical trials, overall gastrointestinal symptomatology was no different with alendronate compared to placebo.

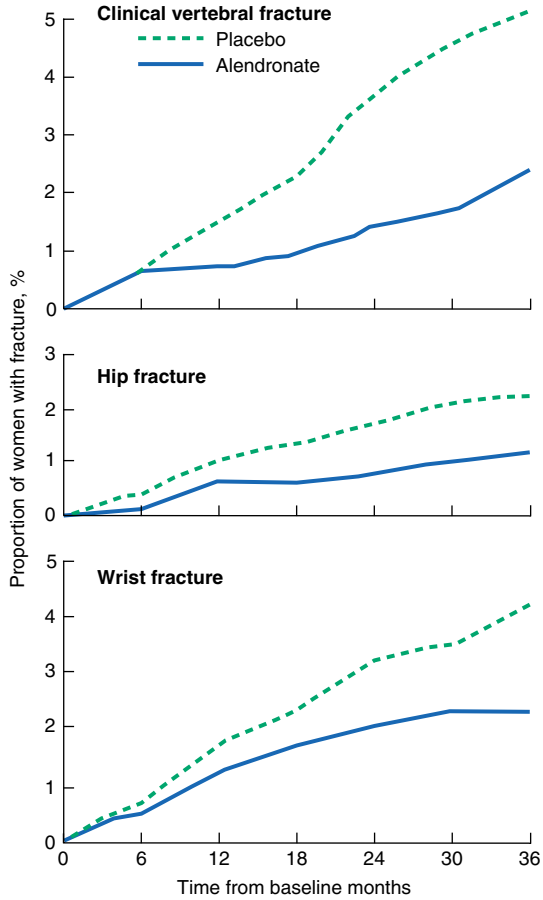

FIGURE 333-9 Cumulative proportions of women with osteoporosis who suffered clinical vertebral, hip, or wrist fracture during 3 years of treatment with alendronate or placebo (FIT 1). (*From DM Black et al: Lancet 348:1535, 1996.*)

Risedronate also reduces bone turnover and increases bone mass. Controlled clinical trials have demonstrated 40 to 50% reduction in vertebral fracture risk over 3 years, accompanied by a 40% reduction in clinical nonspine fractures. The only clinical trial specifically designed to evaluate hip fracture outcome (HIP) indicated that risedronate reduced hip fracture risk in women in their 70s with confirmed osteoporosis by 40%. In contrast, risedronate was not effective at reducing hip fracture occurrence in older women without proven osteoporosis. Studies have shown that 35 mg of risedronate administered once weekly is therapeutically equivalent to 5 mg/d. Patients should take risedronate with a full glass of plain water [0.18 to 0.25 L (6 to 8 oz)], to facilitate delivery to the stomach, and should not lie down for 30 min after taking the drug. The incidence of gastrointestinal side effects in trials with risedronate was similar to that of placebo.

Etidronate was the first bisphosphonate to be approved, initially for use in Paget's disease and hypercalcemia. This agent has also been used in osteoporosis trials of smaller magnitude than those performed for alendronate and risedronate but is not approved by the FDA for treatment of osteoporosis. Etidronate probably has some efficacy

against vertebral fracture when given as an intermittent cyclical regimen (2 weeks on, 2 1/2 months off). There has not been any study of its effectiveness against nonvertebral fractures.

Zoledronate and ibandronate are potent bisphosphonates with unique administration regimens (once yearly intravenously, once monthly orally) and are currently in clinical development.

Mode of Action Bisphosphonates are structurally related to pyrophosphates, compounds that are incorporated into bone matrix. Bisphosphonates specifically impair osteoclast function and reduce osteoclast number, in part by the induction of apoptosis. Recent evidence suggests that the nitrogen-containing bisphosphonates also inhibit protein prenylation, one of the end products in the mevalonic acid pathway. This effect disrupts intracellular protein trafficking and may ultimately lead to apoptosis. Some bisphosphonates have very long retention in the skeleton and may exert long-term effects.

CALCITONIN Calcitonin is a polypeptide hormone produced by the thyroid gland (Chap. 332). Its physiologic role is unclear as no skeletal disease has been described in association with calcitonin deficiency or calcitonin excess. Calcitonin preparations are approved by the FDA for Paget's disease, hypercalcemia, and osteoporosis in women >5 years past menopause.

Injectable calcitonin produces small increments in bone mass of the lumbar spine. However, difficulty of administration and frequent reactions, including nausea and facial flushing, make general use limited. In 1995, a nasal spray containing calcitonin (200 IU/d) was approved for treatment of osteoporosis in postmenopausal women. One study suggests that nasal calcitonin produces small increments in bone mass and a small reduction in new vertebral fractures in calcitonin-treated patients versus those on calcium alone. There has been no proven effectiveness against nonvertebral fractures.

Calcitonin is not indicated for prevention of osteoporosis and is not sufficiently potent to prevent bone loss in early postmenopausal women. As mentioned above, calcitonin might have an analgesic effect on bone pain, both in the subcutaneous and possibly the nasal form.

Mode of Action Calcitonin suppresses osteoclast activity by direct action on the osteoclast calcitonin receptor. Osteoclasts exposed to calcitonin cannot maintain their active ruffled border, which normally maintains close contact with underlying bone.

PARATHYROID HORMONE Endogenous PTH is an 84-amino-acid peptide that is largely responsible for calcium homeostasis (Chap. 332). Although chronic elevation of PTH, as occurs in hyperparathyroidism, is associated with bone loss (particularly cortical bone), PTH can also exert anabolic effects on bone. Consistent with this, some observational studies have indicated that mild elevations in PTH are associated with maintenance of trabecular bone mass. On the basis of these findings, preclinical and early clinical studies have been performed using an exogenous PTH analogue (1-34 PTH). The first randomized controlled trial in postmenopausal women showed that PTH, when superimposed on ongoing estrogen therapy, produced substantial increments in bone mass (13% over a 3-year period compared to estrogen alone) and reduced the risk of vertebral compression deformity. In one study (median 19 months' duration), 20 μg PTH(1-34) reduced vertebral fractures by 65% and nonvertebral fractures by 45% (Fig. 333-10). PTH(1-34) has now been approved by the FDA for treatment of patients with osteoporosis (both women and men) at high risk of fracture. Treatment is administered as a single daily injection given for a maximum of 2 years. Although there are no randomized controlled studies to confirm the need for an antiresorptive agent after PTH withdrawal, based on observational data and animal studies, it is likely that antiresorptive agents will be required to maintain PTH-induced benefits on bone mass and fracture. In contrast to combination

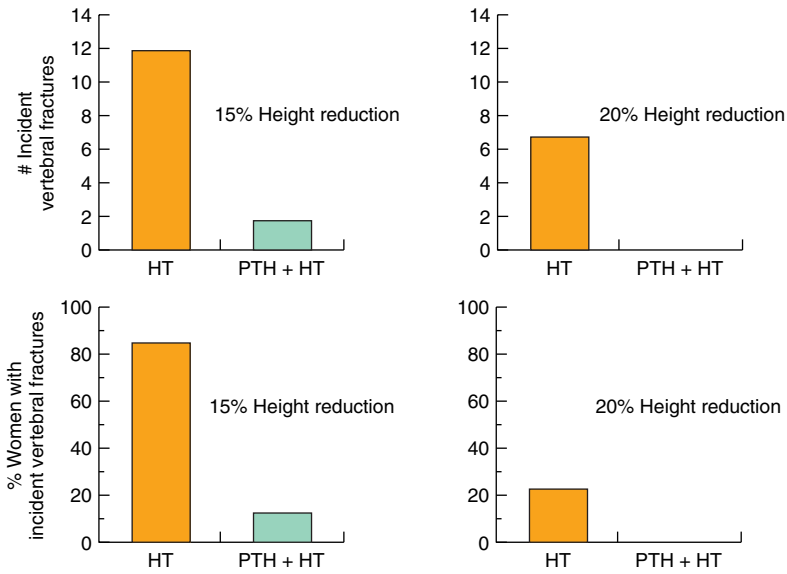

FIGURE 333-10 Number of incident vertebral deformities (15% and 20% reductions) in women with osteoporosis on hormone therapy (HT), compared to HT + PTH over 3 years. (HT, hormone therapy; PTH, parathyroid hormone.) (*From Cosman et al.*)

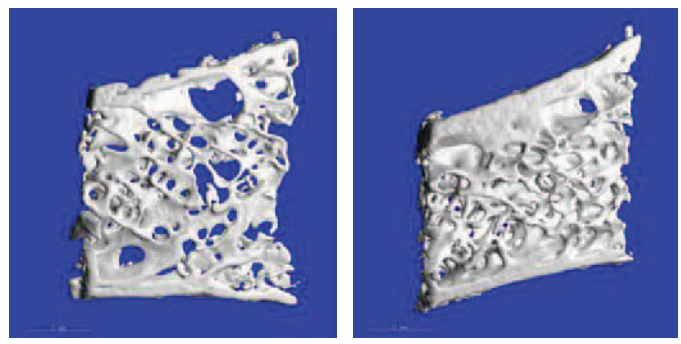
treatment with estrogen, there are no published data on use of PTH in combination with bisphosphonates or SERMs.

Side effects are generally mild and can include muscle pains, weakness, dizziness, headache, and nausea. Rodents given prolonged treatment with PTH in relatively high doses developed osteogenic sarcomas. It is not believed that this finding has any relevance to humans.

PTH use may be limited by its mode of administration; alternative modes of delivery are being investigated. The optimal frequency of administration also remains to be established, and it is possible that PTH might also be effective when used intermittently. Cost may also be a limiting factor.

Mode of Action Exogenously administered PTH appears to have direct actions on osteoblast activity, with biochemical and histomorphometric evidence of de novo bone formation early in response to PTH, prior to activation of bone resorption. Subsequently, PTH activates bone remodeling but still appears to favor bone formation over bone resorption. PTH stimulates IGF-I and collagen production and appears to increase osteoblast number by stimulating replication, enhancing osteoblast recruitment, and inhibiting apoptosis. Unlike all other treatments, PTH produces a true increase in bone tissue and an apparent restoration of bone microarchitecture (Fig. 333-11).

FLUORIDE Fluoride has been available for many years and is a potent stimulator of osteoprogenitor cells when studied in vitro. It has been used in multiple osteoporosis studies with conflicting results, in part related to use of varying doses and preparations. Despite increments



A ***B***

FIGURE 333-11 Effect of parathyroid hormone (PTH) treatment on bone microarchitecture. Paired biopsy specimens from a 64-year-old woman before (*A*) and after (*B*) treatment with PTH. (*From DW Dempster et al: J Bone Miner Res 16:1846, 2001.*)

in bone mass of up to 10%, there are no consistent effects of fluoride on vertebral or nonvertebral fracture, which might actually increase when high doses of fluoride are used. Fluoride remains an experimental agent, despite its long history and multiple studies.

OTHER POTENTIAL ANABOLIC AGENTS Several small studies of growth hormone (GH), alone or in combination with other agents, have not shown consistent or substantial positive effects on skeletal mass. Many of these studies are relatively short-term, and the effects of GH, growth hormone–releasing hormone, and the IGFs are still under investigation. Anabolic steroids, mostly derivatives of testosterone, act primarily as antiresorptive agents to reduce bone turnover but may also stimulate osteoblastic activity. Effects on bone mass remain unclear but appear weak, in general, and use is limited by masculinizing side effects. Several recent observational studies suggest that the statin drugs, currently used to treat hypercholesterolemia, may be associated with increased bone mass and reduced fractures, but conclusions from clinical trials are mixed.

Nonpharmacologic Approaches Protective pads worn around the outer thigh, which cover the trochanteric region of the hip can prevent hip fractures in elderly residents in nursing homes. The use of hip protectors is limited largely by compliance and comfort, but new devices are being developed that may circumvent these problems and provide adjunctive treatments.

Kyphoplasty and *vertebroplasty* are also useful nonpharmacologic approaches for the treatment of painful vertebral fractures. However, no long-term data are available.

Treatment Monitoring There are currently no well-accepted guidelines for monitoring treatment of osteoporosis. Because most osteoporosis treatments produce small or moderate bone mass increments on average, it is reasonable to consider BMD as a monitoring tool. Changes must exceed ~4% in the spine and 6% in the hip to be considered significant in any individual. The hip is the preferred site due to larger surface area and greater reproducibility. Medication-induced increments may require several years to produce changes of this magnitude (if they do at all). Consequently, it can be argued that BMD should not be repeated at intervals <2 years. Only significant BMD reductions should prompt a change in medical regimen, as it is expected that many individuals will not show responses greater than the detection limits of the current measurement techniques.

Biochemical markers of bone turnover may prove useful for treatment monitoring, but there is currently little hard evidence to support this concept; it remains unclear which endpoint is most useful. If bone turnover markers are used, a determination should be made before starting therapy and repeated ≥4 months after therapy is initiated. In general, a change in bone turnover markers must be 30 to 40% lower than the baseline to be significant because of the biologic and technical variability in these tests. A positive change in biochemical markers and/or bone density can be useful to help patients adhere to treatment regimens.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Osteoporotic fractures are a well-characterized consequence of the hypercortisolism associated with Cushing's syndrome. However, the therapeutic use of glucocorticoids is by far the most common form of glucocorticoid-induced osteoporosis. Glucocorticoids are widely used in the treatment of a variety of disorders, including chronic lung disorders, rheumatoid arthritis and other connective tissue diseases, inflammatory bowel disease, and posttransplantation. Osteoporosis and related fractures are serious side effects of chronic glucocorticoid therapy. Because the effects of glucocorticoids on the skeleton are often superimposed upon the consequences of aging and menopause, it is not surprising that women and the elderly are most frequently affected. The skeletal response to steroids is remarkably heterogeneous, however, and even young, growing individuals treated with glucocorticoids can present with fractures.

The risk of fractures depends on the dose and duration of glucocorticoid therapy, although recent data suggest that there may be no completely safe dose. Bone loss is more rapid during the early months of treatment, and trabecular bone is more severely affected than cortical bone. As a result, fractures have been shown to increase within 3 months of steroid treatment. There is an increase in fracture risk in both the axial and appendicular skeleton, including risk of hip fracture. Bone loss can occur with any route of steroid administration including high-dose inhaled glucocorticoids and intraarticular injections. Alternate-day delivery does not appear to ameliorate the skeletal effects of glucocorticoids.

Pathophysiology Glucocorticoids increase bone loss by multiple mechanisms including: (1) inhibition of osteoblast function and an increase in osteoblast apoptosis, resulting in impaired synthesis of new bone; (2) stimulation of bone resorption, probably as a secondary effect; (3) impairment of the absorption of calcium across the intestine, probably by a vitamin D–independent effect; (4) increase of urinary calcium loss and induction of some degree of secondary hyperparathyroidism; (5) reduction of adrenal androgens and suppression of ovarian and testicular secretion of estrogens and androgens; and (6) induction of glucocorticoid myopathy, which may exacerbate effects on skeletal and calcium homeostasis as well as increase the risk of falls.

Evaluation of the Patient Because of the prevalence of glucocorticoid-induced bone loss, it is important to evaluate the status of the skeleton in all patients starting or already receiving long-term glucocorticoid therapy. Modifiable risk factors should be identified, including those for falls. Examination should include height and muscle strength testing. Laboratory evaluation should include an assessment of 24-h urinary calcium. All patients on long-term (>3 months) glucocorticoids should have measurement of bone mass at both the spine and hip using DXA. If only one skeletal site can be measured, it is best to assess the spine in individuals <60 years and the hip for those >60 years.

Prevention Bone loss caused by glucocorticoids can be prevented, and the risk of fractures significantly reduced. Strategies must include using the lowest dose of glucocorticoid for disease management. Topical and inhaled routes of administration are preferred, where appropriate. Risk factor reduction is important, including smoking cessation, limitation of alcohol consumption, and participation in weight-bearing exercise, when appropriate. All patients should receive an adequate calcium and vitamin D intake from the diet or from supplements.

Rx TREATMENT

Only bisphosphonates have been demonstrated in large clinical trials to reduce the risk of fractures in patients being treated with glucocorticoids. Risedronate prevents bone loss and reduces vertebral fracture risk by about 70%. Similar beneficial effects are observed in studies of alendronate and etidronate. Controlled trials of hormone therapy have shown bone-sparing effects, and calcitonin also has some protective effect in the spine. Thiazides reduce urine calcium loss, but their role in prevention of fractures is unclear. PTH has also been studied in a small group of women with glucocorticoid-induced osteoporosis. Bone mass increased substantially, but no fracture data are available.

334 PAGET DISEASE AND OTHER DYSPLASIAS OF BONE

Murray J. Favus, Tamara J. Vokes

PAGET DISEASE OF BONE

Paget disease is a localized bone disorder that often affects widespread areas of the skeleton through increased bone remodeling. The pathologic process is initiated by overactive osteoclastic bone resorption followed by a compensatory increase in osteoblastic new bone formation. New pagetic bone is structurally disorganized and more susceptible to deformities and fractures. Although most patients are asymptomatic, a variety of symptoms and complications may result directly from bony involvement or secondarily from the expansion of bone and subsequent compression of surrounding neural tissue.

EPIDEMIOLOGY There is a marked geographic variation in the frequency of Paget disease, with high prevalence in Western Europe (Great Britain, France, and Germany but not Switzerland or Scandinavia) and among those who have immigrated to Australia, New Zealand, South Africa, and North and South America. The disease is rare in native populations of the Americas, Africa, Asia, and the Middle East. The prevalence is greater in males and increases with age. Autopsy series reveal Paget disease in about 3% of those over age 40. Prevalence of positive skeletal radiographs in patients over age 55 is 2.5% for men and 1.6% for women. Elevated alkaline phosphatase (ALP) levels in asymptomatic patients has an age-adjusted incidence of 12.7 and 7 per 100,000 person-years in men and women, respectively. The frequency of diagnosis by either radiographic or biochemical criteria has decreased during the past 20 years.

ETIOLOGY The etiology of Paget disease of bone remains unknown, but evidence supports both genetic and viral etiologies. A positive family history is found in 5 to 25% of patients and, when present, raises the prevalence of the disease seven- to tenfold among first-degree relatives. Familial patterns of disease in several large kindred are consistent with an autosomal dominant pattern of inheritance with variable penetrance. A susceptibility locus for Paget disease has been mapped to chromosome 18q21-22, a region that contains the gene responsible for a rare Paget disease–like skeletal disorder known as familial expansile osteolysis. The gene encodes the receptor activator of nuclear factor-κB (RANK), a member of the tumor necrosis factor superfamily critical for osteoclast differentiation (Fig. 334-1). In other families, susceptibility loci have been mapped to loci on chromosomes 18q23, 6p21.3, 5q31, and 5q35. A homozygous deletion of the *TNFRSF11B* gene, which encodes osteoprotegrin (Fig. 334-1), causes juvenile Paget disease, a disorder characterized by uncontrolled osteoclastic differentiation and resorption. Thus, it is likely that Paget disease is genetically heterogeneous with divergent pathogenetic mechanisms in sporadic and familial forms.

Several lines of evidence suggest a viral etiology of Paget disease, including (1) the presence of cytoplasmic and nuclear inclusions resembling paramyxoviruses (measles and respiratory syncytial virus) in pagetic osteoclasts, and (2) viral mRNA in precursor and mature osteoclasts. The viral etiology is further supported by conversion of osteoclast precursors to pagetic-like osteoclasts by vectors containing the measles virus nucleocapsid or matrix genes. However, the viral etiology has been questioned by the inability to culture a live virus from pagetic bone and by failure to clone the full-length viral genes from material obtained from patients with Paget disease.

PATHOPHYSIOLOGY The principal abnormality in Paget disease is the increased number and activity of osteoclasts. Pagetic osteoclasts are large, increased 10- to 100-fold in number, and have a greater number of nuclei (as many as 100 compared to 3 to 5 nuclei in the normal osteoclast). The overactive osteoclasts create a sevenfold increase in resorptive surfaces and an erosion rate of 9 μg/d (normal is 1 μg/d). Several causes for the increased number and activity of pagetic osteoclasts have been identified: (1) osteoclastic precursors are hypersensitive to $1,25(OH)_2D_3$; (2) osteoclasts are hyperresponsive to RANK ligand (RANKL), the osteoclast stimulatory factor that mediates the effects of most osteotropic factors on osteoclast formation; (3) marrow stromal cells from pagetic lesions have increased RANKL expression; (4) osteoclast precursor recruitment is increased by interleukin (IL) 6, which is increased in the blood of patients with active Paget disease and is overexpressed in pagetic osteoclasts; (5) expression of the proto-oncogene c-*fos*, which increases osteoclastic activity, is increased; and (6) the antiapoptotic oncogene *Bcl*-2 in pagetic bone is overexpressed. Numerous osteoblasts are recruited to active resorption sites and produce large amounts of new bone matrix. As a result, bone turnover is high and bone mass is normal or increased, not reduced.

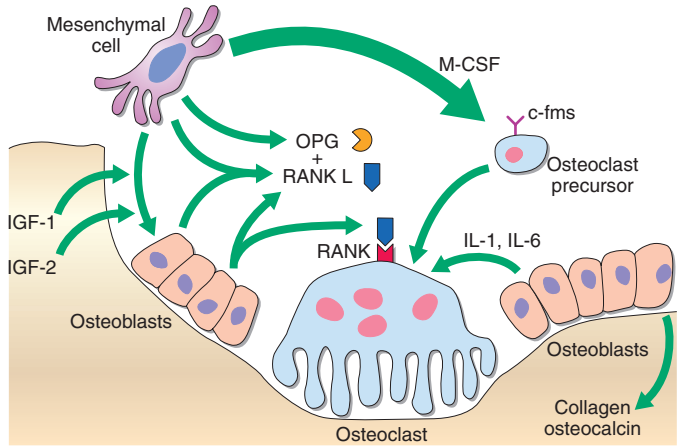

FIGURE 334-1 Diagram illustrating factors that promote differentiation and function of osteoclasts and osteoblasts and the role of the RANK pathway. Stromal bone marrow (mesenchymal) cells and differentiated osteoblasts produce multiple growth factors and cytokines, including macrophage colony-stimulating factor (M-CSF), to modulate osteoclastogenesis. RANKL (receptor activator of NFκB ligand) is produced by osteoblast progenitors and mature osteoblasts and can bind to a soluble decoy receptor known as OPG (osteoprotegrin) to inhibit RANKL action. Alternatively, a cell-cell interaction between osteoblast and osteoclast progenitors allows RANKL to bind to its membrane-bound receptor, RANK, thereby stimulating osteoclast differentiation and function. RANK binds intracellular proteins called TRAFS (tumor necrosis factor receptor-associated factors) that mediate receptor signaling through transcription factors such as NFκB. M-CSF binds to its receptor, c-fms, which is the cellular homologue of the *fms* oncogene. See text for the potential role of these pathways in disorders of osteoclast function such as Paget disease and osteopetrosis.

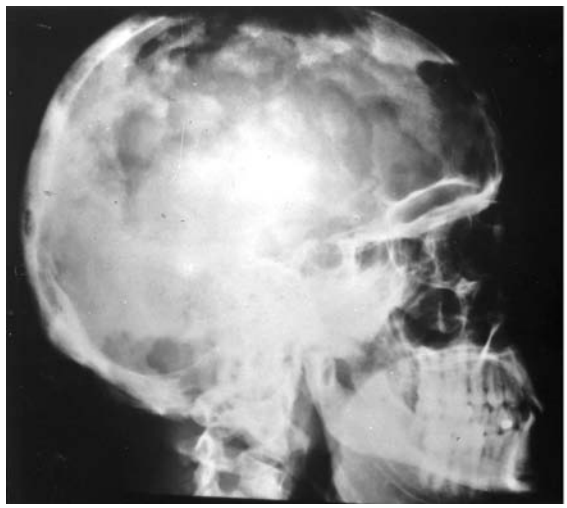
The characteristic feature of Paget disease is increased bone resorption accompanied by accelerated bone formation. An initial osteolytic phase involves prominent bone resorption and marked hypervascularization. Radiographically, this manifests as an advancing lytic wedge, or "blade of grass" lesion. The second phase is a period of very active bone formation and resorption that replaces normal lamellar bone with haphazard (woven) bone. The mosaic pattern of woven bone is structurally inferior and can bow and fracture more readily. At the same time, fibrous connective tissue may replace normal bone marrow. In the final sclerotic phase, bone resorption declines progressively and leads to a hard, dense, less vascular pagetic or mosaic bone, which represents the so-called burned-out phase of Paget disease. All three phases may be present at the same time at different skeletal sites.

CLINICAL MANIFESTATIONS Asymptomatic patients are often diagnosed by discovery of an elevated ALP level on routine blood chemistry testing or from an abnormality on a skeletal radiograph obtained for another indication. The skeletal sites most commonly involved are the pelvis, vertebral bodies, skull, femur, and tibia. Numerous active sites of skeletal involvement are more common in familial cases with an early presentation.

Pain is the most common presenting symptom. It results from in-



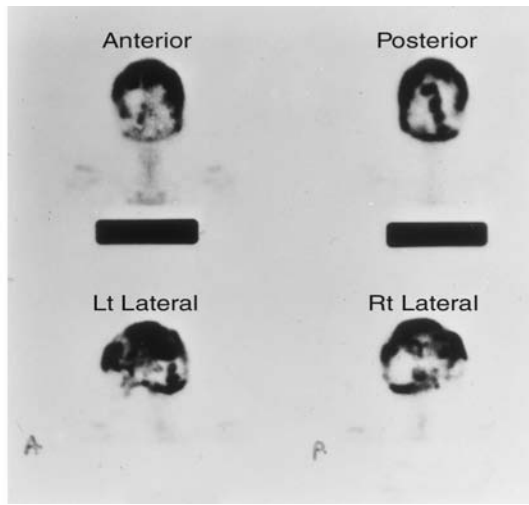


FIGURE 334-2 A 48-year-old woman with Paget disease of the skull. *Left*. Lateral radiograph showing areas of both bone resorption and sclerosis. *Right*. ^{99m}Tc HDP bone scan with anterior, posterior, and lateral views of the skull showing diffuse isotope uptake by the frontal, parietal, occipital, and petrous bones.

creased bony vascularity, expanding lytic lesions, fractures, bowing, or other deformities of the extremities. Bowing of the femur or tibia causes gait abnormalities and abnormal mechanical stresses with secondary osteoarthritis of the hip or knee joints. Long bone bowing also causes extremity pain by stretching the muscles attached to the bone softened by the pagetic process. Back pain results from enlarged pagetic vertebrae, vertebral compression fractures, spinal stenosis, degenerative changes of the joints, and altered body mechanics with kyphosis and forward tilt of the upper back. Rarely, spinal cord compression may result from bone enlargement or from the vascular steal syndrome. Skull involvement may cause headaches, symmetric or asymmetric enlargement of the parietal or frontal bones (frontal bossing), and increased head size. Cranial expansion may narrow cranial foramina and cause neurologic complications including hearing loss from cochlear nerve damage from temporal bone involvement, cranial nerve palsies, and softening of the base of the skull (*platybasia*) and the risk of brainstem compression. Pagetic involvement of the facial bones may cause facial deformity, loss of teeth and other dental conditions, and rarely, airway compression.

Fractures are serious complications of Paget disease and usually occur in long bones at areas of active or advancing lytic lesions. Common fracture sites are the femoral shaft and subtrochanteric regions. Neoplasms arising from pagetic bone are rare. The incidence of sarcoma appears to be decreasing, possibly because of earlier, more effective treatment with potent antiresorptive agents. The majority of tumors are osteosarcomas, which usually present with new pain in a long-standing pagetic lesion. Osteoclast-rich benign giant cell tumors may arise in areas adjacent to pagetic bone and respond to glucocorticoid therapy.

Cardiovascular complications may occur in patients with involvement of large (15 to 35%) portions of the skeleton and a high degree of disease activity (ALP four times above normal). The extensive arteriovenous shunting and marked increases in blood flow through the vascular pagetic bone lead to a high-output state and cardiac enlargement. However, high-output heart failure is relatively rare and usually develops in patients with concomitant cardiac pathology. In addition, calcific aortic stenosis and diffuse vascular calcifications have been associated with Paget disease.

DIAGNOSIS The diagnosis may be suggested on clinical examination by the presence of enlarged skull with frontal bossing, bowing of an extremity, or short stature with simian posturing. An extremity with an area of warmth and tenderness to palpation may suggest an underlying pagetic lesion. Other findings include bony deformity of the pelvis, skull, spine and extremities; arthritic involvement of the joints adjacent to lesions; and leg length discrepancy resulting from deformities of the long bones.

Paget disease is usually diagnosed from radiologic and biochemical abnormalities. Radiographic findings typical of Paget disease include enlargement or expansion of an entire bone or area of a long bone, cortical thickening, coarsening of trabecular markings, and typical lytic and sclerotic changes. Skull radiographs (Fig. 334-2) reveal regions of "cotton wool," or osteoporosis circumscripta; thickening of diploic areas; and enlargement and sclerosis of a portion or all of one or more skull bones. Vertebral cortical thickening of the superior and inferior end plates creates a "picture frame" vertebra. Diffuse radiodense enlargement of a vertebra is referred to as "ivory vertebra." Pelvic radiographs may demonstrate disruption or fusion of the sacroiliac joints; porotic and radiodense lesions of the ilium with whorls of coarse trabeculation; thickened and sclerotic ileopectinal line (Brim sign); and softening with protrusio acetabuli, with axial migration of the hips and functional flexion contracture. Radiographs of long bones reveal bowing deformity and typical pagetic changes of cortical thickening and expansion and areas of lucency and sclerosis (Fig. 334-3). Radionuclide ^{99m}Tc bone scans are less specific but are more sensitive than standard radiographs for identifying sites of active skeletal lesions. Suspected areas of malignant transformation are best distinguished from pagetic bone by computed tomography (CT) or magnetic

FIGURE 334-3 Radiograph of a 73-year-old man with Paget disease of the right proximal femur. Note the coarsening of the trabecular pattern with marked cortical thickening and narrowing of the joint space consistent with osteoarthritis secondary to pagetic deformity of the right femur.

resonance imaging (MRI). Definitive diagnosis of malignancy requires bone biopsy.

Biochemical evaluation is useful in the diagnosis and management of Paget disease. The marked increase in bone turnover can be monitored using biochemical markers of bone formation and resorption. The parallel rise in serum ALP and urinary hydroxyproline levels, markers of bone formation and resorption, respectively, confirm the coupling of bone formation and resorption in Paget disease. The degree of bone marker elevation reflects the extent and severity of the disease. Patients with the highest elevation of ALP (10 times the upper limit of normal) typically have involvement of the skull and at least one other skeletal site. Lower values suggest less extensive involvement or a quiescent phase of the disease. For most patients, serum total ALP remains the test of choice both for diagnosis and assessing response to therapy. Occasionally, a symptomatic patient with evidence of progression at a single site may have a normal total ALP level but increased bone-specific ALP. Serum osteocalcin, a marker of bone formation, is not always elevated in patients with active Paget disease and is not recommended for use in diagnosis or management.

TABLE 334-1 *Pharmacologic Agents Approved for Treatment of Paget Disease*

Name (Brand)	Potency[a]	Dose	Mode of Administration[b]
Etidronate (Didronel)	1	400 mg/d for 6 mos	Fasting with 6 oz tap water 2 h before or after a meal
Tiludronate (Skelid)	10	400 mg/d for 3 mos	Fasting with 6 oz tap water and wait 45 min before food, liquids are taken
Pamidronte (Aredia)	100	30 mg IV daily for 3 days or 60 to 90 mg IV at various intervals as determined by disease	
Alendronate (Fosamax)	700	40 mg/d for 6 mos	Fasting with 6 oz tap water and wait 45 min before food, liquids are taken
Risedronate (Actonel)	1000	30 mg/d for 2 mos	Fasting with 6 oz tap water and wait 45 min before food, liquids are taken
Calcitonin (Miacalcin)	NA	100 U sc daily	Dose may be reduced to 50 U qod for 6–18 mos

[a] Potency is relative to etidronate. For each tablet, etidronate strength is 400 mg; tiludronate is 200 mg; alendronate is 40 mg; and risedronate is 30 mg. Miacalcin nasal spray is not approved for use in Paget disease.
[b] 6 oz is 175 mL.

Urinary and serum deoxypyridinoline, N-telopeptide, and C-telopeptide levels are products of type I collagen degradation and are more specific for bone resorption than hydroxyproline. These newer bone resorption markers have distinct advantages over measurement of 24-h or second-morning void hydroxyproline/creatinine ratio, which requires control of dietary gelatin intake and precise urine collection and analysis. The new resorption markers decrease more rapidly in response to therapy than does ALP.

Serum calcium and phosphate levels are normal in Paget disease. Immobilization of a patient with active Paget disease may rarely cause hypercalcemia and hypercalciuria and increase the risk for nephrolithiasis. However, the discovery of hypercalcemia, even in the presence of immobilization, should prompt a search for another cause of hypercalcemia. In contrast, hypocalcemia or mild secondary hyperparathyroidism may develop in Paget patients with very active bone formation and insufficient dietary calcium intake. Hypocalcemia can occur during bisphosphonate therapy when bone resorption is rapidly suppressed and active bone formation continues. Hypocalcemia may be prevented by adequate calcium and vitamin D intake.

TREATMENT

The development of effective and potent pharmacologic agents (Table 334-1) has changed the treatment philosophy from treating only symptomatic patients to treating asymptomatic patients who are at risk for complications. Pharmacologic therapy is indicated in the following circumstances: to control symptoms caused by metabolically active Paget disease such as bone pain, fracture, headache, pain from pagetic radiculopathy or arthropathy, or neurologic complications; to decrease local blood flow and minimize operative blood loss in patients undergoing surgery at an active pagetic site; to reduce hypercalciuria that may occur during immobilization; and to decrease the risk of complications when disease activity is high (elevated ALP) and when the site of involvement involves weight-bearing bones, areas adjacent to major joints, vertebral bodies, and skull. Whether early therapy prevents late complications remains to be determined. However, the restoration of normal bone architecture following suppression of pagetic activity suggests that treatment may prevent further deformities and complications.

Agents approved for treatment of Paget disease suppress the very high rates of bone resorption and secondarily decrease the high rates of bone formation (Table 334-1). As a result of decreasing bone turnover, pagetic structural patterns, including areas of poorly mineralized woven bone, are replaced by more normal cancellous or lamellar bone. The improvement in skeletal structure can be demonstrated on standard radiographs and ^{99m}Tc bone scans, which show decreased isotope accumulation in pagetic sites. Reduced bone turnover can be documented by a decline in urine or serum resorption markers (pyridinoline, deoxypyridinoline, N-telopeptide, C-telopeptide) and serum markers of bone formation (ALP, osteocalcin).

The potencies of various bisphosphonates are expressed relative to that of etidronate, the first clinically useful agent in this class. Etidronate use is now limited as the doses required to suppress bone resorption may impair mineralization. Thus, etidronate is administered in 6-month treatment cycles followed by a 6-month drug-free period. Failure to adhere to the cyclic regimen can produce osteomalacia manifested by bone pain and fractures. Etidronate should not be used in patients with advanced lytic lesions in weight-bearing bones. The major advantage of etidronate is that it is relatively well tolerated and only occasionally causes transient diarrhea or bone pain.

The second-generation oral bisphosphonates tiludronate, alendronate, and risedronate are more potent than etidronate in controlling bone turnover and thus induce a longer remission at a lower dose. The lower doses reduce the risks of impaired mineralization and osteomalacia. Oral bisphosphonates are poorly absorbed and have a potential to produce esophageal ulceration, reflux, and rarely, perforation. They should be taken first thing in the morning on an empty stomach, followed by maintenance of upright posture with no food or drink for 30 to 60 min. Other medications, liquids, and food should be delayed for at least 30 to 60 min after taking bisphosphonates to optimize absorption. Tiludronate daily for 3 months normalizes ALP in 24 to 35% of moderately affected patients. In patients with moderate to severe disease, alendronate for 6 months normalizes ALP in >67% of patients, with an overall fall in ALP of 79% compared to 44% with etidronate. In patients with moderately active disease, risedronate daily for 2 to 3 months reduces serum ALP by 80% and normalizes indices of bone turnover in 73% of patients compared to 15% of those receiving etidronate.

Pamidronate is the only bisphosphonate currently approved for intravenous use in Paget disease. The recommended dose is 30 mg dissolved in 500 mL of normal saline or dextrose intravenously over 4 h on three consecutive days. The dose can be adjusted to each patient's requirements. A single 60-mg dose of pamidronate intravenously may normalize bone turnover in patients with mild disease. In contrast, patients with moderate to severe disease (elevation of ALP of three to four times normal) may require two to four doses of pamidronate, 60 to 90 mg intravenously, every 1 to 2 weeks. Patients with very severe disease may require a total dose of pamidronate of 300 to 500 mg given weekly over several weeks. Although suppression of urinary

bone markers occurs after a few days to weeks, normalization of serum ALP levels often requires at least 3 months. Consequently, the effects of pamidronate are best evaluated 3 months after the initial dose. Pamidronate is generally well tolerated; however, a small number of patients experience a flulike syndrome that may begin 24 h after the first infusion. In patients with high bone turnover, vitamin D (400 to 800 IU daily) and calcium (500 mg three times daily) should be provided to prevent hypocalcemia and secondary hyperparathyroidism. Indications for intravenous therapy include mild disease and normalization of bone turnover after a single infusion, previous prevention of disease progression, refractoriness to oral therapy, need for rapid response such for those with neurologic symptoms or with severe bone pain due to a lytic lesion, risk of an impending fracture, and as pretreatment prior to elective surgery in an area of active disease. Remission following pamidronate therapy may persist for as long as 1 year. Other bisphosphonate agents are in development.

The subcutaneous injectable form of salmon calcitonin is approved for the treatment of Paget disease. Intranasal calcitonin spray is approved for osteoporosis at a dose of 200 U/d; however, the efficacy of this dose in Paget disease has not been thoroughly studied. The usual starting dose of injectable calcitonin (100 U/d) reduces ALP by 50% and may relieve skeletal symptoms. The dose may be reduced to 50 U/day three times weekly after an initial favorable response to 100 U daily; however, the lower dose may require long-term use to sustain efficacy. The common side effects of calcitonin therapy are nausea and facial flushing. Secondary resistance after prolonged use may be due to either the formation of anti-calcitonin antibodies or downregulation of osteoclastic cell-surface calcitonin receptors. The lower potency and injectable mode of delivery make this agent a less attractive treatment option that should be reserved for patients who either do not tolerate or do not respond to bisphosphonates.

SCLEROSING BONE DISORDERS

OSTEOPETROSIS *Osteopetrosis* refers to a group of disorders caused by severe impairment of osteoclast-mediated bone resorption. Other terms that are often used include marble bone disease, which captures the solid x-ray appearance of the involved skeleton, and Albers-Schonberg disease, which refers to the milder, adult form of osteopetrosis also known as autosomal dominant osteopetrosis type II. The major types of osteopetrosis include malignant (severe, infantile, autosomal recessive) osteopetrosis and benign (adult, autosomal dominant) osteopetrosis types I and II. A rare autosomal recessive intermediate form has a more benign prognosis. Autosomal recessive carbonic anhydrase (CA) II deficiency produces osteopetrosis of intermediate severity associated with renal tubular acidosis and cerebral calcification.

Etiology and Genetics Naturally occurring and gene knockout animal models with phenotypes similar to those of the human disorders have been used to explore the genetic basis of osteopetrosis. The primary defect in osteopetrosis is the loss of osteoclastic bone resorption and preservation of normal osteoblastic bone formation. Osteoprotegerin (OPG) is a soluble decoy receptor that binds osteoblast-derived RANK ligand, which mediates osteoclast differentiation and activation (Fig. 334-1). Transgenic mice that overexpress OPG develop osteopetrosis, presumably by blocking RANK ligand. Mice deficient in RANK lack osteoclasts and develop severe osteopetrosis.

Recessive mutations of CA II prevent osteoclasts from generating an acid environment in the clear zone between its ruffled border and the adjacent mineral surface. Absence of CA II, therefore, impairs osteoclastic bone resorption. Other forms of human disease have less clear genetic defects. About one-half of the patients with malignant infantile osteopetrosis have a mutation in the *TCIRG1* gene encoding the osteoclast-specific subunit of the vacuolar proton pump, which mediates the acidification of the interface between bone mineral and the osteoclast ruffled border. Mutations in the *CICN7* chloride channel gene cause autosomal dominant osteopetrosis type II.

Clinical Presentation The incidence of autosomal recessive severe (malignant) osteopetrosis ranges from 1 in 200,000 to 1 in 500,000 live births. As bone and cartilage fail to undergo modeling, paralysis of one or more cranial nerves may occur due to narrowing of the cranial foramina. Failure of skeletal modeling also results in inadequate marrow space, leading to extramedullary hematopoiesis with hypersplenism and pancytopenia. Hypocalcemia due to lack of osteoclastic bone resorption may occur in infants and young children. The untreated infantile disease is fatal, often before age 5.

Adult (benign) osteopetrosis is an autosomal dominant disease that is usually diagnosed by the discovery of typical skeletal changes in young adults who undergo radiologic evaluation of a fracture. The prevalence is 1 in 100,000 to 1 in 500,000 adults. The course is not always benign, as fractures may be accompanied by loss of vision, deafness, psychomotor delay, mandibular osteomyelitis, and other complications usually associated with the juvenile form. In some kindred, nonpenetrance results in skip generations, while in other families severely affected children are born into families with benign disease. The milder form of the disease does not usually require treatment.

Radiography Typically, there are generalized symmetric increases in bone mass with thickening of both cortical and trabecular bone. Diaphyses and metaphyses are broadened, and alternating sclerotic and lucent bands may be seen in the iliac crests, at the ends of long bones, and in vertebral bodies. The cranium is usually thickened, particularly at the base of the skull, and the paranasal and mastoid sinuses are underpneumatized.

Laboratory Findings The only significant laboratory findings are elevated serum levels of osteoclast-derived tartrate-resistant acid phosphatase (TRAP) and the brain isoenzyme of creatine kinase. Serum calcium may be low in severe disease, and parathyroid hormone and 1,25-dihydroxyvitamin D levels may be elevated in response to hypocalcemia.

℞ TREATMENT

Allogenic HLA-identical bone marrow transplantation has been successful in some children. Following transplantation, the marrow contains progenitor cells and normally functioning osteoclasts. A cure is most likely when children are transplanted before age 4. Marrow transplantation from nonidentical HLA-matched donors has a much higher failure rate. Limited studies in small numbers of patients have suggested variable benefits following treatment with interferon gamma-1b, 1,25-dihydroxyvitamin D (which stimulates osteoclasts directly), methylprednisolone, and a low calcium/high-phosphate diet.

Surgical intervention is indicated to decompress optic or auditory nerve compression. Orthopedic management is required for the surgical treatment of fractures and their complications including malunion and post-fracture deformity.

PYKNODYSOSTOSIS This is an autosomal recessive form of osteosclerosis that is believed to have affected the French impressionist painter Henri de Toulouse-Lautrec. The molecular basis involves mutations in the gene that encodes cathepsin K, a lysosomal metalloproteinase highly expressed in osteoclasts and important for bone matrix degradation. Osteoclasts are present but do not function normally. Pyknodysostosis is a form of short-limb dwarfism that presents with frequent fractures but usually normal life span. Clinical features include short stature; kyphoscoliosis and deformities of the chest; high arched palate; proptosis; blue sclerae; dysmorphic features including small face and chin, frontooccipital prominence, pointed beaked nose, large cranium, and obtuse mandibular angle; and small square hands with hypoplastic nails. Radiographs demonstrate a generalized increase in bone density, but in contrast to osteopetrosis, the long bones are normally shaped. Separated cranial sutures, including the persistent patency of the anterior fontanel, are characteristic of the disorder. There may also be hypoplasia of the sinuses, mandible, distal clavicles, and terminal phalanges. Persistence of deciduous teeth and sclerosis of the calvarium and base of the skull are also common. Histologic evalua-

tion shows normal cortical bone architecture with decreased osteoblastic and osteoclastic activities. Serum chemistries are normal, and unlike osteopetrosis, there is no anemia. There is no known treatment for this condition, and no reports of attempted bone marrow transplant.

PROGRESSIVE DIAPHYSEAL DYSPLASIA Also known as Camurati-Engelman disease, progressive diaphyseal dysplasia is an autosomal dominant disorder that is characterized radiographically by diaphyseal hyperostosis and a symmetric thickening and increased diameter of the endosteal and periosteal surfaces of the diaphyses of the long bones, particularly the femur and tibia, and, less often, the fibula, radius, and ulna. The genetic defect responsible for the disease has been localized to the area of chromosome 19q13.2 encoding tumor growth factor (TGF)-β1. The mutation promotes activation of TGF-β1. The clinical severity is variable. The most common presenting symptoms are pain and tenderness of the involved areas, fatigue, muscle wasting, and gait disturbance. The weakness may be mistaken for muscular dystrophy. Characteristic body habitus includes thin limbs with little muscle mass yet prominent and palpable bones and, when the skull is involved, large head with prominent forehead and proptosis. Patients may also display signs of cranial nerve palsies, hydrocephalus, central hypogonadism, and Raynaud phenomenon. Radiographically, patchy progressive endosteal and periosteal new bone formation is observed along the diaphyses of the long bones. Bone scintigraphy shows increased radiotracer uptake in involved areas.

Treatment with low-dose glucocorticoids relieves bone pain and may reverse the abnormal bone formation. Intermittent bisphosphonate therapy has produced clinical improvement in a limited number of patients.

HYPEROSTOSIS CORTICALIS GENERALISATA This is also known as Van Buchem disease; it is an autosomal recessive disorder characterized by endosteal hyperostosis in which osteosclerosis involves the skull, mandible, clavicles, and ribs. The major manifestations are due to narrowed cranial foramina with neural compressions that may result in optic atrophy, facial paralysis, and deafness. Adults may have an enlarged mandible. Serum ALP levels may be elevated, which reflects the uncoupled bone remodeling with high osteoblastic formation rates and low osteoclastic resorption. As a result, there is increased accumulation of normal bone. Endosteal hyperostosis with syndactyly, known as *sclerosteosis*, is a more severe form. The genetic defects for both sclerosteosis and van Buchem disease have been assigned to the same region of the chromosome 17q12-q21. It is possible that both conditions may have deactivating mutations in the *BEER* (bone-expressed equilibrium regulator) gene.

MELORHEOSTOSIS Melorheostosis (Greek, "flowing hyperostosis") may occur sporadically or follow a pattern consistent with an autosomal recessive disorder. The major manifestation is progressive linear hyperostosis in one or more bones of one limb, usually a lower extremity. The name comes from the radiographic appearance of the involved bone, which resembles melted wax that has dripped down a candle. Symptoms appear during childhood as pain or stiffness in the area of sclerotic bone. There may be associated ectopic soft tissue masses, composed of cartilage or osseous tissue, and skin changes overlying the involved bone, consisting of scleroderma-like areas and hypertrichosis. The disease does not progress in adults, but pain and stiffness may persist. Laboratory tests are unremarkable. No specific etiology is known. There is no specific treatment. Surgical interventions to correct contractures are often unsuccessful.

OSTEOPOIKILOSIS The literal translation of osteopoikilosis is "spotted bones"; it is a benign autosomal dominant condition in which numerous small, variably shaped (usually round or oval) foci of bony sclerosis are seen in the epiphyses and adjacent metaphyses. The lesions may involve any bone except the skull, ribs, and vertebrae. They may be misidentified as metastatic lesions. The main differentiating points are that bony lesions of osteopoikilosis are stable over time and do not accumulate radionucleotide on bone scanning. In some kindred, osteopoikilosis is associated with connective tissue nevi known as *dermatofibrosis lenticularis disseminata*, also known as *Buschke-Ollendorf syndrome*. Histologic inspection reveals thickened but otherwise normal trabeculae and islands of normal cortical bone. No treatment is indicated.

DISORDERS ASSOCIATED WITH DEFECTIVE MINERALIZATION

HYPOPHOSPHATASIA This is a rare inherited disorder that presents as rickets in infants and children or osteomalacia in adults with paradoxically low serum levels of ALP. The frequency of the severe neonatal and infantile forms is about 1 in 100,000 live births in Canada, where the disease is most common because of its high prevalence among Mennonites and Hutterites. It is rare in African Americans. The severity of the disease is remarkably variable, ranging from intrauterine death associated with profound skeletal hypomineralization at one extreme, to premature tooth loss as the only manifestation in some adults. Severe cases are inherited in an autosomal recessive manner, but the genetic patterns are less clear for the milder forms. The disease is caused by a deficiency of tissue nonspecific (bone/liver/kidney) ALP (*TNSALP*), which, although ubiquitous, results only in bone abnormalities. Protein levels and functions of the other ALP isozymes (germ cell, intestinal, placental) are normal. Defective ALP permits accumulation of its major naturally occurring substrates including phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP). The accumulation of PPi interferes with mineralization through its action as a potent inhibitor of hydroxyapatite crystal growth.

Perinatal hypophosphatasia becomes manifest during pregnancy and is often complicated by polyhydroamnios and intrauterine death. The infantile form becomes clinically apparent before age 6 months with failure to thrive, rachitic deformities, functional craniosynostosis despite widely open fontanels (which are actually hypomineralized areas of the calvarium), raised intracranial pressure, and flail chest and predisposition to pneumonia. Hypercalcemia and hypercalciuria are common. This form has a mortality rate of about 50%. Prognosis seems to improve for the children who survive infancy. Childhood hypophosphatasia has variable clinical presentation. Premature loss of deciduous teeth (before age 5 years) is the hallmark of the disease. Rickets causes delayed walking with waddling gait, short stature, and dolichocephalic skull with frontal bossing. The disease often improves during puberty but may recur in adult life. Adult hypophosphatasia presents during middle age with painful, poorly healing metatarsal stress fractures or thigh pain due to femoral pseudofractures.

Laboratory investigation reveals low ALP levels and normal or elevated levels of serum calcium and phosphorus despite clinical and radiologic evidence of rickets or osteomalacia. Serum parathyroid hormone, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D levels are normal. The elevation of PLP is specific for the disease and may even be present in asymptomatic parents of severely affected children. As vitamin B_6 increases PLP levels, vitamin B_6 supplements should be discontinued 1 week before testing.

There is no established medical therapy. In contrast to other forms of rickets and osteomalacia, calcium and vitamin D supplementation should be avoided as they may aggravate hypercalcemia and hypercalciuria. A low-calcium diet, glucocorticoids, and calcitonin have been used in a small number of patients with variable responses. Because fracture healing is poor, placement of intramedullary rods is best for acute fracture repair and for prophylactic prevention of fractures.

AXIAL OSTEOMALACIA This is a rare disorder characterized by defective skeletal mineralization despite normal serum calcium and phosphate levels. Clinically, the disorder presents in middle-aged or elderly men with chronic axial skeletal discomfort. Cervical spine pain may also be present. Radiographic findings are mainly osteosclerosis due to coarsened trabecular patterns typical of osteomalacias. Spine, pelvis, and ribs are most commonly affected. Histologic changes show defective mineralization and flat, inactive osteoblasts. The primary defect

appears to be an acquired defect in osteoblast function. The course is benign and there is no established treatment. Calcium and vitamin D therapies are not effective.

FIBROGENESIS IMPERFECTA OSSIUM The is a rare condition of unknown etiology. It presents in both sexes, in middle age or later, with progressive, intractable skeletal pain and fractures, worsening immobilization, and a debilitating course. Radiographic evaluation reveals generalized osteomalacia, osteopenia, and occasional pseudofractures. Histologic features include a tangled pattern of collagen fibrils with abundant osteoblasts and osteoclasts. There is no effective treatment. Spontaneous remission has been reported in a small number of patients. Calcium and vitamin D have not been beneficial.

FIBROUS DYSPLASIA AND McCUNE ALBRIGHT SYNDROME

Fibrous dysplasia is a sporadic disorder characterized by the presence of one (monoostotic) or more (polyostotic) expanding fibrous skeletal lesions composed of bone-forming mesenchyme. The association of the polyostotic form with café-au-lait spots and hyperfunction of an endocrine system such as pseudo-precocious puberty of ovarian origin is known as *McCune-Albright syndrome* (MAS). A spectrum of the phenotypes is caused by activating mutations in the *GNAS1* gene, which encodes the α subunit of the stimulatory G protein ($G_s\alpha$). As the postzygotic mutations occur at different stages of early development, the extent and type of tissue affected are variable and explain the mosaic pattern of skin and bone changes. GTP binding activates the $G_s\alpha$ regulatory protein and mutations in regions of $G_s\alpha$ that selectively inhibit GTPase activity, which results in constitutive stimulation of the cyclic AMP–protein kinase A signal transduction pathway. Such mutations of the $G_s\alpha$ protein–coupled receptor may cause autonomous function in bone (parathyroid hormone receptor); skin (melanocyte-stimulating hormone receptor); and various endocrine glands including ovary (follicle-stimulating hormone receptor), thyroid (thyroid-stimulating hormone receptor), adrenal (adrenocorticotropic hormone receptor), and pituitary (growth hormone–releasing hormone receptor). The skeletal lesions are composed largely of mesenchymal cells that do not differentiate into osteoblasts, resulting in the formation of imperfect bone. In some areas of bone, fibroblast-like cells develop features of osteoblasts in that they produce extracellular matrix that organizes into woven bone. Calcification may occur in some areas. In other areas, cells have features of chondrocytes and produce cartilage-like extracellular matrix.

CLINICAL PRESENTATION Fibrous dysplasia occurs with equal frequency in both sexes, whereas MAS with precocious puberty is more common (10:1) in girls. The monoostotic form is the most common and is usually diagnosed in patients between 20 and 30 years of age without associated skin lesions. The polyostotic form typically manifests in children $<$10 years of age and may progress with age. Early-onset disease is generally more severe. Lesions may become quiescent in puberty and progress during pregnancy or with estrogen therapy. In polyostotic fibrous dysplasia, the lesions most commonly involve the maxilla and other craniofacial bones, ribs, and metaphyseal or diaphyseal portions of the proximal femur or tibia. Expanding bone lesions may cause pain, deformity, fractures, and nerve entrapment. Sarcomatous degeneration involving the facial bones or femur is infrequent ($<$1%). The risk of malignant transformation is increased by radiation, which has proven to be ineffective treatment. In rare patients with widespread lesions, renal phosphate wasting and hypophosphatemia may cause rickets or osteomalacia. Hypophosphatemia may be due to production of a phosphaturic factor by the abnormal fibrous tissue.

MAS patients may have café-au-lait spots, which are flat, hyperpigmented skin lesions that have rough borders ("coast of Maine") in contrast to the café-au-lait lesions of neurofibromatosis that have smooth borders ("coast of California"). The most common endocrinopathy is isosexual pseudo-precocious puberty in girls. Other less common endocrine disorders include thyrotoxicosis, Cushing syndrome, acromegaly, hyperparathyroidism, hyperprolactinemia, and pseudo-precocious puberty in boys.

RADIOGRAPHIC FINDINGS In long bones, the fibrous dysplastic lesions are typically well-defined, radiolucent areas with thin cortices and a ground-glass appearance. Lesions may be lobulated with trabeculated areas of radiolucency (Fig. 334-4). Involvement of facial bones usually presents as radiodense lesions, which may create a leonine appearance (leontiasis osea). Expansile cranial lesions may narrow foramina and cause optic lesions, reduce hearing, and create other manifestations of cranial nerve compression.

LABORATORY RESULTS Serum ALP is occasionally elevated but calcium, parathyroid hormone, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D levels are normal. Patients with extensive polyostotic lesions may have hypophosphatemia, hyperphosphaturia, and osteomalacia. Biochemical markers of bone turnover may be elevated.

TREATMENT

Spontaneous healing of the lesions does not occur, and there is no established effective treatment. Improvement in bone pain and partial or complete resolution of radiographic lesions have been reported after intravenous bisphosphonate therapy. Surgical stabilization is used to prevent pathologic fracture or destruction of a major joint space, and to relieve nerve root or cranial nerve compression or sinus obstruction.

OTHER DYSPLASIAS OF BONE AND CARTILAGE

PACHYDERMOPERIOSTOSIS Pachydermoperiostosis, or hypertrophic osteoarthropathy (primary or idiopathic), is an autosomal dominant disorder characterized by periosteal new bone formation that involves the distal extremities. The lesions present as clubbing of the digits and hyperhydrosis and thickening of the skin, primarily of the face and forehead. The changes usually appear during adolescence, progress over the next decade, and then become quiescent. During the active phase, progressive enlargement of the hands and feet produces a paw-like appearance, which may be mistaken for acromegaly. Arthralgias, pseudogout, and limited mobility may also occur. The disorder must be differentiated from secondary hypertrophic osteopathy that develops during the course of serious pulmonary disorders. The two con-

FIGURE 334-4 Radiograph of a 16-year-old male with fibrous dysplasia of the right proximal femur. Note the multiple cystic lesions, including the large lucent lesion in the proximal mid-shaft with scalloping of the interior surface. The femoral neck contains two lucent cystic lesions.

ditions can be differentiated by standard radiography of the digits in which secondary pachydermoperiostosis has exuberant periosteal new bone formation and a smooth and undulating surface. In contrast, primary hypertrophic osteopathy has an irregular periosteal surface.

There are no diagnostic blood or urine tests. Synovial fluid does not have an inflammatory profile. There is no specific therapy, although a limited experience with colchicine suggests some benefit in controlling the arthralgias.

OSTEOCHONDRODYSPLASIAS These include several hundred heritable disorders of connective tissue. These primary abnormalities of cartilage manifest as disturbances in cartilage and bone growth. Selected growth plate chondrodysplasias are described here. →***For discussion of chondrodysplasias, see Chap. 342.***

Achondrodysplasia This is a relatively common form of short-limb dwarfism that occurs in 1 in 15,000 to 1 in 40,000 live births. The disease is caused by a mutation of the fibroblast growth factor receptor 3 (*FGFR3*) gene that results in a gain-of-function state. Most cases are sporadic mutations. However, when the disorder appears in families, the inheritance pattern is consistent with an autosomal dominant disorder. The primary defect is abnormal chondrocyte proliferation at the growth plate that causes development of short but proportionately thick long bones. Other regions of the long bones may be relatively unaffected. The disorder is manifest by the presence of short limbs (particularly the proximal portions), normal trunk, large head, saddle nose, and an exaggerated lumbar lordosis. Severe spinal deformity may lead to cord compression. The homozygous disorder is more serious than the sporadic form and may cause neonatal death. Pseudoachondroplasia clinically resembles achondroplasia but has no skull abnormalities.

Enchondromatosis This is also called dyschondroplasia, or Ollier disease; it is also a disorder of the growth plate in which the primary cartilage is not resorbed. Cartilage ossification proceeds normally but it is not resorbed normally, leading to cartilage accumulation. The changes are most marked at the ends of long bones where the highest growth rates occur. Chondrosarcoma develops infrequently. The association of enchondromatosis and cavernous hemangiomas of the skin and soft tissues is known as *Maffucci syndrome*. Both Ollier disease and Maffucci syndrome are associated with various malignancies, including granulosa cell tumor of the ovary and cerebral glioma.

Multiple Exostoses This is also called diaphyseal aclasis, or osteochondromatosis; it is a genetic disorder that follows an autosomal dominant pattern of inheritance. In this condition, areas of growth plates become displaced, presumably by growing through a defect in the perichondrium. The lesion begins with vascular invasion of the growth plate cartilage, resulting in a characteristic radiographic finding of a mass that is in direct communication with the marrow cavity of the parent bone. The underlying cortex is resorbed. The disease is caused by inactivating mutations of the *EXT1* and *EXT2* genes, whose products normally regulate processing of chondrocyte cytoskeletal proteins. The products of the *EXT* gene likely function as tumor suppressors, with the loss-of-function mutation resulting in abnormal proliferation of growth plate cartilage. Solitary or multiple lesions are located in the metaphyses of long bones. Although usually asymptomatic, the lesions may interfere with joint or tendon function or compress peripheral nerves. The lesions stop growing when growth ceases but may recur during pregnancy. There is a small risk for malignant transformation into chondrosarcoma.

EXTRASKELETAL (ECTOPIC) CALCIFICATION AND OSSIFICATION

Deposition of calcium phosphate crystals (*calcification*) or formation of true bone (*ossification*) in nonosseous soft tissue may occur by one of three mechanisms: (1) metastatic calcification due to a supranormal calcium x phosphate concentration product in extracellular fluid; (2) dystrophic calcification due to mineral deposition into metabolically impaired or dead tissue despite normal serum levels of calcium and phosphate; and (3) ectopic ossification, or true bone formation. Disorders that may cause extraskeletal calcification or ossification are listed in Table 334-2.

METASTATIC CALCIFICATION Soft tissue calcification may complicate diseases associated with significant hypercalcemia, hyperphosphatemia, or both. In addition, vitamin D and phosphate treatments or calcium administration in the presence of mild hyperphosphatemia, such as during hemodialysis, may induce ectopic calcification. Calcium phosphate precipitation may complicate any disorder when the serum calcium × phosphate concentration product >75. The initial calcium phosphate deposition is in the form of small, poorly organized crystals, which subsequently organize into hydroxyapatite crystals. Calcifications that occur in hypercalcemic states with normal or low phosphate have a predilection for kidney, lungs, and gastric mucosa. Hyperphosphatemia with normal or low serum calcium may promote soft tissue calcification with predilection for the kidney and arteries. The disturbances of calcium and phosphate in renal failure and hemodialysis are common causes of soft tissue (metastatic) calcification.

TUMORAL CALCINOSIS This is a rare genetic disorder characterized by masses of metastatic calcifications in soft tissues around major joints, most often shoulders, hips, and ankles. Tumoral calcinosis differs from other disorders in that the periarticular masses contain hydroxyapatite crystals or amorphous calcium phosphate complexes, while in fibrodysplasia ossificans progressiva (below), true bone is formed in soft tissues. About one-third of tumoral calcinosis cases are familial, with both autosomal recessive and autosomal dominant modes of inheritance reported. The disease is also associated with a variably expressed abnormality of dentition marked by short bulbous roots, pulp calcification, and radicular dentin deposited in swirls. The primary defect responsible for the metastatic calcification appears to be hyperphosphatemia resulting from the increased capacity of the renal tubule to reabsorb filtered phosphate. Spontaneous soft tissue calcification is related to the elevated serum phosphate, which along with normal serum calcium exceeds the concentration product of 75.

All of the North American patients reported have been African-American. The disease usually presents in childhood and continues lifelong. The calcific masses are typically painless and grow at variable rates, sometimes becoming large and bulky. The masses are often located near major joints but remain extracapsular. Joint range of motion is not usually restricted unless the tumors are very large. Complications include compression of neural structures and ulceration of the overlying skin with drainage of chalky fluid and risk of secondary infection. Small deposits not detected by standard radiographs may be detected by ^{99m}Tc bone scanning. The most common laboratory findings are hyperphosphatemia and elevated serum 1,25-dihydroxyvitamin D levels. Serum calcium, parathyroid hormone, and ALP levels are usually normal. Renal function is also usually normal. Urine cal-

TABLE 334-2 Diseases and Conditions Associated with Ectopic Calcification and Ossification

- Metastatic calcification
  - Hypercalcemic states
    - Primary hyperparathyroidism
    - Sarcoidosis
    - Vitamin D intoxication
    - Milk-alkali syndrome
    - Renal failure
  - Hyperphosphatemia
    - Tumoral calcinosis
    - Secondary hyperparathyroidism
    - Pseudohypoparathyroidism
    - Renal failure
    - Hemodialysis
    - Cell lysis following chemotherapy
    - Therapy with vitamin D and phosphate
- Dystrophic calcification
  - Inflammatory disorders
    - Scleroderma
    - Dermatomyositis
    - Systemic lupus erythematosus
  - Trauma-induced
- Ectopic ossification
  - Myositis ossificans
    - Post surgery
    - Burns
    - Neurologic injury
    - Other trauma
  - Fibrodysplasia ossificans progressiva

cium and phosphate excretions are low, and calcium and phosphate balances are positive.

An acquired form of the disease may occur with other causes of hyperphosphatemia, such as secondary hyperparathyroidism associated with hemodialysis, hypoparathyroidism, pseudohypoparathyroidism, and massive cell lysis following chemotherapy for leukemia. Tissue trauma from joint movement may contribute to the periarticular calcifications. Metastatic calcifications are also seen in conditions associated with hypercalcemia, such as in sarcoidosis, vitamin D intoxication, milk-alkali syndrome, and primary hyperparathyroidism. In these conditions, however, mineral deposits are more likely to occur in proton-transporting organs such as kidney, lungs, and gastric mucosa in which an alkaline milieu is generated by the proton pumps.

TREATMENT

Therapeutic successes have been achieved with surgical removal of subcutaneous calcified masses, which tend not to recur if all calcification is removed from the site. Reduction of serum phosphate by chronic phosphorus restriction may be accomplished using low dietary phosphorus intake alone or in combination with oral phosphate binders. The addition of the phosphaturic agent acetazolamide may be useful. Limited experience using the phosphaturic action of calcitonin deserves further testing.

DYSTROPHIC CALCIFICATION Posttraumatic calcification may occur with normal serum calcium and phosphate levels and normal ion solubility product. The deposited mineral is either in the form of amorphous calcium phosphate or hydroxyapatite crystals. Soft tissue calcification complicating connective tissue disorders such as scleroderma, dermatomyositis, and systemic lupus erythematosus may involve localized areas of the skin or deeper subcutaneous tissue and is referred to as *calcinosis circumscripta*. Mineral deposition at sites of deeper tissue injury including periarticular sites is called *calcinosis universalis*.

ECTOPIC OSSIFICATION True extraskeletal bone formation that begins in areas of fasciitis following surgery, trauma, burns, or neurologic injury is referred to as *myositis ossificans*. The bone formed is organized as lamellar or trabecular, with normal osteoblasts and osteoclasts conducting active remodeling. Well-developed haversian systems and marrow elements may be present. A second cause of ectopic bone formation occurs in an inherited disorder, *fibrodysplasia ossificans progressiva*.

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA This is also called *myositis ossificans progressiva*; it is a rare autosomal dominant disorder characterized by congenital deformities of the hands and feet and episodic soft tissue swellings that ossify. Ectopic bone formation occurs in fascia, tendons, ligaments, and connective tissue within voluntary muscles. Tender, rubbery induration, sometimes precipitated by trauma, develops in the soft tissue and gradually calcifies. Eventually, heterotopic bone forms at these sites of soft tissue trauma. Morbidity results from heterotopic bone interfering with normal movement and function of muscle and other soft tissues. Mortality is usually related to restrictive lung disease caused by an inability of the chest to expand. Laboratory tests are unremarkable.

There is no effective medical therapy. Bisphosphonates, glucocorticoids, and a low-calcium diet have largely been ineffective in halting progression of the ossification. Surgical removal of ectopic bone is not recommended, as the trauma of surgery may precipitate formation of new areas of heterotopic bone. Dental complications including frozen jaw may occur following injection of local anesthetics. Thus, CT imaging of the mandible should be undertaken to detect early sites of soft tissue ossification before they are appreciated by standard radiography.

ACKNOWLEDGMENT

The authors wish to acknowledge the contributions of Dr. Stephen M. Krane to this chapter in previous editions of Harrison's.

Section 3 Disorders of Intermediary Metabolism

335 DISORDERS OF LIPOPROTEIN METABOLISM

Daniel J. Rader, Helen H. Hobbs

Lipoproteins are complexes of lipids and proteins that are essential for the transport of cholesterol, triglycerides, and fat-soluble vitamins. Until recently, lipoprotein disorders were the purview of lipidologists, but the demonstration that lipid-lowering therapy significantly reduces the clinical complications of atherosclerotic cardiovascular disease (ASCVD) has brought the diagnosis and treatment of these disorders into the domain of the general internist. The metabolic consequences associated with changes in diet and lifestyle have increased the number of hyperlipidemic individuals who could benefit from lipid-lowering therapy. The development of safe, effective, and well-tolerated pharmacologic agents has greatly expanded the therapeutic armamentarium available to the physician to treat disorders of lipid metabolism. Therefore, the appropriate diagnosis and management of lipid disorders is critically important to the practice of medicine. This chapter reviews normal lipoprotein physiology, the pathophysiology of the known single-gene disorders of lipoprotein metabolism, the environmental factors that influence lipoprotein metabolism, and the practical approaches to their diagnosis and management.

LIPOPROTEIN METABOLISM

LIPOPROTEIN CLASSIFICATION AND COMPOSITION Lipoproteins are large, mostly spherical complexes that transport lipids (primarily triglycerides, cholesteryl esters, and fat-soluble vitamins) through body fluids (plasma, interstitial fluid, and lymph) to and from tissues. Lipoproteins play an essential role in the absorption of dietary cholesterol, long-chain fatty acids, and fat-soluble vitamins; the transport of triglycerides, cholesterol, and fat-soluble vitamins from the liver to peripheral tissues; and the transport of cholesterol from peripheral tissues to the liver.

Lipoproteins contain a core of hydrophobic lipids (triglycerides and cholesteryl esters) surrounded by hydrophilic lipids (phospholipids, unesterified cholesterol) and proteins that interact with body fluids.

The plasma lipoproteins are divided into five major classes based on their relative densities (Fig. 335-1 and Table 335-1): chylomicrons, very low density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). Each lipoprotein class comprises a family of particles that vary slightly in density, size, migration during electrophoresis, and protein composition. The density of a lipoprotein is determined by the amount of lipid and protein per particle. HDL is the smallest and most dense lipoprotein, whereas chylomicrons and VLDL are the largest and least dense lipoprotein particles. Most triglyceride is transported in chylomicrons or VLDL, and most cholesterol is carried as cholesteryl esters in LDL and HDL.

TABLE 335-1 *Major Lipoprotein Classes*[a]

Lipoprotein	Density, g/mL[b]	Size nm[c]	Electrophoretic Mobility[d]	Apolipoproteins		Other Constituents
				Major	Other	
Chylomicrons	0.930	75–1200	Origin	ApoB-48	A-I, A-IV, C-I, C-II, C-III	Retinyl esters
Chylomicron remnants	0.930–1.006	30–80	Slow pre-β	ApoB-48	E, A-I, A-IV, C-I, C-II, C-III	Retinyl esters
VLDL	0.930–1.006	30–80	Pre-β	ApoB-100	E, A-I, A-II, A-V, C-I, C-II, C-III	Vitamin E
IDL	1.006–1.019	25–35	Slow pre-β	ApoB-100	E, C-I, C-II, C-III	Vitamin E
LDL	1.019–1.063	18–25	β	ApoB-100		Vitamin E
HDL	1.063–1.210	5–12	Alpha	ApoA-I	A-II, A-IV, E, C-III	LCAT, CETP paroxonase
Lp(a)	1.050–1.120	25	Pre-β	ApoB-100	Apo(a)	

[a] All of the lipoprotein classes contain phospholipids, esterified and unesterified cholesterol, and triglycerides to varying degrees.
[b] The density of the particle is determined by ultracentrifugation.
[c] The size of the particle is measured using gel electrophoresis.
[d] The electrophoretic mobility of the particle on agarose gel electrophoresis reflects the size and surface charge of the particle, with β being the position of LDL and α the position of HDL.
Note: VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; Lp(a), lipoprotein A; LCAT, lecithin-cholesterol acyltransferase; CETP, cholesteryl ester transfer protein.

The apolipoproteins are required for the assembly and structure of lipoproteins (Table 335-2). Apolipoproteins also serve to activate enzymes important in lipoprotein metabolism and to mediate the binding of lipoproteins to cell-surface receptors. ApoA-I, which is synthesized in the liver and intestine, is found on virtually all HDL particles. ApoA-II is the second most abundant HDL apolipoprotein and is found on approximately two-thirds of all HDL particles. ApoB is the major structural protein of chylomicrons, VLDL, IDL, and LDL; one molecule of apoB, either apoB-48 (chylomicrons) or apoB-100 (VLDL, IDL, or LDL), is present on each lipoprotein particle. The human liver makes only apoB-100, and the intestine makes apoB-48, which is derived from the same gene by mRNA editing. ApoE is present in multiple copies on chylomicrons, VLDL, and IDL and plays a critical role in the metabolism and clearance of triglyceride-rich particles. Three apolipoproteins of the C-series (apoC-I, -II, and -III) also participate in the metabolism of triglyceride-rich lipoproteins. The other apolipoproteins are listed in Table 335-2.

TRANSPORT OF DIETARY LIPIDS (EXOGENOUS PATHWAY) The exogenous pathway of lipoprotein metabolism permits efficient transport of dietary lipids (Fig. 335-2). Dietary triglycerides are hydrolyzed by pancreatic lipases within the intestinal lumen and are emulsified with bile acids to form micelles. Dietary cholesterol and retinol are esterified (by the addition of a fatty acid) in the enterocyte to form cholesteryl esters and retinyl esters, respectively. Longer-chain fatty acids (>12 carbons) are incorporated into triglycerides and packaged with apoB-48, cholesteryl esters, retinyl esters, phospholipids, and cholesterol to form chylomicrons. Nascent chylomicrons are secreted into the intestinal lymph and delivered directly to the systemic circulation, where they are extensively processed by peripheral tissues before reaching the liver. The particles encounter lipoprotein lipase (LPL), which is anchored to proteoglycans that decorate the capillary endothelial surfaces of adipose tissue, heart, and skeletal muscle (Fig. 335-2). The triglycerides of chylomicrons are hydrolyzed by LPL, and free fatty acids are released; apoC-II, which is transferred to circulating chylomicrons, acts as a cofactor for LPL in this reaction. The released free fatty acids are taken up by adjacent myocytes or adipocytes and either oxidized or reesterified and stored as triglyceride. Some free fatty acids bind albumin and are transported to other tissues, especially the liver. The chylomicron particle progressively shrinks in size as the hydrophobic core is hydrolyzed and the hydrophilic lipids (cholesterol and phospholipids) on the particle surface are transferred to HDL. The resultant smaller, more cholesterol ester–rich particles are referred to as *chylomicron remnants*. The remnant particles are rapidly removed from the circulation by the liver in a process that requires apoE. Consequently, few, if any, chylomicrons are present in the blood after a 12-h fast, except in individuals with disorders of chylomicron metabolism.

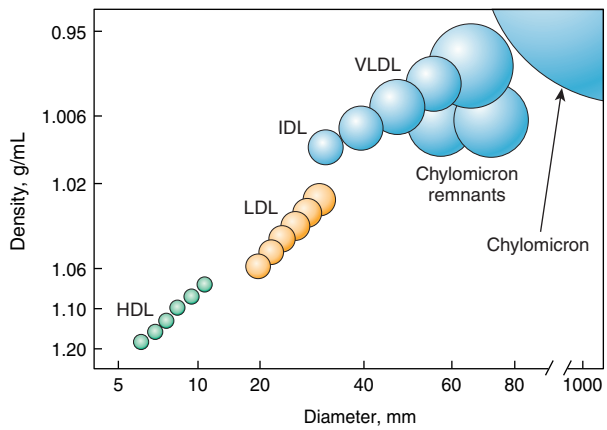

FIGURE 335-1 The density and size-distribution of the major classes of lipoprotein particles. Lipoproteins are classified by density and size, which are inversely related. VLDL, very low density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; HDL, high-density lipoproteins.

TRANSPORT OF HEPATIC LIPIDS (ENDOGENOUS PATHWAY) The *endogenous pathway of lipoprotein metabolism* refers to the hepatic secretion and metabolism of VLDL to IDL and LDL (Fig. 335-2). VLDL particles resemble chylomicrons in protein composition but contain apoB-100 rather than apoB-48 and have a higher ratio of cholesterol to triglyceride (~1 mg of cholesterol for every 5 mg of triglyceride). The triglycerides of VLDL are derived predominantly from the esterification of long-chain fatty acids. The packaging of hepatic triglycerides with the other major components of the nascent VLDL particle (apoB-100, cholesteryl esters, phospholipids, and vitamin E) requires the action of the enzyme microsomal transfer protein (MTP). After secretion into the plasma, VLDL acquires multiple copies of apoE and apolipoproteins of the C series. The triglycerides of VLDL are hydrolyzed by LPL, especially in muscle and adipose tissue. As VLDL remnants undergo further hydrolysis, they continue to shrink in size and become *IDL*, which contain similar amounts of cholesterol and triglyceride. The liver removes approximately 40 to 60% of VLDL remnants and IDL by LDL receptor–mediated endocytosis via binding to apoE. The remainder of IDL is remodeled by hepatic lipase (HL) to form LDL; during this process, most of the triglyceride in the particle is hydrolyzed and all apolipoproteins except apoB-100 are transferred to other lipoproteins. The cholesterol in LDL accounts for ~70% of the plasma cholesterol in most individuals. Approximately 70% of circulating LDLs are cleared by LDL receptor–mediated endocytosis in the liver.

TABLE 335-2 *Major Apolipoproteins*

Apolipoprotein	Primary Source	Lipoprotein Association	Function
ApoA-I	Intestine, liver	HDL, chylomicrons	Structural protein for HDL; activates LCAT
ApoA-II	Liver	HDL, chylomicrons	Structural protein for HDL
ApoA-IV	Intestine	HDL, chylomicrons	Unknown
ApoA-V	Liver	VLDL	Unknown
ApoB-48	Intestine	Chylomicrons	Structural protein for chylomicrons
ApoB-100	Liver	VLDL, IDL, LDL, Lp(a)	Structural protein for VLDL, LDL, IDL, Lp(a); ligand for binding to LDL receptor
ApoC-I	Liver	Chylomicrons, VLDL, HDL	Unknown
ApoC-II	Liver	Chylomicrons, VLDL, HDL	Cofactor for LPL
ApoC-III	Liver	Chylomicrons, VLDL, HDL	Inhibits lipoprotein binding to receptors
ApoD	Spleen, brain, testes, adrenals	HDL	Unknown
ApoE	Liver	Chylomicron remnants, IDL, HDL	Ligand for binding to LDL receptor
ApoH	Liver	Chylomicrons, VLDL, LDL, HDL	B_2 glycoprotein I
ApoJ	Liver	HDL	Unknown
ApoL	Unknown	HDL	Unknown
Apo(a)	Liver	Lp(a)	Unknown

Note: HDL, high-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein A; LPL, lipoprotein lipase.

Lipoprotein(a) [Lp(a)] is a lipoprotein similar to LDL in lipid and protein composition, but it contains an additional protein called apolipoprotein(a) [apo(a)]. Apo(a) is synthesized in the liver and is attached to apoB-100 by a disulfide linkage. The mechanism by which Lp(a) is removed from the circulation is not known.

HDL METABOLISM AND REVERSE CHOLESTEROL TRANSPORT All nucleated cells synthesize cholesterol but only hepatocytes can efficiently metabolize and excrete cholesterol from the body. The predominant route of cholesterol elimination is by excretion into the bile, either directly or after conversion to bile acids. Cholesterol in peripheral cells is transported from the plasma membranes of peripheral cells to the liver by an HDL-mediated process termed *reverse cholesterol transport* (Fig. 335-3).

Nascent HDL particles are synthesized by the intestine and the liver. The newly formed discoidal HDL particles contain apoA-I and phospholipids (mainly lecithin) but rapidly acquire unesterified cholesterol and additional phospholipids from peripheral tissues via transport by the membrane protein ATP-binding cassette protein A1 (ABCA1). Once incorporated in the HDL particle, cholesterol is esterified by lecithin-cholesterol acyltransferase (LCAT), a plasma enzyme associated with HDL. As HDL acquires more cholesteryl ester it becomes spherical, and additional apolipoproteins and lipids are transferred to the particles from the surfaces of chylomicrons and VLDL during lipolysis.

HDL cholesterol is transported to hepatoctyes by both an indirect and a direct pathway. HDL cholesteryl esters are transferred to apoB-containing lipoproteins in exchange for triglyceride by the cholesteryl ester transfer protein (CETP). The cholesteryl esters are then removed from the circulation by LDL receptor–mediated endocytosis. HDL cholesterol can also be taken up directly by hepatocytes via the scavenger receptor class BI (SR-BI), a cell-surface receptor that mediates the selective transfer of lipids to cells.

HDL particles undergo extensive remodeling within the plasma compartment as they transfer lipids and proteins to lipoproteins and cells. For example, after CETP-mediated lipid exchange, the triglyceride-enriched HDL becomes a substrate for HL, which hydrolyzes the triglycerides and phospholipids to generate smaller HDL particles.

DISORDERS OF LIPOPROTEIN METABOLISM

The identification and characterization of genes responsible for the genetic forms of hyperlipidemia have provided important molecular insight into the critical roles of apolipoproteins, enzymes, and receptors in lipid metabolism.

PRIMARY DISORDERS OF ApoB-CONTAINING LIPOPROTEIN BIOSYNTHESIS CAUSING LOW PLASMA CHOLESTEROL LEVELS (KNOWN ETIOLOGY) The synthesis and secretion of apoB-containing lipoproteins in the enterocytes of the proximal small bowel and in the hepatocytes of the liver involve a complex series of events that coordinate the coupling of various lipids with apoB-48 and apoB-100, respectively.

Abetalipoproteinemia Abetalipoproteinemia is a rare autosomal recessive disease caused by mutations in the gene encoding MTP, which transfers lipids to nascent chylomicrons and VLDL in the intestine and liver, respectively. Plasma cholesterol and triglyceride levels are extremely low in this disorder, and no chylomicrons, VLDL, LDL, or apoB are detectable. The parents of patients with abetalipoproteinemia (who are obligate heterozygotes) have normal plasma lipid and apoB levels. Abetalipoproteinemia usually presents in early childhood with diarrhea and failure to thrive and is characterized clinically by fat malabsorption, spinocerebellar degeneration, pigmented retinopathy, and acanthocytosis. The initial neurologic manifestations are loss of deep-tendon reflexes, followed by decreased distal lower extremity vibratory and proprioceptive sense, dysmetria, ataxia, and the development of a spastic gait, often by the third or fourth decade. Patients with abetalipoproteinemia also develop a progressive pigmented retinopathy presenting with decreased night and color vision, followed by reductions in daytime visual acuity and ultimately progressing to near blindness. The presence of spinocerebellar degeneration and pigmented retinopathy in this disease has resulted in misdiagnosis of Friedreich's ataxia. Rarely, patients with abetalipoproteinemia develop a cardiomyopathy with associated life-threatening arrhythmias.

Most clinical manifestations of abetalipoproteinemia result from defects in the absorption and transport of fat-soluble vitamins. Vitamin E and retinyl esters are normally transported from enterocytes to the liver by chylomicrons, and vitamin E is dependent on VLDL for transport out of the liver and into the circulation. Patients with abetalipoproteinemia are markedly deficient in vitamin E and are also mildly to moderately deficient in vitamin A and vitamin K. Treatment of abetalipoproteinemia consists of a low-fat, high-caloric, vitamin-enriched diet accompanied by large supplemental doses of vitamin E. It is imperative for treatment to be initiated as soon as possible to obviate the development of neurologic sequelae.

Familial Hypobetalipoproteinemia Familial homozygous hypobetalipoproteinemia has a clinical picture similar to abetalipoproteinemia but is autosomal codominant in inheritance pattern. The disease can be differentiated from abetalipoproteinemia since the parents of the probands with this disorder have levels of plasma LDL-C and apoB that are less than half of the normal levels. Mutations in the gene encoding apoB-100 that interfere with protein synthesis are common causes of this disorder. These patients, like those with abetalipoproteinemia, should be referred to specialized centers for confirmation of the diagnosis and appropriate therapy.

PRIMARY DISORDERS OF ApoB-CONTAINING LIPOPROTEIN CATABOLISM CAUSING ELEVATED PLASMA CHOLESTEROL LEVELS (KNOWN ETIOLOGY) Single-gene defects can result in the accumulation of specific classes of lipoprotein particles. Mutations in genes encoding key proteins in the metabolism and clearance of apoB-containing lipoproteins cause type I (chylomicronemia), type II (elevations in LDL) and type III (elevations in IDL) hyperlipoproteinemias (Table 335-3).

Lipoprotein Lipase and ApoC-II Deficiency (Familial Chylomicronemia Syndrome; Type I Hyperlipoproteinemia) LPL is required for the hydrolysis of triglycerides in chylomicrons and VLDL. ApoC-II is a cofactor for LPL (Fig. 335-2). Genetic deficiency of either LPL or apoC-II results in impaired lipolysis and profound elevations in plasma chylomicrons. These patients also have elevations in plasma VLDL, but chylomicronemia predominates. Normally chylomicrons are delipidated and removed from the circulation within 12 h of the last meal, but in LPL-deficient patients, the triglyceride-rich chylomicrons persist in the circulation for days. The fasting plasma is turbid, and if left at 4°C for a few hours, the chylomicrons float to the top and form a creamy supernatant. In these disorders, called *familial chylomicronemia syndromes*, fasting triglyceride levels are almost invariably >11.3 mmol/L (1000 mg/dL). Fasting cholesterol levels are also usually elevated, but to a much less severe degree.

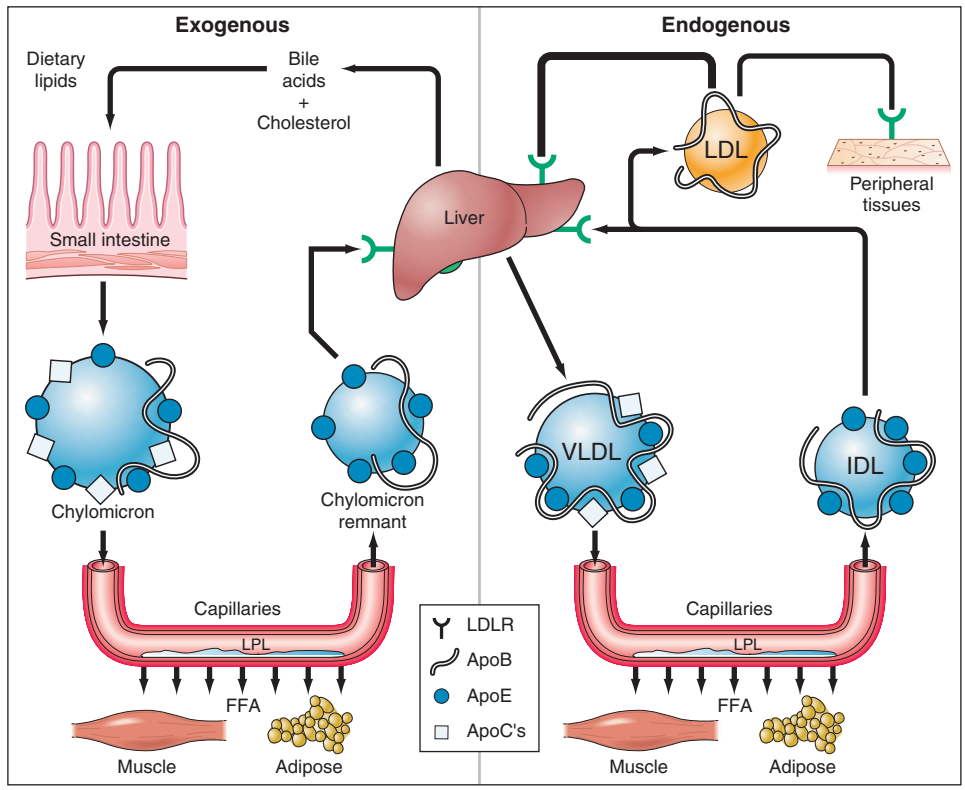

FIGURE 335-2 The exogenous and endogenous lipoprotein metabolic pathways. The exogenous pathway transports dietary lipids to the periphery and the liver. The endogenous pathway transports hepatic lipids to the periphery. LPL, lipoprotein lipase; FFA, free fatty acids; VLDL, very low density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; LDLR, low-density lipoprotein receptor.

LPL deficiency is autosomal recessive and has a population frequency of approximately one in a million. ApoC-II deficiency is also recessive in inheritance pattern and is even less common than LPL deficiency. Multiple mutations in the LPL and apoC-II genes cause these diseases. Obligate LPL heterozygotes have normal or mild to moderate elevations in plasma triglyceride levels, whereas individuals heterozygous for mutation in apoC-II are not hypertriglyceridemic.

Both LPL and apoC-II deficiency usually present in childhood with recurrent episodes of severe abdominal pain caused by acute pancreatitis. On fundoscopic examination the retinal blood vessels are opalescent (*lipemia retinalis*). Eruptive xanthomas, which are small yellowish-white papules, often appear in clusters on the back, buttocks, and extensor surfaces of the arms and legs. These typically painless skin lesions may become pruritic as they regress. Hepatosplenomegaly results from the uptake of circulating chylomicrons by reticuloendothelial cells in the liver and spleen. For reasons unknown, some patients with persistent and pronounced chylomicronemia never develop pancreatitis, eruptive xanthomas, or hepatosplenomegaly. Premature ASCVD has not been consistently demonstrated to be a feature of familial chylomicronemia syndromes.

The diagnoses of LPL and apoC-II deficiency are established enzymatically by assaying triglyceride lipolytic activity in post-heparin plasma. Blood is sampled after an intravenous heparin injection to release the endothelial-bound lipases. LPL activity is profoundly reduced in both LPL and apoC-II deficiency; in patients with apoC-II deficiency, the addition of normal pre-heparin plasma (a source of apoC-II) normalizes LPL activity, but this correction does not occur in patients with LPL deficiency.

The major therapeutic intervention in familial chylomicronemia syndromes is dietary fat restriction (to as little as 15 g/d) with fat-

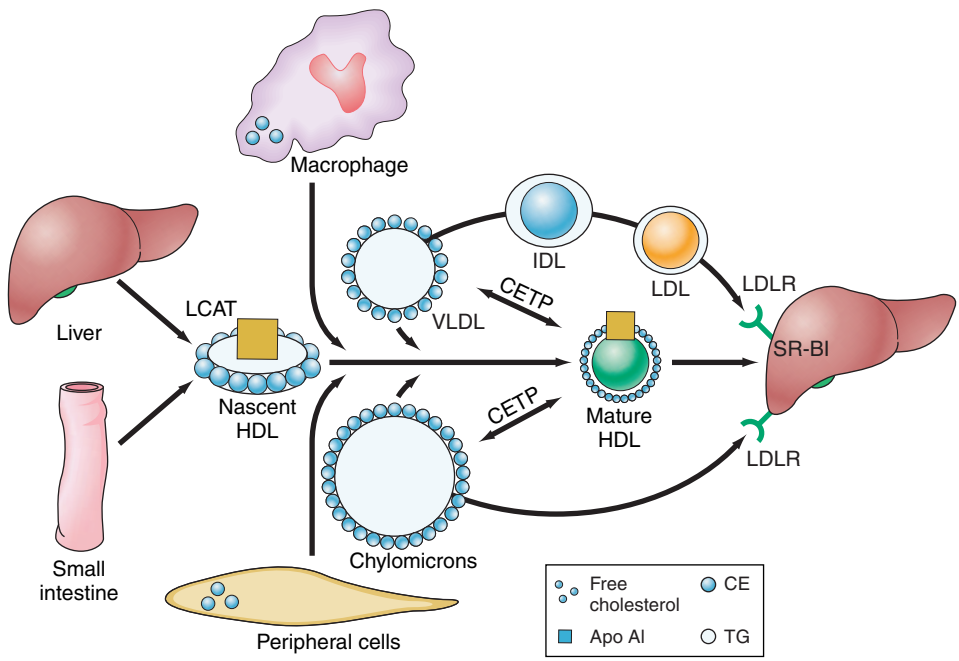

FIGURE 335-3 HDL metabolism and reverse cholesterol transport. This pathway transports excess cholesterol from the periphery back to the liver for excretion in the bile. The liver and the intestine produce nascent HDL. Free cholesterol is acquired from macrophages and other peripheral cells and esterfied by LCAT, forming mature HDL. HDL cholesterol can be selectively taken up by the liver via SR-BI. Alternatively, HDL cholesteryl ester can be transferred by CETP from HDL to VLDL and chylomicrons, which can then be taken up by the liver. LCAT, lecithin-cholesterol acyltransferase; CETP, cholesteryl ester transfer protein; VLDL, very low density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; HDL, high-density lipoproteins; LDLR, low-density lipoprotein receptor; TG, triglycerides.

TABLE 335-3 *Primary Hyperlipoproteinemias Caused by Known Single Gene Mutations*

Genetic Disorder	Gene Defect	Lipoproteins Elevated	Clinical Findings	Genetic Transmission	Estimated Incidence
Lipoprotein lipase deficiency	LPL (*LPL*)	Chylomicrons	Eruptive xanthomas, hepatosplenomegaly pancreatitis	AR	1/1,000,000
Familial apolipoprotein C-II deficiency	ApoC-II (*APOC2*)	Chylomicrons	Eruptive xanthomas, hepatosplenomegaly pancreatitis	AR	<1/1,000,000
Familial hepatic lipase deficiency	Hepatic lipase (*LIPC*)	VLDL remnants	Premature atherosclerosis	AR	<1/1,000,000
Familial dysbetalipoproteinemia	ApoE (*APOE*)	Chylomicron and VLDL remnants	Palmar and tuberoeruptive xanthomas, CHD, PVD	AR AD	1/10,000
Familial hypercholesterolemia	LDL receptor (*LDLR*)	LDL	Tendon xanthomas, CHD	AD	1/500
Familial defective apoB-100	ApoB-100 (*APOB*) ($Arg_{3500} \rightarrow Gln$)	LDL	Tendon xanthomas, CHD	AD	1/1000
Autosomal recessive hypercholesterolemia	ARH *(ARH)*	LDL	Tendon xanthomas, CHD	AR	<1/1,000,000
Sitosterolemia	*ABCG5* or *ABCG8*	LDL	Tendon xanthomas, CHD	AR	<1/1,000,000

Note: AR, autosomal recessive; AD, autosomal dominant; VLDL, very low density lipoprotein; CHD, coronary heart disease; PVD, peripheral vascular disease; LDL, low-density lipoprotein.

soluble vitamin supplementation. Consultation with a registered dietician familiar with this disorder is essential. Caloric supplementation with medium-chain triglycerides, which are absorbed directly into the portal circulation, can be useful but may be associated with hepatic fibrosis if used for prolonged periods. If dietary fat restriction alone is not successful in resolving the chylomicronemia, fish oils have been effective in some patients. In patients with apoC-II deficiency, apoC-II can be provided by infusing fresh-frozen plasma to resolve the chylomicronemia. Management of patients with familial chylomicronemia syndrome is particularly challenging during pregnancy when VLDL production is increased. Plasmapheresis may be required if pancreatitis develops and the chylomicronemia is not responsive to diet therapy.

Hepatic Lipase Deficiency HL is a member of the same gene family as LPL and hydrolyzes triglycerides and phospholipids in remnant lipoproteins and HDL. HL deficiency is a very rare autosomal recessive disorder characterized by elevated plasma cholesterol and triglycerides (mixed hyperlipidemia) due to the accumulation of lipoprotein remnants. HDL-C is normal or elevated. The diagnosis is confirmed by measuring HL activity in post-heparin plasma. Due to the small number of patients with HL deficiency, the association of this genetic defect with ASCVD is not known, but lipid-lowering therapy is recommended.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia) Like HL deficiency, familial dysbetalipoproteinemia (FDBL) (also known as *type III hyperlipoproteinemia* or *familial broad β disease*) is characterized by a mixed hyperlipidemia due to the accumulation of remnant lipoprotein particles. ApoE is present in multiple copies on chylomicron and VLDL remnants and mediates their removal via hepatic lipoprotein receptors (Fig. 335-2). FDBL is due to genetic variations in apoE that interfere with its ability to bind lipoprotein receptors. The *APOE* gene is polymorphic in sequence resulting in the expression of three common isoforms: apoE3, apoE2, and apoE4. Although associated with slightly higher LDL-C levels and increased coronary heart disease (CHD) risk, the apoE4 allele is not associated with FDBL. Patients with apoE4 have an increased incidence of late-onset Alzheimer disease. ApoE2 has a lower affinity for the LDL receptor. Therefore, chylomicron and VLDL remnants containing apoE2 are removed from plasma at a slower rate. Individuals who are homozygous for the E2 allele (the E2/E2 genotype) comprise the most common subset of patients with FDBL.

Approximately 1% of the general population are apoE2/E2 homozygotes but only a small minority of these individuals develop FDBL. In most cases an additional, identifiable factor precipitates the development of hyperlipoproteinemia. The most common precipitating factors are a high-caloric, high-fat diet, diabetes mellitus, obesity, hypothyroidism, renal disease, estrogen deficiency, alcohol use, or the presence of another genetic form of hyperlipidemia, most commonly familial combined hyperlipidemia (FCHL) or familial hypercholesterolemia (FH). Rare mutations in apoE cause dominant forms of FDBL; in this case the hyperlipidemia is fully manifest in the heterozygous state.

Patients with FDBL usually present in adulthood with xanthomas and premature coronary and peripheral vascular disease. The disease seldom presents in women before menopause. Two distinctive types of xanthomas are seen in FDBL patients: tuberoeruptive and palmar xanthomas. *Tuberoeruptive xanthomas* begin as clusters of small papules on the elbows, knees, or buttocks and can grow to the size of small grapes. *Palmar xanthoma* (alternatively called *xanthomata striata palmaris*) are orange-yellow discolorations of the creases in the palms. In FDBL, the plasma cholesterol and triglyceride are elevated to a relatively similar degree until the triglyceride levels reach ~5.6 mol/L (~500 mg/dL), and then the triglycerides tends to be greater than cholesterol.

The traditional approach to diagnose this disorder is to use lipoprotein electrophoresis; in FDBL, the remnant lipoproteins accumulate in a broad β band. The preferred method to confirm the diagnosis of FDBL is to measure VLDL-C by ultracentrifugation and determine the ratio of VLDL-C to total plasma triglyceride; a ratio >0.30 is consistent with the diagnosis of FDBL. Protein methods (apoE phenotyping) or DNA-based methods (apoE genotyping) can be performed to confirm homozygosity for apoE2. However, absence of the apoE2/2 genotype does not rule out the diagnosis of FDBL, since other mutations in apoE can cause this condition.

Because FDBL is associated with increased risk of premature ASCVD, it should be treated aggressively. Other metabolic conditions that can worsen the hyperlipidemia (see above) should be actively treated. Patients with FDBL are typically very diet responsive and can respond dramatically to weight reduction and to low-cholesterol, low-fat diets. Alcohol intake should be curtailed. In postmenopausal women with FDBL, the dyslipidemia responds to estrogen-replacement therapy. HMG-CoA reductase inhibitors, fibrates, and niacin are all generally effective in the treatment of FDBL, and combination drug therapy is sometimes required.

Familial Hypercholesterolemia FH is an autosomal codominant disorder characterized by elevated plasma LDL-C with normal triglycerides, tendon xanthomas, and premature coronary atherosclerosis. FH is caused by >750 mutations in the LDL receptor gene and has a higher incidence in certain populations, such as Afrikaners, Christian Lebanese, and French Canadians, due to the founder effect. The elevated levels of LDL-C in FH are due to delayed catabolism of LDL and its

precursor particles from the blood, resulting in increased rates of LDL production. There is a major gene dose effect, in that individuals with two mutated LDL receptor alleles (FH homozygotes) are much more affected than those with one mutant allele (FH heterozygotes).

Homozygous FH occurs in approximately 1 in 1 million persons world-wide. Patients with homozygous FH can be classified into one of two groups based on the amount of LDL receptor activity measured in their skin fibroblasts: those patients with <2% of normal LDL receptor activity (receptor negative) and those patients with 2 to 25% of normal LDL receptor activity (receptor defective). Most patients with homozygous FH present in childhood with cutaneous xanthomas on the hands, wrists, elbows, knees, heels, or buttocks. Arcus cornea is usually present and some patients have xanthelasmas. Total cholesterol levels are usually >12.93 mmol/L (500 mg/dL) and can be >25.86 mmol/L (1000 mg/dL). Accelerated atherosclerosis is a devastating complication of homozygous FH and can result in disability and death in childhood. Atherosclerosis often develops first in the aortic root and can cause aortic valvular or supravalvular stenosis and typically extends into the coronary ostia. Children with homozygous FH often develop symptomatic vascular disease before puberty, when symptoms can be atypical and sudden death is common. Untreated, receptor-negative patients with homozygous FH rarely survive beyond the second decade; patients with receptor-defective LDL receptor defects have a better prognosis but almost invariably develop clinically apparent atherosclerotic vascular disease by age 30, and often much sooner. Carotid and femoral disease develop later in life and are usually not clinically significant.

A careful family history should be taken, and plasma lipid levels should be measured in the parents and other first-degree relatives of patients with homozygous FH. The diagnosis can be confirmed by obtaining a skin biopsy and measuring LDL receptor activity in cultured skin fibroblasts or by quantifying the number of LDL receptors on the surfaces of lymphocytes using cell-sorting technology.

Combination therapy with an HMG-CoA reductase inhibitor and a bile acid sequestrant sometimes results in modest reductions in plasma LDL-C in the FH homozygote. Patients with homozygous FH invariably require additional lipid-lowering therapy. Since the liver is quantitatively the most important tissue for removing circulating LDL via the LDL receptor, liver transplantation is effective in decreasing plasma LDL-C levels in this disorder. Liver transplantation is, however, associated with substantial risks, including the requirement for long-term immunosuppression. The current treatment of choice for homozygous FH is LDL apheresis (a process where the LDL particles are selectively removed from the circulation), which can promote regression of xanthomas and may slow the progression of atherosclerosis. Initiation of LDL apheresis should be delayed until approximately 5 years of age except when evidence of atherosclerotic vascular disease is present.

Heterozygous FH is caused by the inheritance of one mutant LDL receptor allele and occurs in approximately 1 in 500 persons worldwide, making it one of the most common single gene disorders. It is characterized by elevated plasma LDL-C [usually 5.17 to 10.34 mmol/L (200 to 400 mg/dL)] and normal triglyceride levels. Patients with heterozygous FH have hypercholesterolemia from birth, although the disease is often not detected until adulthood, usually due to the detection of hypercholesterolemia on routine screening, the appearance of tendon xanthomas, or the premature development of symptomatic coronary atherosclerotic disease. Since the disease is codominant in inheritance and has a high penetrance (>90%), one parent and ~50% of the patient's siblings are usually hypercholesterolemic. The family history is frequently positive for premature ASCVD on one side of the family, particularly among male relatives. Corneal arcus is common, and tendon xanthomas involving the dorsum of the hands, elbows, knees, and especially the Achilles tendons are present in ~75% of patients. The age of onset of ASCVD is highly variable and depends in part on the molecular defect in the LDL receptor gene and other coexisting cardiac risk factors. FH heterozygotes with elevated plasma Lp(a) appear to be at greater risk for cardiovascular complications. Untreated men with heterozygous FH have an ~50% chance of having a myocardial infarction before age 60. Although the age of onset of atherosclerotic heart disease is later in women with FH, coronary disease is significantly more common in women with FH than in the general female population.

No definitive diagnostic test for heterozygous FH is available. Although FH heterozygotes tend to have reduced levels of LDL receptor function in skin fibroblasts, there is significant overlap with the levels in normal fibroblasts. The clinical diagnosis is usually not problematic, but it is critical that hypothyroidism, nephrotic syndrome, and obstructive liver disease be excluded before initiating therapy.

FH patients should be treated aggressively to lower plasma levels of LDL-C. Initiation of a low-cholesterol, low-fat diet is recommended, but heterozygous FH patients inevitably require lipid-lowering drug therapy. HMG-CoA reductase inhibitors are especially effective in heterozygous FH, inducing upregulation of the normal LDL receptor allele in the liver. Many heterozygous FH patients can achieve desired LDL-C levels with HMG-CoA reductase inhibitor therapy alone, but combination drug therapy with the addition of a bile acid sequestrant or nicotinic acid is frequently required. Heterozygous FH patients who cannot be adequately controlled on combination drug therapy are candidates for LDL apheresis.

Familial Defective ApoB-100 Familial defective apoB-100 (FDB) is a dominantly inherited disorder that clinically resembles heterozygous FH. FDB occurs with a frequency of ~1 in 1000 in western populations. The disease is characterized by elevated plasma LDL-C levels with normal triglycerides, tendon xanthomas, and an increased incidence of premature ASCVD. FDB is caused by mutations in the LDL receptor–binding domain of apoB-100. Almost all patients with FDB have a substitution of glutamine for arginine at position 3500 in apoB-100, although other rarer mutations have been reported to cause this disease. As a consequence of the mutation in apoB-100, LDL binds the LDL receptor with reduced affinity and LDL is removed from the circulation at a reduced rate. Patients with FDB cannot be clinically distinguished from patients with heterozygous FH, although patients with FDB tend to have lower plasma LDL-C than FH heterozygotes. The apoB-100 gene mutation can be detected directly, but currently genetic diagnosis is not encouraged since the recommended management of FDB and heterozygous FH is identical.

Autosomal Recessive Hypercholesterolemia Autosomal recessive hypercholesterolemia (ARH) is a rare disorder (except in Sardinia) due to mutations in a protein (ARH) involved in LDL receptor–mediated endocytosis in the liver. ARH clinically resembles homozygous FH and is characterized by hypercholesterolemia, tendon xanthomas, and premature coronary artery disease. The hypercholesterolemia tends to be intermediate between the levels seen in FH homozygotes and FH heterozygotes. LDL receptor function in cultured fibroblasts is normal or only modestly reduced in ARH, whereas LDL receptor function in lymphocytes and the liver is negligible. Unlike FH homozygotes, the hyperlipidemia responds partially to treatment with HMG-CoA reductase inhibitors, but these patients usually require LDL apheresis to lower plasma LDL-C to recommended levels.

Wolman Disease and Cholesteryl Ester Storage Disease Wolman disease is an autosomal recessive disorder caused by complete deficiency of lysosomal acid lipase. After LDL is taken up from the cell surface by LDL receptor–mediated endocytosis, it is delivered from endosomes to lysosomes. In the acidic environment of the endosome, the particle dissociates from the receptor, which recycles to the cell surface. In the lysosome, apoB-100 is degraded and the cholesteryl esters and triglycerides of LDL are hydrolyzed by lysosomal acid lipase. Patients with Wolman disease fail to hydrolyze the neutral lipids, resulting in their accumulation within cells. The disease presents within the first weeks of life with hepatosplenomegaly, steatorrhea, adrenal calcification, and failure to thrive. The disease is usually fatal within the first year of life and can be diagnosed by measuring acid lipase activity in

fibroblasts or liver tissue biopsy specimens. Cholesteryl ester storage disease is a less severe form of the same genetic disorder in which there is low, but detectable, acid lipase activity. Patients with this disorder sometimes present in childhood with hepatomegaly and a mixed hyperlipidemia, due to elevations in the levels of plasma LDL and VLDL. Other patients present later in life with hepatic fibrosis, portal hypertension, or with premature atherosclerosis.

Sitosterolemia Sitosterolemia is a rare autosomal recessive disease caused by mutations in one of two members of the adenosine triphosphate (ATP)-binding cassette transporter family, ABCG5 and ABCG8. These genes are expressed in the intestine and liver, where they form a functional complex to limit intestinal absorption and promote biliary excretion of plant- and animal-derived neutral sterols. In normal individuals, <5% of dietary plant sterols, of which sitosterol is the most plentiful, are absorbed by the proximal small intestine and delivered to the liver. Plant sterols in the liver are preferentially secreted into the bile, and plasma plant sterol levels are normally very low. In sitosterolemia, the intestinal absorption of plant sterols is increased and biliary excretion of the sterols is reduced, resulting in increased plasma levels of sitosterol and other plant sterols. The trafficking of cholesterol is also impaired. Patients with sitosterolemia can have either normal or elevated plasma levels of cholesterol. Irrespective of the plasma cholesterol level, these patients develop cutaneous and tendon xanthomas as well as premature atherosclerosis. Episodes of hemolysis, presumably secondary to the incorporation of plant sterols into the red blood cell membrane, are a distinctive clinical feature of this disease. The hypercholesterolemia in patients with sitosterolemia is unusually responsive to reductions in dietary cholesterol content. Sitosterolemia should be suspected when the plasma cholesterol level falls by >40% on a low-cholesterol diet (without associated weight loss).

Sitosterolemia is confirmed by demonstrating an elevated plasma sitosterol level. The hypercholesterolemia does not respond to HMG-CoA reductase inhibitors, but bile acid sequestrants and cholesterol-absorption inhibitors, such as ezetimibe, are effective in reducing plasma sterol levels in these patients.

PRIMARY DISORDERS OF ApoB-CONTAINING LIPOPROTEIN METABOLISM (UNKNOWN ETIOLOGY) A large proportion of patients with elevated levels of apoB-containing lipoproteins have disorders in which the molecular defect has not been defined, largely because multiple other genetic and nongenetic factors contribute to the hyperlipidemia.

Familial Hypertriglyceridemia Familial hypertriglyceridemia (FHTG) is a relatively common (1 in 500) autosomal dominant disorder of unknown etiology characterized by moderately elevated plasma triglycerides accompanied by more modest elevations in cholesterol. VLDL is the major class of lipoproteins elevated in this disorder, which is often referred to as type IV hyperlipoproteinemia (Frederickson classification, Table 335-4). The elevated plasma VLDL is due to increased VLDL production, impaired VLDL catabolism, or a combination of the two. Some patients with FHTG have a more severe form of hyperlipidemia in which both VLDL and chylomicrons are elevated (type V hyperlipidemia), as these two classes of lipoproteins compete for the same lipolytic pathway. Increased intake of simple carbohydrates, obesity, insulin resistance, alcohol use, or estrogen treatment, all of which increase VLDL synthesis, can precipitate the development of chylomicronemia. FHTG does not appear to be associated with increased risk of ASCVD in many families.

The diagnosis of FHTG is suggested by the triad of elevated plasma triglycerides [2.8 to 11.3 mmol/L (250 to 1000 mg/dL)], normal or only mildly increased cholesterol levels [<6.5 mmol/L (<250 mg/dL)], and reduced plasma HDL-C. Plasma LDL-C is generally not increased and is often reduced due to defective metabolism of the triglyceride-rich particles. The identification of other first-degree relatives with hypertriglyceridemia is useful in making the diagnosis. FDBL and FCHL should also be ruled out as these two conditions are associated with a significantly increased risk of ASCVD. The plasma apoB levels and the ratio of plasma cholesterol to triglyceride tend to be lower in FHTG than in either FDBL or FCHL.

It is important to exclude secondary causes of the hypertriglyceridemia before making the diagnosis of FHTG. Lipid-lowering drug therapy can frequently be avoided with appropriate dietary and lifestyle changes. Patients with plasma triglyceride levels >4.5 to 6.8 mmol/L (>400 to 600 mg/dL), after a trial of diet and exercise, should be considered for drug therapy to avoid the development of chylomicronemia and pancreatitis. A fibrate is a reasonable first line drug for FHTG, and niacin can also be considered in this condition.

Familial Combined Hyperlipidemia The molecular etiology of FCHL is unknown but is likely to involve defects in several different genes. FCHL is the most common primary lipid disorder, occurring in approximately 1 in 200 persons. Approximately 20% of patients who develop CHD before age 60 have FCHL.

FCHL is characterized by moderate elevation of plasma triglycerides and cholesterol and reduced plasma HDL-C. The disease is autosomal dominant, and affected family members typically have one of three possible phenotypes: (1) elevated plasma LDL-C, (2) elevated plasma triglycerides and VLDL-C, or (3) elevated plasma LDL-C and VLDL-C. A classic feature of FCHL is that the lipoprotein phenotype can switch among these phenotypes. FCHL can manifest in childhood but is sometimes not fully expressed until adulthood. Visceral obesity, glucose intolerance, insulin resistance, hypertension, and hyperuricemia are often present. These patients do not develop xanthomas.

Patients with FCHL almost always have significantly elevated plasma apoB. The levels of apoB are disproportionately high relative to plasma LDL-C due to the presence of small dense LDL particles,

TABLE 335-4 *Frederickson Classification of Hyperlipoproteinemias*

Phenotype	*I*	*IIa*	*IIb*	*III*	*IV*	*V*

Molecular defects	LPL and apoC-II	LDL receptor and apoB-100	Unknown	ApoE	Unknown	Unknown
Genetic nomenclature	FCS	FH, FDB	FCHL	FDBL	FHTG	FHTG

Note: LPL, lipoprotein lipase; apo, apolipoprotein; FCS, familial chylomicronemia syndrome; FH, familial hypercholesterolemia; FDB, familiar defective apoB; FCHL, familial combined hyperlipidemia; FDBL, familial dysbetalipoproteinemia; FHTG, familial hypertriglyceridemia.

which are characteristic of this syndrome and are highly atherogenic. *Hyperapobetalipoproteinemia* has been used as a term to describe the coupling of elevated plasma apoB with normal plasma cholesterol, and is probably a form of FCHL.

A mixed dyslipidemia [plasma triglyceride levels between 2.3 and 9.0 mmol/L (200 and 800 mg/dL), cholesterol levels between 5.2 and 10.3 mmol/L (200 and 400 mg/dL), and HDL-C levels <1.0 mmol/L (<40 mg/dL)] and a family history of hyperlipidemia and/or premature CHD suggests the diagnosis of FCHL. An elevated plasma apoB level or an increased number of small dense LDL particles in the plasma supports this diagnosis. FDBL should be considered and ruled out by beta-quantification in suspected patients with a mixed hyperlipidemia.

Individuals with FCHL should be treated aggressively due to significantly increased risk of premature CHD. Decreased dietary intake of saturated fat and simple carbohydrates, aerobic exercise, and weight loss have beneficial effects on the lipid profile. Patients with diabetes should be aggressively treated to maintain good glucose control. Most patients with FCHL require lipid-lowering drug therapy to reduce lipoprotein levels to the recommended range. HMG-CoA reductase inhibitors are very effective in lowering plasma levels of LDL-C and can also significantly reduce VLDL-C. Nicotinic acid decreases both LDL-C and VLDL-C, while raising plasma HDL-C, and is frequently effective for this condition when used in combination with HMG-CoA reductase inhibitors.

Polygenic Hypercholesterolemia Polygenic hypercholesterolemia is characterized by hypercholesterolemia with a normal plasma triglyceride in the absence of secondary causes of hypercholesterolemia. Plasma LDL-C levels are not as elevated as they are in FH and FDB. Family studies are useful to differentiate polygenic hypercholesterolemia from the single-gene disorders described above; half of the first-degree relatives of patients with FH and FDB are hypercholesterolemic, whereas <10% of first-degree relatives of patients with polygenic hypercholesterolemia are hypercholesterolemic. Treatment of polygenic hypercholesterolemia is identical to that of other forms of hypercholesterolemia.

GENETIC DISORDERS OF HDL METABOLISM (KNOWN ETIOLOGY) Mutations in certain genes encoding critical proteins in HDL synthesis and catabolism cause marked variations in plasma HDL-C levels. Unlike the genetic forms of hypercholesterolemia, which are invariably associated with premature coronary atherosclerosis, genetic forms of hypoalphalipoproteinemia (low HDL-C) are not always associated with accelerated atherosclerosis. Whereas high plasma LDL-C is invariably associated with increased atherosclerosis, the risk associated with low plasma levels of HDL-C depends on the underlying mechanism. Analysis of the genetic disorders of HDL metabolism has provided insights into the less well understood etiologic relationship between plasma HDL-C levels and atherosclerosis.

ApoA-I Deficiency and ApoA-I Mutations Complete genetic deficiency of apoA-I due to mutations in the apoA-I gene result in the virtual absence of HDL from the plasma. The genes encoding apoA-I, apoC-III, apoA-IV, and apoA-V are clustered together on chromosome 11, and some patients with complete absence of apoA-I have deletions that include more than one of these genes. Because apoA-I is required for LCAT function, plasma and tissue levels of free cholesterol are increased, resulting in the development of corneal opacities and planar xanthomas. Clinically apparent coronary atherosclerosis typically appears between the fourth and seventh decade in the apoA-I-deficient patient.

Although missense mutations in the apoA-I gene have been identified in selected patients with low plasma HDL [usually 0.39 to 0.78 mmol/L (15 to 30 mg/dL)], they are very rare causes of low HDL-C levels in the general population. Patients with apoA-I_{Milano} have very low plasma levels of HDL due to the rapid catabolism of the apolipoprotein, but these patients do not have an increased risk of premature CHD. Other than corneal opacities, most individuals with low plasma HDL-C levels due to missense mutations in apoA-I have no clinical sequelae. A few specific mutations in apoA-I cause systemic amyloidosis, and the mutant apoA-I has been found as a component of the amyloid plaque.

Tangier Disease Tangier disease is a rare autosomal codominant form of low plasma HDL-C caused by mutations in the gene encoding ABCA1, a cellular transporter that facilitates efflux of unesterified cholesterol and phospholipids from cells to apoA-I (Fig. 335-3). ABCA1 plays a critical role in the generation and stabilization of the mature HDL particle. In its absence, HDL is rapidly cleared from the circulation. Patients with Tangier disease have plasma HDL-C levels <0.13 mmol/L (<5 mg/dL) and extremely low circulating levels of apoA-I. The disease is associated with cholesterol accumulation in the reticuloendothelial system, resulting in hepatosplenomegaly and pathognomonic enlarged, grayish yellow or orange tonsils. An intermittent peripheral neuropathy (mononeuritis multiplex) or a sphingomyelia-like neurologic disorder can also be seen in this disorder. Tangier disease is associated with premature atherosclerotic disease, but the risk is not as high as might be anticipated given the markedly decreased plasma HDL-C and apoA-I. Plasma LDL-C is also low and this may attenuate the atherosclerotic risk. Obligate heterozygotes for ABCA1 mutations have moderately reduced plasma HDL-C levels and are also at increased risk of premature CHD.

LCAT Deficiency LCAT deficiency is a rare disorder caused by mutations in lecithin:cholesterol acyltransferase (Fig. 335-3). LCAT is synthesized in the liver and secreted into the plasma, where it circulates associated with lipoproteins. Because the enzyme mediates the esterification of cholesterol, the proportion of free cholesterol in circulating lipoproteins is greatly increased (from ~25% to >70% of total plasma cholesterol). Lack of normal cholesterol esterification impairs the formation of mature HDL particles and leads to rapid catabolism of circulating apoA-I. Two genetic forms of LCAT deficiency have been described in humans—complete deficiency (also called *classic LCAT deficiency*) and partial deficiency (also called *fish-eye disease*). Progressive corneal opacification due to the deposition of free cholesterol in the lens, very low plasma HDL-C [usually <0.26 mmol/L (<10 mg/dL)], and variable hypertriglyceridemia are characteristic of both types. In partial LCAT deficiency, there are no other known clinical sequelae. In contrast, complete LCAT deficiency is characterized by a hemolytic anemia and progressive renal insufficiency that eventually leads to end-stage renal disease (ESRD). Despite the extremely low plasma levels of HDL-C and apoA-I, premature ASCVD is not a feature of either complete or partial LCAT deficiency, once again exemplifying the complex relationship between low plasma levels of HDL-C and the development of ASCVD. The diagnosis can be confirmed by assaying LCAT activity in the plasma.

CETP Deficiency Mutations in the gene encoding cholesteryl ester transfer protein (CETP) cause a high HDL-C condition called *CETP deficiency*. CETP facilitates the transfer of cholesteryl esters among lipoproteins, especially from HDL to apoB-containing lipoproteins in exchange for triglycerides (Fig. 335-3). Homozygous deficiency of CETP, which occurs predominantly in Japan, results in very high plasma HDL-C [>3.88 mmol/L (>150 mg/dL)] due to accumulation of large, cholesterol-rich HDL particles. Heterozygotes for CETP deficiency have only modestly elevated HDL-C. The relationship of CETP deficiency to risk of ASCVD remains a matter of debate.

PRIMARY DISORDERS OF HDL METABOLISM (UNKNOWN ETIOLOGY) The gene defect in other individuals with either very high or very low plasma HDL-C is not known.

Primary Hypoalphalipoproteinemia The most common inherited cause of low plasma HDL-C is termed *primary or familial hypoalphalipoproteinemia*. Hypoalphalipoproteinemia is defined as a plasma HDL-C level below the 10th percentile in the setting of relatively normal cholesterol and triglyceride levels, no apparent secondary causes of low plasma HDL-C, and no clinical signs of LCAT deficiency or Tangier disease. This syndrome is often referred to as "isolated low HDL." A

family history of low HDL-C facilitates the diagnosis of an inherited condition, which usually follows an autosomal dominant pattern. The metabolic etiology of this disease appears to be primarily accelerated catabolism of HDL and its apolipoproteins. Several kindreds with primary hypoalphalipoproteinemia have been described in association with an increased incidence of premature ASCVD.

Familial Hyperalphalipoproteinemia Familial hyperalphalipoproteinemia has a dominant inheritance pattern. Plasma HDL-C is usually >2.07 mmol/L (80 mg/dL) in affected women and >1.81 mmol/L (70 mg/dL) in affected men. The genetic basis of primary hyperalphalipoproteinemia is not known, and the condition may be associated with decreased risk of CHD and increased longevity in some cases.

SECONDARY DISORDERS OF LIPOPROTEIN METABOLISM Significant changes in plasma levels of lipoproteins are seen in a variety of diseases. It is critical that secondary causes of hyperlipidemias (Table 335-5) are considered prior to initiation of lipid-lowering therapy.

Obesity Obesity is frequently, though not invariably, accompanied by hyperlipidemia. The increase in adipocyte mass and accompanying decrease in insulin sensitivity associated with obesity have multiple effects on lipid metabolism. More free fatty acids are delivered from the expanded adipose tissue to the liver where they are re-esterified in hepatocytes to form triglycerides, which are packaged into VLDL for secretion into the circulation. High dietary intake of simple carbohydrates also drives hepatic production of VLDL, leading to increases in VLDL and/or LDL in some obese individuals. Plasma HDL-C tends to be low in obesity. Weight loss is often associated with a reduction of plasma apoB-containing lipoproteins and an increase of plasma HDL-C.

Diabetes Mellitus Patients with type 1 diabetes mellitus are generally not hyperlipidemic if they are under good glycemic control. Diabetic ketoacidosis is frequently accompanied by hypertriglyceridemia due to increased hepatic influx of free fatty acids from adipose tissue. The hypertriglyceridemia responds dramatically to administration of insulin in the insulinopenic diabetic.

Patients with type 2 diabetes mellitus are usually dyslipidemic, even if under relatively good glycemic control. The high levels of insulin and insulin resistance associated with type 2 diabetes have multiple effects on fat metabolism: (1) a decrease in LPL activity resulting in reduced catabolism of chylomicrons and VLDL, (2) an increase in the release of free fatty acid from the adipose tissue, (3) an increase in fatty acid synthesis in the liver, and (4) an increase in hepatic VLDL production. Patients with type 2 diabetes mellitus have several lipid abnormalities, including elevated plasma triglycerides (due to increased VLDL and lipoprotein remnants), elevated dense LDL, and decreased HDL-C. In some diabetic patients, especially those with a genetic defect in lipid metabolism, the triglycerides can be extremely elevated. Elevated plasma LDL-C levels are usually not a feature of diabetes mellitus and suggest the presence of an underlying lipoprotein abnormality or may indicate the development of diabetic nephropathy. Patients with lipodystrophy, who have profound insulin resistance, have markedly elevated VLDL and chylomicrons.

Thyroid Disease Hypothyroidism is associated with elevated plasma LDL-C due primarily to a reduction in hepatic LDL receptor function and delayed clearance of LDL. Conversely, plasma LDL-C is often reduced in the hyperthyroid patient. Hypothyroid patients may have increased circulating IDL, and some are mildly hypertriglyceridemic [<3.34 mmol/L (<300 mg/dL)]. Because hypothyroidism is easily overlooked, all patients presenting with elevated plasma LDL-C or IDL should be screened for hypothyroidism. Thyroid replacement therapy usually ameliorates the hypercholesterolemia.

Renal Disorders Nephrotic syndrome is associated with hyperlipoproteinemia, which is usually mixed but can manifest as hypercholesterolemia or hypertriglyceridemia alone. The hyperlipidemia of nephrotic syndrome appears to be due to a combination of increased hepatic production and decreased clearance of VLDL, with increased LDL production. Effective treatment of the underlying renal disease normalizes the lipid profile, but most patients with chronic nephrotic syndrome require lipid-lowering drug therapy.

ESRD is often associated with mild hypertriglyceridemia [<3.34 mmol/L (<300 mg/dL)] due to the accumulation of VLDL and remnant lipoproteins in the circulation. Triglyceride lipolysis and remnant clearance are both reduced in patients with renal failure. Because the risk of ASCVD is increased in hyperlipidemic patients with ESRD, they should be treated aggressively with lipid-lowering agents.

Patients with renal transplants are usually hyperlipidemic due to immunosuppression drugs (cyclosporine and glucocorticoids); they present a difficult management problem as HMG-CoA reductase inhibitors must be used cautiously in these patients.

Liver Disorders Because the liver is the principal site of formation and clearance of lipoproteins, it is not surprising that liver diseases can

TABLE 335-5 *Secondary Forms of Hyperlipidemia*

Note: LDL, low-density lipoprotein; HDL, high-density lipoprotein; VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; Lp(a), lipoprotein A; DM, diabetes mellitus.

profoundly affect plasma lipid levels in a variety of ways. Hepatitis due to infection, drugs, or alcohol is often associated with increased VLDL synthesis and mild to moderate hypertriglyceridemia. Severe hepatitis and liver failure are associated with dramatic reductions in plasma cholesterol and triglycerides due to reduced lipoprotein biosynthetic capacity. Cholestasis is associated with hypercholesterolemia, which sometimes can be very severe. The major pathway by which cholesterol is excreted is via secretion into bile, either directly or after conversion to bile acids. Cholestasis blocks this critical excretory pathway. In cholestasis, free cholesterol coupled with phospholipids are secreted into the plasma as constituents of a lamellar particle called *Lp(X)*. These particles can deposit in skin folds, producing lesions resembling those seen in patients with FDBL (xanthomata strata palmaris). Planar and eruptive xanthomas can also be seen in patients with cholestasis.

Alcohol Regular alcohol consumption has a variable effect on plasma lipid levels. The most common effect of alcohol is to increase plasma triglyceride levels. Alcohol consumption stimulates hepatic secretion of VLDL, possibly by inhibiting the hepatic oxidation of free fatty acids, which then promote hepatic triglyceride synthesis and VLDL secretion. The usual lipoprotein pattern seen with alcohol consumption is type IV (increased VLDL), but persons with an underlying primary lipid disorder may develop severe hypertriglyceridemia (type V) if they drink alcohol. Regular alcohol use is also associated with a mild to moderate increase in plasma levels of HDL-C.

Estrogen Estrogen administration is associated with increased VLDL and HDL synthesis resulting in elevated plasma triglycerides and HDL-C. This lipoprotein pattern is distinctive since the levels of plasma triglyceride and HDL-C are typically inversely related. Estrogen treatment may convert a person with type IV to type V hyperlipidemia. Plasma triglyceride levels should be monitored when birth control pills or estrogen replacement therapy is initiated. Use of low-dose estrogen preparations or the estrogen patch can minimize the effect of exogenous estrogen on lipids.

Glycogen Storage Diseases Other rarer causes of secondary hyperlipidemias include glycogen storage diseases such as *von Gierke's disease*, which is caused by mutations in glucose-6-phosphatase. The inability to mobilize hepatic glucose during fasting results in hypoinsulinemia and increased release of free fatty acids from adipose tissue. Hepatic fatty acids synthesis is also increased, resulting in fat accumulation in the liver and increased VLDL secretion. The hyperlipidemia associated with this disease can be very severe but responds well to treatment of the underlying disorder.

Cushing Syndrome Glucocorticoid excess is associated with increased VLDL synthesis and hypertriglyceridemia. Patients with Cushing syndrome can also have mild elevations in plasma LDL-C.

Drugs Many drugs have a significant impact on lipid metabolism and can result in significant alterations in the lipoprotein profile (Table 335-5).

SCREENING

Guidelines for the screening and management of lipid disorders have been provided by an expert Adult Treatment Panel (ATP) convened by the National Cholesterol Education Program (NCEP) of the National Heart Lung and Blood Institute. The NCEP ATPIII guidelines published in 2001 recommend that all adults over age 20 have plasma levels of cholesterol, triglyceride, LDL-C, and HDL-C measured after a 12-h overnight fast. In most clinical laboratories, the total cholesterol and triglycerides in the plasma are measured enzymatically and then the cholesterol in the supernatant is measured after precipitation of apoB-containing lipoproteins to determine the HDL-C. The LDL-C is estimated using the following equation:

$$\text{LDL-C} = \text{total cholesterol} - (\text{triglycerides}/5) - \text{HDL-C}$$

The VLDL-C is estimated by dividing the plasma triglyceride by 5, reflecting the ratio of cholesterol to triglyceride in VLDL particles. This formula is reasonably accurate if test results are obtained on fasting plasma and if the triglyceride level $<\sim$4.0 mmol/L (350 mg/dL). The accurate determination of LDL-C levels in patients with triglyceride levels greater than this requires application of ultracentrifugation techniques (beta quantification), although direct assays for LDL-C are also available in some laboratories. →***For further discussion about screening, see Chap. 225.***

TREATMENT

Multiple epidemiologic studies have demonstrated a strong relationship between serum cholesterol and CHD. Randomized controlled clinical trials have unequivocally documented that lowering plasma cholesterol reduces the risk of clinical events due to atherosclerosis (Chaps. 224 and 225). Although the proportional benefit accrued from reducing plasma LDL-C is similar over the entire range of LDL-C values, the absolute risk reduction depends on the baseline LDL-C, the presence of established CHD, and other cardiovascular risk factors.

Elevated plasma triglyceride levels are also associated with increased risk of CHD, but this relationship weakens considerably when statistical corrections are made for the plasma levels of LDL-C and HDL-C. Plasma levels of HDL-C are strongly and consistently inversely related to the prevalence and incidence of CHD, and yet no clinical trial data are available demonstrating that increasing plasma levels of HDL-C reduces the frequency of cardiovascular events. No pharmacologic agents are available that exclusively either lower plasma triglyceride levels or increase plasma HDL-C levels, contributing to the dearth of clinical trial data addressing the role of treatment of these lipid abnormalities in CHD prevention. Since both hypertriglyceridemia and low plasma levels of HDL-C confer higher ASCVD risk, the NCEP ATPIII recommends more aggressive therapy to lower the plasma LDL-C in patients with these dyslipidemias.

Nonpharmacologic Treatment ■ *DIET* Dietary modification is an important component in the management of hyperlipidemia. In the hypercholesterolemic patient, dietary saturated fat and cholesterol should be restricted. For patients who are hypertriglyceridemic, the intake of simple sugars should also be curtailed. For severe hypertriglyceridemia [>11.3 mmol/L (>1000 mg/dL)], restriction of total fat intake is critical. The most widely used diet to lower the LDL-C level is the "Step 1 diet" developed by the American Heart Association. Most patients have a relatively modest (<10%) decrease in plasma levels of LDL-C on a step I diet in the absence of any associated weight loss. Almost all persons experience a decrease in plasma HDL-C levels with a reduction in the amount of total and saturated fat in their diet.

FOODS AND ADDITIVES Certain foods and dietary additives are associated with modest reductions in plasma cholesterol levels. Plant stanol and sterol esters are available in a variety of foods such as spreads, salad dressings, and snack bars. They interfere with cholesterol absorption and reduce plasma LDL-C levels by ~10 to 15% when taken three times per day. The addition to the diet of psyllium, soy protein, or Chinese red yeast rice (which contains lovastatin) can have modest cholesterol-lowering effects. Other herbal approaches such as guggulipid require further study to assess their effectiveness.

WEIGHT LOSS AND EXERCISE The treatment of obesity, if present, can have a favorable impact on plasma lipid levels and should be actively encouraged. Plasma triglyceride and LDL-C levels tend to fall and HDL-C levels tend to increase in obese persons who lose weight. Aerobic exercise has a very modest elevating effect on plasma levels of HDL-C in most individuals but has cardiovascular benefits that extend beyond the effects on plasma lipid levels.

Pharmalogic Treatment The decision to use drug therapy depends on the cardiovascular risk (Chap. 225). An effective way to estimate absolute risk of a cardiovascular event over 10 years is to use a scoring system based on the Framingham Heart Study database. Patients with a 10-year absolute CHD risk of > 20% are considered "CHD risk equivalents." Current NCEP ATPIII guidelines call for drug therapy to reduce LDL-C to <2.6 mmol/L (<100 mg/dL) in patients with established

CHD, other ASCVD (aortic aneurysm, peripheral vascular disease, or cerebrovascular disease), diabetes mellitus, or CHD risk equivalents. Based on these guidelines, most CHD and CHD risk–equivalent patients require cholesterol-lowering drug therapy. Moderate risk patients with two or more risk factors and a 10-year absolute risk of 10 to 20% should be treated to a goal LDL-C of <3.4 mmol/L (<130 mg/dL). All other individuals have a goal of LDL-C <4.1 mmol/L (<160 mg/dL), but not all persons are candidates for drug therapy to achieve this goal.

Persons with markedly elevated plasma LDL-C levels [>4.9 mmol/L (>190 mg/dL)] should be considered for drug therapy even if their 10-year absolute CHD risk is not particularly elevated. The decision to initiate drug treatment in individuals with plasma LDL-C levels between 3.4 and 4.9 mmol/L (130 and 190 mg/dL) can be difficult. Although it is desirable to avoid drug treatment in patients who are unlikely to develop CHD, a very high proportion of patients who eventually develop CHD have plasma LDL-C levels that are in this range. Other clinical information can assist in the decision-making process. For example, a low plasma HDL-C [<1.0 mmol/L (<40 mg/dL) supports a decision in favor of more aggressive therapy. The diagnosis of the metabolic syndrome (Chap. 225) also identifies a higher risk individual who should be targeted for therapeutic life-style changes and might be a candidate for more aggressive drug therapy. Other laboratory tests, such as an elevated plasma Lp(a) or high-sensitivity C-reactive protein, may help to identify additional high-risk individuals. In persons at low risk, the emphasis should primarily be on dietary and life-style modification.

Drug treatment is also indicated in patients with triglycerides >11.3 mmol/L (>1000 mg/dL) who have been screened and treated for secondary causes of chylomicronemia. The goal is to reduce plasma triglycerides to <4.5 mmol/L (400 mg/dL) to prevent the risk of acute pancreatitis. Most major clinical end-point trials with statins have excluded persons with triglyceride levels >3.9 to 5.1 mmol/L (>350 to 450 mg/dL), and therefore there are few data regarding the effectiveness of statins in reducing cardiovascular risk in persons with triglycerides higher than this threshold. Combination therapy is often required for optimal control of mixed dyslipidemia.

HMG-COA REDUCTASE INHIBITORS 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA reductase) is the rate-limiting step in cholesterol biosynthesis, and inhibition of this enzyme decreases cholesterol synthesis. By inhibiting cholesterol biosynthesis, HMG-CoA reductase inhibitors (statins) lead to increased hepatic LDL receptor activity and accelerated clearance of circulating LDL, resulting in a dose-dependent reduction in plasma LDL-C. There is wide interindividual variation in the initial response to a statin, but once a patient is on the medication, the doubling of the dose produces a 6% further reduction of plasma LDL-C. The HMG-CoA reductase inhibitors currently available differ in their LDL-C reducing effects (Table 335-6). HMG-CoA reductase inhibitors also reduce plasma triglycerides in a dose-dependent fashion, which is proportional to their LDL-C lowering effects [if the triglycerides are <3.9 mmol/L (<350 mg/dL)]. HMG-CoA reductase inhibitors have a modest HDL-raising effect (5 to 10%), and this effect is not dose-dependent.

HMG-CoA reductase inhibitors are well tolerated and can be taken in tablet form once a day. Potential side effects include dyspepsia, headaches, fatigue, and muscle or joint pains. Severe myopathy and even rhabdomyolysis occurs rarely. The risk of myopathy is increased by the presence of renal insufficiency and by coadministration of drugs that interfere with the metabolism of HMG-CoA reductase inhibitors, such as erythromycin and related antibiotics, antifungal agents, immunosuppressive drugs, and fibric acid derivatives. Severe myopathy can usually be avoided by careful patient selection, avoidance of interacting drugs, and by instructing the patient to contact the physician immediately in the event of unexplained muscle pain. In the event of muscle symptoms, the plasma creatine phosphokinase (CPK) level should be obtained to document the myopathy, but serum CPK levels do not need to be monitored on a routine basis as an elevated CPK in the absence of symptoms does not predict the development of myopathy and does not necessarily suggest the need for discontinuing the drug.

Another side effect of HMG-CoA reductase inhibitor therapy is hepatitis. Liver transaminases (ALT and AST) should be checked before starting therapy, at 8 weeks, and then every 6 months. Substantial (>3 × upper limit of normal) elevation in transaminases is relatively rare, and mild to moderate (1 to 3 × normal) elevation in transaminases in the absence of symptoms need not mandate discontinuing the medication. Severe clinical hepatitis associated with HMG-CoA reductase inhibitors is exceedingly rare, and the trend is toward less frequent monitoring of transaminases in patients taking HMG-CoA reductase inhibitors. The HMG-CoA reductase inhibitor–associated elevation in liver enzymes resolves after discontinuation of the medication.

TABLE 335-6 *Summary of the Major Drugs Used for the Treatment of Hyperlipidemia*

Drug	Major Indications	Starting Dose	Maximal Dose	Mechanism	Common Side Effects
HMG-CoA reductase inhibitors (statins)	Elevated LDL			↓ Cholesterol synthesis, ↓ hepatic LDL receptors, ↓ VLDL production	Myalgias, arthralgias, elevated transaminases, dyspepsia
Lovastatin		20 mg daily	80 mg daily		
Pravastatin		40 mg qhs	80 mg qhs		
Simvastatin		20 mg qhs	80 mg qhs		
Fluvastatin		20 mg qhs	80 mg qhs		
Atorvastatin		10 mg qhs	80 mg qhs		
Rosuvastatin		10 mg qhs	40 mg qhs		
Bile acid sequestrants	Elevated LDL			↑ Bile acid excretion and ↑ LDL receptors	Bloating, constipation, elevated triglycerides
Cholestyramine		4 g daily	32 g daily		
Colestipol		5 g daily	40 g daily		
Colesevelam		3750 mg daily	4375 mg daily		
Nicotinic acid	Elevated LDL, low HDL, elevated TG			↓ VLDL hepatic synthesis	Cutaneous flushing; GI upset; elevated glucose, uric acid, and liver function tests
Immediate-release		100 mg tid	2 g tid		
Sustained-release		250 mg bid	1.5 g bid		
Extended-release		500 mg qhs	2 g qhs		
Fibric acid derivatives	Elevated TG, elevated remnants			↑ LPL, ↓ VLDL synthesis	Dyspepsia, myalgia, gallstones, elevated transaminases
Gemfibrozil		600 mg bid	600 mg bid		
Fenofibrate		160 mg qd	160 mg qd		
Fish oils	Severely elevated TG	3 g daily	12 g daily	↓ Chylomicron and VLDL production	Dyspepsia, diarrhea, fishy odor to breath
Cholesterol absorption inhibitors				↓ Intestinal cholesterol absorption	Elevated transaminases
Ezetimibe	Elevated LDL	10 mg daily	10 mg daily		

Note: LDL, low-density lipoprotein; VLDL, very low density lipoprotein; HDL, high-density lipoprotein; TG, triglycerides; LPL, lipoprotein lipase.

Overall, HMG-CoA reductase inhibitors appear to be remarkably safe. Over 50,000 patients have been treated with HMG-CoA reductase inhibitors for over 5 to 6 years as a part of large randomized controlled clinical trials and no increase in any major noncardiac diseases have been seen in these individuals. HMG-CoA reductase inhibitors are the drug class of choice for LDL-C reduction and are by far the most widely used class of lipid-lowering drugs.

BILE ACID SEQUESTRANTS (RESINS) Bile acid sequestrants bind bile acids in the intestine and promote their excretion in the stool. In order to maintain an adequate bile acid pool, the liver diverts cholesterol to bile acid synthesis. The decreased hepatic intracellular cholesterol content upregulates the LDL receptor and enhances LDL clearance from the plasma. Bile acid sequestrants, including cholestyramine, colestipol, and colesevelam (Table 335-6), primarily reduce plasma LDL-C levels but can increase plasma triglycerides. Therefore, patients with hypertriglyceridemia should not be treated with bile acid–binding resins.

Cholestyramine and colestipol are insoluble resins that must be mixed with liquids. Colestipol is also available in large tablets but multiple tablets must be taken to achieve significant lowering of plasma LDL-C levels. The newest bile acid sequestrant, colesevelam, has greater bile acid–binding capacity than traditional resins. The colesevelam tablets are smaller, and fewer tablets per day are required. Most side effects of resins are limited to the gastrointestinal tract and include bloating and constipation. Bile acid sequestrants may bind other drugs (e.g., digoxin, warfarin) and interfere with their absorption. Therefore, all other medications should be taken either 1 h before or 4 h after the bile acid sequestrants.

Bile acid sequestrants are not systemically absorbed and are very safe. They are the cholesterol-lowering drug of choice in children and in women of childbearing age who are lactating, pregnant, or could become pregnant. These drugs can also be useful in young, well-motivated patients with moderate hypercholesterolemia who wish to avoid systemic drug therapy. This class of drugs is also useful in combination with HMG-CoA reductase inhibitors in patients who are unable to reach their LDL-C goal on HMG-CoA reductase inhibitor monotherapy and have relatively normal triglyceride levels.

NICOTINIC ACID (NIACIN) Nicotinic acid, or niacin, is a B-complex vitamin that reduces plasma triglyceride and LDL-C levels and raises the plasma HDL-C (Table 335-6) in high doses. Niacin is the only currently available lipid-lowering drug that significantly reduces plasma levels of Lp(a). If properly prescribed and monitored, niacin is a safe and effective lipid-lowering agent.

The cheapest form of niacin is immediate-release crystalline niacin. Niacin should be started at a low dose (100 mg three times a day) and taken with meals to delay absorption. The dose of niacin should be increased every 4 to 7 days by 100 mg until a dose of 500 mg tid is obtained. After 1 month on this dose, lipids and pertinent chemistries (glucose, uric acid, liver transaminases) should be measured. The dose can be further increased as needed up to a total dose of 6 g/d. The most frequent side effect is cutaneous flushing, but this improves with continued administration. In many patients, taking an aspirin 30 min prior to the niacin prevents flushing. Over-the-counter sustained-release forms of niacin are generally administered twice a day and are associated with less flushing, but some have been associated with rare cases of severe hepatitis. A clue to the development of niacin-induced hepatitis is a sudden, precipitous drop in the plasma lipid levels. A prescription form of extended-release niacin that is administered once daily at bedtime has not been associated with severe hepatic toxicity. Mild elevations in transaminases occur in up to 15% of patients treated with any form of niacin, but these elevations rarely require discontinuation of the medication. Niacin potentiates the effect of warfarin, and these two drugs should be prescribed together with caution. Acanthosis nigricans and maculopathy are infrequent side effects of niacin. Niacin is contraindicated in patients with peptic ulcer disease and can exacerbate the symptoms of esophageal reflux. Niacin can raise plasma levels of uric acid and precipitate gouty attacks in susceptible patients.

Niacin can raise fasting plasma glucose levels, but concerns regarding the use of niacin in diabetic patients have been allayed by the results of two studies. In one study, short-acting niacin treatment of dyslipidemia was associated with only a slight increase in fasting glucose and no significant change from baseline in the HbA1c. In the other, low-dose niacin was found to reduce triglycerides effectively and raise HDL-C in diabetics without adversely impacting glycemic control.

Successful therapy with niacin requires careful education and motivation of the patient. Its advantages are its low cost and long-term safety. It is the most effective drug currently available for raising HDL-C levels. It is particularly useful in patients with combined hyperlipidemia and low plasma levels of HDL-C and is effective in combination with statins.

FIBRIC ACID DERIVATIVES (FIBRATES) Fibric acid derivatives, or fibrates, are agonists of PPARα, a nuclear receptor involved in the regulation of carbohydrate and lipid metabolism. Fibrates stimulate LPL activity (enhancing triglyceride hydrolysis), reduce apoC-III synthesis (enhancing lipoprotein remnant clearance), and may reduce VLDL production. Fibrates are the most effective drugs available for reducing triglyceride levels, and they also raise HDL-C levels (Table 335-6). Fibrates have variable effects on LDL-C, and in hypertriglyceridemic patients can sometimes be associated with increases in plasma LDL-C levels.

Fibrates are generally very well tolerated. The most common side effect is dyspepsia. Myopathy and hepatitis occur rarely in the absence of other lipid-lowering agents. Fibrates promote cholesterol secretion into bile and are associated with an increased risk of gallstones. Importantly, fibrates can potentiate the effect of warfarin and certain oral hypoglycemic agents; the anticoagulation status and plasma glucose levels should be closely monitored in patients on these agents.

Fibrates are the drug class of choice in patients with severe hypertriglyceridemia [11.3 mmol/L (>1000 mg/dL)] and are a reasonable consideration in patients with moderate hypertriglyceridemia [4.5 to 11.3 mmol/L (400 to 1000 mg/dL)]. The Veterans Affairs High-Density Lipoprotein Intervention Trial study also suggests that they may have a role in high-risk patients with well-controlled LDL-C levels but elevated plasma triglyceride levels and low plasma levels of HDL-C. The relative indications of fibrates vs. statins and the role of combined therapy will be determined by ongoing and future trials.

Omega-3 Fatty Acids (Fish Oils) N-3 polyunsaturated fatty acids (PUFAs) are present in high concentration in fish and in flax seeds. The most widely used n-3 PUFAs for the treatment of hyperlipidemias are the two active molecules in fish oil, eicosapentanoic acid (EPA) and decohexanoic acid (DHA). N-3 PUFAs have been concentrated into tablets and in doses of 3 to 6 g/d decrease fasting and postprandial triglycerides. At least 6 g/d is usually required for a substantial triglyceride-lowering effect, and many patients require 9 to 12 g/d. Fish oil treatment of hypertriglyceridemia can be associated with a significant increase in plasma LDL-C levels. Fish oil supplements can be used in combination with fibrates, niacin, or statins to treat hypertriglyceridemia. In general, fish oils are well tolerated and appear to be safe, at least at doses up to 3 g. The large number of capsules required for a therapeutic effect, the associated dyspepsia, and fishy aftertaste have limited the clinical use of these agents. Although fish oil administration is associated with a prolongation in the bleeding time, no increase in bleeding has been seen in clinical trials.

CHOLESTEROL ABSORPTION INHIBITORS A new mechanism of cholesterol-lowering is the inhibition of intestinal cholesterol absorption. Ezetimibe (Table 335-6) inhibits the absorption of dietary and biliary cholesterol from the intestinal lumen. It reduces LDL-C cholesterol levels by ~18% as monotherapy or in combination with a statin. Cholesterol absorption inhibitors are particularly useful in combination with a statin in patients unable to reach their LDL-C goal on statin monotherapy.

COMBINATION DRUG THERAPY Combination drug therapy is frequently used in the following situations: (1) patients unable to reach their LDL-C goal on a single drug, (2) patients with combined hypertriglyceridemia and hypercholesterolemia that cannot be adequately controlled with a single drug, and (3) patients with elevated LDL-C and low HDL-C levels. Inability to achieve LDL-C goal is not uncommon on statin monotherapy. If the patient has a normal plasma triglyceride level, a bile acid sequestrant can be added. A cholesterol absorption inhibitor can also be used in this setting. Combination of niacin with a statin is an attractive option for high-risk patients who do not attain their target LDL-C level on statin monotherapy and who have an HDL-C <10.3 mmol/L (<40 mg/dL). One product currently available offers the combination of lovastatin and extended-release niacin in a single tablet.

Patients with combined hyperlipidemia frequently have persistent hypertriglyceridemia on statin monotherapy. Addition of niacin or a fibrate can reduce the plasma triglyceride level in these patients. Conversely, hypertriglyceridemic patients treated with a fibrate often fail to reach their LDL-C goal and are therefore candidates for the addition of a statin. Coadministration of statins and fibrates has obvious appeal in patients with combined hyperlipidemia, but no clinical trials have assessed the effectiveness of a statin-fibrate combination compared with either a statin or a fibrate alone in reducing cardiovascular events and the long-term safety of this combination is not known. Statin-fibrate combinations are known to be associated with an increased incidence of severe myopathy (up to 2.5%) and rhabdomyolysis, and patients treated with these two drugs must be carefully counseled and monitored. This combination of drugs should be used cautiously in patients with underlying renal or hepatic insufficiency; in the elderly, frail, and chronically ill; and in those on multiple medications.

Other Approaches Occasionally, patients cannot tolerate any of the existing lipid-lowering drugs at doses required for adequate control of their lipid levels. Some patients, mostly those with genetic lipid disorders, remain significantly hypercholesterolemic despite combination drug therapy. These patients are at high risk for development or progression of CHD and clinical CHD events.

LDL APHERESIS The preferred option for management of patients with refractory or drug-resistant hypercholesterolemia is LDL apheresis. In this process, the patient's plasma is passed over a column that selectively removes the LDL, and the LDL-depleted plasma is returned to the patient. Patients on maximally tolerated combination drug therapy who have CHD and a plasma LDL-C level >5.2 mmol/L (>200 mg/dL) or no CHD and a plasma LDL-C level >7.8 mmol/L (>300 mg/dL), are candidates for every-other-week LDL apheresis.

PARTIAL ILEAL BYPASS Partial ileal bypass interrupts the enterohepatic circulation of bile acids, resulting in upregulation of the hepatic LDL receptor and reduction in plasma LDL-C levels. Diarrhea is a common side effect, and the incidence of kidney stones, gallstones, and intestinal obstruction is increased after ileal bypass surgery. The clinical utility of partial ileal bypass at this time is limited to severely hypercholesterolemic patients with normal triglycerides who cannot tolerate existing lipid-lowering medications and do not have access to LDL apheresis. Partial ileal bypass has not been proven effective in patients with severe hypercholesterolemia who have not responded adequately to statins.

Management of Low HDL-C Severely reduced plasma HDL-C [<0.5 mmol/L (<20 mg/dL)] accompanied by triglycerides <4.5 mmol/L (<400 mg/dL) usually indicates the presence of a genetic disorder, such as a mutation in apoA-I, LCAT deficiency, or Tangier disease. HDL-C levels <0.5 mmol/L (<20 mg/dL) are common in the setting of severe hypertriglyceridemia, in which case the primary focus should be on the management of the triglycerides. Secondary causes of more moderate reductions in plasma HDL [0.5 to 10.3 mmol/L (20 to 40 mg/dL)] should be considered (Table 335-5). Smoking should be discontinued, obese persons should be encouraged to lose weight, sedentary persons should be encouraged to exercise, and diabetes should be optimally controlled. When possible, medications associated with reduced plasma levels of HDL-C should be discontinued. The presence of an isolated low plasma HDL-C level in a patient with a borderline plasma LDL-C should prompt consideration of LDL-lowering drug therapy in high-risk individuals. Statins increase plasma levels of HDL-C only modestly (~5 to 10%). Fibrates also have a modest effect on plasma HDL-C levels (increasing levels ~5 to 15%) except in patients with coexisting hypertriglyceridemia, where they can be more effective. Niacin is the most effective therapeutic agent and can increase plasma HDL-C levels by up to ~30%.

The issue of whether pharmacologic intervention should be used to specifically raise HDL-C levels has not been adequately addressed in clinical trials. Pending these studies, it may be reasonable to initiate therapy (with a fibrate or niacin) directed specifically at reducing plasma triglyceride levels and raising the plasma HDL-C level in persons with established CHD and low HDL-C levels whose plasma LDL-C levels are at or below the goal.

336 HEMOCHROMATOSIS

Lawrie W. Powell

DEFINITION

Hemochromatosis is a common disorder of iron storage in which an inappropriate increase in intestinal iron absorption results in deposition of excessive amounts of iron in parenchymal cells with eventual tissue damage and impaired function of organs. The iron-storage pigment in tissues was called *hemosiderin* because it was believed to be derived from the blood. The term *hemosiderosis* is used to describe the presence of stainable iron in tissues, but tissue iron must be quantified to assess body iron status accurately (see below and Chap. 90). *Hemochromatosis* implies potentially severe progressive iron overload leading to fibrosis and organ failure. Cirrhosis of the liver, diabetes mellitus, arthritis, cardiomyopathy, and hypogonadotrophic hypogonadism are common manifestations.

Although there is debate about definitions, it seems logical to use the following terminology:

1. *Hereditary hemochromatosis* or *genetic hemochromatosis*: This disorder is most often caused by inheritance of a mutant gene, termed *HFE*, which is tightly linked to the HLA-A locus on chromosome 6p (see below). Rarer forms of non-*HFE* hemochromatosis due to mutation in other key genes involved in iron metabolism have recently been described (Table 336-1). The disease can be recognized during its early stages when iron overload and organ damage are min-

TABLE 336-1 Classification of Iron Overload States

HEREDITARY HEMOCHROMATOSIS	
Hemochromatosis, *HFE*-related (type 1)	
C282Y homozygosity	
C282Y/H63D compound heterozygosity	
Hemochromatosis non-*HFE*-related	
Juvenile hemochromatosis (type 2)	
Mutated transferrin receptor 2 *TFR2* (type 3)	
Mutated ferroportin 1 (Ireg1) gene, *SLC11A3* (type 4)	
Mutated H Ferritin IRE (type 5)	
Solomon Island hemochromatosis (?defect) (type 6)	
ACQUIRED IRON OVERLOAD	
Iron-loading anemias	Chronic liver disease
Thalassemia major	Hepatitis C
Sideroblastic anemia	Alcoholic cirrhosis, especially when advanced
Chronic hemolytic anemias	Nonalcoholic steatohepatitis
Transfusional and parenteral iron overload	Porphyria cutanea tarda
Dietary iron overload	Dysmetabolic iron overload syndrome
	Post portacaval shunting
MISCELLANEOUS	
Iron overload in sub-Sahara Africa	
Neonatal iron overload	
Aceruloplasminemia	
Congenital atransferrinemia	

imal. At this stage the disease is best referred to as *early hemochromatosis* or *precirrhotic hemochromatosis*.

2. *Secondary iron overload*: Tissue injury usually occurs secondary to an iron-loading anemia such as thalassemia or sideroblastic anemia, in which increased erythropoiesis is ineffective. In the acquired iron-loading disorders, massive iron deposits in parenchymal tissues can lead to the same clinical and pathologic features as in hemochromatosis.

PREVALENCE

HFE-associated hemochromatosis is one of the most common genetic diseases, although its prevalence varies in different ethnic groups. It is most common in populations of northern European extraction in whom approximately 1 in 10 persons are heterozygous carriers and 0.3 to 0.5% are homozygotes. However, expression of the disease is modified by several factors, especially alcohol consumption and dietary iron intake, blood loss associated with menstruation and pregnancy, and blood donation. The clinical expression of the disease is 5 to 10 times more frequent in men than in women. Nearly 70% of affected patients develop the first symptoms between ages 40 and 60. The disease is rarely evident before age 20, although with family screening (see below) and periodic health examinations, asymptomatic subjects with iron overload can be identified, including young menstruating women. Recent studies in European non-blood bank populations have revealed that 30% or more of homozygous individuals do not have evidence of iron overload. Thus, the penetrance of the mutation is variable.

GENETIC BASIS AND MODE OF INHERITANCE

The *HFE* gene involved in the most common form of hemochromatosis was cloned in 1996. A homozygous G → A mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) is the most common mutation. It is identified in 85 to 100% of patients with hereditary hemochromatosis in populations of northern European descent but is found in only 60% of cases from Mediterranean populations (e.g., southern Italy). A second, relatively common *HFE* mutation has also been identified. This results in an amino acid substitution of histidine to aspartic acid at position 63 (H63D). Homozygosity for H63D is not associated with clinically significant iron overload. Some compound heterozygotes (e.g., one copy each of C282Y and H63D) have mild to moderately increased body iron stores. Thus, *HFE*-associated hemochromatosis is inherited as an autosomal recessive trait; heterozygotes have no, or minimal, increase in iron stores. However, in some cases this slight increase in hepatic iron acts as a cofactor that aggravates other diseases such as porphyria cutanea tarda (PCT) and nonalcoholic steatohepatitis.

Mutations in other genes are responsible for non-*HFE* associated hemochromatosis, including juvenile hemochromatosis, which affects persons in the second and third decade of life (Table 336-1).

PATHOGENESIS

Normally, the body iron content of 3 to 4 g is maintained such that intestinal mucosal absorption of iron is equal to iron loss. This amount is approximately 1 mg/d in men and 1.5 mg/d in menstruating women. In hemochromatosis, mucosal absorption is inappropriate to body needs and amounts to 4 mg/d or more. The progressive accumulation of iron causes an early elevation in plasma iron, an increased saturation of transferrin, and progressive elevation of plasma ferritin level (Fig. 336-1). A liver protein, hepcidin, is proposed to increase *HFE*-mediated reticuloendothelial cell iron retention and to decrease intestinal iron uptake, thereby linking body stores with intestinal iron absorption.

The *HFE* gene encodes a 343-amino-acid protein that is structurally related to MHC class I proteins. The basic defect in hemochromatosis is a lack of cell surface expression of HFE (due to the C282Y mutation). The normal (wild type) HFE protein forms a complex with β_2-microglobulin and transferrin, and the C282Y mutation completely abrogates this interaction. As a result, the mutant HFE protein remains trapped intracellularly, reducing transferrin receptor–mediated iron uptake by the intestinal crypt cell. This is postulated to upregulate the divalent metal transporter (DMT-1) on the brush border of the villus cells, leading to inappropriately increased intestinal iron absorption (Fig. 336-2). In advanced disease, the body may contain 20 g or more of iron that is deposited mainly in parenchymal cells of the liver, pancreas, and heart. Iron may be increased 50- to 100-fold in the liver and pancreas and 5- to 25-fold in the heart. Iron deposition in the pituitary causes hypogonadotropic hypogonadism in both men and women. Tis-

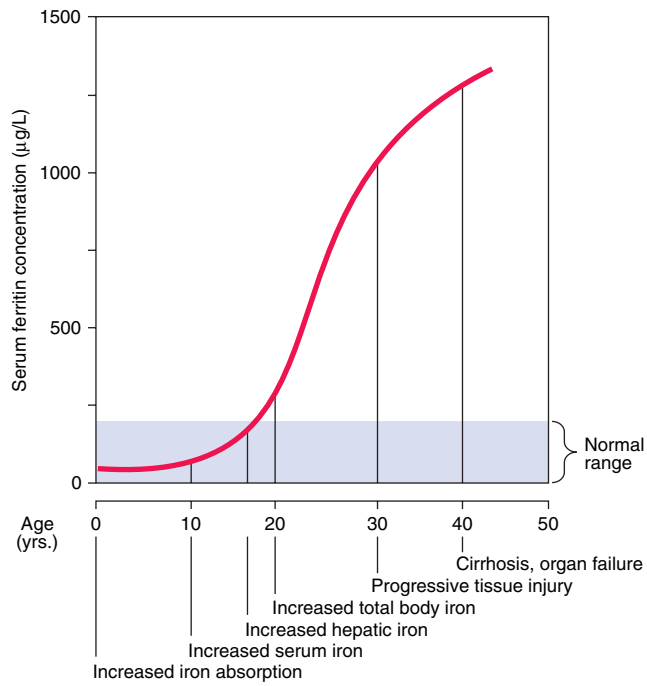

FIGURE 336-1 Sequence of events in genetic hemochromatosis and their correlation with the serum ferritin concentration. Increased iron absorption is present throughout life. Overt, symptomatic disease usually develops between ages 40 and 60, but latent disease can be detected long before this.

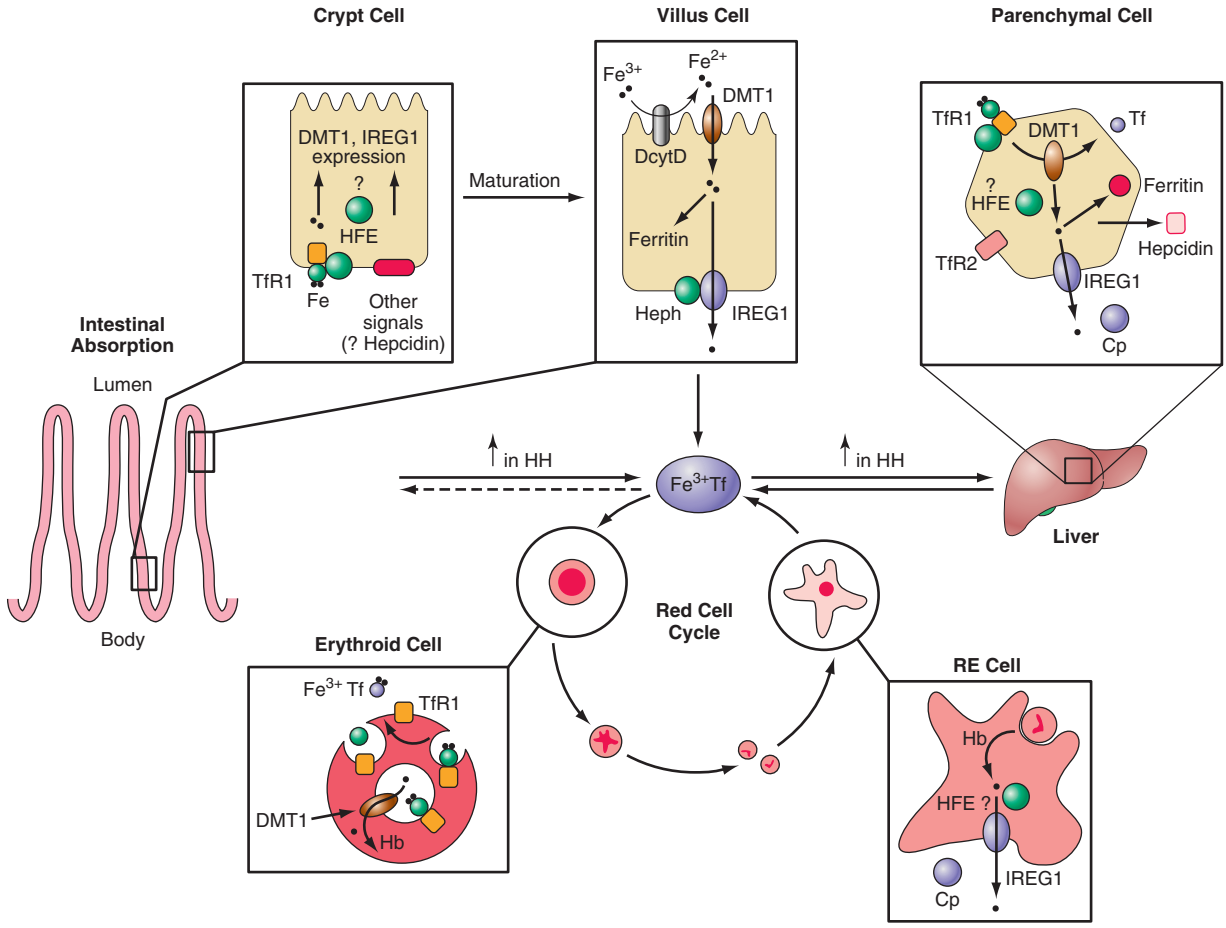

FIGURE 336-2 Pathways of normal iron homeostasis. Iron is absorbed in the proximal intestine after conversion from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state by duodenal cytochrome D (DcytD), a ferrireductase. At the apical membrane of the mature villus cell, iron is imported by the divalent metal transporter (DMT1). Iron may be stored within the cell as ferritin or transferred across the basolateral membrane by the transporter, IREG1 (ferroportin-1), and is reoxidized by hephaestin (Heph) before binding to the transport protein, transferrin (Tf). Circulating iron is acquired by the liver primarily through the classic transferrin receptor-1 (TfR1) and by the related transferrin receptor-2 (TfR2). Reticuloendothelial macrophages acquire iron mainly by phagocytosis of senescent erythrocytes, and the iron is released via the iron export protein, IREG1. The released iron is oxidized to the ferric state by ceruloplasmin (Cp) before binding to transferrin. In response to increased iron, the liver produces hepcidin, which appears to communicate the level of iron stores to intestinal cells and reticuloendothelial (RE) cells. Hepcidin deficiency mimics hemochromatosis, as it is associated with increased intestinal iron absorption and decreased iron uptake in reticuloendothelial cells. HFE is a MHC class 1 molecule that forms a complex with β_2 microglobulin (β_2-M) and binds to TfR1.

Patients with hereditary hemochromatosis (HH) caused by *HFE* mutations fail to express a functional β_2-M:HFE:TfR complex. In addition, they have decreased hepatic expression of hepcidin. Although the pathogenesis of HH is incompletely understood, decreased expression of HFE in the intestine is thought to result in low iron levels in the crypt cells, leading to inappropriate upregulation of DMT1 and IREG1. This causes increased intestinal iron absorption, leading to increased tissue iron stores, with paradoxical sparing of iron loading in the RE system, perhaps because iron is efficiently exported by IREG1. Hb, hemoglobin. Also, a decreased expression of HPE in the liver may result in decreased hepcidin synthesis and upregulation of iron absorption.

sue injury may result from disruption of iron-laden lysosomes, from lipid peroxidation of subcellular organelles by excess iron, or from stimulation of collagen synthesis by activated stellate cells.

Secondary iron overload with deposition in parenchymal cells occurs in chronic disorders of erythropoiesis, particularly in those due to defects in hemoglobin synthesis or ineffective erythropoiesis such as sideroblastic anemia and thalassemia (Chap. 91). In these disorders, the absorption of iron is increased. Moreover, these patients require blood transfusions and are frequently treated inappropriately with iron. PCT, a disorder characterized by a defect in porphyrin biosynthesis (Chap. 337), is also sometimes associated with excessive parenchymal iron deposits. The magnitude of the iron load in PCT is usually insufficient to produce tissue damage. However, recent reports have found that many patients with PCT also have mutations in the *HFE* gene, and some have associated hepatitis C infection. Although the relationship among these disorders remains to be clarified, iron overload accentuates the inherited enzyme deficiency in PCT and should be avoided along with other agents (alcohol, estrogens, haloaromatic compounds) that may exacerbate PCT. Another cause of hepatic parenchymal iron overload is hereditary aceruloplasminemia. In this disorder, impairment of iron mobilization due to deficiency of ceruloplasmin (a ferroxidase) causes iron overload in hepatocytes. End-stage liver disease may also be associated with iron overload of the degree seen in hemochromatosis. The mechanism is uncertain, although hemolysis plays a role. Hemochromatosis in a heavy drinker can be distinguished from alcoholic liver disease by the presence of the C282Y mutation.

Excessive iron ingestion over many years rarely results in hemochromatosis. An important exception has been reported in South Africa among groups who brew fermented beverages in vessels made of iron. Hemochromatosis has been described in apparently normal persons who have taken medicinal iron over many years, but such individuals probably had a genetic disorder.

The common denominator in all patients with hemochromatosis is *excessive amounts of iron in parenchymal tissues*. Parenteral administration of iron in the form of blood transfusions or iron preparations results predominantly in reticuloendothelial cell iron overload. This appears to lead to less tissue damage than iron loading of parenchymal cells.

PATHOLOGY

At autopsy, the enlarged nodular liver and pancreas are rusty in color. Histologically, iron is increased in many organs, particularly in the liver, heart, and pancreas, and to a lesser extent in the endocrine glands.

The epidermis of the skin is thin, and melanin is increased in the cells of the basal layer. Deposits of iron are present around the synovial lining cells of the joints.

In the liver of patients with hemochromatosis, parenchymal iron is in the form of ferritin and hemosiderin. In the early stages these deposits are seen in the periportal parenchymal cells, especially within lysosomes in the pericanalicular cytoplasm of the hepatocytes. This stage progresses to perilobular fibrosis and eventually to deposition of iron in bile duct epithelium, Kupffer cells, and fibrous septa due to activation of stellate cells. In the advanced stage, a macronodular or mixed macro- and micronodular cirrhosis develops.

CLINICAL MANIFESTATIONS

Initial symptoms include weakness, lassitude, change in skin color, abdominal pain, loss of libido, and symptoms of diabetes mellitus. Hepatomegaly, increased pigmentation, spider angiomas, splenomegaly, arthropathy, ascites, cardiac arrhythmias, congestive heart failure, loss of body hair, testicular atrophy, and jaundice are prominent in advanced disease.

The *liver* is usually the first organ to be affected, and hepatomegaly is present in more than 95% of symptomatic patients. Hepatic enlargement may exist in the absence of symptoms or of abnormal liver function tests. Indeed, over half of patients with symptomatic hemochromatosis have little laboratory evidence of functional impairment of the liver, in spite of hepatomegaly and fibrosis. Loss of body hair, palmar erythema, testicular atrophy, and gynecomastia are common. Manifestations of portal hypertension and esophageal varices occur less commonly than in cirrhosis from other causes. Hepatocellular carcinoma develops in about 30% of patients with cirrhosis, and it is the most common cause of death in treated patients; hence the importance of early diagnosis and therapy. Its incidence increases with age, is more common in men, and occurs almost exclusively in cirrhotic patients. Splenomegaly occurs in approximately half of symptomatic cases.

Excessive skin pigmentation is present in over 90% of symptomatic patients at the time of diagnosis. The characteristic metallic or slate gray hue is sometimes referred to as bronzing and results from increased melanin and iron in the dermis. Pigmentation usually is diffuse and generalized, but it may be more pronounced on the face, neck, extensor aspects of the lower forearms, dorsa of the hands, lower legs, genital regions, and in scars.

Diabetes mellitus occurs in about 65% of patients and is more likely to develop in those with a family history of diabetes, suggesting that direct damage to the pancreatic islets by iron deposition occurs in combination with a genetic predisposition. The management is similar to that of other forms of diabetes, although pronounced insulin resistance is more common in association with hemochromatosis. Late complications are the same as seen in other causes of diabetes mellitus.

Arthropathy develops in 25 to 50% of patients. It usually occurs after age 50, but may occur as a first manifestation, or long after therapy. The joints of the hands, especially the second and third metacarpophalangeal joints, are usually the first joints involved, a feature that helps to distinguish the chondrocalcinosis associated with hemochromatosis from the idiopathic form (Chap. 313). A progressive polyarthritis involving wrists, hips, ankles, and knees may also ensue. Acute brief attacks of synovitis may be associated with deposition of calcium pyrophosphate (chondrocalcinosis or pseudogout), mainly in the knees. Radiologic manifestations include cystic changes of the subchondral bones, loss of articular cartilage with narrowing of the joint space, diffuse demineralization, hypertrophic bone proliferation, and calcification of the synovium. The arthropathy tends to progress despite removal of iron by phlebotomy. Although the relation of these abnormalities to iron metabolism is not known, the fact that similar changes occur in other forms of iron overload suggests that iron is directly involved.

Cardiac involvement is the presenting manifestation in about 15% of patients. The most common manifestation is congestive heart failure, which occurs in about 10% of young adults with the disease, especially those with juvenile hemochromatosis. Symptoms of congestive failure may develop suddenly, with rapid progression to death if untreated. The heart is diffusely enlarged and may be misdiagnosed as idiopathic cardiomyopathy if other overt manifestations are absent. Cardiac arrhythmias include premature supraventricular beats, paroxysmal tachyarrhythmias, atrial flutter, atrial fibrillation, and varying degrees of atrioventricular block.

Hypogonadism occurs in both sexes and may antedate other clinical features. Manifestations include loss of libido, impotence, amenorrhea, testicular atrophy, gynecomastia, and sparse body hair. These changes are primarily the result of decreased production of gonadotropins due to impairment of hypothalamic-pituitary function by iron deposition; however, primary testicular dysfunction may be seen in some cases. Adrenal insufficiency, hypothyroidism, and hypoparathyroidism may also occur.

DIAGNOSIS

The association of (1) hepatomegaly, (2) skin pigmentation, (3) diabetes mellitus, (4) heart disease, (5) arthritis, and (6) hypogonadism should suggest the diagnosis. However, a parenchymal iron overload of comparatively short duration or modest degree may exist with none or only some of these manifestations [e.g., in young patients (Fig. 336-1)]. Therefore, a high index of suspicion is needed to make the diagnosis early. Treatment before there is permanent organ damage can reverse the iron toxicity and restore life expectancy to normal.

The history should be particularly detailed in regard to disease in other family members, alcohol ingestion, iron intake, and ingestion of large doses of ascorbic acid, which promotes iron absorption (Chap. 61). Appropriate tests should be performed to exclude iron deposition due to hematologic disease. The presence of liver, pancreatic, cardiac, and joint disease should be confirmed by physical examination, roentgenography, and standard function tests of these organs. The degree of increase in total-body iron stores should be assessed with particular attention to an increase in parenchymal iron concentration, with or without tissue damage.

The methods available for assessing parenchymal iron stores include (1) measurement of serum iron and the percent saturation of transferrin (or the unsaturated iron-binding capacity); (2) measurement of serum ferritin concentration; (3) liver biopsy with measurement of the iron concentration and calculation of the hepatic iron index (Table 336-2), (4) estimation of chelatable iron stores following the administration of deferoxamine; and (5) computed tomography (CT) and/or magnetic resonance imaging (MRI) of the liver. Each has its advantages and limitations. The serum iron level and percent saturation of transferrin are elevated early in the course, but their specificity is reduced by significant false-positive and false-negative rates. For example, serum iron concentration may be increased in patients with alcoholic liver disease without iron overload; in this situation, however, the hepatic iron index is usually not increased as in hemochromatosis (Table 336-1). In otherwise healthy persons, a fasting serum transferrin saturation greater than 50% is abnormal and suggests homozygosity for hemochromatosis.

The serum ferritin concentration is usually a good index of body iron stores, whether decreased or increased. In fact, an increase of 1 μg/L in serum ferritin level reflects an increase of about 65 mg in body stores. In most untreated patients with hemochromatosis, the serum ferritin level is greatly increased (Fig. 336-1 and Table 336-1). However, in patients with inflammation and hepatocellular necrosis, serum ferritin levels may be elevated out of proportion to body iron stores due to increased release from tissues. A repeat determination of serum ferritin should therefore be carried out after acute hepatocellular damage has subsided, e.g., in alcoholic liver disease. Ordinarily, the combined measurements of the percent transferrin saturation and serum ferritin level provide a simple and reliable screening test for hemochromatosis, including the precirrhotic phase of the disease. If ei-

TABLE 336-2 *Representative Iron Values in Normal Subjects, Patients with Hemochromatosis, and Patients with Alcoholic Liver Disease*

Determination	Normal	Symptomatic Hemochromatosis	Homozygotes with Early, Asymptomatic Hemochromatosis	Heterozygotes	Alcoholic Liver Disease
Plasma iron, μmol/L (μg/dL)	9–27 (50–150)	32–54 (180–300)	Usually elevated	Elevated or normal	Often elevated
Total iron-binding capacity, μmol/L (μg/dL)	45–66 (250–370)	36–54 (200–300)	36–54 (200–300)	Elevated or normal	45–66 (250–370)
Transferrin saturation, percent	22–46	50–100	50–100	Normal or elevated	27–60
Serum ferritin, μg/L	10–200	900–6000	200–500	Usually <500	10–500
Urinary iron,[a] mg/24 h	0–2	9–23	2–5	2–5	Usually <5
Liver iron, μg/g dry wt	300–1400	6000–18,000	2000–4000	300–3000	300–2000
Hepatic iron index $\frac{(\mu g/g \text{ dry wt})}{56 \times \text{age}}$	<1.0	>2	Usually >2	<2	<2

[a] After intramuscular administration of 0.5 g deferoxamine.

ther of these tests is abnormal, genetic testing for hemochromatosis should be performed (Fig. 336-3).

The role of liver biopsy in the diagnosis and management of hemochromatosis has been reassessed as a result of the widespread availability of genetic testing for the C282Y mutation. The absence of severe fibrosis can be accurately predicted in most patients using clinical and biochemical variables. Thus, there is virtually no risk of severe fibrosis in a C282Y homozygous subject with: (1) serum ferritin level less than 1000 μg/L; (2) normal serum alanine amino transaminase values; (3) no hepatomegaly; and (4) no excess alcohol intake. However, it should be emphasized that liver biopsy is the only reliable method for establishing or excluding the presence of hepatic cirrhosis, which is the critical factor determining prognosis and the risk of developing hepatocellular carcinoma. Biopsy also permits histochemical estimation of tissue iron and measurement of hepatic iron concentration. Increased density of the liver due to iron deposition can be demonstrated by CT or MRI. A retrospective assessment of body iron storage is also provided by performing weekly phlebotomy and calculating the amount of iron removed before iron stores are exhausted (1 mL blood = approximately 0.5 mg iron).

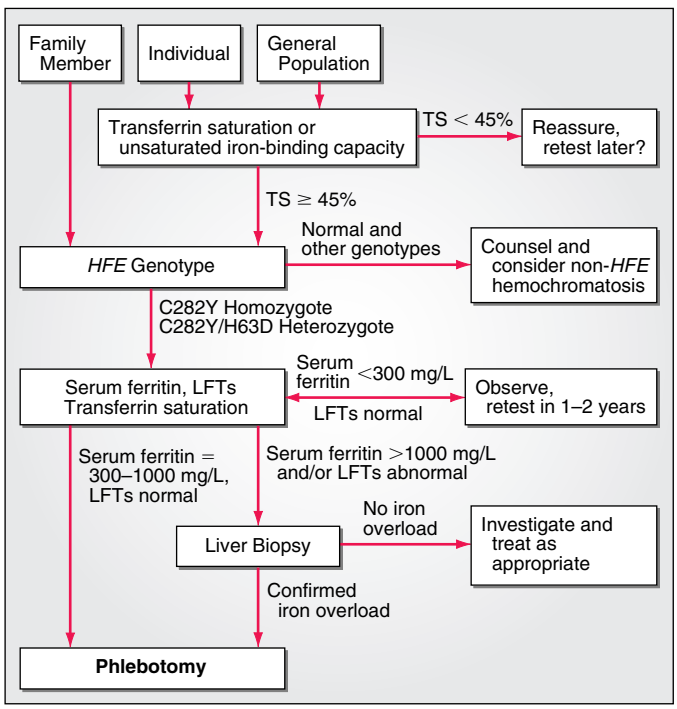

FIGURE 336-3 Algorithm for screening for *HFE*-associated hemochromatosis. LFT, liver function tests; TS, transferrin saturation. (*With permission from The Canadian Journal of Gastroenterology.*)

SCREENING FOR HEMOCHROMATOSIS

When the diagnosis of hemochromatosis is established, it is important to counsel and screen other family members (Chap. 58). Asymptomatic as well as symptomatic family members with the disease usually have an increased saturation of transferrin and an increased serum ferritin concentration. These changes occur even before the iron stores are greatly increased (Fig. 336-1). All first-degree relatives of patients with hemochromatosis should be tested for the C282Y and H63D mutations and advised appropriately. In affected individuals, it is important to confirm or exclude the presence of cirrhosis and begin therapy as early as possible. When children of a proband are affected, a homozygote-heterozygote mating is most likely.

The role of population screening for hemochromatosis is controversial. Hemochromatosis fulfills the criteria established by the World Health Organization for population screening, and DNA testing could, in principle, be performed along with other neonatal tests. However, because iron overload does not develop until the second, third, or fourth decades, and the degree of penetrance is still uncertain, screening for phenotypic expression in adults is more practical at present (Fig. 336-3).

TREATMENT

The therapy of hemochromatosis involves removal of the excess body iron and supportive treatment of damaged organs. Iron removal is best begun by weekly or twice-weekly phlebotomy of 500 mL. Although there is an initial modest decline in the volume of packed red blood cells to about 35 mL/dL, the level stabilizes after several weeks. The plasma transferrin saturation remains increased until the available iron stores are depleted. In contrast, the plasma ferritin concentration falls progressively, reflecting the gradual decrease in body iron stores. Since one 500-mL unit of blood contains 200 to 250 mg iron and about 25 g iron should be removed, weekly phlebotomy may be required for 1 or 2 years. When the transferrin saturation and ferritin level become normal, phlebotomies are performed at appropriate intervals to maintain levels within the normal range. The measurements promptly become abnormal with iron reaccumulation. Usually one phlebotomy every 3 months will suffice.

Chelating agents such as deferoxamine, when given parenterally, remove 10 to 20 mg iron per day, which is much less than that mobilized by once-weekly phlebotomy. Phlebotomy is also less expensive, more convenient, and safer for most patients. However, chelating agents are indicated when anemia or hypoproteinemia is severe enough to preclude phlebotomy. Subcutaneous infusion of deferoxamine using a portable pump is the most effective means of administration.

Alcohol consumption should be severely curtailed or eliminated as it increases the risk of cirrhosis in hereditary hemochromatosis nearly tenfold. The management of hepatic failure, cardiac failure, and diabetes mellitus is similar to conventional therapy for these conditions. Loss of libido and change in secondary sex characteristics are partially

relieved by parenteral testosterone or gonadotropin therapy (Chap. 325).

PROGNOSIS

The principal causes of death are cardiac failure (30%), hepatocellular failure or portal hypertension (25%), and hepatocellular carcinoma (30%).

Life expectancy is improved by removal of the excessive stores of iron and maintenance of these stores at near-normal levels. The 5-year survival rate with therapy increases from 33 to 89%. With repeated phlebotomy, the liver and spleen decrease in size, liver function improves, pigmentation of skin decreases, and cardiac failure may be reversed. Diabetes improves in about 40%, but removal of excess iron has little effect on hypogonadism or arthropathy. Hepatic fibrosis may decrease, but cirrhosis is irreversible. End-stage liver disease can be treated with orthotopic liver transplantation, but the results are suboptimal unless excess iron stores are first corrected. Hepatocellular carcinoma usually occurs as a late sequela in patients who are cirrhotic at presentation. The apparent increase in its incidence in treated patients is probably related to their increased life span. Hepatocellular carcinoma does not appear to develop if the disease is treated in the precirrhotic stage. Indeed, the life expectancy of homozygotes treated before the development of cirrhosis is normal.

The importance of family screening and early therapy cannot be emphasized too strongly. Asymptomatic individuals detected by family studies should have phlebotomy therapy if iron stores are moderately to severely increased. Assessment of iron stores at appropriate intervals is also important. With this management approach, most manifestations of the disease can be prevented.

337 THE PORPHYRIAS

Robert J. Desnick

The porphyrias are inherited disorders, each involving a specific enzyme in the heme biosynthetic pathway (Fig. 337-1). These disorders are classified as either *hepatic* or *erythropoietic* depending on the primary site of overproduction and accumulation of the porphyrin precursor or porphyrin (Tables 337-1 and 337-2), although some have overlapping features. The major manifestations of the hepatic porphyrias are neurologic, including neuropathic abdominal pain, neuropathy, and mental disturbances, whereas the erythropoietic porphyrias characteristically cause cutaneous photosensitivity. The reason for neurologic involvement in the hepatic porphyrias is poorly understood. Cutaneous sensitivity to sunlight is due to long-wave ultraviolet light excitation of excess porphyrins in the skin, leading to cell damage, scarring, and deformation. Steroid hormones, drugs, and nutrition influence the production of porphyrin precursors and porphyrins, thereby precipitating or increasing the severity of some porphyrias. Thus, the porphyrias are ecogenetic disorders in which environmental, physiologic, and genetic factors interact to cause disease.

Because many symptoms of the porphyrias are nonspecific, diagnosis is often delayed. Laboratory testing is required to confirm or exclude the various types of porphyria (Table 337-2). Urinary δ-aminolevulinic acid (ALA) and porphobilinogen (PBG) are easily quantitated by chemical methods; the urinary porphyrin isomers can be separated and quantitated by high-performance liquid chromatography. The diagnostic profile of accumulated precursors and/or porphyrins in each disorder can also be defined by extraction and thin-layer chromatography of fecal porphyrins. However, a definite diagnosis requires demonstration of the specific enzyme deficiency or gene defect. The isolation and characterization of the cDNAs encoding the heme biosynthetic enzymes have permitted identification of the genetic basis of each porphyria. Molecular genetic analyses now make it possible to provide precise heterozygote identification and prenatal diagnoses in families with known mutations.

HEME BIOSYNTHESIS The first and last three enzymes in the heme biosynthetic pathway are located in the mitochondrion, whereas the other four are cytosolic (Fig. 337-1). The first enzyme, δ-aminolevulinate synthase (ALA-synthase), catalyzes the condensation of glycine, activated by pyridoxal phosphate and succinyl coenzyme A, to form ALA. In the liver, this rate-limiting enzyme can be induced by a variety of drugs, steroids, and other chemicals. Distinct erythroid-specific and nonerythroid (e.g., housekeeping) forms of ALA-synthase are encoded by separate genes; defects in the erythroid form cause X-linked sideroblastic anemia (XLSA).

The second enzyme, δ-aminolevulinate dehydratase (ALA-dehydratase), catalyzes the condensation of two molecules of ALA to form PBG. Four molecules of PBG condense to form the tetrapyrrole uroporphyrinogen (URO) III by a two-step process catalyzed by hydroxymethylbilane (HMB) synthase (also known as PBG-deaminase or URO I synthase) and URO III synthase. HMB-synthase catalyzes the head-to-tail condensation of four PBG molecules by a series of deaminations to form the linear tetrapyrrole, HMB. URO-synthase catalyzes the rearrangement and rapid cyclization of HMB to form the asymmetric, physiologic, octacarboxylate porphyrinogen URO III isomer.

The fifth enzyme in the pathway, URO-decarboxylase, catalyzes the sequential removal of the four carboxyl groups from the acetic acid side chains of URO III to form coproporphyrinogen (COPRO) III, a tetracarboxylate porphyrinogen. This compound then enters the mitochondrion, where COPRO-oxidase, the sixth enzyme, catalyzes the decarboxylation of two of the four propionic acid groups to form the two vinyl groups of protoporphyrinogen (PROTO) IX, a dicarboxylate porphyrinogen. Next, PROTO-oxidase oxidizes PROTO IX to protoporphyrin IX by the removal of six hydrogen atoms. The product of the reaction is a porphyrin (oxidized form), in contrast to the preceding tetrapyrrole intermediates, which are porphyrinogens (reduced forms). Finally, ferrous iron is inserted into protoporphyrin IX to form heme, a reaction catalyzed by the eighth enzyme in the pathway, ferrochelatase (also known as heme synthetase or protoheme ferrolyase).

Mutations causing their respective porphyria have been identified in each of these genes. Thus, molecular diagnosis is now available for each porphyria, which is important in many cases where the diagnosis by other methods may be difficult.

REGULATION OF HEME BIOSYNTHESIS About 85% of the heme produced in the body is synthesized in erythroid cells to provide heme for hemoglobin; most of the remainder is produced in the liver, where the

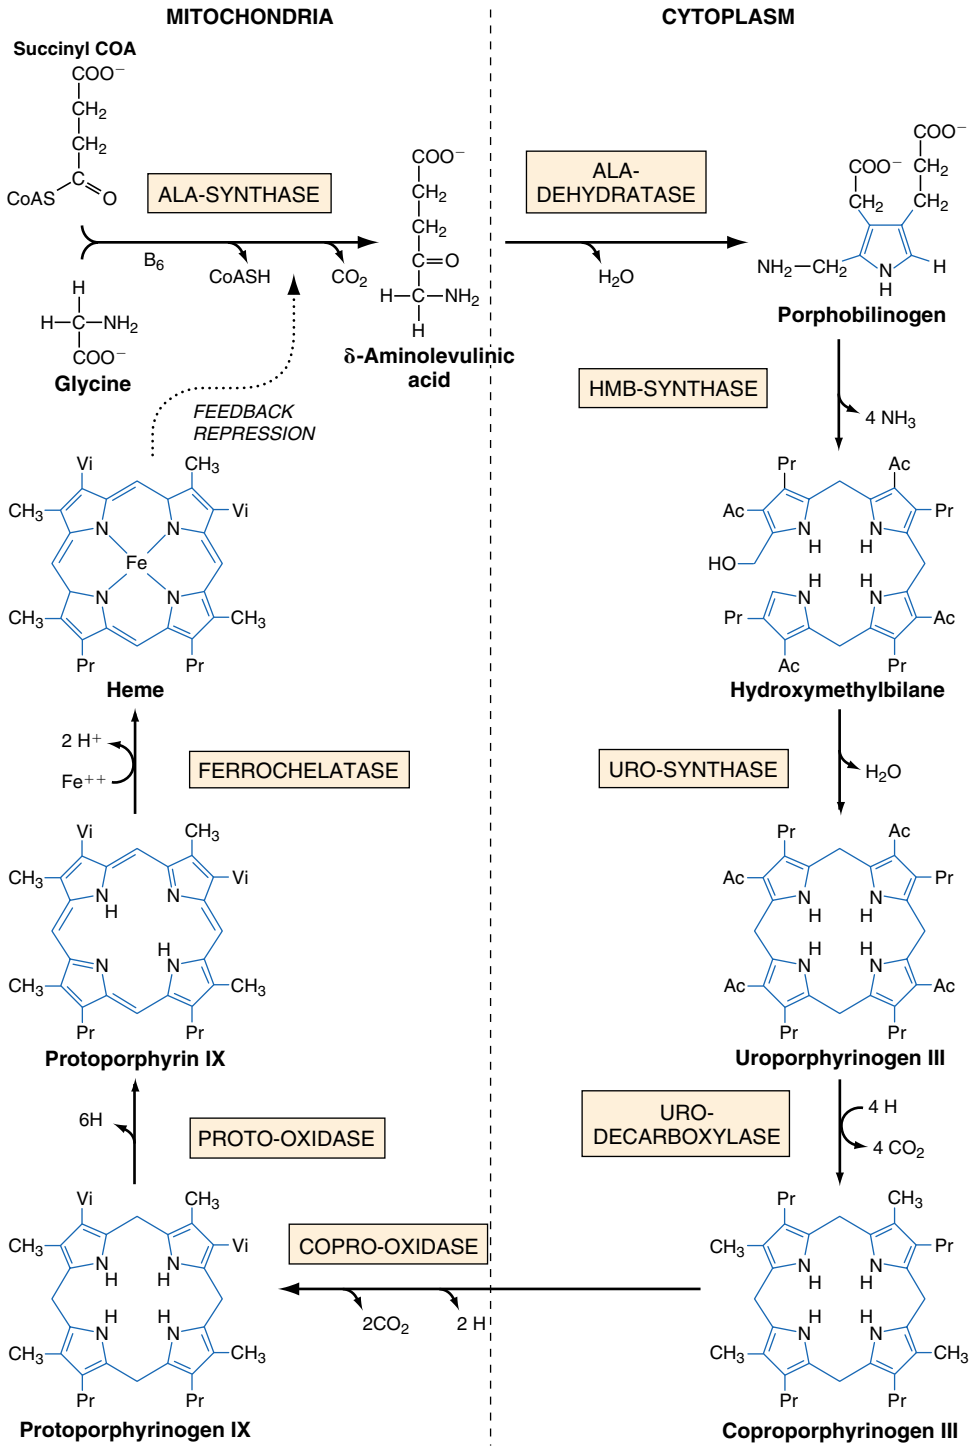

FIGURE 337-1 The human heme biosynthetic pathway.

biosynthetic pathway is under negative feedback control. "Free" heme in the liver regulates the synthesis and mitochondrial translocation of the housekeeping form of ALA-synthase. Heme represses the synthesis of the ALA-synthase mRNA and interferes with the transport of the enzyme from the cytosol into mitochondria. ALA-synthase is increased by many of the same chemicals that induce the cytochrome P450 enzymes in the endoplasmic reticulum of the liver. Because most of the heme in the liver is used for the synthesis of cytochrome P450 enzymes, hepatic ALA-synthase and the cytochrome P450s are regulated in a coordinated fashion.

Different regulatory mechanisms control the production of heme for hemoglobin. The erythroid-specific ALA-synthase is encoded on the X-chromosome and it is expressed at higher levels than the hepatic enzyme. An erythroid-specific control mechanism regulates iron transport into erythroid cells. During erythroid differentiation, the activities of the heme biosynthetic enzymes are increased.

THE HEPATIC PORPHYRIAS

The acute hepatic porphyrias are characterized by the rapid onset of neurologic manifestations. During the acute attack, individuals have markedly elevated plasma and urinary concentrations of the porphyrin precursors ALA and PBG, which originate from the liver.

ALA-DEHYDRATASE–DEFICIENT PORPHYRIA

This is a rare autosomal recessive disorder that has been described in only a few patients. Onset and severity of the disease are variable, presumably depending on the amount of residual ALA-dehydratase activity. Clinical features include abdominal pain and neuropathy, resembling acute intermittent porphyria (AIP; see below). Patients have increased urinary levels of ALA and coproporphyrin. ALA-dehydratase activity in erythrocytes is <5% of normal. Lead intoxication and hereditary tyrosinemia (fumarylacetoacetase deficiency) should be considered in the differential diagnosis of ALA-dehydratase–deficient porphyria, as they can inhibit ALA-dehydratase. DNA analyses reveal a variety of missense mutations that result in the amino acid substitutions in ALA-dehydratase. Heterozygotes are clinically asymptomatic and do not excrete increased levels of ALA, but they can be detected by demonstration of intermediate levels of erythrocyte ALA-dehydratase activity or by demonstrating a specific mutation in the *ALA-dehydratase* gene. Prenatal diagnosis of this disorder has not been achieved but should be possible by determination of the ALA-dehydratase activity and/or gene mutation in cultured chorionic villi or amniocytes. Treatment and prevention of the neurologic complications are the same as for other acute porphyrias (see below).

ACUTE INTERMITTENT PORPHYRIA This hepatic porphyria is an autosomal dominant condition resulting from the half-normal level of HMB-synthase activity. The disease is widespread but is especially common in Scandinavia and Great Britain. The enzyme deficiency can be demonstrated in most heterozygous individuals, but clinical expression is highly variable. Activation of the disease is related to environmental or hormonal factors, such as drugs, diet, and steroid hormones, which can precipitate the manifestations. Attacks can be prevented by avoiding known precipitating factors.

Clinical Features Most heterozygotes remain clinically asymptomatic (latent) unless exposed to factors that increase the production of porphyrins. Endogenous and exogenous gonadal steroids, porphyrinogenic drugs, alcohol ingestion, and low-calorie diets, usually instituted

for weight loss, are common precipitating factors. Table 337-3 provides a partial list of the major drugs that are harmful in AIP [and also in hereditary coproporphyria (HCP) and variegate porphyria (VP)] and some drugs and anesthetic agents known to be safe. More extensive lists of drugs considered harmful or safe are available (Anderson et al., 2001), but information is incomplete for many of them. Attacks also can be provoked by infections and surgery.

[a] AR, autosomal recessive; AD, autosomal dominant; XLR, X-linked recessive.
Note: ALA, δ-aminolevulinic acid; HMB, hydroxymethylbilane; URO, uroporphyrinogen; COPRO, coproporphyrinogen; PROTO, protoporphyrinogen.

Because the neurovisceral symptoms rarely occur before puberty and are often nonspecific, a high index of suspicion is required to make the diagnosis. The disease can be disabling but is rarely fatal. Abdominal pain, the most common symptom, is usually steady and poorly localized but may be due to cramps. Ileus, abdominal distention, and decreased bowel sounds are common. However, increased bowel sounds and diarrhea may occur. Abdominal tenderness, fever, and leukocytosis are usually absent or mild because the symptoms are neurologic rather than inflammatory. Nausea, vomiting, constipation, tachycardia, hypertension, mental symptoms, pain in the limbs, head, neck, or chest, muscle weakness, sensory loss, dysuria, and urinary retention are characteristic. Tachycardia, hypertension, restlessness, tremors, and excess sweating are due to sympathetic overactivity.

The peripheral neuropathy is due to axonal degeneration (rather than demyelination) and primarily affects motor neurons. Significant neuropathy does not occur with all acute attacks; abdominal symptoms are usually more prominent. Motor neuropathy affects the proximal muscles initially, more often in the shoulders and arms. The course and degree of involvement are variable. Deep tendon reflexes may be normal or hyperactive but are usually decreased or absent with advanced neuropathy. Motor weakness can be asymmetric and focal and may involve cranial nerves. Sensory changes such as paresthesia and loss of sensation are less prominent. Progressive muscle weakness can lead to respiratory and bulbar paralysis and death when diagnosis and treatment are delayed. Sudden death may result from sympathetic overactivity and cardiac arrhythmia.

Mental symptoms such as anxiety, insomnia, depression, disorientation, hallucinations, and paranoia can occur in acute attacks. Seizures can be due to neurologic effects or to hyponatremia. Treatment of seizures is difficult because virtually all antiseizure drugs (except bromides) may exacerbate AIP (clonazepam may be safer than phenytoin or barbiturates). Hyponatremia results from hypothalamic involvement and inappropriate vasopressin secretion or from electrolyte depletion due to vomiting, diarrhea, poor intake, or excess renal sodium loss. Persistent hypertension and impaired renal function may occur. When an attack resolves, abdominal pain may disappear within hours, and paresis begins to improve within days and may continue to improve over several years.

Diagnosis ALA and PBG levels are increased in plasma and urine during acute attacks. Urinary PBG excretion is usually 220 to 880 μmol/d (50 to 200 mg/d) [normal, 0 to 18 μmol/d (0 to 4 mg/d)], and urinary ALA excretion is 150 to 760 μmol/d (20 to 100 mg/d) [normal, 8 to 53 μmol/d (1 to 7 mg/d)]. The excretion of these compounds generally decreases with clinical improvement, particularly after hematin infusions (see below). A normal urinary PBG level effectively excludes AIP as a cause for current symptoms. Fecal porphyrins are usually normal or minimally increased in AIP, in contrast to HCP and VP. Most asymptomatic ("latent") heterozygotes with HMB-synthase deficiency have normal urinary excretion of ALA and PBG. Therefore, measurement of HMB-synthase in erythrocytes, or better, the detection of the family's HMB-synthase mutation, will diagnose asymptomatic family members.

The enzyme deficiency is detectable in erythrocytes from most AIP heterozygotes (*classic AIP*). Note that the activity is higher in young erythrocytes and may increase into the normal range in AIP when erythropoiesis is increased due to a concurrent condition. However, patients with the rare erythroid form of AIP (*erythroid, or variant, AIP*) have normal enzyme levels in erythrocytes and deficient activity in nonerythroid tissues (see below). The erythroid and housekeeping forms of HMB-synthase are encoded by a single gene, which has two promoters: one promoter generates the ubiquitously expressed housekeeping mRNA; the other promoter transcribes the erythroid-specific mRNA. Several deletions and >175 different mutations have been

found in the coding region of the gene in unrelated AIP families. These mutations alter the kinetic properties and/or stability of the mutant enzymes or create premature termination codons. Mutations that cause erythroid AIP variants with half-normal enzyme in nonerythroid tissues, but normal activity in erythrocytes, include point mutations in the initiation methionine codon (which prevent translation) and in the 5′ donor splice site of intron 1 (which cause abnormal splicing of the HMB-synthase transcript) and a mutation in the housekeeping promoter. The prenatal diagnosis of a fetus at risk can be made with cultured amniotic cells or chorionic villi.

TREATMENT

During acute attacks, narcotic analgesics may be required for abdominal pain, and phenothiazines are useful for nausea, vomiting, anxiety, and restlessness. Chloral hydrate can be given for insomnia, and benzodiazepines are probably safe in low doses, if a minor tranquilizer is required. Although intravenous glucose (at least 300 g/d) can be effective in acute attacks of porphyria, a more complete parenteral nutritional regimen may be beneficial if oral feeding is not possible for a prolonged period. However, intravenous heme is more effective than glucose in reducing porphyrin precursor excretion and probably leads to more rapid recovery. The response to heme therapy is reduced if delayed. Therefore, 3 to 4 mg of heme, in the form of hematin (Abbott Laboratories), heme albumin, or heme arginate (Leiras Oy, Turku, Finland), may be infused daily for 4 days beginning as soon as possible after onset of an attack. Heme arginate and heme albumin are chemically stable and are less likely than hematin to produce phlebitis or an anticoagulant effect. The rate of recovery from an acute attack depends on the degree of neuronal damage and may be rapid (1 to 2 days) with prompt therapy. Recovery from severe motor neuropathy may require months or years. Identification and avoidance of inciting factors can hasten recovery from an attack and prevent future attacks. Multiple inciting factors may contribute to a symptomatic episode. Frequent clear-cut cyclical attacks occur in some women and can be prevented with a long-acting gonadotropin-releasing hormone analogue (this indication is not approved by the U.S. Food and Drug Administration).

PORPHYRIA CUTANEA TARDA Porphyria cutanea tarda (PCT), the most common of the porphyrias, can be sporadic (type I) or familial (types II and III) and can also develop after exposure to halogenated aromatic hydrocarbons. Hepatic URO-decarboxylase is deficient in all types of PCT; however, in types I and III PCT, URO-decarboxylase activity is normal in erythrocytes. In type II PCT, an autosomal dominant disorder, the enzyme is deficient in erythrocytes and other tissues. In type III PCT, deficiency of the enzyme is limited to the liver. Deficient hepatic URO-decarboxylase and a porphyrin pattern resembling PCT can be produced by exposure of normal individuals to a number of halogenated aromatic hydrocarbons. Hepatoerythropoietic porphyria (HEP) is an autosomal recessive form of porphyria that results from marked systemic deficiency of URO-decarboxylase activity.

Clinical Features Cutaneous photosensitivity is the major clinical feature. Neurologic manifestations are not observed. Fluid-filled vesicles and bullae develop on sun-exposed areas such as the face, the dorsa of the hands and feet, the forearms, and the legs. The skin in these areas is friable, and minor trauma may lead to the formation of bullae. The appearance of small white plaques, termed *milia*, may precede or follow vesicle formation. Bullae and denuded skin heal slowly and are subject to infection. Other features include hypertrichosis and hyperpigmentation, especially of the face, and thickening, scarring, and calcification resembling the cutaneous changes of systemic sclerosis.

A number of factors contribute to the development of hepatic URO-decarboxylase deficiency, including excess alcohol, iron, and estrogens. The importance of excess hepatic iron as a precipitating factor is underscored by the finding that the incidence of the common hemochromatosis-causing mutations, *HFE* C282Y and H63D, are increased in patients with types I and II PCT (Chap. 336). Various chemicals can also induce PCT; an epidemic of PCT occurred in eastern Turkey in the 1950s as a consequence of wheat contaminated with the fungicide hexachlorobenzene. PCT also occurs after exposure to other chemicals, including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-(*p*)-dioxin (TCDD, dioxin). Patients with PCT characteristically have liver damage and are at risk for hepatocellular carcinoma. These carcinomas do not produce porphyrins.

HEP resembles congenital erythropoietic porphyria (CEP) and usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood.

Diagnosis Porphyrins are increased in the liver, plasma, urine, and stool. The urinary ALA level may be slightly increased, but the PBG level is normal. Urinary porphyrins consist mostly of uroporphyrin and 7-carboxylate porphyrin, with lesser amounts of coproporphyrin and 5- and 6-carboxylate porphyrins. Plasma porphyrins are also increased in a pattern that resembles that in urine. Isocoproporphyrins are increased in feces and sometimes in plasma and urine. The finding of increased isocoproporphyrins is diagnostic for hepatic URO-decarboxylase deficiency.

Type II PCT and HEP can be distinguished from types I and III by finding decreased URO-decarboxylase in erythrocytes. URO-decarboxylase activity in liver, erythrocytes, and cultured skin fibroblasts in type II PCT is approximately 50% of normal in affected individuals and in family members with latent disease. In HEP, the URO-decarboxylase activity is markedly deficient, with typical levels of 3 to 10% of normal. Over 50 mutations have been identified in the coding region of the *URO-decarboxylase* gene from unrelated type II PCT and HEP patients. Excess hepatic iron contributes to development of sporadic and familial forms of PCT. As noted above, coinheritance of *HFE* mutations that cause hemochromatosis increases susceptibility to PCT-precipitating factors. In the familial forms (types II and III), iron inhibits the residual normal enzyme, so that enzymatic activity in liver is $<50\%$ of normal. In type I PCT the decreased hepatic URO-decarboxylase activity is not accompanied by a decrease in the amount of enzyme protein, suggesting that the enzyme is present in an inactive form; hepatic URO-decarboxylase activity gradually increases after a remission is induced by phlebotomy.

TREATMENT

Alcohol, estrogens, iron supplements, and, if possible, any drugs that may exacerbate the disease should be discontinued, but this step does not always lead to improvement. A complete response can almost always be achieved by repeated phlebotomy to reduce hepatic iron. A unit (450 mL) of blood can be removed every 1 to 2 weeks. Because iron overload is not marked in most cases, remission may occur after only five or six phlebotomies. Hemoglobin levels and serum ferritin should be followed closely to prevent development of iron deficiency

and anemia. After remission, continued phlebotomy may not be needed even if ferritin levels return to normal. Relapses are treated by additional phlebotomy.

PCT can also be treated with chloroquine or hydroxychloroquine, both of which form a complex with the excess porphyrins and promote their excretion. Small doses (e.g., 125 mg chloroquine phosphate twice weekly) should be given, because standard doses can induce transient, sometimes marked increases in photosensitivity and hepatocellular damage. Hepatic imaging can diagnose or exclude complicating hepatocellular carcinoma. Treatment of PCT in patients with end-stage renal disease is facilitated by administration of erythropoietin.

HEREDITARY COPROPORPHYRIA HCP is an autosomal dominant form of hepatic porphyria that results from half-normal levels of COPRO-oxidase activity. Photosensitivity may occur. A few cases of homozygous HCP have been reported.

Clinical Features HCP is influenced by the same factors that cause attacks in AIP. The disease is latent before puberty, and symptoms are more common in women. Neurovisceral symptoms and other manifestations are virtually identical to those of AIP. Photosensitivity may resemble that in PCT and VP. Cutaneous lesions may begin in childhood in rare homozygous cases.

Diagnosis Coproporphyrin is markedly increased in the urine and feces in symptomatic disease and sometimes when there are no symptoms. Urinary ALA and PBG levels are increased during acute attacks but may return to normal when symptoms resolve. Although the diagnosis can be confirmed by measuring COPRO-oxidase activity, these assays are not widely available and require cells other than erythrocytes. Since the *COPRO-oxidase* gene has been cloned and >30 mutations, two-thirds of which are missense, have been identified in unrelated patients, DNA diagnosis of suspected patients is also available.

℞ TREATMENT

Neurologic symptoms are treated as in AIP (see above). Phlebotomy and chloroquine are ineffective when cutaneous lesions are present.

VARIEGATE PORPHYRIA VP, a hepatic porphyria that results from the deficient activity of PROTO-oxidase, is transmitted in an autosomal dominant manner and can present with neurologic symptoms, photosensitivity, or both.

Clinical Features Neurovisceral signs and symptoms develop after puberty and are similar to those of AIP or HCP (see above). Attacks are provoked by the same drugs, steroids, and nutritional factors that are detrimental in AIP. Skin manifestations are more common than in HCP but usually occur apart from the neurovisceral symptoms. Because the skin lesions in VP, HCP, and PCT are not distinguishable by clinical examination or biopsy, these conditions are diagnosed by assay of porphyrins and porphyrin precursors in blood, urine, and feces.

VP is particularly common in South Africa, where 3 of every 1000 whites have the disorder. Most are descendants of a couple who emigrated from Holland to South Africa in 1688. Homozygous VP is associated with photosensitivity, neurologic symptoms, and developmental disturbances, including growth retardation in infancy or childhood; all cases had increased erythrocyte levels of zinc protoporphyrin, a characteristic finding in all homozygous porphyrias so far described.

Dual porphyria, the simultaneous occurrence of VP and familial PCT, has been documented in several kindreds. *Chester porphyria* was described in a large British family in which individuals had acute porphyric attacks and deficiency of both PROTO-oxidase and HMB-synthase. Photosensitivity was not observed. It is unclear whether Chester porphyria is a variant of VP or AIP.

Diagnosis When VP is symptomatic, levels of fecal protoporphyrin and coproporphyrin and of urinary coproporphyrin are increased. Urinary ALA and PBG levels are increased during acute attacks. Plasma levels of porphyrins are increased, particularly when there are cutaneous lesions. VP can be distinguished rapidly from all other porphyrias by examining the fluorescence emission spectrum of porphyrins in plasma at neutral pH. This test is particularly useful for differentiating VP from PCT.

Assays of PROTO-oxidase activity in cultured fibroblasts or lymphocytes are not widely available. Some latent cases of VP can be diagnosed by measurement of fecal porphyrins in relatives of VP patients. Over 90 mutations have been found in the *PROTO-oxidase* gene; 52% are missense mutations and 30% are small deletions or insertions.

℞ TREATMENT

Acute attacks are treated with hematin as in AIP. Other than avoiding sun exposure, there are few effective measures for treating the skin lesions. β-Carotene, phlebotomy, and chloroquine are not helpful.

THE ERYTHROPOIETIC PORPHYRIAS

In the erythropoietic porphyrias, porphyrins from bone marrow erythrocytes and plasma are deposited in the skin and lead to cutaneous photosensitivity.

X-LINKED SIDEROBLASTIC ANEMIA XLSA results from the deficient activity of the erythroid form of ALA-synthase and is associated with ineffective erythropoiesis, weakness, and pallor.

Clinical Features Typically, males with XLSA develop refractory hemolytic anemia, pallor, and weakness during infancy. They have secondary hypersplenism, become iron overloaded, and can develop hemosiderosis. The severity depends on the level of residual erythroid ALA-synthase activity and on the responsiveness of the specific mutation to pyridoxal 5′-phosphate supplementation (see below). Peripheral blood smears reveal a hypochromic, microcytic anemia with striking anisocytosis, poikilocytosis, and polychromasia; the leukocytes and platelets appear normal. Hemoglobin content is reduced, and the mean corpuscular volume and mean corpuscular hemoglobin concentration are decreased. Patients with milder, late-onset disease have been reported.

Diagnosis Bone marrow examination reveals hypercellularity with a left shift and megaloblastic erythropoiesis with abnormal maturation. A variety of Prussian blue–staining sideroblasts are observed. Levels of urinary porphyrin precursors and of both urinary and fecal porphyrins are normal. The level of erythroid ALA-synthase is decreased in bone marrow, but this enzyme is difficult to measure in the presence of the normal ALA-synthase housekeeping enzyme. Definitive diagnosis requires the demonstration of mutations in the *erythroid ALA-synthase* gene.

℞ TREATMENT

The severe anemia may respond to pyridoxine supplementation. This cofactor is essential for ALA-synthase activity, and mutations in the pyridoxine-binding site of the enzyme have been found in several responsive patients. Cofactor supplementation may make it possible to eliminate or reduce the frequency of transfusion. Unresponsive patients may be transfusion-dependent and require chelation therapy.

CONGENITAL ERYTHROPOIETIC PORPHYRIA CEP (also known as *Gunther's disease*) is an autosomal recessive disorder due to markedly deficient activity of URO-synthase; it is associated with hemolytic anemia and cutaneous lesions. CEP is characterized by accumulation of uroporphyrin I and coproporphyrin I isomers.

Clinical Features Severe cutaneous photosensitivity begins in early infancy. The skin over sun-exposed areas is friable, and bullae and vesicles are prone to rupture and infection. Skin thickening, focal hypo- and hyperpigmentation, and hypertrichosis of the face and extremities are characteristic. Secondary infection of the cutaneous lesions can lead to disfigurement of the face and hands. Porphyrins are deposited

in teeth and in bones. As a result, the teeth are reddish-brown and fluoresce on exposure to long-wave ultraviolet light. Hemolysis is probably due to the marked increase in erythrocyte porphyrins and leads to splenomegaly. Adults with a milder form of the disease have been described.

Diagnosis Uroporphyrin and coproporphyrin (mostly type I isomers) accumulate in the bone marrow, erythrocytes, plasma, urine, and feces. The diagnosis should be confirmed by demonstration of markedly deficient URO-synthase activity. The disease can be detected in utero by measuring porphyrins in amniotic fluid and URO-synthase activity in cultured amniotic cells or chorionic villi. Molecular analyses of the mutant alleles have revealed multiple different mutations, including four mutations in the recently discovered erythroid-specific promoter of the *URO-synthase* gene.

TREATMENT

The transfusion of sufficient blood to suppress erythropoiesis is effective but results in iron overload. Splenectomy may reduce hemolysis and decrease transfusion requirements. Protection from sunlight and minor skin trauma is important. β-Carotene may be of some value. Complicating bacterial infections should be treated promptly. Recently, bone marrow transplantation has proven effective in several transfusion-dependent children, providing the rationale for stem-cell gene therapy.

ERYTHROPOIETIC PROTOPORPHYRIA Erythropoietic protoporphyria (EPP) is an autosomal dominant disorder due to the partial deficiency of ferrochelatase activity. Protoporphyrin accumulates in erythroid cells and plasma and is excreted in bile and feces. EPP is the most common erythropoietic porphyria and, after PCT, the second most common porphyria.

Clinical Features Skin photosensitivity usually begins in childhood. The skin manifestations differ from those of other porphyrias. Vesicular lesions are uncommon. Redness, swelling, burning, and itching can develop within minutes of sun exposure and resemble angioedema. Symptoms may seem out of proportion to the visible skin lesions. Sparse vesicles and bullae occur in 10% of cases. Chronic skin changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes. Severe scarring is rare, as are pigment changes, friability, and hirsutism.

The primary source of excess protoporphyrin is the bone marrow reticulocyte. Erythrocyte protoporphyrin is free (not complexed with zinc) and is mostly bound to hemoglobin. In plasma, protoporphyrin is bound to albumin. Hemolysis and anemia are usually absent or mild.

Liver function is usually normal, but in some patients accumulation of protoporphyrin causes chronic liver disease that can progress to liver failure and death. The hepatic complications are often preceded by increasing levels of erythrocyte and plasma protoporphyrin and probably result, in part, from protoporphyrin accumulation in the liver. Protoporphyrin is insoluble, forms crystalline structures in liver cells, and can decrease hepatic bile flow. Gallstones composed at least in part of protoporphyrin occur in some patients.

Some obligate heterozygotes are asymptomatic and have little or no increase in erythrocyte protoporphyrin. Thus there is phenotypic variation in this disease.

Diagnosis Protoporphyrin levels are increased in bone marrow, circulating erythrocytes, plasma, bile, and feces. Urinary levels of porphyrin and porphyrin precursors are normal. Ferrochelatase activity in cultured lymphocytes or fibroblasts is decreased. DNA diagnosis by mutation analysis is possible, and multiple missense and nonsense mutations have been identified in the *ferrochelatase* gene.

TREATMENT

Oral β-carotene (120 to 180 mg/d) improves tolerance to sunlight in many patients. The dosage may need to be adjusted to maintain serum carotene levels in the recommended range of 10 to 15 μmol/L (600 to 800 μg/dL). Mild skin discoloration due to carotenemia is the only significant side effect. The beneficial effects of β-carotene may involve quenching of singlet oxygen or free radicals. Unfortunately, this drug is less effective in other forms of porphyria associated with photosensitivity.

Treatment of hepatic complications is difficult. However, cholestyramine and other porphyrin absorbents such as activated charcoal may interrupt the enterohepatic circulation of protoporphyrin and promote its fecal excretion, leading to some improvement. Splenectomy may be helpful when the disease is accompanied by hemolysis and significant splenomegaly. Caloric restriction and drugs or hormones that may induce the heme pathway or impair hepatic excretory function should be avoided. Iron deficiency should be prevented or treated. Transfusions or intravenous heme therapy may suppress erythroid and hepatic protoporphyrin production and are sometimes beneficial. Liver transplantation has been carried out in some patients with severe liver complications.

338 DISORDERS OF PURINE AND PYRIMIDINE METABOLISM

Robert L. Wortmann

Purines (adenine and guanine) and pyrimidines (cytosine, thymine, uracil) serve fundamental roles in the replication of genetic material, gene transcription, protein synthesis, and cellular metabolism. Disorders that involve abnormalities of nucleotide metabolism range from relatively common diseases such as hyperuricemia and gout, in which there is increased production or impaired excretion of a metabolic end product of purine metabolism (uric acid), to rare enzyme deficiencies that affect purine and pyrimidine synthesis or degradation. Understanding these biochemical pathways has led, in some instances, to the development of specific forms of treatment, such as the use of allopurinol to reduce uric acid production.

URIC ACID METABOLISM

Uric acid is the final breakdown product of purine degradation in humans. It is a weak acid with pK_as of 5.75 and 10.3. Urates, the ionized forms of uric acid, predominate in plasma extracellular fluid and synovial fluid, with approximately 98% existing as monosodium urate at pH 7.4. Monosodium urate is easily dialyzed from plasma. Binding of urate to plasma proteins has little physiologic significance.

Plasma is saturated with monosodium urate at a concentration of 415 μmol/L (6.8 mg/dL) at 37°C. At higher concentrations, plasma is therefore supersaturated, creating the potential for urate crystal precipitation. However, precipitation sometimes does not occur even at

plasma urate concentrations as high as 4800 μmol/L (80 mg/dL), perhaps because of the presence of solubilizing substances in plasma.

Uric acid is more soluble in urine than in water, possibly because of the presence of urea, proteins, and mucopolysaccharides. The pH of urine greatly influences its solubility. At pH 5.0, urine is saturated with uric acid at concentrations ranging from 360 to 900 μmol/L (6 to 15 mg/dL). At pH 7.0, saturation is reached at concentrations between 9480 and 12,000 μmol/L (158 and 200 mg/dL). Ionized forms of uric acid in urine include mono- and disodium, potassium, ammonium, and calcium urates.

Although purine nucleotides are synthesized and degraded in all tissues, urate is produced only in tissues that contain xanthine oxidase, primarily the liver and small intestine. Urate production varies with the purine content of the diet and the rates of purine biosynthesis, degradation, and salvage (Fig. 338-1). Normally, two-thirds to three-fourths of urate is excreted by the kidneys, and most of the remainder is eliminated through the intestines. A four-component model describes the renal handling of uric acid in humans: (1) glomerular filtration, (2) tubular reabsorption, (3) secretion, and (4) postsecretory reabsorption (Fig. 338-2). Approximately 8 to 12% of urate filtered by the glomeruli is excreted in the urine as uric acid. After filtration, 98 to 100% of the urate is reabsorbed; about half of the reabsorbed urate is secreted back into the proximal tubule, and about 40% of that is again reabsorbed.

Serum urate levels vary with age and sex. Most children have serum urate concentrations of 180 to 240 μmol/L (3.0 to 4.0 mg/dL). Levels begin to rise in males during puberty but remain low in females until menopause. Mean serum urate values of adult men and premenopausal women are 415 and 360 μmol/L (6.8 and 6.0 mg/dL), respectively. After menopause, values for women increase to approximate those of men. In adulthood, concentrations rise steadily over time and vary with height, body weight, blood pressure, renal function, and alcohol intake.

HYPERURICEMIA

Hyperuricemia can result from increased production or decreased excretion of uric acid or from a combination of the two processes. Sustained hyperuricemia predisposes some individuals to develop clinical manifestations including gouty arthritis (Chap. 313), urolithiasis, and renal dysfunction (see below).

Hyperuricemia is defined as a plasma (or serum) urate concentration >420 μmol/L (7.0 mg/dL). The risk of developing gouty arthritis or urolithiasis increases with higher urate levels and escalates in proportion to the degree of elevation. Hyperuricemia is present in between

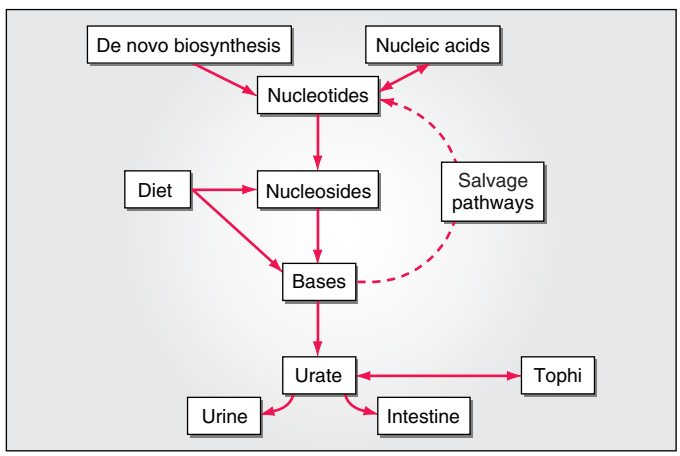

FIGURE 338-1 The total-body urate pool is the net result between urate production and excretion. Urate production is influenced by dietary intake of purines and the rates of de novo biosynthesis of purines from nonpurine precursors, nucleic acid turnover, and salvage by phosphoribosyltransferase activities. The formed urate is normally excreted by urinary and intestinal routes. Hyperuricemia can result from increased production, decreased excretion, or a combination of both mechanisms. When hyperuricemia exists, urate can precipitate and deposit in tissues as tophi.

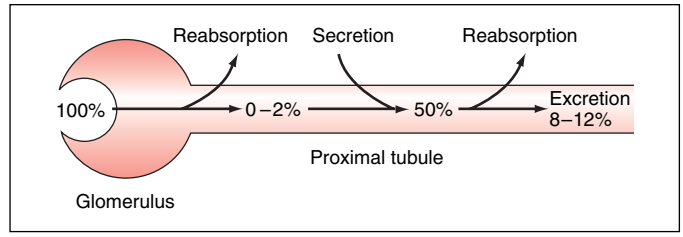

FIGURE 338-2 Schematic for handling of uric acid by the kidney. Components are illustrated with the percentage of filtered urate.

2.0 and 13.2% of ambulatory adults and is even more frequent in hospitalized individuals.

CAUSES OF HYPERURICEMIA Hyperuricemia may be classified as primary or secondary depending on whether the cause is innate or is the result of an acquired disorder. However, it is more useful to classify hyperuricemia in relation to the underlying pathophysiology, i.e., whether it results from increased production, decreased excretion, or a combination of the two (Fig. 338-1, Table 338-1).

Increased Urate Production Diet contributes to the serum urate in proportion to its purine content. Strict restriction of purine intake reduces the mean serum urate level by about 60 μmol/L (1.0 mg/dL) and urinary uric acid excretion by approximately 1.2 mmol/d (200 mg/d). Foods high in nucleic acid content include liver, "sweetbreads" (i.e., thymus and pancreas), kidney, and anchovy.

Endogenous sources of purine production also influence the serum urate level (Fig. 338-3). De novo purine biosynthesis is an 11-step process that forms inosine monophosphate (IMP). The rates of purine biosynthesis and urate production are determined, for the most part, by amidophosphoribosyltransferase (amidoPRT), which combines phosphoribosylpyrophosphate (PRPP) and glutamine. AmidoPRT is regulated by the substrate PRPP, which drives the reaction forward, and by the end products of biosynthesis (IMP and other ribonucleotides), which provide feedback inhibition. A secondary regulatory pathway is the salvage of purine bases by hypoxanthine phosphoribosyltransferase (HPRT). HPRT catalyzes the combination of the purine bases hypoxanthine and guanine with PRPP to form the respective ribonucleotides IMP and guanosine monophosphate (GMP). Increased

TABLE 338-1 *Classification of Hyperuricemia by Pathophysiology*

URATE OVERPRODUCTION		
Primary idiopathic	Myeloproliferative diseases	Rhabdomyolysis
HPRT deficiency	Polycythemia vera	Exercise
PRPP synthetase overactivity	Psoriasis	Alcohol
Hemolytic processes	Paget's disease	Obesity
Lymphoproliferative diseases	Glycogenosis III, V, and VII	Purine-rich diet
DECREASED URIC ACID EXCRETION		
Primary idiopathic	Starvation ketosis	Drug ingestion
Renal insufficiency	Berylliosis	Salicylates (>2 g/d)
Polycystic kidney disease	Sarcoidosis	Diuretics
Diabetes insipidus	Lead intoxication	Alcohol
Hypertension	Hyperparathyroidism	Levodopa
Acidosis	Hypothyroidism	Ethambutol
Lactic acidosis	Toxemia of pregnancy	Pyrazinamide
Diabetic ketoacidosis	Bartter's syndrome	Nicotinic acid
	Down syndrome	Cyclosporine
COMBINED MECHANISM		
Glucose-6-phosphatase deficiency	Fructose-1-phosphate aldolase deficiency	Alcohol
		Shock

Note: HPRT, hypoxanthine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate.

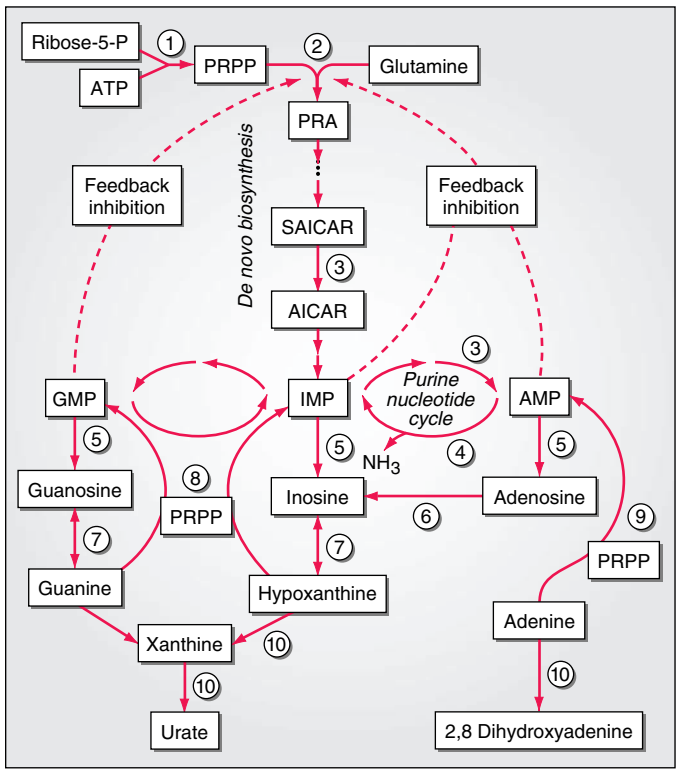

FIGURE 338-3 Abbreviated scheme of purine metabolism. (1) Phosphoribosylpyrophosphate (PRPP) synthetase, (2) amidophosphoribosyltransferase (amidoPRT), (3) adenylosuccinate lyase, (4) adenylate (AMP) deaminase, (5) 5′-nucleotidase, (6) adenosine deaminase, (7) purine nucleoside phosphorylase, (8) hypoxanthine phosphoribosyltransferase (HPRT), (9) adenine phosphoribosyltransferase (APRT), and (10) xanthine oxidase. PRA, phosphoribosylamine; SAICAR, succinylaminoimidazole carboxamide ribotide; AICAR, aminoimidazole carboxamide ribotide; GMP, guanylate; IMP, inosine monophosphate.

salvage activity thus retards de novo synthesis by reducing PRPP levels and increasing concentrations of inhibitory ribonucleotides.

Serum urate levels are closely coupled to the rates of de novo purine biosynthesis, which is driven in part by the level of PRPP, as evidenced by two X-linked inborn errors of purine metabolism. Both increased PRPP synthetase activity and HPRT deficiency are associated with overproduction of purines, hyperuricemia, and hyperuricaciduria (see below for clinical descriptions).

Accelerated purine nucleotide degradation can also cause hyperuricemia, i.e., with conditions of rapid cell turnover, proliferation, or cell death, as in leukemic blast crises, cytotoxic therapy for malignancy, hemolysis, or rhabdomyolysis. Hyperuricemia can result from excessive degradation of skeletal muscle ATP after strenuous physical exercise or status epilepticus and in glycogen storage diseases types III, V, and VII (Chap. 341). The hyperuricemia of myocardial infarction, smoke inhalation, and acute respiratory failure may also be related to accelerated breakdown of ATP.

Decreased Uric Acid Excretion Over 90% of individuals with sustained hyperuricemia have a defect in the renal handling of uric acid. Gouty individuals excrete approximately 40% less uric acid than nongouty individuals for any given plasma urate concentration. Uric acid excretion increases in gouty and nongouty individuals when plasma urate levels are raised by purine ingestion or infusion, but in those with gout, plasma urate concentrations must be 60 to 120 μmol/L (1 to 2 mg/dL) higher than normal to achieve equivalent uric acid excretion rates.

Altered uric acid excretion could theoretically result from decreased glomerular filtration, decreased tubular secretion, or enhanced tubular reabsorption. Decreased urate filtration does not appear to cause primary hyperuricemia but does contribute to the hyperuricemia of renal insufficiency. Although hyperuricemia is invariably present in chronic renal disease, the correlation between serum creatinine, urea nitrogen, and urate concentration is poor. Uric acid excretion per unit of glomerular filtration rate increases progressively with chronic renal insufficiency, but tubular secretory capacity tends to be preserved, tubular reabsorptive capacity is reduced, and extrarenal clearance of uric acid increases as renal damage becomes more severe.

Decreased tubular secretion of urate causes the secondary hyperuricemia of acidosis. Diabetic ketoacidosis, starvation, ethanol intoxication, lactic acidosis, and salicylate intoxication are accompanied by accumulations of organic acids (β-hydroxybutyrate, acetoacetate, lactate, or salicylates) that compete with urate for tubular secretion. Hyperuricemia may be due to enhanced reabsorption of uric acid distal to the site of secretion. This mechanism is known to be responsible for the hyperuricemia of extracellular volume depletion that occurs with diabetes insipidus or diuretic therapy.

Alcohol promotes hyperuricemia because of increased urate production and decreased uric acid excretion. Excessive alcohol consumption accelerates hepatic breakdown of ATP to increase urate production. Alcohol consumption can also induce hyperlacticacidemia, which blocks uric acid secretion. The higher purine content in some alcoholic beverages such as beer may also be a factor.

EVALUATION OF HYPERURICEMIA Hyperuricemia does not necessarily represent a disease, nor is it a specific indication for therapy. The decision to treat depends on the cause and the potential consequences of the hyperuricemia in each individual.

Quantification of uric acid excretion can be used to determine whether hyperuricemia is caused by overproduction or decreased excretion. On a purine-free diet, men with normal renal function excrete <3.6 mmol/d (600 mg/d). Thus, the hyperuricemia of individuals who excrete uric acid above this level while on a purine-free diet is due to purine overproduction; for those who excrete lower amounts on the purine-free diet, it is due to decreased excretion. If the assessment is performed while the patient is on a regular diet, the level of 4.2 mmol/d (800 mg/d) can be used as the discriminating value.

Pyrazinamide, which has a suppressive action on tubular secretion, can be used to investigate presecretory reabsorption of uric acid. Probenecid, an agent that inhibits postsecretory reabsorption, can be used to evaluate tubular secretion and postsecretory reabsorption.

COMPLICATIONS OF HYPERURICEMIA The most recognized complication of hyperuricemia is *gouty arthritis*. In the general population the prevalence of hyperuricemia ranges between 2.0 and 13.2%, and the prevalence of gout is between 1.3 and 3.7%. The higher the serum urate level, the more likely an individual is to develop gout. In one study, the incidence of gout was 4.9% for individuals with serum urate concentrations >540 μmol/L (9.0 mg/dL) compared with 0.5% for those with values between 415 and 535 μmol/L (7.0 and 8.9 mg/dL). The complications of gout correlate with both the duration and severity of hyperuricemia. →***For further discussion of gout, see Chap. 313.***

Hyperuricemia also causes several renal problems: (1) nephrolithiasis; (2) urate nephropathy, a rare cause of renal insufficiency attributed to monosodium urate crystal deposition in the renal interstitium; and (3) uric acid nephropathy, a reversible cause of acute renal failure resulting from deposition of large amounts of uric acid crystals in the renal collecting ducts, pelvis, and ureters.

Nephrolithiasis Uric acid nephrolithiasis occurs most commonly, but not exclusively, in individuals with gout. In gout, the prevalence of nephrolithiasis correlates with the serum and urinary uric acid levels, reaching approximately 50% with serum urate levels of 770 μmol/L (13 mg/dL) or urinary uric acid excretion >6.5 mmol/d (1100 mg/d).

Uric acid stones can develop in individuals with no evidence of arthritis, only 20% of whom are hyperuricemic. Uric acid can also play a role in other types of kidney stones. Some nongouty individuals with calcium oxalate or calcium phosphate stones have hyperuricemia

or hyperuricaciduria. Uric acid may act as a nidus on which calcium oxalate can precipitate or lower the formation product for calcium oxalate crystallization.

Urate Nephropathy Urate nephropathy, sometimes referred to as *urate nephrosis*, is a late manifestation of severe gout and is characterized histologically by deposits of monosodium urate crystals surrounded by a giant cell inflammatory reaction in the medullary interstitium and pyramids. The disorder is now rare and cannot be diagnosed in the absence of gouty arthritis. The lesions may be clinically silent or cause proteinuria, hypertension, and renal insufficiency.

Uric Acid Nephropathy This reversible cause of acute renal failure is due to precipitation of uric acid in renal tubules and collecting ducts that causes obstruction to urine flow. Uric acid nephropathy develops following sudden urate overproduction and marked hyperuricaciduria. Factors that favor uric acid crystal formation include dehydration and acidosis. This form of acute renal failure occurs most often during an aggressive "blastic" phase of leukemia or lymphoma prior to or coincident with cytolytic therapy but has also been observed in individuals with other neoplasms, following epileptic seizures, and after vigorous exercise with heat stress. Autopsy studies have demonstrated intraluminal precipitates of uric acid, dilated proximal tubules, and normal glomeruli. The initial pathogenic events are believed to include obstruction of collecting ducts with uric acid and obstruction of distal renal vasculature.

If recognized, uric acid nephropathy is potentially reversible. Appropriate therapy has reduced the mortality from about 50% to practically nil. Serum levels cannot be relied on for diagnosis because this condition has developed in the presence of urate concentrations varying from 720 to 4800 μmol/L (12 to 80 mg/dL). The distinctive feature is the urinary uric acid concentration. In most forms of acute renal failure with decreased urine output, urinary uric acid content is either normal or reduced, and the ratio of uric acid to creatinine is <1. In acute uric acid nephropathy the ratio of uric acid to creatinine in a random urine sample or 24-h specimen is >1, and a value that high is essentially diagnostic.

HYPERURICEMIA AND SYNDROME X Syndrome X is characterized by abdominal obesity with visceral adiposity, impaired glucose tolerance due to insulin resistance with hyperinsulinemia, hypertriglyceridemia, increased low-density lipoprotein cholesterol, decreased high-density lipoprotein cholesterol, and hyperuricemia. Hyperinsulinemia reduces the renal excretion of uric acid and sodium. Not surprisingly, hyperuricemia resulting from euglycemic hyperinsulinemia may precede the onset of type 2 diabetes, hypertension, coronary artery disease, and gout in individuals with syndrome X.

Rx TREATMENT

ASYMPTOMATIC HYPERURICEMIA Hyperuricemia is present in approximately 5% of the population and in up to 25% of hospitalized individuals. The vast majority are at no clinical risk. Hyperuricemia does not appear to have a causal role in the development of coronary heart disease or death from cardiovascular disease. In the past, the association of hyperuricemia with cardiovascular disease and renal failure led to the use of urate-lowering agents for people with asymptomatic hyperuricemia. This practice is no longer recommended except for individuals receiving cytolytic therapy for neoplastic disease, in which treatment is given in an effort to prevent uric acid nephropathy. Because hyperuricemia can be a component of syndrome X, its presence is an indication to screen for and aggressively treat any accompanying obesity, hyperlipidemia, diabetes mellitus, or hypertension.

Hyperuricemic individuals are at risk to develop gouty arthritis, especially those with higher serum urate levels. However, most hyperuricemic persons never develop gout and prophylactic treatment is not indicated. Furthermore, neither structural kidney damage nor tophi are identifiable before the first attack. Reduced renal function cannot be attributed to asymptomatic hyperuricemia, and treatment of asymptomatic hyperuricemia does not alter the progression of renal dysfunction in patients with renal disease. Increased risk of stone formation in people with asymptomatic hyperuricemia is not established.

Thus, because treatment with antihyperuricemic agents entails inconvenience, cost, and potential toxicity, routine treatment of asymptomatic hyperuricemia cannot be justified other than for prevention of acute uric acid nephropathy. In addition, routine screening for asymptomatic hyperuricemia is not recommended. If hyperuricemia is diagnosed, however, the cause should be determined. Causal factors should be corrected if the condition is secondary, and associated problems such as hypertension, hypercholesterolemia, diabetes mellitus, and obesity should be treated.

Symptomatic Hyperuricemia ■ *NEPHROLITHIASIS* (See Chap. 313 for treatment of gout.) Antihyperuricemic therapy is recommended for the individual who has both gouty arthritis and either uric acid– or calcium-containing stones, both of which may occur in association with hyperuricaciduria. Regardless of the nature of the calculi, fluid ingestion should be sufficient to produce a daily urine volume >2 L. Alkalinization of the urine with sodium bicarbonate or acetazolamide may be justified to increase the solubility of uric acid. Specific treatment of uric acid calculi requires reducing the urine uric acid concentration with allopurinol. Allopurinol administration decreases the serum urate concentration and the urinary excretion of uric acid in the first 24 h, with a maximum reduction occurring within 2 weeks. The average effective dose of allopurinol is 300 mg/d. Allopurinol can be given once a day because of the long half-life (18 h) of its active metabolite oxypurinol. The drug is effective in patients with renal insufficiency, but the dose should be reduced. Allopurinol is also useful in reducing the recurrence of calcium oxalate stones in gouty patients and in nongouty individuals with hyperuricemia or hyperuricaciduria. Potassium citrate (30 to 80 mmol/d orally in divided doses) is an alternative therapy for patients with uric acid stones alone or mixed calcium/uric acid stones. Allopurinol is also indicated for the treatment of 2,8-dihydroxyadenine kidney stones.

URIC ACID NEPHROPATHY Uric acid nephropathy is often preventable, and immediate, appropriate therapy has greatly reduced the mortality rate. Vigorous intravenous hydration and diuresis with furosemide dilute the uric acid in the tubules and promote urine flow to $\geq$100 mL/h. The administration of acetazolamide, 240 to 500 mg every 6 to 8 h, and sodium bicarbonate, 89 mmol/L, intravenously enhances urine alkalinity and thereby solubilizes more uric acid. It is important to ensure that the urine pH remains >7.0 and to watch for circulatory overload. In addition, antihyperuricemic therapy in the form of allopurinol in a single dose of 8 mg/kg is administered to reduce the amount of urate that reaches the kidney. If renal insufficiency persists, subsequent daily doses should be reduced to 100 to 200 mg because oxypurinol, the active metabolite of allopurinol, accumulates in renal failure. Despite these measures, hemodialysis may be required.

TABLE 338-2 Medications with Uricosuric Activity

Acetohexamide	Glyceryl guaiacolate
ACTH	Glycopyrrolate
Ascorbic acid	Halofenate
Azauridine	Meclofenamate
Benzbromarone	Phenolsulfonphthalein
Calcitonin	Phenylbutazone
Chlorprothixene	Probenecid
Citrate	Radiographic contrast agents
Dicumarol	Salicylates (>2 g/2d)
Diflunisal	Sulfinpyrazone
Estrogens	Tetracycline that is outdated
Glucocorticoids	Zoxazolamine

TABLE 338-3 *Inborn Errors of Purine Metabolism*

Enzyme	Activity	Inheritance	Clinical Features
Hypoxanthine phosphoribosyltransferase	Complete deficiency	X-linked	Self-mutilation, choreoathetosis, hyperuricemia, gout, and uric acid lithiasis
	Partial deficiency	X-linked	Hyperuricemia, gout, and uric acid lithiasis
Phosphoribosylpyrophosphate synthetase	Overactivity	X-linked	Hyperuricemia, gout, uric acid lithiasis, and deafness
Adenine phosphoribosyltransferase	Deficiency	Autosomal recessive	2,8-Dihydroxyadenine lithiasis
Xanthine oxidase	Deficiency	Autosomal recessive	Xanthinuria and xanthine lithiasis
Adenylosuccinate lyase	Deficiency	Autosomal recessive	Autism and psychomotor retardation
Myoadenylate deaminase	Deficiency	Autosomal recessive	Myopathy with exercise intolerance or asymptomatic
Adenosine deaminase	Deficiency	Autosomal recessive	Severe combined immunodeficiency disease and chrondro-osseous dysplasia
Purine nucleoside phosphorylase	Deficiency	Autosomal recessive	T cell–mediated immunodeficiency

HYPOURICEMIA

Hypouricemia, defined as a serum urate concentration <120 μmol/L (2.0 mg/dL) can result from decreased production of urate, increased excretion of uric acid, or a combination of both mechanisms. It occurs in $<0.2\%$ of the general population and $<0.8\%$ of hospitalized individuals. Hypouricemia causes no symptoms or pathology and therefore requires no therapy.

Most hypouricemia results from increased renal uric acid excretion. The finding of normal amounts of uric acid in a 24-h urine collection in an individual with hypouricemia is evidence for a renal cause. Medications with uricosuric properties (Table 338-2) include aspirin (at doses >2.0 g/d), x-ray contrast materials, and glycerylguaiacholate. Total parenteral hyperalimentation can also cause hypouricemia, possibly a result of the high glycine content of the infusion formula. Other causes of increased urate clearance include conditions such as neoplastic disease, hepatic cirrhosis, diabetes mellitus, and inappropriate secretion of vasopressin; defects in renal tubular transport such as primary Fanconi syndrome and Fanconi syndromes caused by Wilson's disease, cystinosis, multiple myeloma, and heavy metal toxicity; and isolated congenital defects in the bidirectional transport of uric acid. Hypouricemia can also be caused by inherited forms of decreased urate production.

SELECTED INBORN ERRORS OF PURINE METABOLISM

(See also Table 338-3, Fig. 338-3)

HPRT DEFICIENCY The HPRT gene is located on the X chromosome. Affected males are hemizygous for the mutant gene; carrier females are asymptomatic. A complete deficiency of HPRT, the Lesch-Nyhan syndrome, is characterized by hyperuricemia, self-mutilative behavior, choreoathetosis, spasticity, and mental retardation. A partial deficiency of HPRT, the Kelley-Seegmiller syndrome, is associated with hyperuricemia but no central nervous system manifestations. In both disorders, the hyperuricemia results from urate overproduction and can cause uric acid crystalluria, nephrolithiasis, obstructive uropathy, and gouty arthritis. Early diagnosis and appropriate therapy with allopurinol can prevent or eliminate all the problems attributable to hyperuricemia but have no effect on the behavioral or neurologic abnormalities.

INCREASED PRPP SYNTHETASE ACTIVITY Like the HPRT deficiency states, PRPP synthetase overactivity is X-linked and results in gouty arthritis and uric acid nephrolithiasis. Nerve deafness occurs in some families.

ADENINE PHOSPHORIBOSYLTRANSFERASE (APRT) DEFICIENCY APRT deficiency is inherited as an autosomal recessive trait. Affected individuals develop kidney stones composed of 2,8-dihydroxyadenine. Caucasians with the disorder have a complete deficiency (type I), whereas Japanese subjects have some measurable enzyme activity (type II). Expression of the defect is similar in the two populations, as is the frequency of the heterozygous state (0.4 to 1.1 per 100). Allopurinol treatment prevents stone formation.

HEREDITARY XANTHINURIA A deficiency of xanthine oxidase causes all purine in the urine to occur in the form of hypoxanthine and xanthine. About two-thirds of deficient individuals are asymptomatic. The remainder develop kidney stones composed of xanthine.

MYOADENYLATE DEAMINASE DEFICIENCY Primary (inherited) and secondary (acquired) forms of myoadenylate deaminase deficiency have been described. The primary form is inherited as an autosomal recessive trait. Clinically, some may have relatively mild myopathic symptoms with exercise or other triggers, but most individuals with this defect are asymptomatic. Therefore, another explanation for the myopathy should be sought in symptomatic patients with this deficiency. The acquired deficiency occurs in association with a wide variety of neuromuscular disease, including muscular dystrophies, neuropathies, inflammatory myopathies, and collagen vascular diseases.

ADENYLOSUCCINATE LYASE DEFICIENCY Deficiency of this enzyme is due to an autosomal recessive trait and

causes profound psychomotor retardation, seizures, and other movement disorders. All individuals with this deficiency are mentally retarded, and most are autistic.

ADENOSINE DEAMINASE DEFICIENCY AND PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY See Chap. 297.

PYRIMIDINE DISORDERS

The pyrimidine, cytidine, is found in both DNA and RNA; it is a complementary base pair for guanine. Thymidine is found only in DNA where it is paired with adenine. Uridine is found only in RNA and can pair with either adenine or guanine in RNA secondary structures. Pyrimidines can be synthesized by a de novo pathway (Fig. 338-4) or reused in a salvage pathway. Although more than 25 different enzymes are involved in pyrimidine metabolism, disorders of these pathways are rare. Seven disorders of pyrimidine metabolism have been discovered (Table 338-4), three of which are discussed below.

TABLE 338-4 Inborn Errors of Pyrimidine Metabolism

Enzyme	Activity	Inheritance	Clinical Features
Uridine-5′-monophosphate synthetase	Deficiency	Autosomal recessive	Aortic acid crystalluria; obstructive uropathy, hypochromic megaloblastic anemia
Pyrimidine 5′-nucleotidase	Deficiency	Autosomal recessive	Hemolytic anemia
Pyrimidine 5′-nucleotidase	Superactivity	Uncertain	Developmental delay, seizures, ataxia, language deficit
Thymidine phosphorylase	Deficiency	Autosomal recessive	Mitochondrial neurogastrointestinal encephalopathy
Dihydropyrimidine dehydrogenase	Deficiency	Autosomal recessive	Seizures, motor and mental retardation
Dihydropyrimidinase	Deficiency	Uncertain	Seizures, mental retardation
Ureidopropionase	Deficiency	Uncertain	Hypotonia, dystonia, developmental delay

OROTIC ACIDURIA Hereditary orotic aciduria is caused by mutations in a bifunctional enzyme, uridine-5′-monophosphate (UMP) synthase, which converts orotic acid to UMP in the de novo synthesis pathway (Fig. 338-4). The disorder is characterized by hypochromic megaloblastic anemia that is unresponsive to vitamin B_{12} and folic acid, growth retardation, and neurologic abnormalities. Increased excretion of orotic acid causes crystalluria and obstructive uropathy. Replacement of uridine (100 to 200 mg/kg per day) corrects the anemia, reduces orotic acid excretion, and improves the other sequelae of the disorder.

PYRIMIDINE 5′-NUCLEOTIDASE DEFICIENCY Pyrimidine 5′-nucleotidase catalyzes the removal of the phosphate group from pyrimidine ribonucleoside monophosphates (cytidine-5′-monophosphate or UMP) (Fig. 338-4). An inherited deficiency of this enzyme causes hemolytic anemia with prominent basophilic stippling of erythrocytes. The accumulation of pyrimidines or cytidine diphosphate choline (CDPC) is thought to induce hemolysis. There is no specific treatment. Acquired pyrimidine 5′nucleotidase deficiency has been reported in lead poisoning and in thalassemia.

DIHYDROPYRIMIDINE DEHYDROGENASE DEFICIENCY Dihydropyrimidine dehydrogenase (DPD) is the rate-limiting enzyme in the pathway of uracil and thymine degradation (Fig. 338-4). Deficiency of this enzyme causes excessive urinary excretion of uracil and thymine. DPD deficiency causes nonspecific cerebral dysfunction with convulsive disorders, motor retardation, and mental retardation. No specific treatment is available.

MEDICATION EFFECTS ON PYRIMIDINE METABOLISM A variety of medications can influence pyrimidine metabolism. The anticancer agents fluorodeoxyuridine and 5-fluorouracil (5-FU) and the antimicrobial agent fluorocytosine cause cytotoxicity when converted to fluorodeoxyuridylate (FdUMP), a specific suicide inhibitor of thymidylate synthase. Fluorocytosine must be converted to 5-FU to be effective. This conversion is catalyzed by cytosine deaminase activity. Fluorocytosine's action is selective because cytosine deaminase is present in bacteria and fungi but not in human cells.

DPD is involved in the degradation of 5-FU. Consequently, deficiency of this enzyme is associated with 5-FU neurotoxicity.

Leflunomide, which is used to treat rheumatoid arthritis, inhibits de novo pyrimidine synthesis by inhibiting dihydroorotate dehydrogenase, resulting in an antiproliferative effect on T cells. Allopurinol, which is used to block xanthine oxidase and purine synthesis, also inhibits orotidine-5′-phosphate decarboxylase, a step in UMP synthesis. Consequently, allopurinol use is associated with increased excretion of orotidine and orotic acid; there are no known clinical effects of this inhibition.

339 WILSON DISEASE

George J. Brewer

Wilson disease is an autosomal recessive disorder caused by mutations in the *ATP7B* gene, a membrane-bound copper-transporting ATPase. Clinical manifestations are caused by copper toxicity and primarily involve the liver and the brain. Because effective treatment is available, it is important to make this diagnosis early.

GENETIC CONSIDERATIONS The frequency of Wilson disease in most populations is about 1 in 40,000, and the frequency of carriers of *ATP7B* mutations is about 1%. Based on these gene frequencies, the risk of Wilson disease in the children of an affected patient is about 1 in 200. Because a large number of inactivating mutations have been reported in the *ATP7B* gene, mutation screening is not practical, but DNA haplotype analysis can be used to genotype siblings of an affected patient.

PATHOGENESIS ATP7B protein deficiency impairs biliary copper excretion, resulting in positive copper balance, hepatic copper accumulation, and copper toxicity from oxidant damage. Excess hepatic copper is initially bound to metallothionein, but as this storage capacity is exceeded, liver damage begins as early as 3 years of age. Defective copper incorporation into apoceruloplasmin leads to excess catabolism and low blood levels of ceruloplasmin. Serum copper levels are usually lower than normal because of low blood ceruloplasmin, which normally binds >90% of serum copper. As the disease progresses, non-

TABLE 339-1 *Useful Diagnosis Tests for Wilson Disease*

Test	Usefulness[a]	Normal Value	Heterozygous Carriers	Wilson Disease
Serum ceruloplasmin	+	180–350 mg/L (18–35 mg/dL)	Low in 20%	Low in 85%
KF rings	++	Absent	Absent	Present in 99% + if neurologic or psychiatric symptoms present Present in 30–50% in hepatic presentation and presymptomatic state
24-h urine Cu	+++	0.3–0.8 μmol (20–50 μg)	Normal to 1.3 μmol (80 μg)	>1.6 μmol (>100 μg) in symptomatic patients 0.9 to >1.6 μmol (60 to >100 μg) in presymptomatic patients
Liver Cu	++++	0.3–0.8 μmol/g (20–50 μg) tissue	Normal to 2.0 μmol (125 μg)	>3.1 μmol (200 μg) (obstructive liver disease can cause false-positive results)
Haplotype analysis	++++ (Siblings only)	0 Matches	1 Match	2 Matches

[a] Usefulness: +, somewhat useful, to ++++, very useful.
Abbreviations: KF, Kayser-Fleischer; Cu, copper.

ceruloplasmin serum copper ("free" copper) levels increase, resulting in copper buildup in other parts of the body, such as the brain, leading to neurologic and psychiatric disease.

CLINICAL PRESENTATION ■ Hepatic Wilson disease may present as hepatitis, cirrhosis, or as hepatic decompensation, typically in the mid- to late-teenage years in western countries, although the age of presentation is quite broad and extends into the fourth decade of life. In India and countries in the Far East, the hepatic presentation may occur much earlier, often in children only five or six years of age.

An episode of hepatitis may occur, with elevated blood transaminase enzymes, with or without jaundice, and then spontaneously regress. Hepatitis often reoccurs, and most of these patients eventually develop cirrhosis.

Hepatic decompensation is associated with elevated serum bilirubin, reduced serum albumin and coagulation factors, ascites, peripheral edema, and hepatic encephalopathy. In severe hepatic failure, hemolytic anemia may occur because large amounts of copper are released into the bloodstream. The association of hemolysis and liver disease makes Wilson disease a likely diagnosis.

Neurologic The neurologic manifestations of Wilson disease typically occur in patients in their early twenties, although the age of onset extends from the second to the fifth decades of life. Magnetic resonance imaging and computed tomography scans reveal damage in the basal ganglia and occasionally in the pons, medulla, thalamus, cerebellum, and subcortical areas. The three main neurologic problems are of a movement disorder type: dystonia, incoordination, and tremor. Dysarthria and dysphagia are common. In some patients, the clinical picture closely resembles that of Parkinson's disease. Dystonia can involve any part of the body and eventually leads to grotesque positions of the limbs, neck, and trunk. Tremor, which is common, can be of any type. Autonomic disturbances may include orthostatic hypotension and sweating abnormalities as well as bowel, bladder, and sexual dysfunction. Memory loss, migraine-type headaches, and seizures may occur. Patients have difficulties focusing on tasks, but cognition is not usually grossly impaired. Sensory abnormalities and muscular weakness are not features of the disease.

Psychiatric A history of behavioral disturbances, with onset in the five years before diagnosis, is present in half of patients with neurologic disease. The features are diverse and may include loss of emotional control (temper tantrums, crying bouts), depression, hyperactivity, or loss of sexual inhibition.

Other Manifestations Some female patients have repeated spontaneous abortions, and most become amenorrheic prior to diagnosis. Cholelithiasis and nephrolithiasis occur with increased frequencies. Some patients may have osteoarthritis, particularly of the knee. Microscopic hematuria is common, and increased urinary excretion of phosphates, amino acids, glucose, or urates may occur; however, a full-blown Fanconi syndrome is rare. Sunflower cataracts and Kayser-Fleischer rings (copper deposits in the outer rim of the cornea) may be seen. Electrocardiographic and other cardiac abnormalities have been reported but are not common.

DIAGNOSIS Diagnostic tests for Wilson disease are listed in Table 339-1. Serum ceruloplasmin levels should be used only to affect the index of suspicion, because they are not always low in affected patients and are reduced in 20% of carriers. Kayser-Fleischer rings can only be diagnosed definitively by an ophthalmologist using a slit lamp. They are present in >99% of patients with neurologic/psychiatric forms of the disease and have been described very rarely in the absence of Wilson disease. Kayser-Fleischer rings are present in only about 30 to 50% of patients diagnosed in the hepatic or presymptomatic state; thus, the absence of rings does not exclude the diagnosis.

Symptomatic patients invariably have urine copper levels > 1.6 μmol (>100 μg) per 24 h. Heterozygotes never have values >1.6 μmol (>100 μg) per 24 h. About half of presymptomatic patients who are ultimately diagnosed as affected have urine copper values in an intermediate range between 0.9 and 1.6 μmol (60 and 100 μg) per 24 h. Because heterozygotes may have values up to 1.3 μmol (80 μg) per 24 h, patients in this range may require a liver biopsy for definitive diagnosis.

The "gold standard" for diagnosis remains liver biopsy with quantitative copper assays. Affected patients have values >3.1 μmol/g

TABLE 339-2 *Recommended Anticopper Treatments for Wilson Disease*

Disease Status	First Choice	Second Choice
Initial hepatic		
Hepatitis or cirrhosis without decompensation	Zinc[a]	Trientine
Hepatic decompensation		
Mild	Trientine[b] and zinc	Penicillamine[b] and zinc
Moderate	Trientine and zinc	Hepatic transplantation
Severe	Hepatic transplantation	Trientine and zinc
Initial neurologic/psychiatric	Tetrathiomolybdate[c] and zinc	Trientine and zinc
Maintenance	Zinc	Trientine
Presymptomatic	Zinc	Trientine
Pediatric	Zinc	Trientine
Pregnant	Zinc	Trientine

[a] Zinc acetate is supplied as Galzin. Recommended adult dose for all the above indications is 50 mg of elemental zinc three times daily, each dose separated from food and beverages other than water by at least 1 h, and separated from trientine or penicillamine doses by at least 1 h.
[b] Trientine is supplied as Syprine and penicillamine as Cuprimine. Recommended adult dosage for both drugs is 500 mg twice daily, each dose at least ½ h before or 2 h after meals.
[c] Tetrathiomolybdate is not yet commercially available but is expected to be marketed in the near future.

(>200 μg/g) dry weight of liver. Copper stains are not reliable. False-positive results can occur with long-standing obstructive liver disease, which can elevate hepatic and urine copper and rarely causes Kayser-Fleischer rings.

TABLE 339-3 *Prognostic Index of Nazer*

Laboratory Measurement	Normal Value	Score (in Points) 0	1	2	3	4
Serum bilirubin*	0.2–1.2 mg/dl	<5.8	5.8–8.8	8.8–11.7	11.7–17.5	>17.5
Serum aspartate transferase (AST)	10–35 IU/L	<100	100–150	151–200	201–300	>300
Prolongation of prothrombin time (seconds)	—	<4	4–8	9–12	13–20	>20

* If hemolysis is present, the serum bilirubin cannot be used as a measure of liver function until the hemolysis subsides.

TREATMENT

Recommended anticopper treatments are listed in Table 339-2. Penicillamine was previously the primary anticopper treatment but now plays a minor role because of its toxicity and because it worsens existing neurologic disease if used as initial therapy. If penicillamine is given, it should always be accompanied by 25 mg/d of pyridoxine. Trientine is a less toxic chelator and has largely supplanted penicillamine.

For patients with hepatitis or cirrhosis, without evidence of hepatic decompensation other than a mildly elevated bilirubin level and without neurologic or psychiatric symptoms from Wilson disease, zinc is the therapy of choice, although some advocate therapy with trientene. Zinc has proven efficacy in Wilson disease and is essentially nontoxic. It produces a negative copper balance by blocking intestinal absorption of copper, and it induces hepatic metallothionein synthesis, which sequesters additional toxic copper. All presymptomatic patients should be treated prophylactically, since the disease is close to 100% penetrant.

The first step in evaluating patients presenting with hepatic decompensation is to establish disease severity, which can be estimated using the Nazer prognostic index (Table 339-3). Patients with scores ≤6 can usually be managed with medical therapy. Patients with scores ≥10 should be considered immediately for liver transplantation, and those with scores between 7 and 9 require clinical judgment as to whether to recommend transplantation or medical therapy. A combination of trientine and zinc has been used to treat patients with Nazer scores as high as 9, but such patients should be watched carefully for indications of hepatic deterioration, which mandates transplantation.

For initial medical therapy of patients with hepatic decompensation, a chelator (trientine is preferred) plus zinc is recommended (Table 339-2). Zinc should not, however, be ingested simultaneously with trientine, as it will chelate zinc and form therapeutically ineffective complexes; the two drugs should be separated by at least 1 h. Hepatic transplantation is necessary for patients with severe hepatic decompensation.

For initial neurologic therapy, tetrathiomolybdate is emerging as the drug of choice because of its rapid action, preservation of neurologic function, and low toxicity. However, until tetrathiomolybdate is commercially available, trientine and zinc are recommended for 8 weeks, at which time the trientine can be stopped, and zinc continued for maintenance therapy. Although hepatic transplantation may improve neurologic symptoms, it does so only by removing copper, which can be done more safely and inexpensively with anticopper drugs.

Anticopper therapy must be lifelong. With treatment, liver function usually recovers after about a year, although residual liver damage is usually present. Neurologic and psychiatric symptoms usually improve between 6 and 24 months of treatment.

Monitoring Anticopper Therapy When first using trientine or penicillamine, it is necessary to monitor for drug toxicity, particularly bone marrow suppression and proteinuria. Complete blood counts, standard biochemical profiles, and a urinalysis should be performed at weekly intervals for a month, then at 2-weekly intervals for 2 to 3 months, then at monthly intervals for 3 or 4 months, and at 4- to 6-monthly intervals thereafter.

The anticopper effects of trientine and penicillamine can be monitored by following 24-h "free" serum copper. Changes in urine copper are more difficult to interpret because excretion reflects the effect of the drug, as well as body loading with copper. Free serum copper is calculated by subtracting the ceruloplasmin copper from the total serum copper. Each 10 mg/L (mg/dL) of ceruloplasmin contributes 0.5 μmol/L (3.0 μg/dL) of serum copper. The normal free copper value is 1.6 to 2.4 μmol/L (10 to 15 μg/dL), and it often is as high as 7.9 μmol/L (50 μg/dL) in untreated Wilson disease. With treatment, free copper should be <3.9 μmol/L (<25 μg/dL).

Zinc treatment does not require blood or urine monitoring for toxicity. Its only significant side effect is gastric burning or nausea in about 10% of patients, usually with the first morning dose. This can be mitigated by taking the first dose an hour after breakfast or taking the zinc with a small amount of protein. Because zinc mainly affects stool copper, 24-h urine copper can be used to reflect body loading. The typical value in untreated symptomatic patients is >3.1 μmol (>200 μg) per 24 h. This level should decrease during the first 1 to 2 years of therapy to <2.0 μmol (<125 μg) per 24 h. A normal value [0.3 to 0.8 μmol (20 to 50 μg)] is rarely reached during the first decade of therapy and should raise concern about overtreatment (copper deficiency), the first sign of which is anemia and/or leukopenia.

340 LYSOSOMAL STORAGE DISEASES

Robert J. Hopkin, Gregory A. Grabowski

Lysosomes are heterogeneous subcellular organelles containing specific hydrolyases that allow targeted processing or degradation of proteins, nucleic acids, carbohydrates, and lipids. There are >30 different lysosomal storage diseases and these are classified based on the nature of the stored material (Table 340-1). The most prevalent among these disorders in adults will be reviewed here, including Fabry disease, Gaucher disease, and Niemann-Pick disease. Lysosomal storage diseases should be considered in the differential diagnosis of patients with neurologic, renal, or muscular degeneration and unexplained hepatomegaly, splenomegaly, cardiomyopathy, or skeletal dysplasias and deformations. Physical findings are disease-specific, and definitive diagnosis is made by enzyme assays.

TABLE 340-1 *Selected Lysosomal Storage Diseases*

Disorder[a]	Enzyme Deficiency	Stored Material	Clinical Types (Onset)	Inheritance	Neurologic
MUCOPOLYSACCHARIDOSES (MPS)					
MPS I H, Hurler (136)	α-L-Iduronidase	Dermatan sulfate Heparan sulfate	Infantile	AR	Mental retardation
MPS I H/S, Hurler/Scheie			Intermediate		Mental retardation

PATHOGENESIS OF LYSOSOMAL STORAGE DISEASES

Lysosomal biogenesis involves ongoing synthesis of lysosomal hydrolases, membrane constitutive proteins, and new membranes. Lysosomes originate from the fusion of *trans*-Golgi network (TGN) vesicles with late endosomes. Progressive vesicular acidification accompanies the maturation of TGN vesicles, and this gradient facilitates the pH-dependent dissociation of receptors and ligands, as well as activating lysosomal hydrolases.

Abnormalities at any biosynthetic step can impair enzyme activation and lead to a lysosomal storage disorder. Following leader sequence clipping, complex oligosaccharide modifications occur during transit through the Golgi, including the mannose-6-phosphate modification of high-mannose oligosaccharide chains of many soluble lysosomal hydrolases. Lysosomal integral or associated membrane proteins are sorted to the membrane or interior of the lysosome by several different signals. Phosphorylation, sulfation, additional proteolytic processing, and macromolecular assembly of heteromers occur concurrently. These are critical to enzyme function, and defects can result in multiple enzyme/protein deficiencies.

The final common pathway for lysosomal storage diseases is the accumulation of specific macromolecules within tissues and cells that normally have a high flux of these substrates. The majority of lysosomal enzyme deficiencies result from point mutations or genetic rearrangements at a locus that encodes a single lysosomal hydrolase. However, some mutations cause deficiencies of several different lysosomal hydrolases by altering the enzymes/proteins involved in targeting, active site modifications, or macromolecular association or trafficking. All are inherited as autosomal recessive disorders, except Hunter (mucopolysaccharidosis, type II) and Fabry diseases, which are X-linked. Substrate accumulation leads to lysosomal distortion, which has significant pathologic consequences. In addition, abnormal amounts of metabolites may also have pharmacologic effects important to disease pathophysiology.

For many lysosomal diseases, the accumulated substrates are endogenously synthesized within particular tissue sites of pathology. Other diseases have greater exogenous substrate supplies, For example, they are delivered by low-density lipoprotein receptor–mediated uptake in Fabry and cholesteryl ester storage diseases or by phagocytosis in Gaucher disease type 1. The *threshold hypothesis* refers to a level of enzyme activity below which disease develops. Consequently, small changes in enzyme activity near the threshold can lead to or prevent disease. A critical element of this model is that enzymatic activity can be challenged by changes in substrate flux based on genetic background, cell turnover, recycling, or metabolic demands. Thus, a set level of residual enzyme may be adequate for substrate in some tissues or cells, but not in others.

SELECTED DISORDERS

TAY-SACHS DISEASE About 1 in 30 Ashkenazi Jews is a carrier for Tay-Sachs disease, which is caused by total hexosaminidase A (Hex A) deficiency. The infantile form is a fatal neurodegenerative disease with macrocephaly, loss of motor skills, increased startle reaction, and a macular cherry red spot. The juvenile-onset form presents with ataxia and dementia, with death by age 10 to 15 years. The adult-onset disorder is characterized by clumsiness in childhood; progressive motor weakness in adolescence; and additional spinocerebellar, lower motor neuron symptoms, and dysarthria in adulthood. Intelligence declines slowly, and psychosis is common. Screening for Tay-Sachs disease carriers is recommended in the Ashkenazi Jewish population. *Sandhoff disease* is nearly identical to Tay-Sachs disease, but hepatosplenomegaly and bony dysplasias are also present.

FABRY DISEASE Fabry disease is an X-linked disorder that results from mutations in the α-galactosidase gene. The estimated prevalence of hemizygous males is 1/40,000. Clinically, the disease manifests with angiokeratomas (telangiectatic skin lesions); hypohidrosis; corneal and lenticular opacities; acroparesthesia; and small-vessel disease of the kidney, heart, and brain.

The angiokeratomas and acroparesthesia may appear in childhood and lead to early diagnosis, if suspected. Angiokeratomas are punctate, dark red to blue-black, flat or slightly raised, usually symmetric, and do not blanch with pressure. They range from barely visible to several millimeters in diameter and have a tendency to increase in size and number with age. They usually are most dense between the umbilicus and knees—"the bathing suit area"—but may occur anywhere, including the mucosal surfaces. Angiokeratomas also occur in Fordyce scrotal angiokeratoma and several other lysosomal storage diseases. Corneal and lenticular lesions, detectable on slit-lamp examination, may help in establishing a diagnosis. Debilitating episodic burning pain of the hands, feet, and proximal extremities, acroparesthesia, can last from minutes to days and can be precipitated by changes in temperature, exercise, fatigue, or fever. Abdominal pain can resemble that from appendicitis or renal colic. Proteinuria, isosthenuria, and progressive renal dysfunction occur in the second to fourth decades. Hypertension, left ventricular hypertrophy, anginal chest pain with or without myocardial ischemia or infarction, and congestive heart failure can occur in the third to fourth decades. Leg lymphedema without hypoproteinemia and episodic diarrhea also occur. Death is due to renal failure or cardiovascular or cerebrovascular disease in untreated patients. Variants with residual α-galactosidase activity may have late-onset manifestations limited to the cardiovascular system that resemble hypertrophic cardiomyopathy. Up to 70% of heterozygous females may exhibit clinical manifestations, including central nervous system (CNS) and cardiac disease, but usually do not develop renal failure.

Phenytoin and carbamazepine diminish the chronic and episodic acroparesthesia. Chronic hemodialysis or kidney transplantation can be lifesaving in patients with renal failure. Enzyme therapy clears stored lipids from a variety of cells, particularly those of the renal, cardiac, and skin vascular endothelium. Renal insufficiency appears irreversible. Early institution of enzyme therapy likely will prevent or slow the progression of the life-threatening complications.

GAUCHER DISEASE Gaucher disease is an autosomal recessive disorder that results from defective activity of acid β-glucosidase; >175 mutations have been described. Disease variants are classified based on the absence or presence and severity of neuronopathic involvement.

Type 1 Gaucher disease is a nonneuronopathic disease that can present in childhood to adulthood with slowly to rapidly progressive visceral disease. The average age at diagnosis is ~20 years in Caucasian populations and somewhat younger in other groups. This pattern of presentation is distinctly bimodal, with peaks at <10 to 15 years and at ~25 years. Younger patients tend to have a greater degree of hepatosplenomegaly and accompanying blood cytopenias. In contrast, the older group has a greater tendency for chronic bone disease. Hepatosplenomegaly occurs in virtually all symptomatic patients and can be minor or massive. Accompanying anemia and thrombocytopenia are variable and are not linearly related to liver or spleen volume. Severe liver dysfunction is unusual. Splenic infarctions can resemble an acute abdomen. Pulmonary hypertension and alveolar Gaucher cell accumulation are uncommon, but life-threatening, and can occur at any age.

All patients with Gaucher disease have nonuniform infiltration of bone marrow by lipid-laden macrophages, termed *Gaucher cells*. This can lead to marrow packing with subsequent infarction, ischemia, necrosis, and cortical bone destruction. Bone marrow involvement spreads from proximal to distal in the limbs and can involve the axial skeleton extensively, causing vertebral collapse. In addition to bone marrow involvement, bone remodeling is defective, with loss of total bone calcium leading to osteopenia, osteonecrosis, avascular infarction, and vertebral compression fractures and spinal cord involvement. Aseptic necrosis of the femoral head is common, as is fracture of the femoral neck. The mechanism by which diseased bone marrow macrophages interact with osteoclasts and/or osteoblasts to cause bone

disease is not well understood. Chronic, ill-defined bone pain can be debilitating and poorly correlated with radiographic findings. "Bone crises" are associated with localized, excruciating pain, and, on occasion, local erythema, fever, and leukocytosis. Some patients have frequent crises, whereas other patients experience only one. These crises represent acute infarctions of bone, as evidenced in nuclear scans by localized absent uptake of pyrophosphate agents. Osteomyelitis should be excluded by appropriate cultures.

Decreased acid β-glucosidase activity (0 to 20% of normal) in nucleated cells makes the diagnosis. The enzyme is not present in bodily fluids. The sensitivity of enzyme testing is poor for heterozygote detection; molecular testing is preferred when the mutations are known. The disease frequency varies from about 1 in 1000 in Ashkenazi Jews to $<$1 in 100,000 in other populations. About 1 in 12 to 15 Ashkenazi Jews carries a Gaucher disease allele. Four common mutations account for $\sim$90 to 95% of the mutations in affected patients: N370S (1226G), 84GG (a G insertion at cDNA position 84), L444P (1448C), and IVS-2 (an intron 2 splice junction mutation).

Genotype/phenotype studies indicate a significant correlation, though not absolute, between disease type and severity and the acid β-glucosidase genotype. The most common mutation in the Ashkenazi Jewish population (N370S) shares a 100% association with nonneuronopathic type 1 Gaucher disease. The N370S/N370S and N370S/other mutant allele genotypes are associated with later onset/less severe and with earlier onset/severe disease, respectively. As many as 50 to 60% of patients with the N370S/N370S genotype are discovered as asymptomatic family members. The other alleles are L444P (very low activity), 84GG (null), or IVS-2 (null), and rare/private or uncharacterized alleles. The L444P/L444P patients almost always have life-threatening to very severe/early-onset disease, and many, though not all, develop CNS involvement in the first two decades of life.

Symptomatic management of the blood cytopenias and joint replacement surgeries continue to have important roles in management. However, enzyme therapy is currently the treatment of choice in significantly affected patients and is highly efficacious and safe in diminishing the hepatosplenomegaly and improving bone marrow involvement and hematologic findings. The bone disease is decreased but not eliminated by enzyme replacement therapy. Adult patients may benefit from adjunctive treatment with bisphosphonates, which improves bone mineralization.

Type 2 Gaucher disease is a rare, severe CNS disease that leads to death by 2 years of age. *Type 3 Gaucher disease* has highly variable manifestations in the CNS and viscera. It can present in early childhood with rapidly progressive, massive visceral disease and slowly progressive to static CNS involvement; in adolescence with dementia; or in early adulthood with rapidly progressive, uncontrollable myoclonic seizures and mild visceral disease. Visceral disease in type 3 is nearly identical to that in type 1 but is generally more severe. Early CNS findings may be limited to defects in lateral gaze tracking, which may remain static for decades. Mental retardation can be slowly progressive or static. This variant is most frequent among individuals of Swedish descent.

NIEMANN-PICK DISEASE This is an autosomal recessive disorder that results from defects in acid sphingomyelinase. Types A and B are distinguished by an early age of onset and progressive CNS disease in type A. Type A typically has onset in the first 6 months, with rapidly progressive CNS deterioration, spasticity, failure to thrive, and massive hepatosplenomegaly. In contrast, B has a later, more variable onset and progression of hepatosplenomegaly, with eventual development of cirrhosis and hepatic replacement by foam cells. Affected patients develop progressive pulmonary disease with dyspnea, hypoxemia, and a reticular infiltrative pattern on chest x-ray. Foam cells are present in alveoli, lymphatic vessels, and pulmonary arteries. Progressive hepatic or lung disease lead to demise in adolescence to early adulthood.

The diagnosis is established by markedly decreased (1 to 10% of normal) sphingomyelinase activity in nucleated cells. There is no specific treatment for Neimann-Pick disease. The efficacy of hepatic or bone marrow transplantation has not been proven. Clinical trials using enzyme therapy are anticipated in the near future.

341 GLYCOGEN STORAGE DISEASES AND OTHER INHERITED DISORDERS OF CARBOHYDRATE METABOLISM

Yuan-Tsong Chen

Carbohydrate metabolism plays a vital role in cellular function by providing the energy required for most metabolic processes. The relevant biochemical pathways involved in the metabolism of these carbohydrates are shown in Fig. 341-1. Glucose is the principle substrate of energy metabolism in humans. Metabolism of glucose generates ATP via glycolysis and mitochondrial oxidative phosphorylation. Dietary sources of glucose are obtained by ingesting polysaccharides, primarily starch, and disaccharides including lactose, maltose, and sucrose. Galactose and fructose are two other monosaccharides that provide fuel for cellular metabolism; however, their role as fuel sources is much less significant than that of glucose. Galactose is derived from lactose (galactose + glucose), which is found in milk products, and is an important component for certain glycolipids, glycoproteins, and glycosaminoglycans. The two dietary sources of fructose are sucrose (fructose + glucose), a commonly used sweetener, and fructose itself, which is found in fruits, vegetables, and honey.

Glycogen, the storage form of glucose in animal cells, is composed of glucose residues joined in straight chains by α1-4 linkages and branched at intervals of 4 to 10 residues by α1-6 linkages. Glycogen forms a treelike molecule and can have a molecular weight of many millions; it may aggregate to form structures recognizable by electron microscopy. Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues; hence, the name *glycogen storage diseases*. The defects in gluconeogenesis or glycolytic pathways, including galactose and fructose metabolism, do not usually result in glycogen accumulation.

Clinical manifestations of the various disorders of carbohydrate metabolism differ markedly. The symptoms range from harmless to lethal. Unlike disorders of lipid metabolism, mucopolysaccharidoses, or other storage diseases, dietary therapy has been effective in many of the carbohydrate disorders. All of the genes responsible for the inherited defects of carbohydrate metabolism have been cloned, and mutations have been identified. Advances in our understanding of the molecular basis of these diseases are being used to improve diagnosis and management, and some of these disorders are candidates for enzyme replacement and early trials of gene therapy.

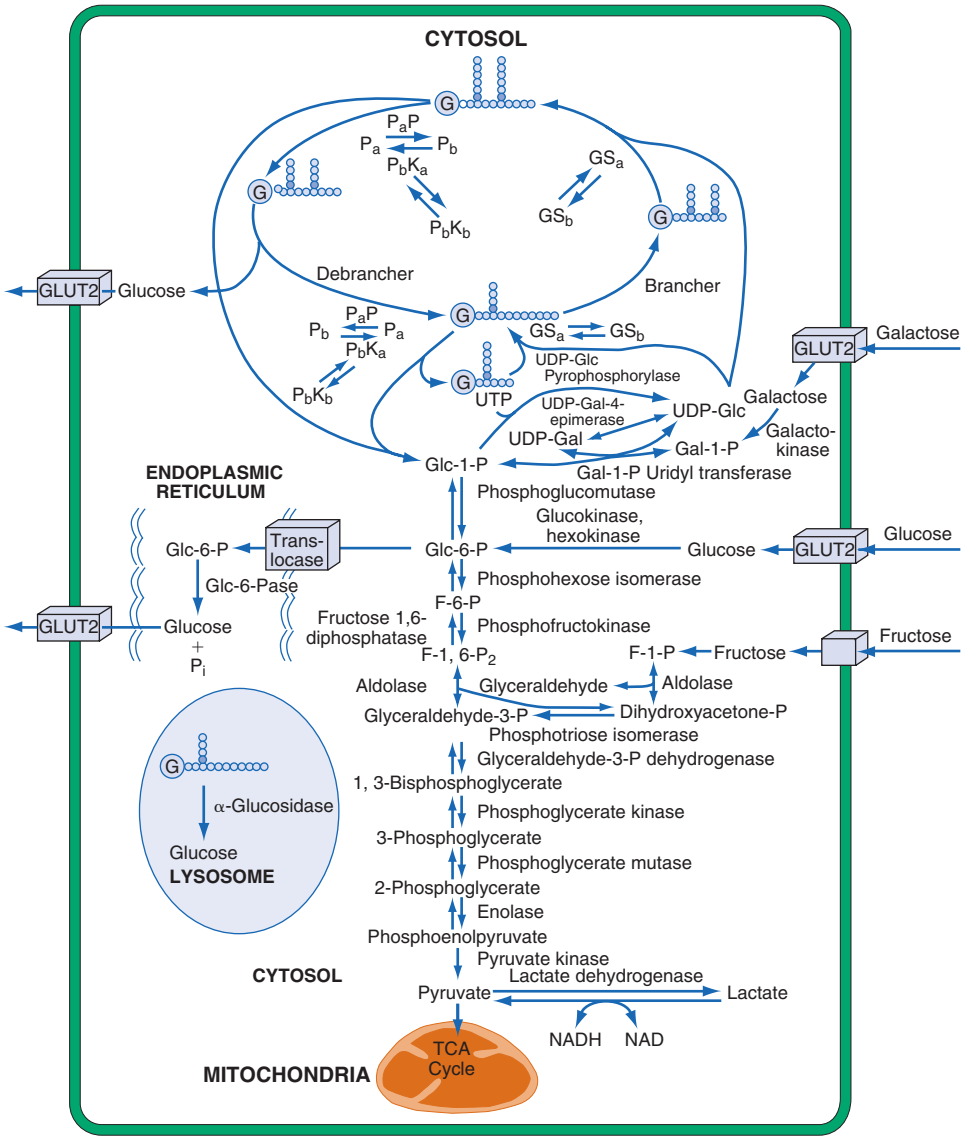

FIGURE 341-1 Metabolic pathways related to glycogen storage diseases and galactose and fructose disorders. Nonstandard abbreviations are as follows: GS_a, active glycogen synthase; GS_b, inactive glycogen synthase; P_a, active phosphorylase; P_b, inactive phosphorylase; P_aP, phosphorylase *a* phosphatase; P_bK_a, active phosphorylase *b* kinase; P_bK_b, inactive phosphorylase *b* kinase; G, glycogenin, the primer protein for glycogen synthesis. *[Modified from AR Beaudet, in KJ Isselbacher et al (eds): Harrison's Principles of Internal Medicine, 13th ed. New York, McGraw-Hill, 1994, p 1855.]*

Historically, the glycogen storage diseases were categorized numerically in the order in which the enzymatic defects were identified. They are also classified by the organs involved and clinical manifestations, the system followed in this chapter (Table 341-1). The overall frequency of all forms of glycogen storage disease is approximately 1 in 20,000 live births; most are inherited as autosomal recessive traits, but phosphoglycerate kinase deficiency and one form of phosphorylase kinase deficiency are X-linked disorders. The most common childhood disorders are glucose-6-phosphatase deficiency (type I), lysosomal acid α-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase deficiency (type IX). The most common adult disorder is myophosphorylase deficiency (type V, or McArdle disease).

SELECTED LIVER GLYCOGENOSES

DISORDERS WITH HEPATOMEGALY AND HYPOGLYCEMIA ■ Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, von Gierke Disease) Type I glycogen storage disease is an autosomal recessive disorder that causes glucose-6-phosphatase deficiency in liver, kidney, and intestinal mucosa. It can be divided into two subtypes: type Ia, in which the glucose-6-phosphatase enzyme is defective, and type Ib, which is due to a defect in the translocase that transports glucose-6-phosphate across the microsomal membrane. The defects in both subtypes lead to inadequate conversion in the liver of glucose-6-phosphate to glucose and thus make affected individuals susceptible to fasting hypoglycemia.

CLINICAL AND LABORATORY FINDINGS Persons with type I disease may develop hypoglycemia and lactic acidosis during the neonatal period, but, more commonly, they present at 3 to 4 months of age with hepatomegaly. Hypoglycemia and lactic acidosis can develop after a short fast. These children often have doll-like faces with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is due to massive hepatomegaly; the kidneys are enlarged, but the spleen and heart are of normal size. The hepatocytes are distended by glycogen and fat with large and prominent lipid vacuoles. Despite hepatomegaly, liver enzymes are usually normal or near normal. Easy bruising and epistaxis are associated with a prolonged bleeding time as a result of impaired platelet aggregation/adhesion. Hyperuricemia is present. Hyperlipidemia includes elevation of triglycerides, cholesterol, and phospholipids.

LONG-TERM COMPLICATIONS Gout usually becomes symptomatic around puberty as a result of the long-term hyperuricemia. Puberty is often delayed. Virtually all females have ultrasound findings consistent with polycystic ovaries; however, the other clinical features of polycystic ovary syndrome, such as acne and hirsutism, are not seen. Secondary to the lipid abnormalities, there is an increased risk of pancreatitis. The dyslipidemia together with elevated erythrocyte aggregation predispose these patients to atherosclerosis. Frequent fractures and radiographic evidence of osteopenia are not uncommon in adult patients, and radial bone mineral content is significantly reduced in prepubertal patients. By the second or third decade of life, most patients with type I glycogen storage disease develop hepatic adenomas that can hemorrhage and, in some cases, become malignant. Renal disease is a serious late complication. Almost all patients older than 20 years have proteinuria and many have hypertension, kidney stones, nephrocalcinosis, and altered creatinine clearance. In some patients, renal function deteriorates and progresses to failure, requiring dialysis or transplantation.

DIAGNOSIS The diagnosis of type I disease can be suspected on the basis of clinical presentation and abnormal plasma lactate and lipid values. Before the glucose-6-phosphatase and glucose-6-phosphate translocase genes were cloned, a definitive diagnosis required a liver biopsy to demonstrate a deficiency. Gene-based mutation analysis now provides a noninvasive way of diagnosis for most patients with types Ia and Ib disease.

℞ TREATMENT

Treatment is designed to maintain normal blood glucose levels and is achieved by continuous nasogastric infusion of glucose or oral admin-

TABLE 341-1 *Features of Glycogen Storage Diseases and Galactose and Fructose Disorders*

Type/Common Name	Basic Defect	Clinical Features	Comments
LIVER GLYCOGENOSES			
Disorders with hepatomegaly and hypoglycemia			
Ia/von Gierke	Glucose-6-phosphatase	Growth retardation, enlarged liver and kidney, hypoglycemia, elevated blood lactate, cholesterol, triglycerides, and uric acid	Common, severe hypoglycemia Late complications in adulthood
Ib	Glucose-6-phosphate translocase	As for Ia, with additional findings of neutropenia and neutrophil dysfunction	~10% of type I
IIIa/Cori or Forbes	Liver and muscle debranching enzyme	Childhood: Hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated liver transaminases; liver symptoms improve with age Adulthood: muscle atrophy and weakness; onset: third to fourth decades; variable cardiomyopathy	Common, intermediate severity of hypoglycemia Liver cirrhosis can occur
IIIb	Liver debranching enzyme (normal muscle debrancher activity)	Liver symptoms same as in type IIIa; no muscle symptoms	~15% of type III
VI/Hers	Liver phosphorylase	Hepatomegaly, mild hypoglycemia, hyperlipidemia and ketosis; symptoms improve with age	Rare, "benign" glycogenosis
IX/phosphorylase kinase deficiency	Liver phosphorylase kinase α subunit	As for VI	Common, "benign glycogenosis," X-linked
0/glycogen synthase deficiency	Glycogen synthase	Fasting hypoglycemia and ketosis, elevated lactic acid and hyperglycemia after glucose load	Decreased glycogen stores
XI/Fanconi-Bickel	Glucose transporter-2	Failure to thrive, rickets, hepatomegaly, proximal renal tubular dysfunction, impaired glucose and galactose utilization	Rare, consanguinity in 70%
Disorders with liver cirrhosis			
IV/Andersen	Branching enzyme	Failure to thrive, hypotonia, hepatomegaly, splenomegaly, progressive liver cirrhosis and failure (death usually before fifth year); some without progression	One of the rarer glycogenoses; other neuromuscular variants exist
MUSCLE GLYCOGENOSES			
Disorders with muscle-energy impairment			
V/McArdle	Muscle phosphorylase	Exercise intolerance, muscle cramps, myoglobinuria on strenuous exercise, increased CK	Common, male predominance
VII/Tarui	Phosphofructokinase—M subunit	As for type V, with additional findings of a compensated hemolysis	Prevalent in Ashkenazi Jews and Japanese
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	As for type V, with additional findings of a hemolytic anemia and CNS dysfunction	Rare, X-linked
Phosphoglycerate mutase deficiency	Phosphoglycerate mutase—M subunit	As for type V	Rare; most patients are African American
Lactate dehydrogenase deficiency	Lactic acid dehydrogenase—M subunit	As for type V, with additional findings of erythematous skin eruption and uterine stiffness resulting in childbirth difficulty in female	Rare
Fructose 1,6-bisphosphate aldolase A deficiency	Fructose 1,6-bisphosphate aldolase A	As for type V, with additional finding of hemolytic anemia	Rare
Pyruvate kinase deficiency	Pyruvate kinase—muscle isozyme	Muscle cramps and/or fixed muscle weakness	Rare
Muscle phosphorylase kinase deficiency	Muscle-specific phosphorylase kinase	As for type V, some patients may have muscle weakness and atrophy	Rare, autosomal recessive
β-enolase deficiency	Muscle β-enolase	Exercise intolerance	Rare
Disorders with progressive skeletal myopathy and/or cardiomyopathy			
II/Pompe	Lysosomal acid α-glucosidase	Infantile: hypotonia, muscle weakness, cardiac enlargement and failure, fatal early Juvenile and adult: progressive skeletal muscle weakness and atrophy, proximal muscle and respiratory muscle are seriously affected	Common, undetectable, or very low level of enzyme activity in infantile form; residual enzyme activity in late-onset
Cardiac phosphorylase kinase deficiency	Cardiac-specific phosphorylase kinase	Severe cardiomyopathy and early heart failure	Very rare
GALACTOSE DISORDERS			
Galactosemia with uridyl transferase deficiency	Galactose 1-phosphate uridyl transferase	Vomiting, hepatomegaly, jaundice, cataracts, amino aciduria, failure to thrive	Long-term complications exist despite early diagnosis and treatment
Galactokinase deficiency	Galactokinase	Cataracts	Benign
Uridine diphosphate galactose 4-epimerase deficiency	Uridine diphosphate galactose 4-epimerase	Similar to transferase deficiency with additional findings of hypotonia and nerve deafness	Benign variant exists
FRUCTOSE DISORDERS			
Essential fructosuria	Fructokinase	Asymptomatic, positive urine reducing substance	Benign
Hereditary fructose intolerance	Fructose 1-phosphate aldolase B	Vomiting, lethargy, failure to thrive, hepatic failure	Prognosis good with early diagnosis and fructose restriction
Fructose 1,6-diphosphatase deficiency	Fructose 1,6-diphosphatase	Episodic hypoglycemia and lactic acidosis	Avoid fasting, good prognosis

Note: CK, creatine kinase; M, muscle; CNS, central nervous system.

istration of uncooked cornstarch. Uncooked cornstarch acts as a slow-release form of glucose and can be given at a dose of 1.6 g/kg every 4 h for infants younger than 2 years. As the child grows older, the cornstarch regimen can be changed to every 6 h, and can be given by mouth as a liquid (1:2, weight:volume) at a dose of 1.75 to 2.5 g/kg of body weight. Because fructose and galactose cannot be converted to free glucose, their dietary intake should be restricted. Dietary supplements of multivitamins and calcium are required. Allopurinol is given to lower uric acid levels. The hyperlipidemia can be reduced with lipid-lowering drugs such as HMG-CoA reductase inhibitors and fibric acids. Preliminary studies of treating microalbuminuria, an early indicator of renal dysfunction in these patients, have also shown angiotensin-converting enzyme (ACE) inhibitors to be beneficial. Citrate supplement may be beneficial in preventing or ameliorating nephrocalcinosis and development of urinary calculi.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis) Type III glycogenoses are autosomal recessive disorders caused by a deficiency of glycogen debranching enzyme. Debranching enzyme and phosphorylase are responsible for complete degradation of glycogen; when debranching enzyme is defective, glycogen breakdown is incomplete and an abnormal glycogen accumulates that has short outer chains and resembles limit dextrin.

CLINICAL AND LABORATORY FINDINGS Deficiency of glycogen debranching enzyme causes hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and cardiomyopathy. The disorder usually involves both liver and muscle and is termed *type IIIa glycogen storage disease*. However, in about 15% of patients, the disease appears to involve only the liver and is classified as *type IIIb*. Remarkably, hepatomegaly and hepatic symptoms in most patients with type III disease improve with age and usually disappear after puberty.

Hypoglycemia, hyperlipidemia, and elevated liver transaminases occur in children. In contrast to type I disease, fasting ketosis is prominent, and blood lactate and uric acid concentrations are usually normal. Serum creatine kinase levels can sometimes be used to identify patients with muscle involvement, but normal levels do not rule out muscle enzyme deficiency.

DIAGNOSIS In type IIIa glycogen storage disease, deficient debranching enzyme activity can be demonstrated in liver, skeletal muscle, and heart. In contrast, patients with type IIIb have debranching enzyme deficiency in the liver but not in muscle. In the past, definitive assignment of subtype required enzyme assays in both liver and muscle. DNA-based analyses now provide a noninvasive way of subtyping these disorders in most patients.

Rx TREATMENT

Dietary management of type III disease is less demanding than that of type I. If hypoglycemia is present, frequent high-carbohydrate meals with cornstarch supplements or nocturnal gastric drip feedings are usually effective. A high-protein diet during the day plus overnight protein enteral infusion may be tried in patients with myopathy, but it is not established whether such a regimen is effective.

Type VI Glycogen Storage Disease [Liver Phosphorylase Deficiency (Hers Disease)] These patients present with hepatomegaly and growth retardation early in childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are usually mild, if present. Plasma lactic acid and uric acid levels are normal. The heart and skeletal muscles are not involved. The hepatomegaly and growth retardation improve with age and usually disappear at puberty. Treatment is symptomatic. A high-carbohydrate diet and frequent feeding are effective in preventing hypoglycemia, but most patients require no specific treatment.

Type IX Glycogen Storage Disease (Liver Phosphorylase Kinase Deficiency) Defects of phosphorylase kinase cause a heterogeneous group of glycogenoses. The phosphorylase kinase enzyme complex consists of four subunits (α, β, γ, and δ), each encoded by different genes (X chromosome as well as autosomes) that are differentially expressed in various tissues. Phosphorylase kinase deficiency can be divided into several subtypes on the basis of the gene/subunit involved, the tissues that are primarily affected, and the mode of inheritance. The most common subtype is X-linked liver phosphorylase kinase deficiency, which is also one of the most common liver glycogenoses. Phosphorylase kinase activity may also be deficient in erythrocytes and leukocytes but is normal in muscle. Typically, a child between the ages of 1 and 5 presents with growth retardation and hepatomegaly. Levels of cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactic and uric acid levels are normal. Hypoglycemia is mild, if present. Hepatomegaly and abnormal blood chemistries gradually return to normal with age. Most adults achieve a normal final height and are practically asymptomatic, despite a persistent phosphorylase kinase deficiency.

Treatment is symptomatic. A high-carbohydrate diet and frequent feedings are effective in preventing hypoglycemia; some patients require no specific treatment. Prognosis is usually good; adult patients have normal stature and minimal hepatomegaly.

Other subtypes of Type IX include an autosomal recessive form of liver and muscle phosphorylase kinase deficiency, an autosomal recessive form of liver phosphorylase kinase deficiency that often develops into liver cirrhosis, a muscle-specific phosphorylase kinase deficiency that causes cramps and myoglobinuria with exercise, and a cardiac-specific phosphorylase kinase deficiency that is lethal during infancy because of massive glycogen deposition in the myocardium.

Other Liver Glycogenoses with Hepatomegaly and Hypoglycemia These disorders include glycogen synthase deficiency (type 0) and hepatic glycogenosis with renal Fanconi syndrome (type XI). The latter is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

SELECTED MUSCLE GLYCOGENOSES

DISORDERS WITH MUSCLE-ENERGY IMPAIRMENT ■ Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease) Type V glycogen storage disease is an autosomal recessive disorder caused by deficiency of muscle phosphorylase. McArdle disease is a prototypical muscle energy disorder as the enzyme deficiency limits ATP generation by glycogenolysis and results in glycogen accumulation.

CLINICAL AND LABORATORY FINDINGS Symptoms usually develop first in adulthood and are characterized by exercise intolerance with muscle cramps. Two types of activity tend to cause symptoms: (1) brief exercise of great intensity, such as sprinting or carrying heavy loads; and (2) less intense but sustained activity, such as climbing stairs or walking uphill. Moderate exercise, such as walking on level ground, can be performed by most patients for long periods. About half of patients report burgundy-colored urine after exercise, the consequence of myoglobinuria secondary to rhabdomyolysis. Intense myoglobinuria after vigorous exercise may cause renal failure. In rare cases, electromyography (EMG) findings may suggest an inflammatory myopathy, and the diagnosis can be confused with polymyositis.

The level of serum creatine kinase is usually elevated at rest and increases after exercise. Exercise also increases the levels of blood ammonia, inosine, hypoxanthine, and uric acid. The latter abnormalities are attributed to accelerated recycling of muscle purine nucleotides in the face of insufficient ATP production.

DIAGNOSIS Lack of an increase in blood lactate and exaggerated blood ammonia elevations after an ischemic exercise test are indicative of muscle glycogenosis and suggest a defect in the conversion of glycogen or glucose to lactate. The abnormal exercise response, however, is not limited to type V disease and can occur with other defects in glycogenolysis or glycolysis, such as deficiencies of muscle phospho-

fructokinase or debranching enzyme (when the test is done after fasting). Definitive diagnosis is made by enzymatic assay in muscle tissue or by mutation analysis of the myophosphorylase gene.

TREATMENT

In general, avoidance of strenuous exercise can prevent major episodes of rhabdomyolysis; however, regular and moderate exercise is recommended to improve exercise capacity. A high-protein diet may increase exercise endurance, and creatine supplement has been shown to improve muscle function in some patients. In general, longevity does not appear to be affected.

DISORDERS WITH PROGRESSIVE SKELETAL MUSCLE MYOPATHY AND/OR CARDIOMYOPATHY ■ Type II Glycogen Storage Disease (Acid α-1,4 Glucosidase Deficiency, Pompe Disease) Type II disease is an autosomal recessive disorder caused by a deficiency of lysosomal acid α-1,4 glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosomal vacuoles. It is characterized by the accumulation of glycogen in lysosomes as opposed to its accumulation in cytoplasm as in the other glycogenoses.

CLINICAL AND LABORATORY FINDINGS The disorder encompasses a range of phenotypes, each including myopathy but differing in age of onset, organ involvement, and clinical severity. The most severe is the infantile-onset disease with cardiomegaly, hypotonia, and death before age 1. Infants appear normal at birth but soon develop generalized muscle weakness with feeding difficulties, macroglossia, hepatomegaly, and congestive heart failure due to a hypertrophic cardiomyopathy.

The juvenile, or late-childhood, form is characterized by skeletal muscle manifestations, usually without cardiac involvement, and a slowly progressive course. The juvenile form typically presents as delayed motor milestones (if age of onset is early enough) and difficulty in walking. These manifestations are followed by swallowing difficulties, proximal muscle weakness, and respiratory muscle involvement. Death may occur before the end of the second decade.

An adult form of type II disease presents as a slowly progressive myopathy without cardiac involvement and has its onset between the second and seventh decades. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement. The pelvic girdle, paraspinal muscles, and the diaphragm are most seriously affected. The initial symptoms may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea.

Laboratory findings include elevated levels of serum creatine kinase, aspartate transaminase, and lactate dehydrogenase, particularly in infants. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen, and muscle acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. EMG reveals myopathic features with irritability of muscle fibers and pseudomyotonic discharges. Serum creatine kinase is not always elevated in adults and, depending on the muscle biopsied or tested, muscle histology or EMG may not be abnormal. It is prudent to examine affected muscle.

DIAGNOSIS Diagnosis can be established by demonstration of the absence or reduced levels of acid α-glucosidase activity in muscle or cultured skin fibroblasts. Deficiency is usually more severe in the infantile form than in the juvenile and adult disorders.

TREATMENT

Definitive therapy is not currently available; a high-protein diet may be useful for the juvenile and adult forms. Nocturnal ventilatory support in late-onset patients improves the quality of life and is beneficial during a period of respiratory decompensation. Clinical trials of enzyme replacement therapy have begun. Preliminary data have shown that recombinant acid α-glucosidase is capable of improving cardiac and skeletal muscle function in these patients.

SELECTED DISORDERS OF GALACTOSE METABOLISM

"Classic" *galactosemia* is due to galactose 1-phosphate uridyl transferase deficiency. It is a serious disease with an early onset of symptoms; the incidence is 1 in 60,000. The newborn infant normally receives up to 20% of caloric intake as lactose, which consists of glucose and galactose. Without the transferase, the infant is unable to metabolize galactose 1-phosphate (Fig. 341-1), the accumulation of which results in injury to parenchymal cells of the kidney, liver, and brain.

Widespread newborn screening for galactosemia has identified these infants early and allowed them to be placed on dietary restriction. Elimination of galactose from the diet reverses growth failure and renal and hepatic dysfunction and improves the prognosis. However, on long-term follow-up, these patients still have ovarian failure manifest as primary or secondary amenorrhea, as well as developmental delay and learning disabilities, which increase in severity with age. In addition, most patients have speech disorders, and a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). The treatment of galactosemia to prevent long-term complications remains a challenge.

Deficiency of *galactokinase* (Fig. 341-1) causes cataracts. Deficiency of *uridine diphosphate galactose 4-epimerase* can be benign when the enzyme deficiency is limited to blood cells but can be as severe as "classic" galactosemia when the enzyme deficiency is generalized.

SELECTED DISORDERS OF FRUCTOSE METABOLISM

Fructokinase deficiency (Fig. 341-1) causes a benign condition that is usually an incidental finding made through the detection of fructose as a reducing substance in the urine.

Deficiency of *fructose 1,6-bisphosphate aldolase* (aldolase B, hereditary fructose intolerance) is a serious disease of infants because of a defect in gluconeogenesis. These patients are healthy and asymptomatic until fructose or sucrose (table sugar) is ingested (usually from fruit, fruit juice, or sweetened cereal). Clinical manifestations may include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. Laboratory findings include prolonged clotting time, hypoalbuminemia, elevation of bilirubin and transaminases, and proximal renal tubular dysfunction. If the disease is not diagnosed and intake of the noxious sugar persists, hypoglycemic episodes recur, and liver and kidney failure progress, eventually leading to death. Treatment consists of the complete elimination of all sources of sucrose, fructose, and sorbitol from the diet. With this treatment, liver and kidney dysfunction improve, and catch-up growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder, even after fructose ingestion, and the long-term prognosis is good.

Fructose 1,6-diphosphatase deficiency is characterized by childhood life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. These episodes are triggered by febrile infections and gastroenteritis when oral food intake decreases. Laboratory findings include low blood glucose, high lactate and uric acid levels, and metabolic acidosis. In contrast to hereditary fructose intolerance, there is usually no aversion to sweets, and renal tubular and liver functions are normal. Treatment of acute attacks consists of correction of hypoglycemia and acidosis by intravenous infusion. Later, avoidance of fasting and elimination of fructose and sucrose from the diet prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Prognosis is good as patients who survive childhood develop normally.

342 INHERITED DISORDERS OF CONNECTIVE TISSUE

Darwin J. Prockop, Leena Ala-Kokko

Heritable disorders that involve the major connective tissues of the body such as bone, skin, cartilage, blood vessels, and basement membranes are among the most common genetic diseases in human beings. Here we will focus primarily on those disorders that can have severe manifestations, are relatively common, and are sufficiently understood at the molecular level to provide useful paradigms: osteogenesis imperfecta (OI), the Ehlers-Danlos syndrome (EDS), chondrodysplasias (CDs), the Marfan syndrome (MFS), epidermolysis bullosa (EB), and the Alport syndrome (AS).

THE CHALLENGE OF CLASSIFYING THE DISEASES The original classification of connective tissue diseases was based on the pattern of inheritance, the cluster of signs and symptoms, the histologic changes in tissues, and limited information about the molecular defects involved. This classification included about a dozen types and subtypes for OI, about the same number for the EDS, and over 150 for the CDs. Several limitations in these original classifications are now apparent. One is that the same mutation does not always produce the same disease phenotype in terms of severity of the condition or its clinical course. Such phenotypic variation occurs in many genetic diseases, including the connective tissue disorders, in which some members of a family are severely affected, whereas others with the same mutation have a mild disorder.

Most patients with classic features of a severe connective tissue disease have a mutation in a gene, or genes, coding for a single protein. For example, the majority of patients with OI have a mutation in one of the two genes coding for type I procollagen. Similarly, most patients with MFS have mutations in a gene for fibrillin. For other disease categories, the situation is more complex. In EDS, for example, the type IV variant is usually caused by mutations in the gene for type III procollagen, the type VI variant by defects in the gene for lysyl hydroxylase, and the type VII variant by defects in a gene required for processing type I procollagen to type I collagen.

Classifications of these disorders also tend to overemphasize the etiologic differences between severe genetic diseases that are apparent in infants and the more common diseases that appear much later in life. Single-gene defects can cause subsets of late-onset diseases such as osteoporosis, aneurysms, and osteoarthritis. For example, a small subset of patients with postmenopausal osteoporosis have mutations in the genes for procollagen I similar to the mutations in the same genes that produce lethal variants of OI. Likewise, a subset of patients with familial aortic aneurysms have mutations in the gene for procollagen III similar to the mutations in the same gene that cause lethal variants of type IV EDS, and occasional patients with osteoarthritis have mutations in the gene for procollagen II similar to the mutations in the same gene that cause lethal CDs.

DEFINITION AND COMPOSITION OF CONNECTIVE TISSUES The distinguishing feature of connective tissues is that it consists of complex macromolecules that are assembled into an insoluble extracellular matrix (Table 342-1). The macromolecules include at least 25 different types of collagens, the related fibrous proteins known as *elastin* and *fibrillin*, a series of proteoglycans, and other components whose structure and function are only partially defined. Differences in the connective tissues of bone, skin, and cartilage are partially explained by differences in the content of specific components (Table 342-1). For example, tendons and ligaments consist primarily of type I collagen fibrils and small amounts of other components that help organize the type I fibrils into thick fibers and fiber bundles. Cartilage consists primarily of fibrils of type II collagen in the form of arcades that are distended by highly charged proteoglycans. The extracellular matrix of the aorta contains collagens that provide tensile strength and elastin that provides elasticity. Differences among the connective tissues also depend on the three-dimensional organization of the molecular components. The type I collagen fibrils in tendon are packed into thick, parallel bundles of fibers, whereas type I collagen fibrils in skin are randomly oriented. In cortical bone, type I collagen fibrils form helical arrays around haversian canals.

TABLE 342-1 *Constituents of Connective Tissues in Various Tissues*

Connective Tissue	Major Constituents	Approximate Amounts, % dry wt	Characteristics or Functions
Dermis, ligaments, tendons	Type I collagen	80	Bundles of fibrils
	Type III collagen	5–15	Thin fibrils
	Type IV collagen, laminin, nidogen	<5	In basal laminae under epithelium and endothelium
	Types V, VI, and VII collagens	<5	VII forms anchoring fibrils; others unknown
	Elastin, fibrillin	<5	Provides elasticity
	Fibronectin	<5	Associated with collagen fibers and cell surfaces
	Proteoglycans,[a] hyaluronate	0.5	Provide resiliency
Bone (demineralized)	Type I collagen	90	Complex fibril network
	Type VI collagen	1–2	Function unclear
	Proteoglycans[a]	1	Function unclear
	Osteonectin, osteopontin, osteocalcin, α2-glycoprotein, sialoproteins	1–5	May regulate mineralization
Aorta	Type I collagen	20–40	Fibril network
	Type III collagen	20–40	Thin fibrils
	Elastin, fibrillin	20–40	Provide elasticity
	Type IV collagen, laminin, nidogen	<5	Form basal lamina
	Types V and VI collagens	<2	Functions unclear
	Proteoglycans[a]	<3	Provide resiliency
Cartilage	Type II collagen	40–50	Arcades of thin fibrils
	Type IX collagen	5–10	Links type II fibrils
	Type X collagen	5–10	Surrounds hypertrophic cells
	Type XI collagen	<10	Function unclear
	Proteoglycans,[a] hyaluronate	15–50	Provides resiliency

[a] As discussed in text, >30 proteoglycans have now been identified. They differ in the structures of their core proteins and their contents of glycosaminoglycan side chains of chondroitin-4-sulfate, chondroitin-6-sulfate, dermatan sulfate, and keratin sulfate. Basal lamina contain a proteoglycan with a side chain of heparan sulfate that resembles heparin.

BIOSYNTHESIS OF CONNECTIVE TISSUE Connective tissues form primarily by a process of self-assembly, in which a molecule of the correct size, shape, and surface property binds to other molecules with the same or similar structure in a spontaneous and precisely ordered manner. The molecular mechanisms and driving forces are similar to those involved in crystal formation.

Collagen Synthesis Collagens have a triple-helical conformation, because each of the three α chains has a simple, repetitive amino acid se-

quence of about 1000 amino acids in which glycine (Gly) appears as every third amino acid. Therefore, the sequence of each α chain can be designated as (-Gly-X-Y-)$_{333}$, where X and Y represent amino acids other than glycine. To fold into a triple helix, every third amino acid in an α chain must be glycine, the smallest amino acid, since this residue must fit in a sterically restricted space where the three chains of the triple helix come together. Many of the X- and Y-position amino acids are proline and hydroxyproline, which, because of their ring structure, provide rigidity to the triple helix.

Twenty-five different collagens have been identified. Many are minor constituents that probably have highly specialized functions. The fibrillar collagens are abundant proteins that are found in tissues as long, highly ordered fibrils with a characteristic banding pattern revealed by electron microscopy. Type I collagen, the most abundant, is composed of two identical α chains called α1(I) and a third called α2(I). Type II collagen, the fibrillar collagen of cartilage, is composed of three identical α chains called α1(II). Type III collagen is found in small amounts in many tissues that contain type I collagen and in large amounts in large blood vessels; it is composed of three identical chains called α1(III). Type IV collagen in basement membranes self-assembles into a complex three-dimensional network that provides a diffusion barrier in the renal glomerulus, pulmonary alveolus, and other tissues.

Collagens are first synthesized as larger and more soluble precursors called *procollagens* that are composed of proα chains. As the proα chains of procollagen are synthesized on ribosomes, the free ends move into the cisternae of the rough endoplasmic reticulum (Fig. 342-1). Hydrophobic signal peptides at the N termini are cleaved, and additional posttranslational reactions begin. Proline residues in the Y position of the repeating -Gly-X-Y- sequences are converted to hydroxyproline by prolyl hydroxylase. The requirement for ascorbic acid as cofactor in the hydroxylation of prolyl residues explains why wounds fail to heal in scurvy (Chap. 61). If sufficient proline residues are not converted to hydroxyproline, collagen cannot fold into a triple helix that is stable at body temperature. The abnormal protein accumulates in the cisternae of the rough endoplasmic reticulum and is slowly degraded. Lysine residues in the Y position are similarly hydroxylated to hydroxylysine by lysyl hydroxylase. Many of the hydroxylysine residues are glycosylated with galactose or with galactose and glucose. A large mannose-rich oligosaccharide is assembled on the C-terminal propeptide of each chain.

After secretion, procollagen is processed to collagen by cleavage of the N-propeptides by procollagen N-proteinase and of the C-propeptides by procollagen C-proteinase. The processing converts the precursor to type I collagen and thereby decreases the solubility of the protein about 1000-fold. The entropic energy that is released drives the spontaneous self-assembly of the collagen into fibrils. Self-assembled collagen fibers have considerable tensile strength, which is increased by cross-linking reactions that form covalent bonds between α chains in one molecule and α chains in adjacent molecules. The first step in cross-linking is oxidation by lysyl oxidase of amino groups on a few lysine or hydroxylysine residues to form aldehydes that interact to form stable covalent bonds.

During growth and development, the collagen fibrils in all tissues undergo repeated synthesis, degradation, and resynthesis. The degradation of collagen fibers in tissues is initiated by specific collagenases. Collagen fibers in most tissues of normal adults undergo very little metabolic turnover. One exception to this is the collagen fibrils that are degraded and resynthesized as part of the continual remodeling of bone. Also, although the collagen in many adult tissues is metabolically stable, the rate of turnover increases under some circumstances. In starvation, a large fraction of the collagen in skin and other connective tissues is degraded, thus providing amino acids for gluconeogenesis. Large losses of collagen also occur in most connective tissues during immobilization or prolonged periods of low-gravitational stress. In rheumatoid arthritis, pannus invasion causes a rapid degradation of collagen in the articular cartilage. Glucocorticoids decrease the collagen content of most connective tissues, including bone, by decreasing the rate of collagen synthesis. Decreases in collagen weaken tissues. In many pathologic states, however, collagen is deposited in excess. With injury to tissue, inflammation is usually followed by increased deposition primarily of type I collagen fibrils in the form of fibrotic tissue and scars. The deposition of collagen fibrils during the repair process is largely irreversible and is a major feature of the pathologic changes in hepatic cirrhosis, pulmonary fibrosis, atherosclerosis, and nephrosclerosis and in the scarring of skin and ligaments after surgery or trauma.

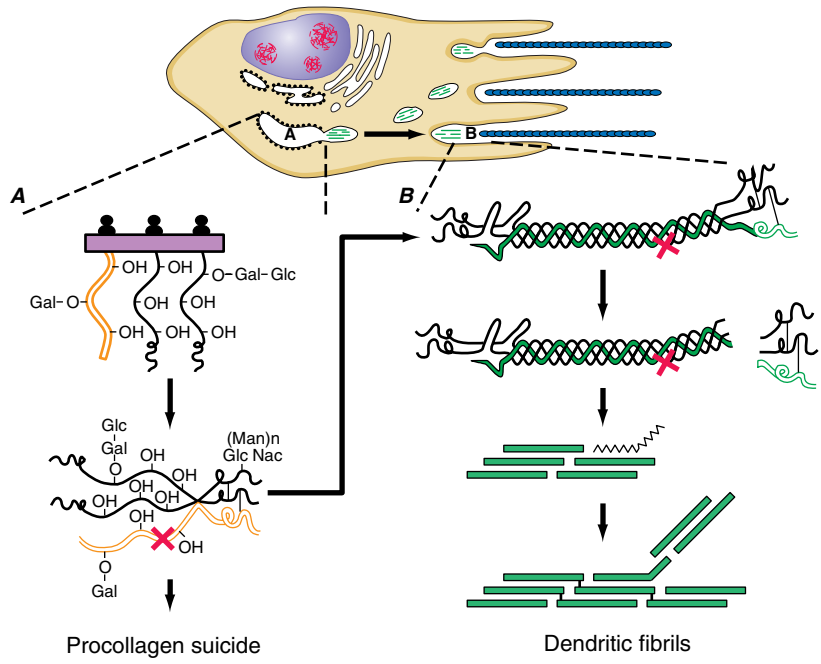

FIGURE 342-1 Schematic representation of synthesis of a type I collagen fibril by a fibroblast. *A.* Intracellular steps in the assembly of the procollagen molecule. Hydroxylations and glycosylations of the proα chains begin soon after the amino termini pass into the cisternae of the rough endoplasmic reticulum and continue after the three chains associate through their carboxy-terminal propeptides and become disulfide linked. *B.* Cleavage of procollagen to collagen, self-assembly of the collagen molecule into quarter-staggered fibrils, and cross-linking of the molecules in the fibrils. Cleavage of the propeptides may occur within crypts of the fibroblast, as shown here, or some distance from the cell. Mutations (depicted by X) cause the synthesis of structurally abnormal proα1(I) or proα2(I) chains of type I procollagen by interfering either with protein assembly (procollagen suicide) (*A*) or with processing to normal collagen fibrils (*B*). *(From DJ Prockop et al, Am J Med Genet 34:60, 1989, with permission.)*

Elastin Synthesis Elastin assembly appears to be closely related to that of collagen, since a few of the prolines in the protein are hydroxylated to hydroxyproline by prolyl hydroxylase. The elastin monomer, however, is a single polypeptide that does not fold into a defined three-dimensional structure and is not synthesized as a larger precursor molecule. Instead, it is slowly secreted from cells into extracellular compartments, where it forms amorphous deposits around previously deposited microfibrils. The elastin deposits then become covalently cross-linked through oxidation of lysine residues to aldehydes by the same lysyl oxidase that initiates the cross-linking of collagen. The microfibrils in elastin deposits are largely composed of fibrillin, a large protein that forms beadlike strands.

Proteoglycan Synthesis The synthesis of proteoglycans begins in the cisternae of the rough endoplasmic reticulum with assembly of a core protein that then undergoes sequential additions of sugars to generate large side chains of glycosaminoglycans. At least 30 proteoglycans have been identified by differences in the structures of their core proteins and their side chains. The major proteoglycan of cartilage, called

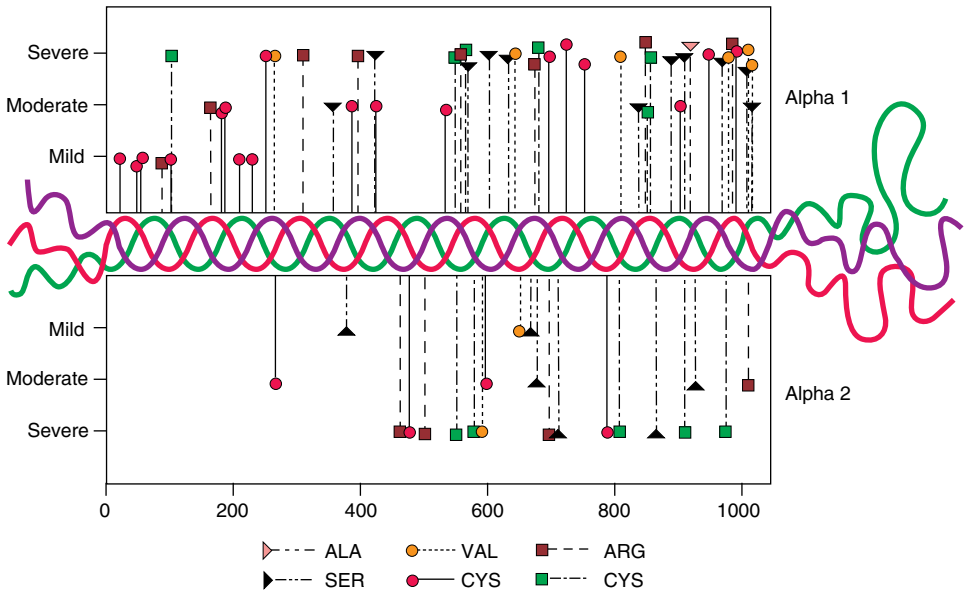

FIGURE 342-2 Examples of single-base mutations found in type I procollagen in patients with osteogenesis imperfecta (OI) and osteoporosis. Mild refers to type I OI, severe to type II OI, and moderate to type III or type IV OI.

aggrecan, has a core protein of about 2000 amino acids, which are bound multiple side chains of chondroitin sulfate and keratin sulfate, polysaccharides consisting of highly charged and repetitive disaccharide sequences. The highly charged proteoglycan aggregate binds water and small ions that distend the collagen network and thereby make the tissue resilient to pressure.

MUTATIONS THAT PRODUCE DISEASES OF CONNECTIVE TISSUES The most complete data on mutations causing heritable disorders of connective tissue are available on OI. Most patients with OI have mutations in either the gene for the proα1(I) chain or the gene for the proα2(I) chain of type I procollagen (the COL1A1 and COL1A2 genes). Most of the mutations in patients with severe OI cause synthesis of a structurally abnormal but partially functional proα chain. They include partial gene deletions, partial gene duplications, and RNA splicing mutations. The most common mutations, however, cause the substitution of single amino acids with bulky side chains for the glycine residues that appear as every third amino acid in the triple-helical domain of a proα chain (Fig. 342-2). The structurally abnormal proα chains exert their effects primarily through one of three mechanisms (Fig. 342-1). First, the presence of an abnormal proα chain in a procollagen molecule containing two normal proα chains can prevent folding of the protein into a triple-helical conformation and lead to degradation of the whole molecule in a process called *procollagen suicide*. Similar dominant negative mutations are seen with other multisubunit proteins. The net result of procollagen suicide is accumulation of the unfolded protein in the rough endoplasmic reticulum of cells and a reduction in the amount of collagen available for fibril assembly. Second, the presence of one abnormal proα chain in a procollagen molecule can interfere with cleavage of the N-propeptide from the protein. The persistence of the N-propeptide on a fraction of the molecules interferes with the self-assembly of normal collagen so that thin and irregular collagen fibrils are formed. Third, the substitution of a bulkier amino acid for glycine can produce a change in the conformation of the molecule and result in the assembly of collagen fibrils that are abnormally branched or abnormally thick and short.

Over 500 mutations in the two genes for type I procollagen have been found in patients with OI (Fig. 342-2). The data on mutations in type I procollagen that cause OI have been used as a paradigm for defining other mutations in other collagen and procollagen genes that cause other disorders of connective tissue.

Several generalizations can be made about mutations in collagen genes. One is that unrelated patients rarely have the same mutation in the same gene. Another is that mutations that cause the most severe disease are usually new mutations in one allele that occur either during the generation of the germline in one of the parents or during meiosis in the fertilized egg (Chap. 56). Another general trend is that similar mutations in different regions of the same gene can produce different disease syndromes in both severity and the major tissues involved. One reason for heterogeneity in pathologic manifestations is that different regions of a large molecule may be more important for its function in some connective tissues than in others. For example, some regions of the type I collagen molecule may be essential for the binding of mineralizing proteins in bone so that mutations in these regions cause fragile bones but do not impair function in skin and other nonmineralizing tissues. It is more difficult, however, to explain how the same mutation can produce a severe phenotype in some and a mild phenotype in other members of the same family. Such phenotypic variation appears to be characteristic of OI, where some subjects are short and have multiple fractures from minor trauma, whereas others in the same family can be of normal stature and free of fractures. In the past, such phenotypic variation was explained by undefined variations in the genetic background of different family members. Studies in transgenic mice, however, demonstrated similar phenotypic variation with expression of a mutated collagen gene in an inbred strain of mice whose genetic background was uniform. Therefore, the phenotypic variation is probably caused by undefined stochastic or chance events during embryonic and fetal development. Although dramatic phenotypic variations are relatively rare in OI and related disorders, it is important to consider in counseling families about the consequences of inherited mutations.

SPECIFIC DISORDERS

OSTEOGENESIS IMPERFECTA OI causes a generalized decrease in bone mass (osteopenia) and makes the bones brittle. The disorder is frequently associated with blue sclerae, dental abnormalities (dentinogenesis imperfecta), progressive hearing loss, and a positive family history. The most severe forms cause death in utero, at birth, or shortly thereafter. The course of mild and moderate forms is more variable. Some patients appear normal at birth and become progressively worse. Some have multiple fractures in infancy and childhood, improve after puberty, and fracture more frequently later in life. Women are particularly prone to fracture during pregnancy and after menopause. A few women from families with mild variants of OI do not develop fractures until after menopause, and their disease may be difficult to distinguish from postmenopausal osteoporosis.

TABLE 342-2 *Classification of Osteogenesis Imperfecta (OI)*

Type	Bone Fragility	Blue Sclerae	Abnormal Dentition	Hearing Loss	Inheritance[a]
I	Mild	Present	Present in some	Present in most	AD
II	Extreme	Present	Present in some	Unknown	S, rarely AR
III	Severe	Bluish at birth	Present in some	High incidence	AD, rarely AR
IV	Variable	Absent	Absent in IVA, present in IVB	High incidence	AD

[a] AD, autosomal dominant; AR, autosomal recessive; S, sporadic.

Classification The most common classification for OI was developed by Sillence (Table 342-2). Type I, the mildest form, is inherited as an

autosomal dominant trait. Most patients have distinctly blue sclerae. Type II is lethal in utero or shortly after birth. Types III and IV are intermediate in severity between types I and II. They differ from type I because they are greater in severity and because blue sclerae are absent or only slightly bluish in infancy and white in adulthood. Type III differs from type IV because it tends to become more severe with age. The distinction between type IV and type III OI may not be helpful. Therefore, it may be sufficient to classify patients simply as mild (type I), lethal (type II), and moderately severe (type III).

Incidence Type I OI has a frequency of about 1 in 30,000. Type II OI has a reported incidence at birth of about 1 in 60,000, but the combined incidence of the three severe forms that are recognizable at birth (types II, III, and IV) may be much higher.

Skeletal Changes In type I OI, the fragility of bones may be severe enough to limit physical activity or so mild that individuals are unaware of any disability. Radiographs of the skull in patients with mild disease may show a mottled appearance because of small islands of irregular ossification. In type II OI, bones and other connective tissues are so fragile that massive injuries can occur in utero or during delivery. Ossification of many bones is frequently incomplete. Continuously beaded or broken ribs and crumpled long bones (accordina femora) may be present. For unclear reasons, the long bones may be either thick or thin. In types III and IV, multiple fractures from minor physical stress can produce severe deformities. Kyphoscoliosis can impair respiration, cause cor pulmonale, and predispose to pulmonary infections. On radiographs the appearance of "popcorn-like" deposits of mineral on the ends of long bones is an ominous sign. Progressive neurologic symptoms may result from basilar compression and communicating hydrocephalus.

In all forms of OI, bone mineral density in unfractured bone is decreased. However, the degree of osteopenia may be difficult to evaluate because recurrent fractures limit exercise and thereby worsen the decrease in bone mass. Surprisingly, fractures appear to heal normally.

Ocular Changes The sclerae can be normal, slightly bluish, or bright blue. The color is probably caused by a thinness of the collagen layers of the sclerae that allows the choroid layers to be seen. Blue sclerae, however, are an inherited trait in some families who do not have increased bone fragility.

Dentinogenesis Imperfecta The teeth may be normal, moderately discolored, or grossly abnormal. The enamel generally appears normal, but the teeth may have a characteristic amber, yellowish brown, or translucent bluish gray color because of improper deposition or deficiency of dentin. The deciduous teeth are usually smaller than normal, whereas permanent teeth are frequently bell-shaped and restricted at the base. In some patients, the teeth readily fracture and need to be extracted. The defect in dentin is directly attributable to the fact that normal dentin is rich in type I collagen. Similar tooth defects, however, can be inherited without any evidence of OI.

Hearing Loss Hearing loss usually begins during the second decade of life and occurs in more than 50% of individuals over age 30. The loss can be conductive, sensorineural, or mixed and varies in severity. The middle ear usually exhibits maldevelopment, deficient ossification, persistence of cartilage in areas that are normally ossified, and abnormal calcium deposits.

Associated Features Changes in other connective tissues can include thin skin that scars extensively, joint laxity with permanent dislocations indistinguishable from those of EDS, and, occasionally, cardiovascular manifestations such as aortic regurgitation, floppy mitral valves, mitral incompetence, and fragility of large blood vessels. For reasons unknown, some patients develop a hypermetabolic state with elevated serum thyroxine levels, hyperthermia, and excessive sweating.

Molecular Defects Most patients with OI have mutations in one of the two genes that encode type I procollagen. Over 90% of patients with type I OI and blue sclerae have mutations in the proα1(I) gene that decrease the steady-state levels of the mRNA for proα1(I) chains and decrease the rates of synthesis of proα1(I) chains relative to those for proα2(I) chains. In more severe forms (types II, III, and IV), the effects of mutations that cause synthesis of abnormal proα chains are amplified by the three mechanisms discussed above (Fig. 342-1). Mutations that change the structure of the protein near the N-proteinase cleavage site cause accumulation of a partially processed procollagen and produce lax joints similar to those in type VII EDS that is caused by mutations in the gene for the N-proteinase. Mutations that change the structure in the middle or near the C terminus of the molecule tend to cause severe or lethal variants of OI. It is difficult, however, to correlate the site or nature of the mutation with the clinical phenotype (Fig. 342-2). Most patients are heterozygotes with mutations in a single allelle, but rare patients are homozygotes with two mutated alleles for proα1(I) or proα2(I) chains.

Mosaicism in Germ-Line Cells and in Somatic Cells Most lethal OI is the result of new autosomal dominant mutations. The frequency of a second child with lethal OI in the same family, however, is about 7% because of germ-line mosaicism in one of the parents. The presence of germ-line mosaicism has been indicated in several fathers of patients with type II OI by demonstrating the mutated gene in a fraction of their sperm. Because of the possibility for germ-line mosaicism, asymptomatic parents of a child with severe OI should be counseled that recurrence can occur.

Diagnosis Diagnosis is usually made on the basis of clinical criteria. The presence of fractures together with blue sclerae, dentinogenesis imperfecta, or family history of the disease is usually sufficient to make the diagnosis. Other causes of pathologic fractures must be excluded, including the battered child syndrome, nutritional deficiencies, malignancies, and other inherited disorders such as CDs and hypophosphatasia. The absence of superficial bruises can be helpful in distinguishing OI from battered child syndrome. X-rays usually reveal a decrease in bone density that can be verified by photon or x-ray absorptiometry. There is no consensus, however, as to whether the diagnosis can be made by microscopy of bone. A molecular defect in type I procollagen can be demonstrated in at least half of patients by incubating skin fibroblasts with radioactive amino acids and then analyzing the proα chains by polyacrylamide gel electrophoresis. The analysis detects decreases in the rate of synthesis of proα1(I) chains relative to proα2(I) chains, abnormally long proα chains, abnormally short proα chains, and proα chains with excessive posttranslational modification because of an amino acid substitution that impairs folding of the triple helix. The mutations themselves can be defined in most patients by the sequencing of genomic DNA. Because each proband and family usually has a "private" mutation, extensive analysis of about 10,000 bases in each of the two genes is required to identify the exact mutation. After a mutation in a type I procollagen gene is identified, a simple test based on the polymerase chain reaction can be used to screen family members at risk and for prenatal diagnosis.

Rx TREATMENT

Many patients with OI have successful careers despite severe deformities. Those with mild disorder may need little treatment when fractures decrease after puberty, but women require special attention during pregnancy and after menopause, when fractures again increase. More severely affected children require a comprehensive program of physical therapy, surgical management of fractures and skeletal deformities, and vocational education.

Many of the fractures are only slightly displaced and have little soft tissue swelling. Therefore, they can be treated with minimal support or traction for a week or two followed by a light cast. If fractures are relatively painless, physical therapy can be initiated early. A judicious amount of exercise prevents loss of bone mass secondary to physical inactivity. Some physicians advocate insertion of steel rods into long bones to correct limb deformities; the risk/benefits and cost/

benefits of such procedures are difficult to evaluate. Aggressive conventional intervention is usually warranted for pneumonia and cor pulmonale. For severe hearing loss, stapedectomy or replacement of the stapes with a prosthesis may be successful. Moderately to severely affected patients should be evaluated periodically to anticipate possible neurologic problems. About half of children have a substantial increase in growth when given growth hormone. Treatment with bisphosphonates to decrease bone loss has been introduced on an experimental basis. Initial results are promising, but the long-term effects of decreasing bone resorption are unknown. Also, a clinical trial has been initiated to use stromal cells from bone marrow that can differentiate into osteoblasts after systemic infusion. In the first phase of the trial, four children with severe OI (type III) showed clinical improvement after marrow ablation and transplantation of whole bone marrow from an HLA-compatible sibling.

Counseling and emotional support are important for patients and their parents; and lay organizations in some countries provide help in these areas. Prenatal ultrasonography will detect severely affected fetuses at about 16 weeks of pregnancy. Diagnosis by demonstrating synthesis of abnormal proα chains or by DNA sequencing can be carried out in chorionic villa biopsies at 8 to 12 weeks of pregnancy.

EHLERS-DANLOS SYNDROME EDS is characterized by hyperelasticity of the skin and hypermobile joints.

Classification Nine types of EDS were initially defined primarily based on the extent to which the skin, joints, and other tissues are involved. Type I is the classic, severe form of the disease, with both severe joint hypermobility and skin that is velvety in texture, hyperextensible, and easily scarred. Type II is similar to type I but milder. In type III, joint hypermobility is more prominent than skin changes. In type IV, the skin changes are more prominent than joint changes. However, type IV patients are predisposed to sudden death from rupture of large blood vessels or other hollow organs. Type V is similar to type II but is inherited as an X-linked trait. Type VI is characterized by scoliosis, ocular fragility, and a cone-shaped deformity of the cornea (keratoconus). Type VII is characterized by marked joint hypermobility that is difficult to distinguish from type III except by the specific molecular defects in the processing of type I procollagen to collagen. Type VIII is distinguished by prominent periodontal changes. Types IX, X, and XI were defined on the basis of preliminary biochemical and clinical data, but these classifications have not proven to be useful. Because of overlapping signs and symptoms, many patients and families with some of the features of EDS cannot be assigned to any of the defined types.

Incidence The incidence of EDS is difficult to establish, largely because patients with mild skin or joint symptoms rarely seek medical attention. It is also difficult to define the normal range of variation for joint mobility or skin elasticity. The incidence may be about 1 in 5000 births, although a higher value has been reported for blacks. Types I, II, and III account for most diagnoses.

Skin The changes vary from thin and velvety skin to skin that is either dramatically hyperextensible ("rubber man" syndrome) or easily torn or scarred. Type I patients develop characteristic "cigarette-paper" scars. In type IV extensive scars and hyperpigmentation develop over bony prominences, and the skin may be so thin that subcutaneous blood vessels are visible. In type VIII the skin is more fragile than hyperextensible, and it heals with atrophic, pigmented scars. Easy bruisability occurs in several types of EDS.

Ligament and Joint Changes Laxity and hypermobility of joints vary from mild to unreducible dislocations of hips and other large joints. In mild forms, patients learn to reduce dislocations by limiting physical activity. In more severe forms, surgical repair may be required. Some patients have progressive difficulty with age, but severe joint laxity is compatible with a normal life span.

Associated Changes Mitral valve prolapse and hernias occur, particularly with type I. Pes planus and mild to moderate scoliosis are common. Extreme joint laxity and repeated dislocations may lead to degenerative arthritis. In type VI, the eye may rupture with minimal trauma, and kyphoscoliosis can cause respiratory impairment. Also, sclerae may be blue.

Molecular Defects Mutations in two of the three genes for type V collagen have been found in patients with types I and II EDS. Mutations in both the α1(V) and α2(V) chain are found in patients with type I EDS, but to date only mutations in the α1(V) chain have been found in patients with type II EDS.

Most patients with type IV EDS have a defect either in the synthesis or structure of type III procollagen, a finding consistent with the fact that these patients are prone to spontaneous rupture of the aorta and intestines, tissues rich in type III collagen. The thinness and scarring of skin are more difficult to explain, since type III constitutes a small fraction of the collagen in skin (Table 342-1). Most of the 500 or more mutations in the type III procollagen gene lead to synthesis of abnormal but partially functional proα1(III) chains that produce procollagen suicide or alter fibril formation by the same mechanisms that amplify the effects of mutations in the genes for type I procollagen. Similar mutations in type III procollagen can cause aortic aneurysms in some individuals without other evidence of EDS type IV, MFS, or other inherited disorders of connective tissue.

Type VI EDS is caused by mutations in the gene that encodes lysyl hydroxylase. In one series, all the patients were homozygous or compound heterozygotes for the mutated genes, and all the mutations caused profound deficiency of lysyl hydroxylase, a decrease in the hydroxylysine content of collagen, and a decrease in the cross-links in collagen fibers. The decrease in cross-links is explained by the observation that some cross-links are less stable if formed from lysine instead of hydroxylysine.

Type VII EDS occurs because of a defect in the conversion of procollagen to collagen caused either by mutations that make type I procollagen resistant to cleavage by procollagen N-proteinase or by mutations that decrease the activity of the enzyme. The type VIIA mutations alter the cleavage site in the proα1(I) chain, and the type VIIB mutations alter the cleavage site in the proα2(I) chain. Both types are dominantly inherited. Type VIIC is caused by mutations that decrease the activity of procollagen N-proteinase and is inherited as an autosomal recessive trait. In all three forms of type VII EDS, the persistence of the N-propeptide causes the formation of collagen fibrils that are thin and irregular. Since most patients do not have clinical osteopenia, the thin and irregular fibrils apparently suffice for the structural integrity of bone but do not provide the necessary tensile strength for ligaments and joint capsules. However, some patients fracture easily, and their disorder is difficult to distinguish from variants of OI.

The cause of type VIII EDS is unknown. Type IX is a disorder of copper transport. The syndrome, also referred to as *Menkes' syndrome*, is due to an X-linked defect and is associated with cutis laxa, hypopigmentation, unusual hair ("kinky"), vascular aneurysms, neurologic degeneration, and mental retardation. Mutations in a gene coding for a copper-transporting ATPase cause the disease (Chaps. 339 and 344). Type X EDS may be caused by defects in fibronectin, but no specific mutations have been defined.

Diagnosis The diagnosis is based on clinical criteria. Biochemical assays and gene analyses for known molecular defects in EDS are difficult and time-consuming, but specific diagnostic tests should be available in the future for families in whom the genes at fault have been defined.

Rx TREATMENT

There is no specific therapy. Surgical repair and tightening of joint ligaments require careful evaluation of individual patients, as the ligaments frequently do not hold sutures. Patients with easy bruisability should be evaluated for other bleeding disorders. Patients with type IV EDS and members of their families should probably be evaluated

at regular intervals by sonography and related techniques for early detection of aneurysms. Surgical repair of aneurysms may be difficult because of increased friability of tissues, and there is limited experience with elective surgery in such patients. Also, women with type IV EDS should be counseled about the increased risk of uterine rupture, bleeding, and other complications of pregnancy.

CHONDRODYSPLASIAS (See also Chap. 334.) The CDs are inherited skeletal disorders that cause dwarfism and abnormal body proportions. The category also includes some individuals with normal stature and body proportions who have features such as ocular changes or cleft palate that are common in more severe CDs. Many patients develop degenerative joint changes, and mild CD in adults may be difficult to differentiate from primary generalized osteoarthritis. Some authors refer to the disorders as "skeletal dysplasias," but CD is a more widely used term.

Classification Over 150 distinct types and subtypes have been defined based on criteria such as "bringing death" (thanatophoric), causing "twisted" bones (diastrophic), affecting metaphyses (metaphyseal), affecting epiphyses (epiphyseal), and producing histologic changes such as an apparent increase in the fibrous material in the epiphyses (fibrochondrogenesis). Also, a number of eponyms are based on the first or most comprehensive case reports. Severe forms of the diseases produce gross distortions of most cartilaginous structures and of the eye. Mild forms are more difficult to classify. Among the features are cataracts, degeneration of the vitreous and retinal detachment, high forehead, hypoplastic facies, cleft palate, short extremities, and gross distortions of the epiphyses, metaphyses, and joint surfaces.

Incidence Data on the frequency of most CDs are not available, but the incidence of the Stickler syndrome may be as high as 1 in 10,000. Therefore, the diseases are probably among the more common heritable disorders of connective tissue.

Molecular Defects The first mutations shown to cause CDs were in the COL2A1 gene for type II collagen, the most abundant protein in cartilage. A number of mutations in this gene have now been reported in variants of CD ranging from mild to lethal. A large fraction of patients with lethal CDs, a smaller number of patients with moderately severe CDs, and about 2% of families with early-onset generalized osteoarthritis have mutations in the same gene. However, similar phenotypes can also be caused by mutations in other genes, including genes for three other collagens, additional components of the cartilage matrix, growth factors, growth factor receptors, and transcription factors. The number of mutated genes reported does not necessarily reflect the incidence of such mutations in the diseases themselves but rather the complexity of the genes and the technical difficulties in searching the complete gene for mutations. Also, it reflects the availability of large families for DNA linkage analysis and the vigor with which investigators have pursued their interest in a given gene. It is likely that mutations in additional genes will be found.

Mutations in the COL2A1 gene were first found in patients with severe CDs characterized by gross deformities of bones and cartilage such as spondyloepiphyseal dysplasia congenita, hypochondrogenesis/achondrogenesis II, and the Kniest syndrome. However, mutations in the COL2A1 gene have been found in a few families where few if any symptoms are present in childhood, but joint stiffness, joint pain, and degenerative changes of osteoarthritis develop in midlife. The mutations in the COL2A1 gene are similar to the mutations in the genes for types I and III procollagens, and the correlations between genotype and the severity of the phenotype are equally difficult. Stickler syndrome and related syndromes are caused by mutations in three different genes: the COL2AI gene for type II collagen and the COL11A1 and COL11A2 genes for type XI collagen. A series of mutations that introduce premature terminal signals in the COL2A1 gene lead to classic Stickler syndrome. However, some patients with classic Stickler syndrome have glycine substitutions in COL11A1. RNA splicing mutations in the COL11A1 gene are found in patients with the Marshall syndrome, which is similar to classic Stickler syndrome but with milder eye changes and more severe hearing loss.

Many individuals with the Schmid metaphyseal CD, characterized by short stature, *coxa vara*, flaring metaphyses, and waddling gait, have mutations in the gene for the type X collagen, a short, network-forming collagen found primarily in the hypertrophic zone of endochondral cartilage.

Mutations in the receptor for fibroblast growth factor (FGFR3) are present in most patients with achondroplasia, the most common cause of short-limbed dwarfism accompanied by macrocephaly and dysplasias of the metaphyses of long bones. The same single-base mutation in the gene that converts glycine to arginine at position 380 is present in >90% of patients. Most patients represent sporadic new mutations, and this nucleotide change must be one of the most common recurring mutations in the human genome. The mutation causes unregulated signal transduction through the receptor and inappropriate development of cartilage. Mutations that alter other domains of FGFRE3 have been found in patients with the more severe disorders hypochondroplasia and thanatophoric dysplasia and in a few families with a variant of craniosynostosis. However, most patients with craniosynostosis appear to have mutations in the related *FGFR2 gene*.

Mutations in the gene for the cartilage oligomeric matrix protein (COMP) have been found in patients with multiple epiphyseal dysplasia or pseudoachondroplasia and in related syndromes characterized by short limbs and degenerative arthritis. However, some families with multiple epiphyseal dysplasia had a mutation in the gene for the α1(IX), α2(IX), or α3(IX) chain of type IX collagen (COL9A1, COL9A2, and COL9A3), or matrilin-3. All the known mutations in these two type IX collagen genes in patients with multiple epiphyseal dysplasia cause splicing out of the codons in the same domain. One predisposing mutation in COL9A2 and one predisposing mutation in COL9A3 were found in Finnish patients with the common condition of sciatica and herniations of vertebral discs.

Diagnosis The diagnosis of severe forms of CD is made on the basis of the physical appearance, x-ray findings, histologic changes, and clinical course.

℞ TREATMENT

No definitive therapy is available. Symptomatic treatment is directed to secondary features such as degenerative arthritis. Many patients require joint replacement surgery and corrective surgery for cleft palate. The eyes should be monitored carefully for the development of cataracts and the need for laser therapy to prevent retinal detachment. Patients should probably be advised to avoid obesity and contact sports. Counseling for the psychological problems of short stature is critical, and support groups have formed in many countries. Ultrasonography is sometimes successful for prenatal diagnosis but is less successful than for OI. Specific DNA tests are available for the CDs caused by mutations in most of the genes identified to date.

MARFAN SYNDROME MFS is characterized by a triad of features: (1) long, thin extremities frequently associated with other skeletal changes, such as loose joints and arachnodactyly; (2) reduced vision as the result of dislocations of the lenses (ectopia lentis); and (3) aortic aneurysms that typically begin at the base of the aorta.

Classification The clinical diagnosis is frequently problematic because some affected members of families with MFS present with only one or two features of the typical clinical triad. Also, many patients present with one or two of the features of MFS without a family history, apparently because they represent sporadic mutations. Therefore, it is frequently difficult to determine whether a patient with ectopia lentis or the characteristic body habitus of MFS is at risk for developing a life-threatening aortic aneurysm on the basis of clinical data alone. The new DNA diagnostic tests for mutations in the fibrillin-1 and fibrillin-2 genes can probably resolve most, but not all, of these prob-

lems. Most patients who are prone to develop an aortic aneurysm as a component of MFS can be identified by detection of mutations in the fibrillin-1 gene. Some of these patients develop aortic aneurysms because of a mutation in the fibrillin-1 gene without the skeletal or ocular changes characteristic of MFS. Patients with the rarer form of MFS, which is characterized by contractural arachnodactyly instead of loose joints, can usually be identified by detection of a mutation in the fibrillin-2 gene that is similar in structure to the gene for fibrillin-1. Preliminary data suggest that patients with mutations in the fibrillin-2 gene are not prone to develop aneurysms. However, affected members of some rare families with a mutation in the fibrillin-1 gene also do not develop aortic aneurysms, even though they may show the skeletal or ocular changes. Therefore, the DNA tests are most helpful if: (1) a mutation is detected in either of the two genes, and (2) informative data are available on the clinical symptoms that the same mutation produces in the patient's family or in other families with similar clinical features.

Incidence and Inheritance MFS has an incidence of about 1 in 10,000 in most racial and ethnic groups. The disorder is inherited as an autosomal dominant trait; at least one-fourth of patients do not have an affected parent, and therefore probably represent new mutations.

Skeletal Changes Patients have long limbs and are usually tall compared to other members of the same family. The ratio of the upper segment (top of the head to the top of the pubic ramus) to the lower segment (top of the pubic ramus to the floor) is usually 2 SDs below mean for age, race, and sex. The fingers and hands are long and slender and have a spider-like appearance (arachnodactyly). Many patients have severe chest deformities, including depression (pectus excavatum), protrusion (pectus carinatum), or asymmetry. Scoliosis is frequent and usually accompanied by kyphosis. High-arched palate and high pedal arches or pes planus are common. A few patients have severe joint hypermobility similar to EDS.

Cardiovascular Changes Cardiovascular abnormalities are the major source of morbidity and mortality (Chap. 231). Mitral valve prolapse develops early in life and in about one-quarter of patients progresses to mitral valve regurgitation of increasing severity because of redundancy of the leaflets, stretching of the chordae tendineae, and dilatation of the valvulae annulus. Dilatation of the root of the aorta and the sinuses of Valsalva are characteristic and ominous features of the disease that can develop at any age and in rare instances may be detected by echocardiography in utero. The rate of dilatation is unpredictable, but it can lead to aortic regurgitation, dissection of the aorta, and rupture. Dilatation is probably accelerated by physical and emotional stress, as well as by pregnancy.

Ocular Changes Dislocations of the lens may be readily apparent, but diagnosis usually requires pupillary dilatation and slit-lamp examination. The displacement is usually not progressive but may contribute to the formation of cataracts. The ocular globe is frequently elongated; most patients are myopic, and some develop retinal detachment. A few patients have lattice degeneration and retinal tears; most have adequate vision.

Associated Changes Striae may occur over the shoulders and buttocks. Otherwise the skin is normal. A number of patients develop spontaneous pneumothorax. Inguinal and incisional hernias are common. Marked dilatation of the dural sac is seen frequently in computed tomography scans, but the condition is usually asymptomatic. Patients are typically thin with little subcutaneous fat, but adults may develop centripetal obesity.

Molecular Defects Most patients with the classic features of MFS are heterozygotes for mutations in a gene on chromosome 15 that encodes fibrillin-1, a glycoprotein of 350 kDa that is a major component of elastin-associated microfibrils. These microfibrils are abundant in large blood vessels and the suspensory ligaments of the lens. Mutations in the fibrillin-1 gene include missense, nonsense, in-frame deletions, and RNA splicing mutations. Many of the mutations are single amino acid substitutions in the epidermal growth factor-like domains of the molecule that may be involved in calcium binding. Mutations in the fibrillin-2 gene that cause the MFS variant characterized by contractures appear to follow a similar pattern. As with most genetic diseases, the nature and location of mutations in the genes are only an approximate guide to the severity of the phenotype unless the same mutation has been seen in other members of the same family or in similar unrelated patients. However, there is a clustering of mutations in the middle portion of the molecule of fibrillin-1 encoded by exons 23 to 32 that causes the most severe phenotype, referred to as *neonatal MFS*. The function of fibrillin has not been defined, but the data suggest that fibrillin self-assembles into a fibrillar structure and that the conformation and surface properties of the entire molecule are critical for normal assembly. Therefore, the functional consequences of mutations that change the amino acid sequence of fibrillin may be similar to the effects of mutations that change the conformation of a fibrillar collagen.

Diagnosis The diagnosis is easily established if the patient and other members of the family have dislocated lenses, aortic dilatation, and long and thin extremities together with kyphoscoliosis or other chest deformities. The diagnosis is frequently made if ectopia lentis and an aneurysm of the ascending aorta occur in the absence of a Marfan habitus or a positive family history. All patients with suspected diagnosis should have a slit-lamp examination and an echocardiogram. Also, homocystinuria should be ruled out by a negative cyanide-nitroprusside test for disulfides in the urine (Chap. 343). A few patients with types I, II, and III EDS have ectopia lentis but lack the Marfan habitus and instead have characteristic skin changes not present in MFS. Patients with familial aortic aneurysms tend to develop aneurysms at the base of the abdominal aorta. The location of the aneurysms, however, is somewhat variable, and the high incidence of aortic aneurysms in the general population (1 in 100) makes the differential diagnosis difficult unless other features of MFS are clearly present. A few families with familial aortic aneurysms have mutations in the gene for type III procollagen.

Rx TREATMENT

There is no established treatment, but several investigators have recommended use of propranolol or other β-adrenergic blocking agents to lower blood pressure and thereby delay or prevent aortic dilatation. Surgical correction of the aorta, aortic valve, and mitral valve has been successful in some patients; all patients should be followed carefully with echocardiography and other techniques for evaluation of cardiovascular changes (Chap. 231). Patients should probably be advised of the risks of severe physical and emotional stress and of pregnancy.

The scoliosis tends to be progressive and should be treated by mechanical bracing and physical therapy if $>20°$ or by surgery if it progresses to $>45°$. Dislocated lenses rarely require surgical removal, but patients should be followed closely for retinal detachment.

Diagnostic tests based on detection of fibrillin defects in cultured skin fibroblasts or DNA analysis of the gene are now available from several laboratories.

DISEASES RELATED TO ELASTIN As may be expected from the role of elastin in maintaining the elasticity of skin, mutations in the elastin gene cause *cutis laxa*, a rare and heterogeneous group of disorders characterized by skin that is both lax and inelastic.

EPIDERMOLYSIS BULLOSA EB consists of a group of similar disorders in which the skin and related epithelial tissues break and blister as the result of minor trauma. As with most heritable disorders of connective tissues, the clinical manifestations range from lethal to mild.

Classification Four types of EB are defined on the basis of the level at which blistering occurs: EB simplex for blistering in the epidermis, EB hemidesmosomal for fissures between kerotinocytes and the basal

lamina, EB junctional for blistering in the dermal-epidermal junction, and EB dystrophica for blistering in the dermis.

Incidence The incidence of EB in the United States is estimated to be 1 in 50,000.

Molecular Defects The molecular basis of several specific variants of EB has been defined. A series of patients with EB simplex were found to have mutations in either keratin 14 or keratin 5, two of the major keratins in basal epithelial cells. Patients with the related syndrome, epidermolytic icthyosis, have mutations in keratin 1 and keratin 10. The new disease phenotype of hemidesmosomal EB has three clinical variants that are caused by mutations in one of four genes: (1) A generalized atrophic and benign form of EB is caused by mutations in the COL17A1 gene for type XVII collagen; (2) a variant with EB associated with pyloric atresia and other intestinal abnormalities is caused by mutations in either the gene for the α6 integrin (ITG A6) or the gene for the β4 integrin (ITG B4); and (3) another variant characterized by relatively mild blistering at birth but associated with late-onset muscular dystrophy is caused by mutations in the gene for plectin (PLEC-1). Junctional EB is caused by mutations in any one of three genes for laminin (LAMA-3, LAMB-3, LAMC-2). The most severe dystrophic form of EB is caused by mutations in the gene for type VII collagen (COL7A1) that forms the anchoring fibers binding the epidermis to the dermis.

Diagnosis The diagnosis is based on skin that readily breaks and forms blisters. Also, DNA diagnostic tests are available. EB simplex and EB hemidesmosomal are generally milder than EB junctional or EB dystrophica. EB dystrophica variants usually cause large and prominent scars. Precise classification within subtypes usually requires electron microscopy. The treatment is symptomatic.

ALPORT SYNDROME AS is an inherited disorder characterized by hematuria. Four forms of the disease are now recognized: (1) classic AS, which is inherited as an X-linked disorder with hematuria, sensorineural deafness, and conical deformation of the anterior surface of the lens (lenticonus); (2) a subtype of the X-linked form associated with diffuse leiomyomatosis; (3) an autosomal recessive form; and (4) an autosomal dominant form. The two autosomal forms can cause renal disease without deafness or lenticonus.

Incidence The incidence of AS is about 1 in 10,000 in the general population and as high as 1 in 5000 in some ethnic groups. About 80% of AS patients have the X-linked variant.

Molecular Defects Electron microscopy of kidneys from patients with classic AS demonstrates that the glomerular basement membrane is up to five times thicker than normal and the lamina densa is distorted and split. The X-linked and autosomal recessive forms are caused primarily by mutations in genes for the α3(IV), α4(IV), α5(IV), or α6(IV) chains of type IV collagen, a major component of basement membranes. The genes for the proteins are arranged in tandem pairs on different chromosomes in a head-to-head orientation and with overlapping promoters, i.e., the α1(IV) and α2(IV) genes are head-to-head on chromosome 13q34, the α3(IV) and α4(IV) genes are on chromosome 2q35-37, and the α5(IV) and α6(IV) genes are on chromosome Xq22. An X-linked variant is caused by mutations in the COL4A5 gene, and the X-linked variant associated with leiomyomatosis is caused by deletions that involve both the COL4A5 gene and the nearby COL4A6 gene. The autosomal recessive variants are caused by mutations in either the COL4A3 or COL4A4 genes. The mutations responsible for the autosomal dominant variants are still unknown, but they have been mapped to the same locus as the COL4A3 and COL4A4 genes.

Diagnosis The diagnosis of classic AS is based on X-linked inheritance of hematuria, sensorineural deafness, and lenticonus. Because of the X-linked transmission, women are generally underdiagnosed and are usually less severely affected than men. The hematuria progresses to nephritis and may cause renal failure in late adolescence in affected males and at older ages in some women. The sensorineural deafness is primarily in the high-tone range. It can frequently be detected only by an audiogram and is usually not progressive. The lenticonus can occur without nephritis but is generally considered to be pathognomonic of classic ASR. Renal transplantation is usually successful.

ACKNOWLEDGMENT

The authors acknowledge the contributions of Helena Kuivaniemi and Gerard Tromp to this chapter in previous editions of Harrison's.

343 INHERITED DISORDERS OF AMINO ACID METABOLISM PRESENTING IN ADULTS

Nicola Longo

Amino acids are not only the building blocks of proteins but also serve as neurotransmitters (glycine, glutamate, γ-aminobutyric acid) or as precursors of hormones, coenzymes, pigments, purines, or pyrimidines. Eight amino acids, referred to as *essential*, cannot be synthesized by humans and must be obtained from dietary sources. The others are formed endogenously. Each amino acid has a unique degradative pathway by which its nitrogen and carbon components are used for the synthesis of other amino acids, carbohydrates, and lipids. Disorders of amino acid metabolism and transport (Chap. 344) are individually rare—the incidences range from 1 in 10,000 for cystinuria or phenylketonuria to 1 in 200,000 for homocystinuria or alkaptonuria—but collectively they affect perhaps 1 in 1000 newborns. Almost all are transmitted as autosomal recessive traits.

The features of inherited disorders of amino acid catabolism are summarized in Table 343-1. In general, these disorders are named for the compound that accumulates to highest concentration in blood (*-emias*) or urine (*-urias*). For many conditions (often called *aminoacidopathies*), the parent amino acid is found in excess; for others, generally referred to as *organic acidemias*, products in the catabolic pathway accumulate. Which compound(s) accumulates depends, of course, on the site of the enzymatic block, the reversibility of the reactions proximal to the lesion, and the availability of alternative pathways of metabolic "runoff." Biochemical and genetic heterogeneity are common. Five distinct forms of hyperphenylalaninemia, seven forms of homocystinuria, and seven types of methylmalonic acidemia are recognized. Such heterogeneity reflects the presence of an even larger array of molecular defects.

The manifestations of these conditions differ widely (Table 343-1). Some, such as sarcosinemia, produce no clinical consequences. At the other extreme, complete deficiency of ornithine transcarbamylase is lethal in the untreated neonate. Central nervous system (CNS) dysfunction, in the form of developmental retardation, seizures, alterations

TABLE 343-1 *Inherited Disorders of Amino Acid Metabolism*

Aminoacid(s)	Condition	Enzyme Defect	Clinical Findings	Inheritance[a]
Phenylalanine	Phenylketonuria type I	Phenylalanine hydroxylase	Mental retardation, microcephaly, hypopigmented skin and hairs, eczema, "mousy" odor	AR
	Phenylketonuria type II	Dihydropteridine reductase	Mental retardation, hypotonia, spasticity, myoclonus	AR
	Phenylketonuria type III	6-Pyruvoyl-tetrahydropterin synthase	Dystonia, neurologic deterioration, seizures, mental retardation	AR
	GTP cyclohydrolase I deficiency	GTP cyclohydrolase I	Mental retardation, seizures, dystonia, temperature instability	AR
	Carbinolamine dehydratase deficiency	Pterin-4α-carbinolamine dehydratase	Transient hyperphenylalaninemia (benign)	AR
Tyrosine	Tyrosinemia type I (hepatorenal)	Fumarylacetoacetate hydrolase	Liver failure, cirrhosis, rickets, failure to thrive, peripheral neuropathy, "boiled cabbage" odor	AR
	Tyrosinemia type II (oculocutaneous)	Tyrosine transaminase	Palmoplantar keratosis, painful corneal erosions with photophobia, mental retardation (?)	AR
	Tyrosinemia type III	4-Hydroxyphenylpyruvate dioxygenase	Hypertyrosinemia with normal liver function, occasional mental delay	AR
	Hawkinsinuria	4-Hydroxyphenylpyruvate dioxygenase	Transient failure to thrive, metabolic acidosis in infancy	AD
	Alkaptonuria	Homogentisic acid oxidase	Ochronosis, arthritis, cardiac valve involvement, coronary artery calcification	AR
	Albinism (oculocutaneous)	Tyrosinase	Hypopigmentation of hair, skin, and optic fundus; visual loss; photophobia	AR
	Albinism (ocular)	Different enzymes or transporters	Hypopigmentation of optic fundus, visual loss	AR, XL
	DOPA-responsive dystonia	Tyrosine hydroxylase	Rigidity, truncal hypotonia, tremor, mental retardation	AR
GABA	4-Hydroxybutyric aciduria	Succinic semialdehyde dehydrogenase	Seizures, mental retardation, ataxia	AR
Tryptophan	Tryptophanuria	Unknown	Mental retardation, ataxia, skin photosensitivity	AR
	Hydroxykinureninuria	Kynureninase	Mental retardation, spasticity	AR
Histidine	Histidinemia	Histidine-ammonia lyase	Benign	AR
	Urocanic aciduria	Urocanase	Benign	AR
	Formiminoglutamic aciduria	Formiminotransferase	Occasional mental retardation	AR
Glycine	Glycine encephalopathy	Glycine cleavage (4 enzymes)	Infantile seizures, lethargy, apnea, profound mental retardation	AR
	Sarcosinemia	Sarcosine dehydrogenase	Benign	AR
	Hyperoxaluria type I	Alanine:glyoxylate aminotransferase	Calcium oxalate nephrolithiasis, renal failure	AR
	Hyperoxaluria type II	D-Glyceric acid dehydrogenase/glyoxylate reductase	Calcium oxalate nephrolithiasis, renal failure	AR
Serine	Phosphoglycerate dehydrogenase deficiency	Phosphoglycerate dehydrogenase	Seizures, microcephaly, mental retardation	AR
Proline	Hyperprolinemia type I	Proline oxidase	Benign	AR
	Hyperprolinemia type II	Δ^1-Pyrroline-5-carboxylate dehydrogenase	Febrile seizures, mental retardation	AR
	Hyperhydroxyprolinemia	Hydroxyproline oxidase	Benign	AR
	Prolidase deficiency	Prolidase	Mild mental retardation, chronic dermatitis	AR
Methionine	Hypermethioninemia	Methionine adenosyltransferase	Usually benign	AR
Homocystine	Homocystinuria	Cystathionine β-synthase	Lens dislocation, thrombotic vascular disease, mental retardation, osteoporosis	AR
	Homocystinuria	5,10-Methylene-tetrahydrofolate reductase	Mental retardation, gait and psychiatric abnormalities, recurrent strokes	AR
	Homocystinuria	Methionine synthase (CblE, -G)	Mental retardation, hypotonia, seizures, megaloblastic anemia	AR
	Homocystinuria and methylmalonic acidemia	Vitamin B_{12} lysosomal efflux and metabolism (CblC, -D, -F)	Mental retardation, lethargy, failure to thrive, hypotonia, seizures, megaloblastic anemia	AR
Cystathionine	Cystathioninuria	γ-Cystathioninase	Benign	AR
Cystine	Cystinosis	Cystinosin CTNS (lysosomal efflux)	Renal Fanconi syndrome, rickets, photophobia, hypotonia, renal failure	AR
S-Sulfo-L-cysteine	Sulfocysteinuria	Sulfate oxidase or molibdenum cofactor deficiency	Seizures, mental retardation, dislocated lenses	AR
Lysine	Hyperlysinemia, saccharopinuria	α-Aminoadipic semialdehyde synthase	Benign	AR
Lysine, tryptophan	α-Ketoadipic acidemia	α-Ketoadipic acid dehydrogenase	Benign	?
	Glutaric acidemia type I	Glutaryl-CoA dehydrogenase	Progressive severe dystonia and athetosis, mild mental retardation	AR
	Glutaric acidemia type II	Electron transfer flavoprotein, ETF ubiquinone oxidoreductase	Hypoglycemia, metabolic acidosis, "sweaty feet" odor, hypotonia, cardiomyopathy	AR

TABLE 343-1 — *(Continued)*

Aminoacid(s)	Condition	Enzyme Defect	Clinical Findings	Inheritance[a]
Ornithine	Gyrate atrophy of the choroid and retina	Ornithine-δ-aminotransferase	Myopia, night blindness, loss of peripheral vision, cataracts, chorioretinal degeneration	AR
Urea cycle	Carbamylphosphate synthase deficiency	Carbamylphosphate synthase I	Lethargy progressing to coma, protein aversion, mental retardation, hyperammonemia	AR
	N-Acetylglutamate synthase deficiency	*N*-Acetylglutamate synthase	Lethargy progressing to coma, protein aversion, mental retardation, hyperammonemia	AR
	Ornithine transcarbamylase deficiency	Ornithine transcarbamylase	Lethargy progressing to coma, protein aversion, mental retardation, hyperammonemia	XL
	Citrullinemia type I	Argininosuccinate synthase	Lethargy progressing to coma, protein aversion, mental retardation, hyperammonemia	AR
	Argininosuccinic acidemia	Argininosuccinate lyase	Lethargy progressing to coma, protein aversion, mental retardation, hyperammonemia	AR
	Arginase deficiency	Arginase	Spastic tetraparesis, mental retardation, mild hyperammonemia	AR
	Hyperornithinemia, hyperammonemia, homocitrullinuria	Mitochondrial ornithine carrier ORNT1	Vomiting, lethargy, failure to thrive, mental retardation, episodic confusion, hyperammonemia, protein intolerance	AR
	Citrullinemia type II	Mitochondrial aspartate/ glutamate carrier CTLN2	Neonatal intrahepatic cholestasis, adult presentation with sudden behavioral changes and stupor, coma, hyperammonemia	AR
Valine	Hypervalinemia	Valine aminotransferase	Vomiting, fever, failure to thrive, hypotonia	AR
Leucine, isoleucine	Hyperleucine-isoleucinemia	Leucine-isoleucine aminotransferase	Seizures, failure to thrive, mental retardation	?
Valine, leucine, isoleucine	Maple syrup urine disease (defective E1α, E1β, E2, E3)	Branched-chain ketoacid dehydrogenase	Lethargy, vomiting, encephalopathy, seizures, mental retardation, "maple syrup" odor, protein intolerance	AR
Leucine	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Acidosis, ketosis, vomiting, coma, hyperammonemia, "sweaty feet" odor, protein intolerance	AR
	3-Methylcrotonyl glycinuria	3-Methylcrotonyl-CoA carboxylase	Stress-induced metabolic acidosis, hypotonia, hypoglycemia, "cat's urine" odor	AR
	3-Methylglutaconic aciduria type I	3-Methylglutaconyl-CoA hydratase deficiency	Stress-induced acidosis, mental retardation, hypotonia, hepatomegaly	AR
	3-Hydroxy-3-methylglutaric aciduria	3-Hydroxy-3-methylglutaryl-CoA lyase	Stress-induced hypoketotic hypoglycemia and acidosis, encephalopathy, hyperammonemia	AR
Isoleucine	3-Oxothiolase deficiency	3-Oxothiolase	Fasting-induced acidosis and ketosis, vomiting, lethargy	AR
Valine, isoleucine, methionine, threonine	Propionic acidemia (pccA, -B,-C)	Propionyl-CoA carboxylase (pcc)	Metabolic ketoacidosis, hyperammonemia, hypotonia, lethargy, coma, protein intolerance, mental retardation, hyperglycinemia	AR
	Multiple carboxylase/ biotinidase deficiency	Holocarboxylase synthase or biotinidase	Metabolic ketoacidosis, diffuse rash, alopecia, seizures, mental retardation	AR
	Methylmalonic acidemia (mutase, CblA, -B)	Methylmalonyl-CoA mutase or cobalamin reductase/ adenosyltransferase	Metabolic ketoacidosis, hyperammonemia, hypertonia, lethargy, coma, protein intolerance, mental retardation, hyperglycinemia	AR

[a] AR, autosomal recessive; XL, X-linked, AD, autosomal dominant.

Note: GTP, guanosine 5′-triphosphate; DOPA, dihydroxyphenylalanine; GABA, γ-aminobutyric acid; Cbl, cobalamin.

in sensorium, or behavioral disturbances, is present in more than half the disorders. Protein-induced vomiting, neurologic dysfunction, and hyperammonemia occur in many disorders of urea cycle intermediates. Metabolic ketoacidosis, often accompanied by hyperammonemia, is a frequent presenting finding in disorders of branched-chain amino acid metabolism. Some disorders produce focal tissue or organ involvement such as liver disease, renal failure, cutaneous abnormalities, or ocular lesions.

The analysis of plasma amino acids (by ion-exchange chromatography) and urine organic acids (by gas chromatography/mass spectrometry) is commonly used to diagnose and monitor most of these disorders. The diagnosis is confirmed by enzyme assay on cells or tissues from the patients or by DNA testing. The clinical manifestations in many of these conditions can be prevented or mitigated if a diagnosis is achieved early and appropriate treatment (i.e., dietary protein or amino acid restriction or vitamin supplementation) is instituted promptly. For this reason, several of these disorders are routinely screened for in newborns. Selected disorders that illustrate the principles, properties, and problems presented by the disorders of amino acid metabolism are discussed in this chapter.

THE HYPERPHENYLALANINEMIAS

The hyperphenylalaninemias (Table 343-1) result from impaired conversion of phenylalanine to tyrosine. The most common and clinically important is *phenylketonuria* (frequency 1:10,000), which is an autosomal recessive disorder characterized by an increased concentration of phenylalanine and its by-products in body fluids and by severe mental retardation if untreated in infancy. It results from reduced activity of phenylalanine hydroxylase (phenylketonuria type I). The accumulation of phenylalanine inhibits the transport of other amino acids required for protein or neurotransmitter synthesis, reduces synthesis and increases degradation of myelin, and leads to inadequate formation of norepinephrine and serotonin. Phenylalanine is a competitive inhibitor of tyrosinase, a key enzyme in the pathway of melanin synthesis, and accounts for the hypopigmentation of hair and skin. Untreated children with classic phenylketonuria are normal at birth, but fail to attain early developmental milestones, develop microcephaly, and demonstrate progressive impairment of cerebral function. Hyperactivity, seizures, and severe mental retardation are major clinical problems later in life. Electroencephalographic abnormalities; "mousy" odor of skin, hair, and urine (due to phenylacetate accumulation); and a ten

dency to hypopigmentation and eczema complete the devastating clinical picture. In contrast, affected children who are detected and treated at birth show none of these abnormalities. To prevent mental retardation, diagnosis and initiation of dietary treatment of classic phenylketonuria must occur before the child is 3 weeks of age. For this reason, most newborns in North America and Europe are screened by determinations of blood phenylalanine levels. Abnormal values are confirmed using quantitative analysis of plasma amino acids. Dietary phenylalanine restriction is usually instituted if blood phenylalanine levels are >250 μmol/L (4 mg/dL). Treatment consists in a special diet low in phenylalanine and supplemented with tyrosine, since tyrosine becomes an essential amino acid in phenylalanine hydroxylase deficiency. With therapy, plasma phenylalanine concentrations should be maintained between 120 and 360 μmol/L (2 and 6 mg/dL). Dietary restriction should be continued and monitored indefinitely. Some patients with milder forms of phenylketonuria (phenylalanine <1200 μm at presentation) show increased tolerance to dietary proteins and improved metabolic control when treated with tetrahydrobiopterin (20 mg/kg per day), an essential cofactor of phenylalanine hydroxylase.

A number of women with phenylketonuria who have been treated since infancy will have reached adulthood and become pregnant. If maternal phenylalanine levels are not strictly controlled before and during pregnancy, their offspring are at increased risk for congenital defects and microcephaly (*maternal phenylketonuria*). After birth, these children have severe mental and growth retardation. Pregnancy risks can be minimized by continuing lifelong phenylalanine-restricted diets and assuring strict phenylalanine restriction 2 months prior to conception and throughout gestation.

THE HOMOCYSTINURIAS (HYPERHOMOCYSTEINEMIAS)

The homocystinurias are seven biochemically and clinically distinct disorders (Table 343-1) characterized by increased concentration of the sulfur-containing amino acid homocystine in blood and urine.

Classic homocystinuria, the most common (frequency 1:200,000), results from reduced activity of cystathionine β-synthase, the pyridoxal phosphate–dependent enzyme that condenses homocysteine with serine to form cystathionine. Most patients present between 3 and 5 years of age with dislocated optic lenses and mental retardation (in about half of cases). Some patients develop a marfanoid habitus and radiologic evidence of osteoporosis. Life-threatening vascular complications (affecting coronary, renal, and cerebral arteries) can occur during the first decade of life and are the major cause of morbidity and mortality. Classic homocystinuria can be diagnosed with analysis of plasma amino acids, showing elevated methionine and presence of free homocystine. Total plasma homocysteine is also extremely elevated (usually >100 μM). Treatment consists in a special diet restricted in protein and methionine and supplemented with cystine. In approximately half of patients, oral pyridoxine (25 to 500 mg/d) produces a fall in plasma methionine and homocystine concentration in body fluids. Folate deficiency should be prevented by adequate supplementation. Betaine is also effective in reducing homocystine levels in pyridoxine-unresponsive patients.

The other forms of homocystinuria are the result of impaired remethylation of homocysteine to methionine. This can be caused by defective methionine synthase or reduced availability of two essential cofactors, 5-methyltetrahydrofolate and methylcobalamin (methyl-vitamin B_{12}).

Hyperhomocysteinemia refers to increased total plasma concentration of homocysteine with or without an increase in free homocystine (disulfide form). Hyperhomocysteinemia, in the absence of significant homocystinuria, is found in some heterozygotes for the genetic defects noted above or in homozygotes for milder variants. Changes of homocysteine levels are also observed with increasing age; in postmenopausal women; in patients with renal failure, hypothyroidism, leukemias, or psoriasis; and during therapy with drugs such as methotrexate, nitrous oxide, isoniazid, and some antiepileptic agents. Homocysteine acts as an atherogenic and thrombophilic agent. An increase in total plasma homocysteine represents an independent risk factor for coronary, cerebrovascular, and peripheral arterial disease as well as for deep-vein thrombosis (Chap. 224). Homocysteine is synergistic with hypertension and smoking, and it is additive with other risk factors that predispose to peripheral arterial disease. In addition, hyperhomocysteinemia and folate and vitamin B_{12} deficiency have been associated with an increased risk of neural tube defects in pregnant women. Vitamin supplements are effective in reducing plasma homocysteine levels in these cases.

ALKAPTONURIA

Alkaptonuria is a rare (frequency 1:200,000) disorder of tyrosine catabolism in which deficiency of homogentisate 1,2-dioxygenase (also known as *homogentisic acid oxidase*) leads to excretion of large amounts of homogentisic acid in urine and accumulation of oxidized homogentisic acid pigment in connective tissues (*ochronosis*). Alkaptonuria may go unrecognized until middle life when degenerative joint disease develops. Prior to this time, about half of the patients might be diagnosed for the presence of dark urine. Foci of gray-brown scleral pigment and generalized darkening of the concha, anthelix, and, finally, helix of the ear usually develop after age 30. Low back pain usually starts between 30 and 40 years of age. *Ochronotic arthritis* is heralded by pain, stiffness, and some limitation of motion of the hips, knees, and shoulders. Acute arthritis may resemble rheumatoid arthritis, but small joints are usually spared. Pigmentation of heart valves, larynx, tympanic membranes, and skin occurs, and occasional patients develop pigmented renal or prostatic calculi. Degenerative cardiovascular disease is increased in older patients. The diagnosis should be suspected in a patient whose urine darkens to blackness. Homogentistic acid in urine is identified by urine organic acid analysis or by a specific colorimetric test. Ochronotic arthritis is treated symptomatically (Chap. 312). Ascorbic acid and protein restriction are not effective in reducing homogentisic acid production. By contrast, nitisone [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione], a drug used in tyrosinemia type I, reduces urinary excretion of homogentisic acid and, in conjunction with a low-protein diet, might prevent the long-term complications of alkaptonuria.

344 INHERITED DEFECTS OF MEMBRANE TRANSPORT

Nicola Longo

Specific membrane transporters mediate the passage of a wide variety of substances across cellular membranes. Classes of substrates include amino acids, sugars, cations, anions, vitamins, and water. The number of inherited disorders of membrane transport continues to increase with the identification of new transporters and the clarification of the molecular basis of diseases with previously unknown pathophysiology. The first transport disorders identified affected the gut or the kidney, but transport processes are now proving essential for the normal function of every organ. Mutations in transporter molecules demonstrate in disorders of the heart, muscle, brain, and endocrine and sensory organs (Table 344-1). Inherited defects impairing the transport of selected amino acids that can present in adults are discussed here as examples of the abnormalities encountered; others are considered elsewhere in this text.

CYSTINURIA Cystinuria (frequency of 1 in 10,000 to 1 in 15,000) is an autosomal recessive disorder caused by defective transporters in the apical brush border of proximal renal tubule and small intestinal cells. It is characterized by impaired reabsorption and excessive urinary excretion of the dibasic amino acids lysine, arginine, ornithine, and cystine. Because cystine is poorly soluble, its overexcretion predisposes to the formation of renal, ureteral, and bladder stones. Such stones are responsible for the signs and symptoms of the disorder.

There are two variants of cystinuria. Homozygotes for both variants have high urinary excretion of cystine, lysine, arginine, and ornithine. Type I heterozygotes have normal urinary amino, whereas non-type I (formerly type II and type III) heterozygotes have moderately increased urinary excretion of each of the four amino acids. The gene for type I cystinuria (*SLC3A1*, chromosome 2p16.3) encodes a membrane glycoprotein. Non-type I cystinuria is caused by mutations in *SLC7A9* (chromosome 19q13) that encodes the $b^{0,+}$ amino acid transporter. The glycoprotein encoded by *SLC3A1* favors the correct processing of the $b^{0,+}$ membrane transporter, and explains why mutations in two different genes cause a similar disease.

Cystine stones account for 1 to 2% of all urinary tract calculi but are the most common cause of stones in children. Cystinuria homozygotes regularly excrete 2400 to 7200 μmol (600 to 1800 mg) of cystine daily. Since the maximum solubility of cystine in the physiologic urinary pH range of 4.5 to 7.0 is about 1200 μmol/L (300 mg/L), cystine needs to be diluted to 2.5 to 7 L of water to prevent crystalluria. Stone formation usually manifests in the second or third decade but may occur in the first year of life. Symptoms and signs are those typical of urolithiasis: hematuria, flank pain, renal colic, obstructive uropathy, and infection (Chap. 268). Recurrent urolithiasis may lead to progressive renal insufficiency.

Cystinuria is suspected after observing typical hexagonal crystals in the sediment of acidified, concentrated, chilled urine or after perfoming a urinary nitroprusside test. Quantitative urine amino acid analysis confirms the diagnosis of cystinuria by showing selective overexcretion of cystine, lysine, arginine, and ornithine. Quantitation is important for differentiating heterozygotes from homozygotes and for following free cystine excretion during therapy.

Management is aimed at preventing cystine crystal formation by increasing urinary volume and by maintaining an alkaline urine pH. Fluid ingestion in excess of 4 L/d is essential, and 5 to 7 L/d is optimal. Urinary cystine concentration should be $<$1000 μmol/L (250 mg/L). The daily fluid ingestion necessary to maintain this dilution of excreted cystine should be spaced over 24 h, with one-third of the total volume ingested between bedtime and 3 A.M. Cystine solubility rises sharply above pH 7.5, and urinary alkalinization (with bicarbonate or polycitrates) can be therapeutic. Penicillamine (1 to 3 g/d) and tiopronin (α-mercaptopropionylglycine, 800 to 1200 mg/d in four divided doses) undergo sulfhydryl-disulfide exchange with cystine to form mixed disulfides. Since these disulfides are much more soluble than cystine, pharmacologic therapy can prevent and promote dissolution of calculi. Penicillamine can have significant side effects and should be reserved for patients who fail to respond to hydration alone or who are in a high-risk category (one remaining kidney, renal insufficiency). When medical management fails, urologic surgery is required but should be a last resort as cystine stones reform more easily in scarred epithelium. Occasional patients progress to renal failure and require kidney transplantation.

DIBASIC AMINOACIDURIA This disorder is characterized by a defect in renal tubular reabsorption of the three dibasic amino acids lysine, arginine, and ornithine but *not* cystine. There are two variants, transmitted as autosomal recessive traits. In the common form of dibasic aminoaciduria (type II), also known as *lysinuric protein intolerance*, homozygotes show defective intestinal transport of dibasic amino acids as well as exaggerated renal losses. It is most common in Finland (1 in 60,000) and is rare elsewhere. The transport defect affects basolateral rather than luminal membrane transport and is associated with impairment of the urea cycle. The defective gene (*SLC7A7*, chromosome 14q11.2) encodes a unique membrane transporter, y^+LAT, which associates with the cell-surface glycoprotein 4F2 heavy chain to form the complete sodium-independent transporter y^+L.

Manifestations are related to the losses of ornithine, arginine, and lysine. Affected patients present in childhood with hepatosplenomegaly, protein intolerance, and episodic ammonia intoxication. Older patients may present with severe osteoporosis, impairment of kidney function, or interstitial changes in the lungs. Plasma concentrations of lysine, arginine, and ornithine are reduced, whereas urinary excretion of lysine and orotic acid are increased. Hyperammonemia may develop after the ingestion of protein loads or with infections, probably because of insufficient amounts of arginine and ornithine to maintain proper function of the urea cycle. The clinical features have been attributed to the hyperammonemia, to insufficient amounts of lysine to support protein synthesis during growth, and to decreased production of nitric oxide caused by arginine deficiency.

Therapy consists of dietary protein restriction and supplementation of citrulline (2 to 8 g/d), a neutral amino acid that fuels the urea cycle when metabolized to arginine and ornithine. Pulmonary disease responds to glycocorticoids or bronchoalveolar lavage in some patients.

HARTNUP DISEASE Hartnup disease (frequency 1 in 24,000) is an autosomal recessive disorder characterized by pellagra-like skin lesions, variable neurologic manifestations, and neutral and aromatic aminoaciduria. Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, glutamine, asparagine, and histidine are excreted in urine in quantities 5 to 10 times normal, and intestinal transport of these same amino acids is defective. The clinical manifestations result from nutritional deficiency of the essential amino acid tryptophan, caused by its intestinal and renal malabsorption, and of niacin, which derives in part from tryptophan metabolism. Only a small fraction of patients with the chemical findings of this disorder develop a pellagra-like syndrome, implying that manifestations depend on other factors in addition to the transport defect. The diagnosis of Hartnup disease should be suspected in any patient with clinical features of pellagra who does not have a history of dietary niacin deficiency (Chap. 61). The neurologic and psychiatric manifestations range from attacks of cerebellar ataxia to mild emotional lability to frank delirium and are usually accompanied by exacerbations of the erythematous, eczematoid skin rash. Fever, sunlight, stress, and sulfonamide therapy provoke clinical relapses. Diagnosis is made by detection of the neutral aminoaciduria, which does not occur in dietary niacin deficiency. Treatment is directed at niacin repletion and includes a high-protein diet and daily nicotinamide supplementation (50 to 250 mg).

TABLE 344-1 *Genetic Disorders of Membrane Transport (Selected Examples)*

Class of Substance and Disorder	Individual Substrates	Tissues Manifesting Transport Defect	Proposed Molecular Basis of Defect	Major Clinical Manifestations	Inheritance
AMINO ACIDS					
Classic cystinuria	Cystine, lysine, arginine, ornithine	Proximal renal tubule, jejunal mucosa	Shared dibasic-cystine transport protein SLC3A1, SLC7A9	Cystine nephrolithiasis	AR
Dibasic amino-aciduria	Lysine, arginine, ornithine	Proximal renal tubule, jejunal mucosa	Dibasic transport protein SLC7A7	Type I: Benign Type II: Protein intolerance, hyperammonemia, retardation	AR
Hypercystinuria	Cystine	Proximal renal tubule	Cystine transport protein	Some risk of cystine nephrolithiasis	AR
Lysinuria	Lysine	Proximal renal tubule, jejunal mucosa	Lysine transport protein	Seizures, physical and mental retardation	Probable AR
Hartnup disease	Neutral amino acids	Proximal renal tubule, jejunal mucosa	Shared neutral amino acid transport protein	Constant neutral aminoaciduria, intermittent symptoms of pellagra	AR
Tryptophan malabsorption	Tryptophan	Jejunal mucosa	Tryptophan transport protein	Indoluria, ?hypercalcemia, ?nephrocalcinosis	Probable AR
Methionine malabsorption	Methionine	Jejunal mucosa	Methionine transport protein	White hair, mental retardation, convulsions, hyperpneic attacks, edema	Probable AR
Histidinuria	Histidine	Proximal renal tubule, jejunal mucosa	Histidine transport protein	Mental retardation	AR
Iminoglycinuria	Glycine, proline, hydroxyproline	Proximal renal tubule, jejunal mucosa	Shared glycine–imino acid transport protein	None	AR
Dicarboxylic-aminoaciduria	Glutamic acid, aspartic acid	Proximal renal tubule, jejunal mucosa	Shared dicarboxylic amino acid transport protein	None	Probable AR
Cystinosis	Cystine	Lysosomal membranes	Cystine transport protein	Renal failure, hypothyroidism, blindness	AR
HEXOSES					
Glucose-galactose malabsorption	D-Glucose D-Galactose	Jejunal mucosa, proximal renal tubule	Shared Na^+-dependent glucose-galactose transport protein SGLT1	Watery diarrhea on feeding glucose, lactose, sucrose, or galactose	AR
Glucose-transport defect	D-Glucose	Ubiquitous	Facilitative glucose transporter GLUT1	Seizures, mental retardation	AD
Fanconi-Bickel syndrome	D-Glucose	Liver, kidney, pancreas, intestine	Facilitative glucose transporter GLUT2	Growth retardation, rickets, hepatorenal glycogenosis, hypo- and hyperglycemia	AR
URATE					
Hypouricemia	Uric acid	Proximal renal tubule	Urate transport protein SLC22A12	Hypouricemia, hyperuricosuria, ?hypercalciuria	AR
ANIONS					
Congenital chloridorrhea	Chloride, sulfate	Ileal and colonic mucosa	Cl^-/HCO_3^- exchange pump carrier protein (DRA)	Hydramnios, watery diarrhea, elevated fecal chloride, metabolic alkalosis with volume depletion, hyperaldosteronism	AR
Dent disease, X-linked recessive hypophosphatemic rickets and nephrocalcinosis	Chloride, phosphate	Proximal renal tubule	Voltage-gated Cl^- channel CLCN5	Proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, rickets	XL
CATIONS					
Nesidioblastosis of pancreas	Potassium	Pancreatic β cell	Sulfonylurea receptor SUR1, K^+ channel KCNJ11	Neonatal hypoglycemia, hyperinsulinemia	AR
Benign familial neonatal epilepsy	Potassium	Brain	Voltage-gated K^+ channels KCNQ2, KCNQ3	Neonatal convulsions, normal development	AD

345 NEUROBIOLOGY OF DISEASE

Stephen L. Hauser, M. Flint Beal

The human nervous system is the organ of consciousness, cognition, ethics, and behavior; as such, it is the most intricate structure known to exist. One-third of the 35,000 genes encoded in the human genome are expressed in the nervous system. Each mature brain is composed of 100 billion neurons, several million miles of axons and dendrites, and $>10^{15}$ synapses. Neurons exist within a dense parenchyma of multifunctional glial cells that synthesize myelin, preserve homeostasis, and regulate immune responses. Measured against this background of complexity, the achievements of molecular neuroscience have been extraordinary. Advances in cell biology and genetics have provided new tools to explore the pathophysiology of nervous system diseases, clarifying their underlying causes, revealing new unanticipated groupings, and raising realistic hope that novel therapies and prevention strategies will be possible. This chapter reviews selected themes in neurobiology that provide a context for understanding fundamental mechanisms underlying neurologic disorders.

ION CHANNELS AND CHANNELOPATHIES The resting potential of neurons and the action potentials responsible for impulse conduction are generated by ion currents and ion channels. Most ion channels are gated, meaning that they can transition between conformations that are open or closed to ion conductance. Individual ion channels are distinguished by the specific ions they conduct; by their kinetics; and by whether they directly sense voltage, are linked to receptors for neurotransmitters or other ligands such as neurotrophins, or are activated by second messengers. The diverse characteristics of different ion channels provide a means by which neuronal excitability can be exquisitely modulated at both the cellular and the subcellular levels. Mutations in ion channels—channelopathies—are responsible for a growing list of human neurologic disorders (Table 345-1). One example is epilepsy, a syndrome of diverse causes characterized by repetitive, synchronous firing of neuronal action potentials. Action potentials are normally generated by the opening of sodium channels and the inward movement of sodium ions down the intracellular concentration gradient. Depolarization of the neuronal membrane opens potassium channels, resulting in outward movement of potassium ions, repolarization, closure of the sodium channel, and hyperpolarization. Sodium or potassium channel subunit genes have long been considered candidate disease genes in inherited epilepsy syndromes, and recently such mutations have been identified (Chap. 348). These mutations appear to alter the normal gating function of these channels, increasing the inherent excitability of neuronal membranes in regions where the abnormal channels are expressed.

Whereas the specific clinical manifestations of channelopathies are quite variable, one common feature is that manifestations tend to be intermittent or paroxysmal, such as occurs in epilepsy, migraine, ataxia, myotonia, or periodic paralysis. Exceptions are clinically progressive channel disorders such as autosomal dominant hearing impairment. The neurologic channelopathies identified to date are all uncommon disorders caused by obvious mutations in channel genes. As the full repertoire of human ion channels and related proteins are identified, it is likely that additional channelopathies will be discovered. In addition to rare disorders that result from obvious mutations, it is possible that subtle allelic variations in channel genes or in their pattern of expression might underlie susceptibility to some common forms of epilepsy, migraine, or other disorders.

NEUROTRANSMITTERS AND NEUROTRANSMITTER RECEPTORS Synaptic neurotransmission is the predominant means by which neurons communicate with each other. Classic neurotransmitters are synthesized in the presynaptic region of the nerve terminal; stored in vesicles; and released into the synaptic cleft, where they bind to receptors on the postsynaptic cell. Secreted neurotransmitters are eliminated by reuptake into the presynaptic neuron (or glia), by diffusion away from the synaptic cleft, and/or by specific inactivation. In addition to the classic neurotransmitters, many neuropeptides have been identified as definite or probable neurotransmitters; these include substance P, neurotensin, enkephalins, β-endorphin, histamine, vasoactive intestinal polypeptide, cholecystokinin, neuropeptide Y, and somatostatin. Peptide neurotransmitters are synthesized in the cell body rather than the nerve terminal and may colocalize with classic neurotransmitters in single neurons. Nitric oxide and carbon monoxide are gases that appear also to function as neurotransmitters, in part by signaling in a retrograde fashion from the postsynaptic to the presynaptic cell.

Neurotransmitters modulate the function of postsynaptic cells by binding to specific neurotransmitter receptors, of which there are two major types. *Ionotropic receptors* are direct ion channels that open after engagement by the neurotransmitter. *Metabotropic receptors* interact with G proteins, stimulating production of second messengers and activating protein kinases, which modulate a variety of cellular events. Ionotropic receptors are multiple subunit structures, whereas metabotropic receptors are composed of single subunits only. One important difference between ionotropic and metabotropic receptors is that the kinetics of ionotropic receptor effects are fast (generally <1 ms) because neurotransmitter binding directly alters the electrical properties of the postsynaptic cell, whereas metabotropic receptors function over longer time periods. These different properties contribute to the potential for selective and finely modulated signaling by neurotransmitters.

Neurotransmitter systems are perturbed in a large number of clinical disorders, examples of which are highlighted in Table 345-2. One example is the involvement of dopaminergic neurons originating in the substantia nigra of the midbrain and projecting to the striatum

TABLE 345-1 *Examples of Neurologic Channelopathies*

(nigrostriatal pathway) in Parkinson's disease (Chap. 351) and in heroin addicts after the ingestion of the toxin MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine).

A second important dopaminergic system arising in the midbrain is the mediocorticolimbic pathway, which is implicated in the pathogenesis of addictive behaviors including drug reward. Its key components include the midbrain ventral tegmental area (VTA), median forebrain bundle, and nucleus accumbens (Fig. 345-1). *Addictive drugs share the property of increasing dopamine release in the nucleus accumbens*. Amphetamine increases intracellular release of dopamine from vesicles and reverses transport of dopamine through the dopamine transporters. Patients prone to addiction show increased activation of the nucleus accumbens following administration of amphetamine. Cocaine binds to dopamine transporters and inhibits dopamine reuptake. Ethanol inhibits inhibitory neurons in the VTA, leading to increased dopamine release in the nucleus accumbens. Opioids also disinhibit these dopaminergic neurons by binding to μ receptors expressed by GABA-containing interneurons in the VTA. Nicotine increases dopamine release by activating nicotinic acetylcholine receptors on cell bodies and nerve terminals of dopaminergic VTA neurons. Tetrahydrocannabinol, the active ingredient of cannabis, also increases dopamine levels in the nucleus accumbens. Blockade of dopamine in the nucleus accumbens can terminate the rewarding effects of addictive drugs.

Not all cell-to-cell communication in the nervous system occurs via neurotransmission. Gap junctions provide for direct neuron-neuron electrical conduction and also create openings for the diffusion of ions and metabolites between cells. In addition to neurons, gap junctions

TABLE 345-2 *Principal Classic Neurotransmitters*

Neurotransmitter	Anatomy	Clinical Aspects
Acetylcholine (ACh) 	Motor neurons in spinal cord → neuromuscular junction	Acetylcholinesterases (nerve gases) Myasthenia gravis (antibodies to ACh receptor) Congenital myasthenic syndromes (mutations in ACh receptor subunits) Lambert-Eaton syndrome (antibodies to Ca channels impair ACh release) Botulism (toxin disrupts ACh release by exocytosis)
	Basal forebrain → widespread cortex	Alzheimer's disease (selective cell death) Autosomal dominant frontal lobe epilepsy (mutations in CNS ACh receptor)
	Interneurons in striatum Autonomic nervous system (preganglionic and postganglionic sympathetic)	Parkinson's disease (tremor)
Dopamine 	Substantia nigra → striatum (nigrostriatal pathway)	Parkinson's disease (selective cell death) MPTP parkinsonism (toxin transported into neurons)
	Substantia nigra → limbic system and widespread cortex	Addiction, behavioral disorders
	Arcuate nucleus of hypothalamus → anterior pituitary (via portal veins)	Inhibits prolactin secretion
Norepinephrine (NE) 	Locus coeruleus (pons) → limbic system, hypothalamus, cortex	Mood disorders (MAOA inhibitors and tricyclics increase NE and improve depression)
	Medulla → locus coeruleus, spinal cord	Anxiety
	Postganglionic neurons of sympathetic nervous system	Orthostatic tachycardia syndrome (mutations in NE transporter)
Serotonin 	Pontine raphe nuclei → widespread projections	Mood disorders (SSRIs improve depression) Migraine pain pathway
	Medulla/pons → dorsal horn of spinal cord	Pain pathway
γ-Aminobutyric acid (GABA) 	Major inhibitory neurotransmitter in brain; widespread cortical interneurons and long projection pathways	Stiff person syndrome (antibodies to glutamic acid decarboxylase, the biosynthetic enzyme for GABA) Epilepsy (gabapentin and valproic acid increase GABA)
Glycine 	Major inhibitory neurotransmitter in spinal cord	Spasticity Hyperekplexia (myoclonic startle syndrome) due to mutations in glycine receptor
Glutamate 	Major excitatory neurotransmitter; located throughout CNS, including cortical pyramidal cells	Seizures due to ingestion of domoic acid (a glutamate analogue) Rasmussen's encephalitis (antibody against glutamate receptor 3) Excitotoxic cell death

Note: CNS, central nervous system; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MAOA, monoamine oxidase A; SSRI, selective serotonin reuptake inhibitor.

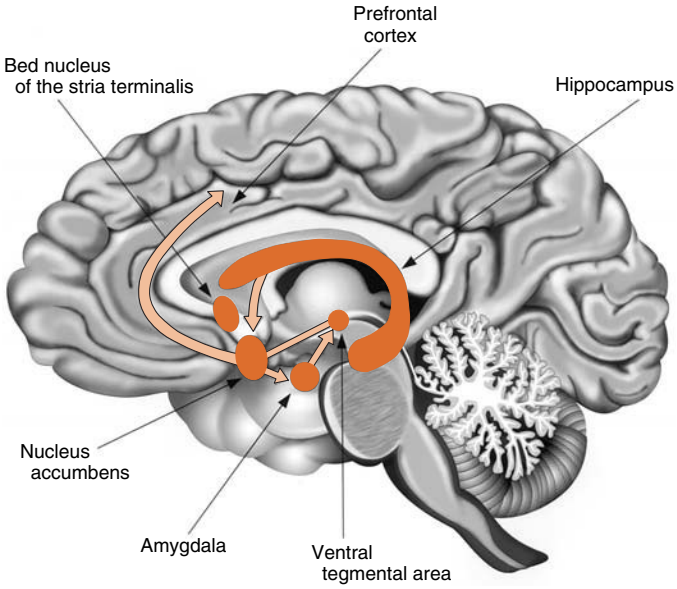

FIGURE 345-1 Mid-sagittal section of the human brain demonstrating limbic structures involved in brain reward pathways.

are also widespread in glia, creating a syncytium that protects neurons by removing glutamate and potassium from the extracellular environment. Gap junctions consist of membrane-spanning proteins, termed *connexins*, that pair across adjacent cells. Mechanisms that involve gap junctions have been related to a variety of neurologic disorders. Mutations in connexin 32, a gap junction protein expressed by Schwann cells, are responsible for the X-linked form of Charcot-Marie-Tooth disease (Chap. 364). Mutations in either of two gap junction proteins expressed in the inner ear—connexin 26 and connexin 31—result in autosomal dominant progressive hearing loss (Chap. 26). Glial calcium waves mediated through gap junctions also appear to explain the phenomenon of spreading depression associated with migraine auras and the march of epileptic discharges. Spreading depression is a neural response that follows a variety of different stimuli and is characterized by a circumferentially expanding negative potential that propagates at a characteristic speed of 20 m/s and is associated with an increase in extracellular potassium.

SIGNALING PATHWAYS AND GENE TRANSCRIPTION

The fundamental issue of how memory, learning, and thinking are encoded in the nervous system is likely to be clarified by identifying the signaling pathways involved in neuronal differentiation, axon guidance, and synapse formation, and by understanding how these pathways are modulated by experience. Many families of transcription factors, each comprising multiple individual components, are expressed in the nervous system. Elucidation of these signaling pathways has already begun to provide insights into the cause of a variety of neurologic disorders, including inherited disorders of cognition such as X-linked mental retardation. This problem affects approximately 1 in 500 males, and linkage studies in different families suggest that as many as 60 different X-chromosome encoded genes may be responsible. Rett syndrome, a common cause of (dominant) X-linked progressive mental retardation in females, is due to a mutation in a gene (*MECP2*) encoding a DNA-binding protein involved in transcriptional repression. As the X chromosome comprises only ~3% of germline DNA, then by extrapolation the number of genes that potentially contribute to clinical disorders affecting intelligence in humans must be potentially very large. As discussed below, there is increasing evidence that abnormal gene transcription may play a role in neurodegenerative diseases such as Huntington's disease in which proteins with polyglutamine expansions bind to and sequester transcription factors. A critical transcription factor for neuronal survival is CREB (cyclic adenosine monophosphate responsive element-binding) protein, which also plays an important role in memory in the hippocampus.

MYELIN Myelin is the multilayered insulating substance that surrounds axons and speeds impulse conduction by permitting action potentials to jump between naked regions of axons (nodes of Ranvier) and across myelinated segments. A single oligodendrocyte usually ensheaths multiple axons in the central nervous system (CNS), whereas in the peripheral nervous system (PNS) each Schwann cell typically myelinates a single axon. Myelin is a lipid-rich material formed by a spiraling process of the membrane of the myelinating cell around the axon, creating multiple membrane bilayers that are tightly apposed (compact myelin) by charged protein interactions. A number of clinically important neurologic disorders are caused by inherited mutations in myelin proteins of the CNS or PNS. Constituents of myelin also have a propensity to be targeted as autoantigens in autoimmune demyelinating disorders (Fig. 345-2).

NEUROTROPHIC FACTORS Neurotrophic factors (Table 345-3) are secreted proteins that modulate neuronal growth, differentiation, repair, and survival; some have additional functions, including roles in neurotransmission and in the synaptic reorganization involved in learning and memory. The neurotrophin (NT) family contains nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), NT3, and NT4/5. The neurotrophins act at TrK and p75 receptors to promote survival of neurons. Because of their survival-promoting and anti-

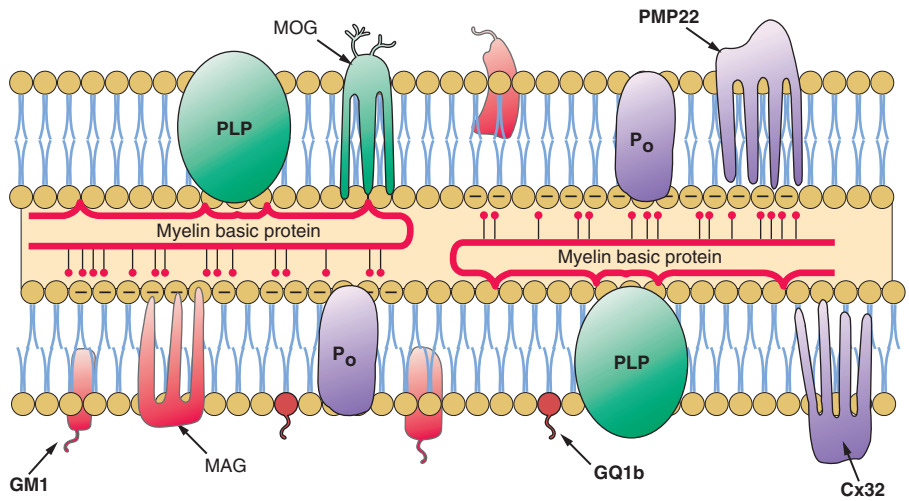

FIGURE 345-2 The molecular architecture of the myelin sheath illustrating the most important disease-related proteins. The illustration represents a composite of CNS and PNS myelin. Proteins restricted to CNS myelin are shown in green, proteins of PNS myelin are lavendar, and proteins present in both CNS and PNS are red. In the CNS, the X-linked allelic disorders, Pelizaeus Merzbacher disease and one variant of familial spastic paraplegia, are caused by mutations in the gene for proteolipid protein (PLP) that normally promotes extracellular compaction between adjacent myelin lamellae. The homologue of PLP in the PNS is the P_0 protein, mutations in which cause the neuropathy Charcot-Marie-Tooth disease (CMT) type 1B. The most common form of CMT is the 1A subtype caused by a duplication of the *PMP22* gene; deletions in *PMP22* are responsible for another inherited neuropathy termed hereditary liability to pressure palsies (Chap. 364).

In multiple sclerosis (MS), myelin basic protein (MBP) and the quantitatively minor CNS protein, myelin oligodendrocyte glycoprotein (MOG), are likely T cell and B cell antigens, respectively (Chap. 359). The location of MOG at the outermost lamella of the CNS myelin membrane may facilitate its targeting by autoantibodies. In the PNS, autoantibodies against myelin gangliosides are implicated in a variety of disorders, including GQ1b in the Fisher variant of Guillain-Barré syndrome, GM1 in multifocal motor neuropathy, and sulfatide constituents of myelin-associated glycoprotein (MAG) in peripheral neuropathies associated with monoclonal gammopathies (Chap. 365).

apoptotic effects, neurotrophic factors are in theory outstanding candidates for therapy of disorders characterized by premature death of neurons such as occurs in amyotrophic lateral sclerosis (ALS) and other degenerative motor neuron disorders. Knockout mice lacking receptors for ciliary neurotrophic factor (CNTF) or BDNF show loss of motor neurons, and experimental motor neuron death can be rescued by treatment with various neurotrophic factors including CNTF and BDNF. However, in phase 3 clinical trials, growth factors were ineffective in human ALS. The growth factor glial-derived neurotrophic factor (GDNF) is important for survival of dopaminergic neurons. It has shown promising neurorestorative effects in experimental models of Parkinson's disease and in early stage human clinical trials.

STEM CELLS AND TRANSPLANTATION The nervous system is traditionally considered to be a nonmitotic organ, in particular with respect to neurons. These concepts have been challenged by the finding that neural progenitor or stem cells exist in the adult CNS that are capable of differentiation, migration over long distances, and extensive axonal arborization and synapse formation with appropriate targets. These capabilities also indicate that the repertoire of factors required for growth, survival, differentiation, and migration of these cells exists in the mature nervous system. In rodents, neural stem cells, defined as progenitor cells capable of differentiating into mature cells of neural or glial lineage, have been experimentally propagated from fetal CNS and neuroectodermal tissues and also from adult germinal matrix and ependyma regions. Human fetal CNS tissue is also capable of differentiation into cells with neuronal, astrocyte, and oligodendrocyte morphology when cultured in the presence of growth factors. Impressively, such cells could be stably engrafted into mouse CNS tissue, creating neural chimeras. Human adult neural stem cells have been identified in an astrocyte layer adjacent to the lateral ventricles; however, these neurons appeared to be unable to migrate or form connections. Once the repertoire of signals required for cell type specification is better understood, differentiation into specific neural or glial subpopulations can be directed in vitro; such cells could also be engineered to express therapeutic molecules. Another promising approach is to utilize growth factors, such as BDNF, to stimulate endogenous stem cells to proliferate and migrate to areas of neuronal damage. Administration of epidermal growth factor with fibroblast growth factor replenished up to 50% of hippocampal CA1 neurons a month after global ischemia in rats. The new neurons made connections and improved performance in a memory task.

Experimental transplantation of human fetal dopaminergic neurons in patients with Parkinson's disease has shown that these transplanted cells can survive within the host striatum; however, some patients developed disabling dyskinesias and this approach is no longer in clinical development. Studies of transplantation for patients with Huntington's disease have also reported encouraging, although very preliminary, results. Oligodendrocyte precurser cells transplanted into mice with a dysmyelinating disorder effectively migrated in the new environment, interacted with axons, and mediated myelination; such experiments raise hope that similar transplantation strategies may be feasible in human disorders of myelin such as multiple sclerosis. The promise of stem cells for treatment of both neurodegenerative diseases and neural injury is great, but development has been slowed by unresolved concerns over safety (including the theoretical risk of malignant transformation of transplanted cells), ethics (particularly with respect to use of fetal tissue), and efficacy.

In developing brain, the extracellular matrix provides stimulatory and inhibitory signals that promote neuronal migration, neurite outgrowth, and axonal extension. After neuronal damage, reexpression of inhibitory molecules such as chondroitin sulfate proteoglycans may prevent tissue regeneration. Chondroitinase degraded these inhibitory molecules and enhanced axonal regeneration and motor recovery in a rat model of spinal cord injury. Several myelin proteins, specifically Nogo, oligodendrocyte myelin glycoprotein (OMGP), and myelin-associated glycoprotein (MAG), may also interfere with axon regeneration. Antibodies against Nogo promote regeneration after experimental focal ischemia. Nogo, OMGP, and MAG all bind to the same neural receptor, the Nogo receptor, which mediates its inhibitory function via the p75 neurotrophin receptor signaling.

CELL DEATH—EXCITOTOXICITY AND APOPTOSIS *Excitotoxicity* refers to neuronal cell death caused by activation of excitatory amino acid receptors (Fig. 345-3). Compelling evidence for a role of excitotoxicity, especially in ischemic neuronal injury, is derived from experiments in animal models. Experimental models of stroke are associated with increased extracellular concentrations of the excitatory amino acid neurotransmitter glutamate, and neuronal damage is attenuated by denervation of glutamate-containing neurons or the administration of glutamate receptor antagonists. The distribution of cells sensitive to ischemia corresponds closely with that of *N*-methyl-D-aspartate (NMDA) receptors (except for cerebellar Purkinje cells, which are vulnerable to hypoxia-ischemia but lack NMDA receptors); and competitive and noncompetitive NMDA antagonists are effective in preventing focal ischemia. In global cerebral ischemia, non-NMDA receptors (kainic acid and AMPA) are activated, and antagonists to these receptors are protective. Experimental brain damage induced by hypoglycemia is also attenuated by NMDA antagonists.

Excitotoxicity is not a single event but rather a cascade of cell injury. Excitotoxicity causes influx of calcium into cells, and much of the calcium is sequestered in mitochondria rather than in the cytoplasm. Increased cytoplasmic calcium causes metabolic dysfunction and free radical generation; activates protein kinases, phospholipases, nitric oxide synthase, proteases, and endonucleases; and inhibits protein synthesis. Activation of nitric oxide synthase generates nitric oxide ($NO^{\cdot}$), which can react with superoxide ($O_2^{\cdot}$) to generate peroxynitrite ($ONOO^-$), which may play a direct role in neuronal injury. Another critical pathway is activation of poly-ADP-ribose polymerase, which occurs in response to free radical–mediated DNA damage. Experimentally, mice with knockout mutations of neuronal nitric oxide synthase or poly-ADP-ribose polymerase, or those that overexpress superoxide dismutase, are resistant to focal ischemia.

Apoptosis, or programmed cell death, plays an important role in both physiologic and pathologic conditions. During embryogenesis, apoptotic pathways operate to destroy neurons that fail to differentiate appropriately or reach their intended targets. There is mounting evidence for an increased rate of apoptotic cell death in a variety of acute and chronic neurologic diseases. Apoptosis is characterized by neuronal shrinkage, chromatin condensation, and DNA fragmentation, whereas necrotic cell death is associated with cytoplasmic and mitochondrial swelling followed by dissolution of the cell membrane. Apoptotic and necrotic cell death can coexist or be sequential events, depending on the severity of the initiating insult. Cellular energy reserves appear to have an important role in these two forms of cell death, with apoptosis favored under conditions in which ATP levels are preserved. Evidence of DNA fragmentation has been found in a number of degenerative neurologic disorders, including Alzheimer's disease, Huntington's disease, and ALS. The best characterized genetic neurologic disorder related to apoptosis is infantile spinal muscular

atrophy (Werdnig-Hoffmann disease), in which two genes thought to be involved in the apoptosis pathways are causative.

Mitochondria are essential in controlling specific apoptosis pathways. The redistribution of cytochrome c, as well as apoptosis-inducing factor (AIF), from mitochondria during apoptosis leads to the activation of a cascade of intracellular proteases known as caspases. Caspase-independent apoptosis occurs after DNA damage, activation of poly-ADP-ribose polymerase, and translocation of AIF into the nucleus. Redistribution of cytochrome c is prevented by overproduction of the apoptotic protein BCL2 and is promoted by the proapoptotic protein BAX. These pathways may be triggered by activation of a large pore in the mitochondrial inner membrane known as the *permeability transition pore*, although in other circumstances they occur independently. Recent studies suggest that blocking the mitochondrial pore reduces both hypoglycemic and ischemic cell death.

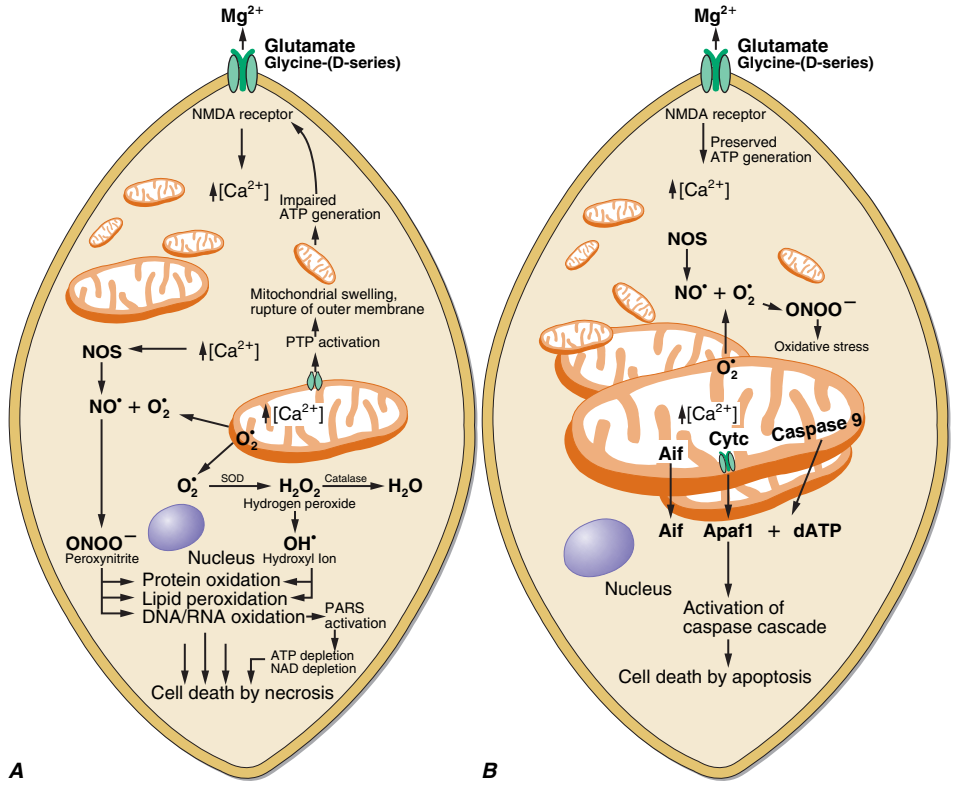

FIGURE 345-3 Involvement of mitochondria in cell death. A severe excitotoxic insult (*A*) results in cell death by necrosis, whereas a mild excitotoxic insult (*B*) results in apoptosis. After a severe insult (such as ischemia), there is a large increase in glutamate activation of NMDA receptors, an increase in intracellular Ca^{2+} concentrations, activation of nitric oxide synthase (NOS), and increased mitochondrial Ca^{2+} and superoxide generation followed by the formation of $ONOO^-$. This sequence results in damage to cellular macromolecules including DNA, leading to activation of poly-ADP-ribose polymerase (PARS). Both mitochondrial accumulation of Ca^{2+} and oxidative damage lead to activation of the permeability transition pore (PTP) that is linked to excitotoxic cell death. A mild excitotoxic insult can occur due either to an abnormality in an excitotoxicity amino acid receptor, allowing more Ca^{2+} flux, or to impaired functioning of other ionic channels or of energy production, which may allow the voltage-dependent NMDA receptor to be activated by ambient concentrations of glutamate. This event can then lead to increased mitochondrial Ca^{2+} and free radical production, yet relatively preserved ATP generation. The mitochondria may then release cytochrome c (Cytc), caspase 9, apoptosis-inducing factor (Aif), and perhaps other mediators that lead to apoptosis. The precise role of the PTP in this mode of cell death is still being clarified, but there does appear to be involvement of the adenine nucleotide transporter that is a key component of the PTP.

PROTEIN AGGREGATION AND NEURODEGENERATION The possibility that protein aggregation plays a role in the pathogenesis of neurodegenerative diseases is a major focus of current research. Protein aggregation is a major histopathologic hallmark of neurodegenerative diseases. Deposition of β-amyloid is strongly implicated in the pathogenesis of Alzheimer's disease. Genetic mutations in familial Alzheimer's disease produce increased amounts of β-amyloid with 42 amino acids, which has an increased propensity to aggregate, as compared to β-amyloid with 40 amino acids. Mutations in genes encoding the microtubule-associated protein tau lead to altered splicing of tau and the production of neurofibrillary tangles in frontotemporal dementia and progressive supranuclear palsy. Familial Parkinson's disease is associated with mutations in α-synuclein, parkin, and the ubiquitin carboxy-terminal hydrolase. Parkin, which causes autosomal recessive early-onset Parkinson's disease, is a ubiquitin ligase. The characteristic histopathologic feature of Parkinson's disease is the Lewy body, an eosinophilic cytoplasmic inclusion that contains both neurofilaments and α-synuclein. Huntington's disease and cerebellar degenerations are associated with expansions of polyglutamine repeats in proteins, which aggregate to produce neuronal intranuclear inclusions. Familial ALS is associated with superoxide dismutase mutations and cytoplasmic inclusions containing superoxide dismutase. In autosomal dominant neurohypophyseal diabetes insipidus, mutations in vasopressin result in abnormal protein processing, accumulation in the endoplasmic reticulum, and cell death (Chap. 319).

The current major scientific question is whether protein aggregates contribute to neuronal death or whether they are merely secondary bystanders. Protein aggregates are usually ubiquinated, which targets them for degradation by the 26S component of the proteosome. An inability to degrade protein aggregates could lead to cellular dysfunction, impaired axonal transport, and cell death by apoptotic mechanisms.

In experimental models of Huntington's disease and cerebellar degeneration, protein aggregates are not well correlated with neuronal death. A substantial body of evidence suggests that the mutant proteins with polyglutamine expansions in these diseases bind to transcription factors and that this contributes to disease pathogenesis. Agents that upregulate gene transcription are neuroprotective in animal models of these diseases. A number of compounds have been developed to block β-amyloid production and/or aggregation, and these agents are being studied in early clinical trials in humans.

NEUROIMMUNOLOGY The nervous system is traditionally considered to be an immunologically privileged organ, a concept originally derived from observations that tissue grafts implanted in the brain were not rejected efficiently. In this context, immune privilege of the CNS may be maintained by a variety of mechanisms, including the lack of an efficient surveillance function by T cells; the absence of a traditional lymphoid system; limited expression of major histocompatibility complex (MHC) molecules required for T cell recognition of antigen; effects of regulatory cytokines secreted spontaneously or in response to mediators such as NGF, creating an immunosuppressive milieu; and also from expression of fas ligand that can induce apoptosis of fas-expressing immune cells that enter the brain. The blood-brain barrier (BBB) partially isolates the brain from the peripheral environment and contributes to immune privilege. Anatomically, the barrier is created by the presence of impermeable tight junctions between endothelial cells and by a relative absence of transendothelial conduits for the passive diffusion of soluble molecules. The BBB serves to preserve CNS homeostasis by excluding neuroactive substances present in the serum, such as neurotransmitters and neurotrophic factors. Because of the BBB, lipid-insoluble molecules must utilize either ion channels or

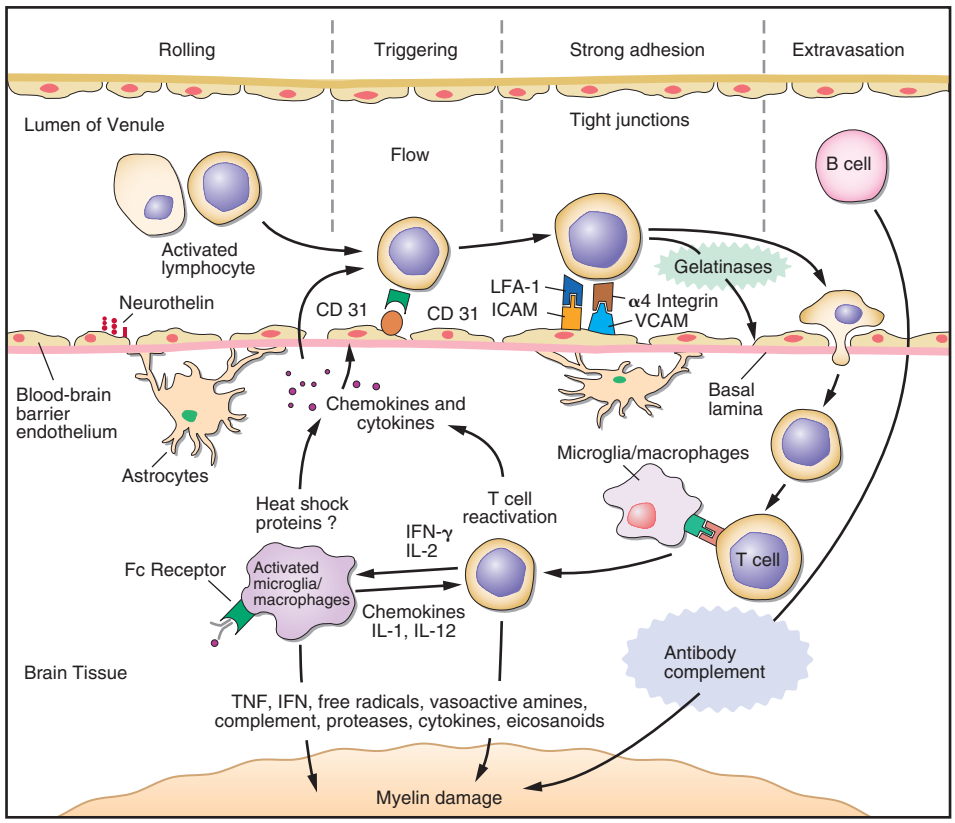

FIGURE 345-4 A model for experimental allergic encephalomyelitis (EAE). Crucial steps for disease initiation and progression include peripheral activation of preexisting autoreactive T cells; homing to the CNS and extravasation across the blood-brain barrier; reactivation of T cells by exposed autoantigens; secretion of cytokines; activation of microglia and astrocytes and recruitment of a secondary inflammatory wave; and immune-mediated myelin destruction. ICAM, intercellular adhesion molecule; LFA-1, leukocyte function-associated antigen-1; VCAM, vascular cell adhesion molecule; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.

specific transport systems (for glucose or various amino acids) to gain entry to the CNS. Astrocyte foot processes that encircle the subendothelial basal surface of small blood vessels in the brain contribute to development and maintenance of the BBB.

The concept of immune privilege is at odds with clinical experience that vigorous immune reactions readily occur in the nervous system in response to infections and that autoimmune diseases of the nervous system are relatively common. Although primary (sensitizing) immune responses are not easily generated in the CNS for the reasons outlined above, this is not the case for secondary immune responses. When sensitization to nervous system antigens occurs *outside* the nervous system (e.g., in a regional lymph node), activated autoreactive T lymphocytes are easily generated, and these cells readily cross the BBB and induce immune-mediated injury. The paradigm for this mechanism of T cell–mediated CNS disease is experimental allergic encephalomyelitis (EAE), a laboratory model for the human autoimmune demyelinating disorders multiple sclerosis and acute disseminated encephalomyelitis; the sequence of events in EAE is illustrated in Fig. 345-4.

Under normal circumstances the BBB is impermeable to antibodies. For autoantibodies to reach the CNS, the BBB must first be disrupted. In inflammatory conditions it is thought that this disruption most often occurs via actions of proinflammatory cytokines elaborated within the brain consequent to interactions between pathogenic T cells and antigen-presenting cells (APCs). In contrast to the BBB, in the PNS the blood-nerve barrier is incomplete. Endothelial tight junctions are lacking, and the capacity of charged molecules, including antibodies, to cross the barrier appears to be greatest in two regions of the PNS: proximally in the spinal roots and distally at neuromuscular junctions. This anatomic feature is likely to contribute to the propensity of antibody-mediated autoimmune disorders of the PNS to target proximal nerves (Guillain-Barré syndrome) or the neuromuscular junction (myasthenia gravis, Eaton-Lambert syndrome).

The major APCs in the CNS are microglial cells and macrophages; both cell types express MHC class 2 molecules as well as co-stimulatory molecules required for antigen presentation. Neurons do not express MHC class 2 molecules; however, some neurons express MHC class 1 proteins, which may be further increased in response to neuronal activity. Neuronal MHC class 1 molecules may function as retrograde postsynaptic signaling molecules that interact with presynaptic CD3 molecules to stabilize active synapses and transynaptically modulate neuronal function. A role of microglial activation as a contributer to cell death in neurodegenerative and chronic neuroinflammatory diseases is likely and is being actively investigated.

346 APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE

Joseph B. Martin, Daniel H. Lowenstein, Stephen L. Hauser

Neurologic diseases are common and costly. According to one estimate, 180 million Americans suffer from a nervous system disorder, resulting in an annual cost of $634 billion (Table 346-1). Globally, these disorders are responsible for 28% of all years lived with a disability. Most patients with neurologic symptoms seek care from internists and other generalists rather than from neurologists, and this situation is likely to continue as primary care–based health care systems become increasingly prevalent. Because useful therapies now exist for these disorders, a skillfull approach to diagnosis is essential. Many errors result from an overreliance on costly neuroimaging procedures and laboratory tests, which, while useful, do not substitute for an adequate history and examination. The proper approach to the patient with a neurologic illness begins with the patient and focuses the clinical problem first in anatomic and then in pathophysiologic terms; only then should a specific diagnosis be entertained. The direct evaluation of the patient also informs the subsequent workup and ensures

that technology is judiciously applied, a correct diagnosis is established in an efficient manner, and treatment is promptly initiated.

THE NEUROLOGIC METHOD ■ Locate the Lesion(s) The first priority is to identify the region of the nervous system that is likely to be responsible for the symptoms. Can the disorder be mapped to one specific location, is it multifocal, or is a diffuse process present? Are the symptoms restricted to the nervous system, or do they arise in the context of a systemic illness? Is the problem in the central nervous system (CNS), the peripheral nervous system (PNS), or both? If in the CNS, is the cerebral cortex, basal ganglia, brainstem, cerebellum, or spinal cord responsible? Are the pain-sensitive meninges involved? If in the PNS, could the disorder be located in peripheral nerves and, if so, are motor or sensory nerves primarily affected, or is a lesion in the neuromuscular junction or muscle more likely?

The first clues to defining the anatomic area of involvement appear in the history, and the examination is then directed to confirm or rule out these impressions and to clarify uncertainties suggested by the history. A more detailed examination of a particular region of the CNS or PNS is often indicated. For example, the examination of a patient who presents with a history of ascending paresthesias and weakness should be directed toward deciding, among other things, if the location of the lesion is in the spinal cord or peripheral nerves. Focal back pain, a spinal cord sensory level, and incontinence suggest a spinal cord origin, whereas a stocking-glove pattern of sensory loss suggests peripheral nerve disease; areflexia usually indicates peripheral neuropathy but may also be present with spinal shock in acute spinal cord disorders.

Deciding "where the lesion is" accomplishes the task of limiting the possible etiologies to a manageable, finite number. In addition, this strategy safeguards against making tragic errors. Symptoms of recurrent vertigo, diplopia, and nystagmus should not trigger "multiple sclerosis" as an answer (etiology) but "brainstem" or "pons" (location); then a diagnosis of brainstem arteriovenous malformation will not be missed for lack of consideration. Similarly, the combination of optic neuritis and spastic ataxic paraparesis should initially suggest optic nerve and spinal cord disease; multiple sclerosis, CNS syphilis, and vitamin B_{12} deficiency are treatable disorders that can produce this syndrome. Once the question, "Where is the lesion?" is answered, then the question, "What is the lesion?" can be addressed.

Define the Pathophysiology Clues to the pathophysiology of the disease process may also be present in the history. Primary neuronal (gray matter) disorders may present as early cognitive disturbances, movement disorders, or seizures, whereas white matter involvement produces predominantly "long tract" disorders of motor, sensory, visual, and cerebellar pathways. Progressive and symmetric symptoms often have a metabolic or degenerative origin; in such cases lesions are usually not sharply circumscribed. Thus, a patient with paraparesis and a clear spinal cord sensory level is unlikely to have vitamin B_{12} deficiency as the explanation. A Lhermitte symptom (electric shock–like sensations evoked by neck flexion) is due to ectopic impulse generation in white matter pathways and occurs with demyelination in the cervical spinal cord. Symptoms that worsen after exposure to heat or exercise may indicate conduction block in demyelinated axons, as occurs in multiple sclerosis. A patient with recurrent episodes of diplopia and dysarthria associated with exercise or fatigue may have a disorder of neuromuscular transmission such as myasthenia gravis. Slowly advancing visual scotoma with luminous edges, termed *fortification spectra*, indicates spreading cortical depression, typically with migraine.

THE NEUROLOGIC HISTORY As in all other aspects of clinical medicine, attention to the description of the symptoms experienced by the patient and substantiated by family members and others often permits an accurate localization and determination of the probable cause of the complaints, even before the neurologic examination is performed. Furthermore, a careful analysis of the history is a necessary prerequisite for bringing a focus to the neurologic examination that follows. Each complaint should be pursued as far as possible to elucidate the location of the lesion, the likely underlying pathophysiology, and potential etiologies. For example, a patient complains of weakness of the right arm. What are the associated features? Does the patient have difficulty with brushing hair or reaching upward (proximal) or buttoning buttons or opening a twist-top bottle (distal)? Also, negative associations may also be crucial. A patient with a right hemiparesis without a language deficit likely has a lesion (internal capsule, brainstem, or spinal cord) different from that of a patient with a right hemiparesis and aphasia (left hemisphere). Additional features of the history include the following:

1. *Temporal course of the illness*. It is important to determine the precise time of appearance and rate of progression of the symptoms experienced by the patient. The rapid onset of a neurologic complaint, occurring within seconds or minutes, usually indicates a vascular event, a seizure, or migraine. The onset of sensory symptoms located in one extremity that spread over a few seconds to adjacent portions of that extremity and then to the other regions of the body suggests a seizure. A more gradual onset and less well localized symptoms point to the possibility of a transient ischemic attack (TIA). A similar but slower temporal march of symptoms accompanied by headache, nausea, or visual disturbance suggests migraine. The presence of "positive" sensory symptoms (e.g., tingling or sensations that are difficult to describe) or involuntary motor movements suggests a seizure; in contrast, transient loss of function (negative symptoms) suggests a TIA. A stuttering onset where symptoms appear, stabilize, and then progress over hours or days also suggests cerebrovascular disease; an additional history of transient remission or regression indicates that the process is more likely due to ischemia rather than hemorrhage. A gradual evolution of symptoms over hours or days suggests a toxic, metabolic, infectious, or inflammatory process. Progressing symptoms associated with the systemic manifestations of fever, stiff neck, and altered level of consciousness imply an infectious process. Relapsing and remitting symptoms involving different levels of the nervous system suggest multiple sclerosis or other inflammatory processes; these disorders can occasionally produce new symptoms that are rapidly progressive over hours. Slowly progressive symptoms without remissions are characteristic of neurodegenerative disorders, chronic infections, gradual intoxications, and neoplasms.

2. *Patients' descriptions of the complaint*. The same words often mean different things to different patients. "Dizziness" may imply impending syncope, a sense of disequilibrium, or true spinning vertigo. "Numbness" may mean a complete loss of feeling, a positive sensation such as tingling, or paralysis. "Blurred vision" may be used to describe unilateral visual loss, as in transient monocular blindness, or diplopia.

The interpretation of the true meaning of the words used by patients to describe symptoms becomes even more complex when there are differences in primary languages and cultures.

3. *Corroboration of the history by others*. It is almost always helpful to obtain additional information from family, friends, or other observers to corroborate or expand the patient's description. Memory loss, aphasia, loss of insight, intoxication, and other factors may impair the patient's capacity to communicate normally with the examiner or prevent openness about factors that have contributed to the illness. Episodes of loss of consciousness necessitate that details be sought from observers to ascertain precisely what has happened during the event.

4. *Family history*. Many neurologic disorders have an underlying genetic component. The presence of a Mendelian disorder, such as Huntington's disease or Charcot-Marie-Tooth neuropathy, is often obvious if family data are available. More detailed questions about family history are often necessary in polygenic disorders such as multiple sclerosis, migraine, and many types of epilepsy. It is important to elicit family history about all illnesses, in addition to neurologic and psychiatric disorders. A familial propensity to hypertension or heart disease is relevant in a patient who presents with a stroke. There are numerous inherited neurologic diseases that are associated with multisystem manifestations that may provide clues to the correct diagnosis (e.g., neurofibromatosis, Wilson's disease, neuro-ophthalmic syndromes).

5. *Medical illnesses*. Many neurologic diseases occur in the context of systemic disorders. Diabetes mellitus, hypertension, and abnormalities of blood lipids predispose to cerebrovascular disease. A solitary mass lesion in the brain may be an abscess in a patient with valvular heart disease, a primary hemorrhage in a patient with a coagulopathy, a lymphoma or toxoplasmosis in a patient with AIDS, or a metastasis in a patient with underlying cancer. Patients with malignancy may also present with a paraneoplastic syndrome (Chap. 87) or complications from chemotherapy or radiotherapy. Marfan's syndrome and related collagen disorders predispose to dissection of the cranial arteries and aneurysmal subarachnoid hemorrhage; the latter may also occur with polycystic kidney disease. A recent onset of asthma suggests the possibility of polyarteritis nodosa. Various neurologic disorders occur with dysthyroid states or other endocrinopathies. It is especially important to look for the presence of systemic diseases in patients with peripheral neuropathy. Most patients with coma in a hospital setting have a metabolic, toxic, or infectious cause.

6. *Drug use and abuse and toxin exposure*. It is essential to inquire about the history of drug use, both prescribed and illicit. Aminoglycoside antibiotics may exacerbate symptoms of weakness in patients with disorders of neuromuscular transmission, such as myasthenia gravis, and may cause dizziness secondary to ototoxicity. Vincristine and other antineoplastic drugs can cause peripheral neuropathy, and immunosuppressive agents such as cyclosporine can produce encephalopathy. Excessive vitamin ingestion can lead to disease; for example vitamin A and pseudotumor cerebri, or pyridoxine and peripheral neuropathy. Many patients are unaware that over-the-counter sleeping pills, cold preparations, and diet pills are actually drugs. Alcohol, the most prevalent neurotoxin, is often not recognized as such by patients, and other drugs of abuse such as cocaine and heroin can cause a wide range of neurologic abnormalities. A history of environmental or industrial exposure to neurotoxins may provide an essential clue; consultation with the patient's co-workers or employer may be required.

7. *Formulating an impression of the patient*. Use the opportunity while taking the history to form an impression of the patient. Is the information forthcoming, or does it take a circuitous course? Is there evidence of anxiety, depression, hypochondriasis? Are there any clues to defects in language, memory, insight, or inappropriate behavior? The neurologic assessment begins as soon as the patient comes into the room and the first introduction is made.

THE NEUROLOGIC EXAMINATION The neurologic examination is challenging and complex; it has many components and includes a number of skills that can be mastered only through repeated use of the same techniques on a large number of individuals with and without neurologic disease. Mastery of the complete neurologic examination is usually important only for physicians in neurology and associated specialties. However, knowledge of the basics of the examination, especially those components that are effective in screening for neurologic dysfunction, is essential for all clinicians, especially generalists.

There is no single, universally accepted sequence of the examination that must be followed, but most clinicians begin with assessment of mental status followed by the cranial nerves, motor system, sensory system, coordination, and gait. Whether the examination is basic or comprehensive, it is essential that it be performed in an orderly and systematic fashion to avoid errors and serious omissions. Thus, the best way to learn and gain expertise in the examination is to choose one's own approach and practice it frequently and do it in the same exact sequence each time.

The detailed description of the neurologic examination that follows describes the more commonly used parts of the examination, with a particular emphasis on the components that are considered most helpful for the assessment of common neurologic problems. Each section also includes a brief description of the minimal examination necessary for adequate screening for abnormalities in a patient who has no symptoms suggesting neurologic dysfunction. A screening examination done in this way can be completed in 3 to 5 min.

Several additional points about the examination are worth noting. First, in recording observations, it is important to describe what is found rather than to apply a poorly defined medical term (e.g., "patient groans to sternal rub" rather than "obtunded"). Second, subtle CNS abnormalities are best detected by carefully comparing a patient's performance on tasks that require simultaneous activation of both cerebral hemispheres (e.g., eliciting a pronator drift of an outstretched arm with the eyes closed; extinction on one side of bilaterally applied light touch, also with eyes closed; or decreased arm swing or a slight asymmetry when walking). Third, if the patient's complaint is brought on by some activity, reproduce the activity in the office. If the complaint is of dizziness when the head is turned in one direction, have the patient do this and look for associated signs on examination (e.g., nystagmus or dysmetria). If pain occurs after walking two blocks, have the patient leave the office and walk this distance and immediately return, and repeat the relevant parts of the examination. Finally, the use of tests that are individually tailored to the patient's problem can be of value in assessing changes over time. Tests of walking a 7.5-m (25-ft) distance (normal, 5 to 6 s; note assistance, if any), repetitive finger or toe tapping (normal, 20 to 25 taps in 5 s), or handwriting are examples.

Mental Status Examination (See also Chaps. 23, 257, and 350)

- *The bare minimum: During the interview, look for difficulties with communication and determine whether the patient has recall and insight into recent and past events.*

The mental status examination is underway as soon as the physician begins observing and talking with the patient. If the history raises any concern for abnormalities of higher cortical function or if cognitive problems are observed during the interview, then detailed testing of the mental status is indicated. The patient's ability to understand the language used for the examination, cultural background, educational experience, sensory or motor problems, or co-morbid conditions need to be factored into the applicability of the tests and interpretation of results.

The Folstein mini-mental status examination (MMSE) (Table 350-4) is a standardized screening examination of cognitive function that is extremely easy to administer and takes <10 min to complete. Using age-adjusted values for defining normal performance, the test is $\sim$85% sensitive and 85% specific for making the diagnosis of dementia that is moderate or severe, especially in educated patients. When there is sufficient time available, the MMSE is one of the best methods for

documenting the current mental status of the patient, and this is especially useful as a baseline assessment to which future scores of the MMSE can be compared.

Individual elements of the mental status examination can be subdivided into level of consciousness, orientation, speech and language, memory, fund of information, insight and judgment, abstract thought, and calculations.

Level of consciousness is the patient's relative state of awareness of the self and the environment, and ranges from fully awake to comatose. When the patient is not fully awake, the examiner should describe the responses to the minimum stimulus necessary to elicit a reaction, ranging from verbal commands to a brief, painful stimulus such as a squeeze of the trapezius muscle. Responses that are directed toward the stimulus and signify some degree of intact cerebral function (e.g., opening the eyes and looking at the examiner or reaching to push away a painful stimulus) must be distinguished from reflex responses of a spinal origin (e.g., triple flexion response—flexion at the ankle, knee, and hip in response to a painful stimulus to the foot). *Orientation* is tested by asking the person to state his or her name, location, and time (day of the week and date); time is usually the first to be affected in a variety of conditions. *Speech* is assessed by observing articulation, rate, rhythm, and prosody (i.e., the changes in pitch and accentuation of syllable and words). *Language* is assessed by observing the content of the patient's verbal and written output, response to spoken commands, and ability to read. A typical testing sequence is to ask the patient to name successively more detailed components of clothing, a watch or a pen; repeat the phrase "No ifs, ands, or buts"; follow a three-step, verbal command; write a sentence; and read and respond to a written command. *Memory* should be analyzed according to three main time scales: (1) immediate memory can be tested by saying a list of three items and having the patient repeat the list immediately, (2) short-term memory is assessed by asking the patient to recall the same three items 5 and 15 min later, and (3) long-term memory is evaluated by determining how well the patient is able to provide a coherent chronologic history of his or her illness or personal events. *Fund of information* is assessed by asking questions about major historic or current events, with special attention to educational level and life experiences. Abnormalities of *insight and judgment* are usually detected during the patient interview; a more detailed assessment can be elicited by asking the patient to describe how he or she would respond to situations having a variety of potential outcomes (e.g., "What would you do if you found a wallet on the sidewalk?"). *Abstract thought* can be tested by asking the patient to describe similarities between various objects or concepts (e.g., apple and orange, desk and chair, poetry and sculpture) or to list items having the same attributes (e.g., a list of four-legged animals). *Calculation ability* is assessed by having the patient carry out a computation that is appropriate to the patient's age and education (e.g., serial subtraction of 7 from 100 or 3 from 20; or word problems involving simple arithmetic).

Cranial Nerve Examination (See also Chaps. 25, 26, and 355)

- *The bare minimum: Check the fundi, visual fields, pupil size and reactivity, extraocular movements, and facial movements.*

The cranial nerves (CN) are best examined in numerical order, except for grouping together CN III, IV, and VI because of their similar function.

CN I (OLFACTORY) Testing is usually omitted unless there is suspicion for inferior frontal lobe disease (e.g., meningioma). With eyes closed, ask the patient to sniff a mild stimulus such as toothpaste or coffee and identify the odorant.

CN II (OPTIC) Check visual acuity (with eyeglasses or contact lens correction) using a Snellen chart or similar tool. Test the visual fields by confrontation, i.e., by comparing the patient's visual fields to your own. As a screening test, it is usually sufficient to examine the visual fields of both eyes simultaneously; individual eye fields should be tested if there is any reason to suspect a problem of vision by the history or other elements of the examination, or if the screening test reveals an abnormality. Face the patient at a distance of approximately 0.6 to 1.0 m (2 to 3 ft) and place your hands at the periphery of your visual fields in the plane that is equidistant between you and the patient. Instruct the patient to look directly at the center of your face and to indicate when and where he or she sees one of your fingers moving. Beginning with the two inferior quadrants and then the two superior quadrants, move your index finger of the right hand, left hand, or both hands simultaneously and observe whether the patient detects the movements. A single small-amplitude movement of the finger is sufficient for a normal response. Focal perimetry and tangent screen examinations should be used to map out visual field defects fully or to search for subtle abnormalities. Optic fundi should be examined with an ophthalmoscope, and the color, size, and degree of swelling or elevation of the optic disc noted, as well as the color and texture of the retina. The retinal vessels should be checked for size, regularity, arterial-venous nicking at crossing points, hemorrhage, exudates, etc.

CN III, IV, VI (OCULOMOTOR, TROCHLEAR, ABDUCENS) Describe the size and shape of pupils and reaction to light and accommodation (i.e., as the eyes converge while following your finger as it moves toward the bridge of the nose). To check extraocular movements, ask the patient to keep his or her head still while tracking the movement of the tip of your finger. Move the target slowly in the horizontal and vertical planes; observe any paresis, nystagmus, or abnormalities of smooth pursuit (saccades, oculomotor ataxia, etc.). If necessary, the relative position of the two eyes, both in primary and multidirectional gaze, can be assessed by comparing the reflections of a bright light off both pupils. However, in practice it is typically more useful to determine whether the patient describes diplopia in any direction of gaze; true diplopia should almost always resolve with one eye closed. Horizontal nystagmus is best assessed at 45° and not at extreme lateral gaze (which is uncomfortable for the patient); the target must often be held at the lateral position for at least a few seconds to detect an abnormality.

CN V (TRIGEMINAL) Examine sensation within the three territories of the branches of the trigeminal nerve (ophthalmic, maxillary, and mandibular) on each side of the face. As with other parts of the sensory examination, testing of two sensory modalities derived from different anatomic pathways (e.g., light touch and temperature) is sufficient for a screening examination. Testing of other modalities, the corneal reflex, and the motor component of CN V (jaw clench—masseter muscle) is indicated when suggested by the history.

CN VII (FACIAL) Look for facial asymmetry at rest and with spontaneous movements. Test eyebrow elevation, forehead wrinkling, eye closure, smiling, and cheek puff. Look in particular for differences in the lower versus upper facial muscles; weakness of the lower two-thirds of the face with preservation of the upper third suggests an upper motor neuron lesion, whereas weakness of an entire side suggests a lower motor neuron lesion.

CN VIII (VESTIBULOCOCHLEAR) Check the patient's ability to hear a finger rub or whispered voice with each ear. Further testing for air versus mastoid bone conduction (Rinne) and lateralization of a 512-Hz tuning fork placed at the center of the forehead (Weber) should be done if an abnormality is detected by history or examination. Any suspected problem should be followed up with formal audiometry. →***For further discussion of assessing vestibular nerve function in the setting of dizziness or coma, see Chaps. 20 and 257, respectively.***

CN IX, X Observe the position and symmetry of the palate and uvula at rest and with phonation ("aah"). The pharyngeal ("gag") reflex is evaluated by stimulating the posterior pharyngeal wall on each side with a sterile, blunt object (e.g., tongue blade), but the reflex is often absent in normal individuals.

CN XI Check shoulder shrug (trapezius muscle) and head rotation to each side (sternocleidomastoid) against resistance.

CN XII Inspect the tongue for atrophy or fasciculations, position with protrusion, and strength when extended against the inner surface of the cheeks on each side.

Motor Examination (See also Chap. 21)

- *The bare minimum: Look for muscle atrophy and check extremity tone. Assess upper extremity strength by checking for pronator drift and strength of wrist or finger extensors. Tap the biceps, patellar, and Achilles reflexes. Test for lower extremity strength by having the patient walk normally and on heels and toes.*

The motor examination includes observations of muscle appearance, tone, strength, and reflexes. Although gait is in part a test of motor function, it is usually evaluated separately at the end of the examination.

APPEARANCE Inspect and palpate muscle groups under good light and with the patient in a comfortable and symmetric position. Check for muscle fasciculations, tenderness, and atrophy or hypertrophy. Involuntary movements may be present at rest (e.g., tics, myoclonus, choreoathetosis), during maintained posture (pill-rolling tremor of Parkinson's disease), or with voluntary movements (intention tremor of cerebellar disease or familial tremor).

TONE Muscle tone is tested by measuring the resistance to passive movement of a relaxed limb. Patients often have difficulty relaxing during this procedure, so it is useful to distract the patient to minimize active movements. In the upper limbs, tone is assessed by rapid pronation and supination of the forearm and flexion and extension at the wrist. In the lower limbs, while the patient is supine the examiner's hands are placed behind the knees and rapidly raised; with normal tone the ankles drag along the table surface for a variable distance before rising, whereas increased tone results in an immediate lift of the heel off the surface. Decreased tone is most commonly due to lower motor neuron or peripheral nerve disorders. Increased tone may be evident as spasticity (resistance determined by the angle and velocity of motion; corticospinal tract disease), rigidity (similar resistance in all angles of motion; extrapyramidal disease), or paratonia (fluctuating changes in resistance; frontal lobe pathways or normal difficulty in relaxing). Cogwheel rigidity, in which passive motion elicits jerky interruptions in resistance, is seen in parkinsonism.

STRENGTH Testing for pronator drift is an extremely useful method for screening upper limb weakness. The patient is asked to hold both arms fully extended and parallel to the ground with eyes closed. This position should be maintained for ~10 s; any flexion at the elbow or fingers or pronation of the forearm, especially if asymmetric, is a sign of potential weakness. Muscle strength is further assessed by having the patient exert maximal effort for the particular muscle or muscle group being tested. It is important to isolate the muscles as much as possible, i.e., hold the limb so that only the muscles of interest are active. It is also helpful to palpate accessible muscles as they contract. Grading muscle strength and evaluating the patient's effort is an art that takes time and practice. Muscle strength is traditionally graded using the following scale:

0 = no movement
1 = flicker or trace of contraction but no associated movement at a joint
2 = movement with gravity eliminated
3 = movement against gravity but not against resistance
4− = movement against a mild degree of resistance
4 = movement against moderate resistance
4+ = movement against strong resistance
5 = full power

However, in many cases it is more practical to use the following terms:

Paralysis = no movement
Severe weakness = movement with gravity eliminated
Moderate weakness = movement against gravity but not against mild resistance
Mild weakness = movement against moderate resistance
Full strength

Noting the pattern of weakness is as important as assessing the magnitude of weakness. Unilateral or bilateral weakness of the upper limb extensors and lower limb flexors ("pyramidal weakness") suggests a lesion of the pyramidal tract, bilateral proximal weakness suggests myopathy, and bilateral distal weakness suggests peripheral neuropathy.

REFLEXES ■ Muscle Stretch Reflexes Those that are typically assessed include the biceps (**C5**, C6), brachioradialis (C5, **C6**), and triceps (**C7**, C8) reflexes in the upper limbs and the patellar or quadriceps (**L3**, L4) and Achilles (**S1**, S2) reflexes in the lower limbs. The patient should be relaxed and the muscle positioned midway between full contraction and extension. Reflexes may be enhanced by asking the patient to voluntarily contract other, distant muscle groups (Jendrassik maneuver). For example, upper limb reflexes may be reinforced by voluntary teeth-clenching, and the Achilles reflex by hooking the flexed fingers of the two hands together and attempting to pull them apart. For each reflex tested, the two sides should be tested sequentially, and it is important to determine the smallest stimulus required to elicit a reflex rather than the maximum response. Reflexes are graded according to the following scale:

0 = absent
1 = present but diminished
2 = normoactive
3 = exaggerated
4 = clonus

Cutaneous Reflexes The plantar reflex is elicited by stroking, with a noxious stimulus such as a tongue blade, the lateral surface of the sole of the foot beginning near the heel and moving across the ball of the foot to the great toe. The normal reflex consists of plantar flexion of the toes. With upper motor neuron lesions above the S1 level of the spinal cord, a paradoxical extension of the toe is observed, associated with fanning and extension of the other toes (termed an *extensor plantar response*, or *Babinski sign*). Superficial abdominal reflexes are elicited by gently stroking the abdominal surface near the umbilicus in a diagonal fashion with a sharp object (e.g., the wooden end of a cotton-tipped swab) and observing the movement of the umbilicus. Normally, the umbilicus will pull toward the stimulated quadrant. With upper motor neuron lesions, these reflexes are absent. They are most helpful when there is preservation of the upper (spinal cord level T9) but not lower (T12) abdominal reflexes, indicating a spinal lesion between T9 and T12, or when the response is asymmetric. Other useful cutaneous reflexes include the cremasteric (ipsilateral elevation of the testicle following stroking of the medial thigh; mediated by L1 and L2) and anal (contraction of the anal sphincter when the perianal skin is scratched; mediated by S2, S3, S4) reflexes. It is particularly important to test for these reflexes in any patient with suspected injury to the spinal cord or lumbosacral roots.

Primitive Reflexes With disease of the frontal lobe pathways, several primitive reflexes not normally present in the adult may appear. The suck response is elicited by lightly touching the center of the lips, and the root response the corner of the lips, with a tongue blade; the patient will move the lips to suck or root in the direction of the stimulus. The grasp reflex is elicited by touching the palm between the thumb and index finger with the examiner's fingers; a positive response is a forced grasp of the examiner's hand. In many instances stroking the back of the hand will lead to its release. The palmomental response is contraction of the mentalis muscle (chin) ipsilateral to a scratch stimulus diagonally applied to the palm.

Sensory Examination (See also Chap. 22)

- *The bare minimum: Ask whether the patient can feel light touch and the temperature of a cool object in each distal extremity. Check double simultaneous stimulation using light touch on the hands.*

Evaluating sensation is usually the most unreliable part of the ex-

amination, because it is subjective and is difficult to quantify. In the compliant and discerning patient, the sensory examination can be extremely helpful for the precise localization of a lesion. With patients who are uncooperative or lack an understanding of the tests, it may be useless. The examination should be focused on the suspected lesion. For example, in spinal cord, spinal root, or peripheral nerve abnormalities, all major sensory modalities should be tested while looking for a pattern consistent with a spinal level and dermatomal or nerve distribution. In patients with lesions at or above the brainstem, screening the primary sensory modalities in the distal extremities along with tests of "cortical" sensation is usually sufficient.

The five primary sensory modalities—light touch, pain, temperature, vibration, and joint position—are tested in each limb. Light touch is assessed by stimulating the skin with single, very gentle touches of the examiner's finger or a wisp of cotton. Pain is tested using a new pin, and temperature is assessed using a metal object (e.g., tuning fork) that has been immersed in cold and warm water. Vibration is tested using a 128-Hz tuning fork applied to the distal phalynx of the great toe or index finger just below the nailbed. By placing a finger on the opposite side of the joint being tested, the examiner compares the patient's threshold of vibration perception with his or her own. For joint position testing, the examiner grasps the digit or limb laterally and distal to the joint being assessed; small 1- to 2-mm excursions can usually be sensed. The Romberg maneuver is primarily a test of proprioception. The patient is asked to stand with the feet as close together as necessary to maintain balance while the eyes are open, and the eyes are then closed. A loss of balance with the eyes closed is an abnormal response.

"Cortical" sensation is mediated by the parietal lobes and represents an integration of the primary sensory modalities; testing cortical sensation is only meaningful when primary sensation is intact. Double simultaneous stimulation is especially useful as a screening test for cortical function; with the patient's eyes closed, the examiner lightly touches one or both hands and asks the patient to identify the stimuli. With a parietal lobe lesion, the patient may be unable to identify the stimulus on the contralateral side when both hands are touched. Other modalities relying on the parietal cortex include the discrimination of two closely placed stimuli as separate (two-point discrimination), identification of an object by touch and manipulation alone (stereognosis), and the identification of numbers or letters written on the skin surface (graphesthesia).

Coordination Examination (See also Chap. 21)

- *The bare minimum: Test rapid alternating movements of the fingers and feet, and the finger-to-nose maneuver.*

Coordination refers to the orchestration and fluidity of movements. Even simple acts require cooperation of agonist and antagonist muscles, maintenance of posture, and complex servomechanisms to control the rate and range of movements. Part of this integration relies on normal function of the cerebellar and basal ganglia systems. However, coordination also requires intact muscle strength and kinesthetic and propioceptive information. Thus, if the examination has disclosed abnormalities of the motor or sensory systems, the patient's coordination should be assessed with these limitations in mind.

Rapid alternating movements in the upper limbs are tested separately on each side by having the patient make a fist, partially extend the index finger, and then tap the index finger on the distal thumb as quickly as possible. In the lower limb, the patient rapidly taps the foot against the floor or the examiner's hand. Finger-to-nose testing is primarily a test of cerebellar function; the patient is asked to touch his or her index finger repetitively to the nose and then to the examiner's outstretched finger, which moves with each repetition. A similar test in the lower extremity is to have the patient raise the leg and touch the examiner's finger with the great toe. Another cerebellar test in the lower limbs is the heel-knee-shin maneuver; in the supine position the patient is asked to slide the heel of each foot from the knee down the shin of the other leg. For all these movements, the accuracy, speed, and rhythm are noted.

Gait Examination (See also Chap. 21)

- *The bare minimum: Observe the patient while walking normally, on the heels and toes, and along a straight line.*

Watching the patient walk is the most important part of the neurologic examination. Normal gait requires that multiple systems—including strength, sensation, and coordination—function in a highly integrated fashion. Unexpected abnormalities may be detected that prompt the examiner to return, in more detail, to other aspects of the examination. The patient should be observed while walking and turning normally, walking on the heels, walking on the toes, and walking heel-to-toe along a straight line. The examination may reveal decreased arm swing on one side (corticospinal tract disease), a stooped posture and short-stepped gait (parkinsonism), a broad-based unstable gait (ataxia), scissoring (spasticity), or a high-stepped, slapping gait (posterior column or peripheral nerve disease), or the patient may appear to be stuck in place (apraxia with frontal lobe disease).

NEUROLOGIC DIAGNOSIS The clinical data obtained from the history and the examination are interpreted in terms of neuroanatomy and neurophysiology and assembled into one of the known syndromes (see Table 346-2; online). From the syndrome the physician should be able to determine the anatomic localization that best explains the clinical findings, to narrow the list of diagnostic possibilities, and to select the laboratory tests most likely to be informative. The laboratory assessment may include (1) serum electrolytes; complete blood count; and renal, hepatic, endocrine, and immune studies; (2) cerebrospinal fluid examination; (3) focused neuroimaging studies (Chap. 347); or (4) electrophysiologic studies (Chaps. 348 and 363). The anatomic localization, mode of onset and course of illness, other medical data, and laboratory findings are then integrated to establish an etiologic diagnosis.

It should be emphasized that the neurologic examination may be normal even in patients with a serious neurologic disease, such as seizures, chronic meningitis, or a TIA. A comatose patient may arrive with no available history, and in such cases the approach is as described in Chap. 257. In other patients, an inadequate history may be overcome by a succession of examinations from which the course of the illness can be inferred. In perplexing cases it is useful to remember that uncommon presentations of common diseases are more likely than rare etiologies. Thus, even in tertiary care settings, multiple strokes are usually due to emboli and not vasculitis, and dementia with myoclonus is usually Alzheimer's disease and not a prionopathy or a paraneoplastic disorder. Finally, the most important task of a primary care physician faced with a patient who has a new neurologic complaint is to assess the urgency of referral to a specialist. Here, the imperative is to rapidly identify patients likely to have nervous system infections, acute strokes, and spinal cord compression or other treatable mass lesions and arrange for immediate care.

347 NEUROIMAGING IN NEUROLOGIC DISORDERS

William P. Dillon

The clinician caring for patients with neurologic symptoms is faced with an expanding number of imaging options, including computed tomography (CT), CT angiography (CTA), perfusion CT (pCT), magnetic resonance imaging (MRI), MR angiography (MRA), functional MRI (fMRI), MR spectroscopy (MRS), MR neurography, and perfusion MRI (pMRI). In addition, an increasing number of interventional neuroradiologic techniques are available including angiography; embolization and stenting of vascular structures; and spine interventions such as discography, selective nerve root injection, and epidural injections. Recent developments, such as multidetector CT angiography and gadolinium-enhanced MRA, have narrowed the indications for conventional angiography, which is now reserved for patients in whom small-vessel detail is essential for diagnosis or for whom interventional therapies are planned (Table 347-1).

In general, MRI is more sensitive than CT for the detection of lesions affecting the central nervous system (CNS), particularly those of the spinal cord, cranial nerves, and posterior fossa structures. Diffusion MR, a sequence that detects reduction of microscopic motion of water, is the most sensitive technique for detecting acute ischemic stroke and is useful in the detection of encephalitis, abscesses, and prion diseases. CT, however, can be quickly obtained and is widely available, making it a pragmatic choice for the initial evaluation of patients with suspected acute stroke, hemorrhage, and intracranial or spinal trauma. CT is also more sensitive than MRI for visualizing fine osseous detail and is indicated in the initial evaluation of conductive hearing loss as well as lesions affecting the skull base and calvarium.

TABLE 347-1 Guidelines for the Use of CT , Ultrasound, and MRI

Condition	Recommended Technique
Hemorrhage	
Acute parenchymal	CT > MR
Subacute/chronic	MRI
Subarachnoid hemorrhage	CT, CTA, lumbar puncture → angiography
Aneurysm	Angiography > CTA, MRA
Ischemic infarction	
Hemorrhagic infarction	CT
Bland infarction	MRI > CT
Carotid or vertebral dissection	MRI/MRA
Vertebral basilar insufficiency	CTA, MRI/MRA
Carotid stenosis	CTA > Doppler ultrasound, MRA
Suspected mass lesion	
Neoplasm, primary or metastatic	MRI + contrast
Infection/abscess	MRI + contrast
Immunosuppressed with focal findings	MRI + contrast
Vascular malformation	MRI +/− angiography
White matter disorders	MRI
Demyelinating disease	MRI +/− contrast
Dementia	MRI
Trauma	
Acute trauma	CT (noncontrast)
Shear injury/chronic hemorrhage	MRI
Headache/migraine	CT (noncontrast) / MRI
Seizure	
First time, no focal neurologic deficits	?CT as screen
Partial complex/refractory	MRI with coronal T2W imaging
Cranial neuropathy	MRI with contrast
Meningeal disease	MRI with contrast
SPINE	
Low back pain	
No neurologic deficits	MRI or CT after 4 weeks
With focal deficits	MRI > CT
Spinal stenosis	MRI or CT
Cervical spondylosis	MRI or CT myelography
Infection	MRI + contrast, CT
Myelopathy	MRI + contrast > myelography
Arteriovenous malformation	MRI, myelography/angiography

Note: CT, computed tomography; MRI, magnetic resonance imaging; MRA, MR angiography; CTA, CT angiography; T2W, T2-weighted.

COMPUTED TOMOGRAPHY ■ Technique The CT image is a cross-sectional representation of anatomy created by a computer-generated analysis of the attenuation of x-ray beams passed through a section of the body. As the x-ray beam, collimated to the desired slice width, rotates around the patient, it passes through selected regions in the body. X-rays that are not attenuated by the body are detected by sensitive x-ray detectors aligned 180° from the x-ray tube. A computer calculates a "back projection" image from the 360° x-ray attenuation profile. Greater x-ray attenuation, e.g., as caused by bone, results in areas of high "density," while soft tissue structures, which have poor attenuation of x-rays, are lower in density. The resolution of an image depends on the radiation dose, the collimation (slice thickness), the field of view, and the matrix size of the display. A modern CT scanner is capable of obtaining sections as thin as 0.5 to 1 mm with submillimeter resolution at a speed of 0.5 to 1 s per section; complete studies of the brain can be completed in 20 to 60 s.

Helical CT is a type of scanner in which continuous CT information is obtained while the patient moves through the x-ray beam. In the helical scan mode, the table moves continuously through the rotating x-ray beam, generating a "helix" of information that can be reformatted into various slice thicknesses. Single or multiple (from 4 to 32) detectors positioned 180 degrees to the x-ray source may result in multiple slices per revolution of the beam around the patient. These "multidetector" scanners have further decreased the time per examination and permit rapid assessment of vascular anatomy as well as perfusion characteristics of brain parenchyma (Figs. 347-1 and 347-2). Advantages of multidetector scanning include shorter scan times, reduced patient and organ motion, and the ability to acquire images dynamically during the infusion of intravenous contrast that can be used to construct CT angiograms of vascular structures and CT perfusion images (Figs. 347-1*B* and 347-2). CTA images may be processed later for display in three dimensions to yield angiogram-like images (Figs. 347-1*C* and 349-12). CTA has proven useful in assessing the carotid bifurcation and intracranial arterial and venous anatomy.

Intravenous contrast is often administered prior to or during a CT study to identify vascular structures and to detect defects in the blood-brain barrier (BBB), which are associated with disorders such as tumors, infarcts, and infections. In the normal CNS, only vessels and structures lacking a BBB (e.g., the pituitary gland, choroid plexus, and dura) enhance after contrast administration. The use of iodinated contrast agents carries a risk of allergic reaction and adds additional expense and radiation dose. While helpful in characterizing mass lesions as well as essential for the acquisition of CTA studies, the decision to use contrast material should always be considered carefully.

Indications CT is the primary study of choice in the evaluation of acute trauma to the brain and spine, suspected subarachnoid hemorrhage, and conductive hearing loss (Table 347-1). CT is complementary to MR in the evaluation of the skull base, orbit, and osseous structures of the spine. In the spine, CT is useful in evaluating patients with osseous spinal stenosis and spondylosis, but MRI is often preferred in those with neurologic deficits. CT can also be obtained following intrathecal contrast injection to evaluate the intracranial cisterns (*CT cisternography*) for cerebrospinal fluid (CSF) fistula, as well as the spinal subarachnoid space (*CT myelography*).

Complications CT is safe, fast, and reliable. Radiation exposure is between 3 and 5 cGy per study. Care must be taken to reduce exposure when imaging children. The most frequent complications are associ-

ated with use of intravenous contrast agents. Two broad categories of contrast media, ionic and nonionic, are in use. Although ionic agents are relatively safe and inexpensive, they are associated with a higher incidence of reactions and side effects. As a result, ionic agents have been largely replaced by safer nonionic compounds (Table 347-2).

Contrast nephropathy may result from hemodynamic changes, renal tubular obstruction and cell damage, or immunologic reactions to contrast agents. A rise in serum creatinine of at least 85 μmol/L (1 mg/dL) within 48 h of contrast administration is often used as a definition of contrast nephropathy, although other causes of acute renal failure must be excluded. The prognosis is usually favorable, with serum creatinine levels returning to baseline within 1 to 2 weeks. Risk factors for contrast nephropathy include advanced age, preexisting renal disease, diabetes, dehydration, and high contrast dose. Patients with diabetes and those with mild renal failure should be well hydrated prior to the administration of contrast agents, although careful consideration should be given to alternative imaging techniques, such as MR imaging. Nonionic, low-osmolar media produce fewer abnormalities in renal blood flow and less endothelial cell damage but should still be used carefully in patients at risk (Table 347-3).

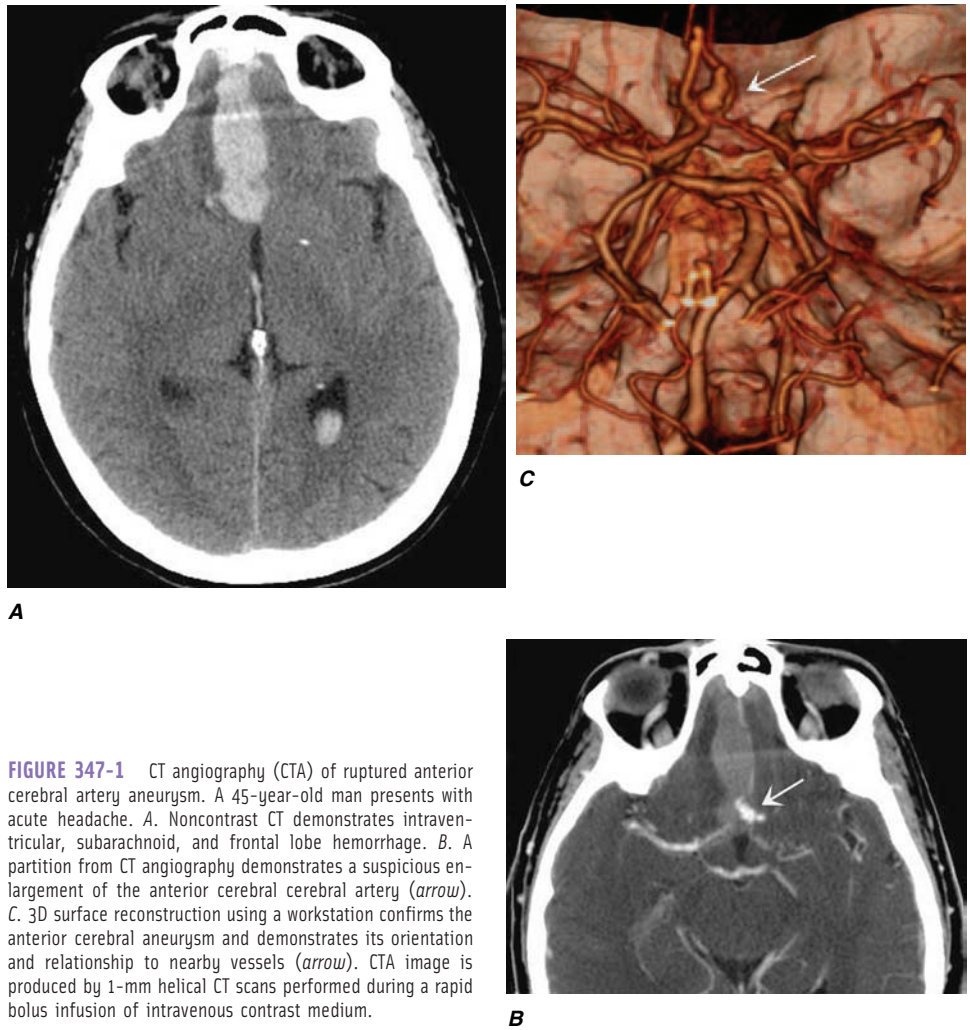

FIGURE 347-1 CT angiography (CTA) of ruptured anterior cerebral artery aneurysm. A 45-year-old man presents with acute headache. *A*. Noncontrast CT demonstrates intraventricular, subarachnoid, and frontal lobe hemorrhage. *B*. A partition from CT angiography demonstrates a suspicious enlargement of the anterior cerebral cerebral artery (*arrow*). *C*. 3D surface reconstruction using a workstation confirms the anterior cerebral aneurysm and demonstrates its orientation and relationship to nearby vessels (*arrow*). CTA image is produced by 1-mm helical CT scans performed during a rapid bolus infusion of intravenous contrast medium.

Other side effects are rare but include a sensation of warmth throughout the body and a metallic taste during intravenous administration of iodinated contrast media. Anaphylactic reactions to intravenous contrast media, while rare, are the most serious side effects and range from mild hives to bronchospasm, acute anaphylaxis, and death. The pathogenesis of these allergic reactions is not fully understood, but it is thought to include the release of mediators such as histamine, antibody-antigen reactions, and complement activation. Severe allergic reactions occur in ~0.04% of patients receiving nonionic media, sixfold fewer than with ionic media. Risk factors include a history of prior contrast reaction, food allergies to shellfish, and atopy (asthma and hay fever). In such patients, a noncontrast CT or MRI procedure should be considered as an alternative to contrast administration. If iodinated contrast is absolutely required, a nonionic agent should be used in conjunction with pretreatment with glucocorticoids and antihistamines (Table 347-4). Patients with allergic reactions to iodinated contrast material do not usually react to gadolinium-based MR contrast material, although it would be wise to pretreat patients with a prior allergic history to MR contrast administration in a similar fashion.

MAGNETIC RESONANCE IMAGING ■ Technique Magnetic resonance is a complex interaction between hydrogen protons in biologic tissues, a static magnetic field (the magnet), and energy in the form of radiofrequency (Rf) waves of a specific frequency introduced by coils placed next to the body part of interest. Spatial localization is achieved by magnetic gradients surrounding the main magnet, which impart slight changes in magnetic field throughout the imaging volume. The energy state of the hydrogen protons is transiently excited by the Rf, which is administered at a frequency specific for the field strength of the magnet. The subsequent return to equilibrium energy state (*relaxation*) of the protons results in a release of Rf energy (the *echo*), which is detected by the coils that delivered the Rf pulses. The echo is transformed by Fourier analysis into the information used to form an MR image. The MR image thus consists of a map of the distribution of hydrogen protons, with signal intensity imparted by both density of hydrogen protons as well as differences in the relaxation time (see below) of hydrogen protons on different molecules.

T1 AND T2 RELAXATION TIMES The rate of return to equilibrium of perturbed protons is called the *relaxation rate*. The relaxation rate varies among normal and pathologic tissues. The relaxation rate of a hydrogen proton in a tissue is influenced by local interactions with surrounding molecules and atomic neighbors. Two relaxation rates, T1 and T2, influence the signal intensity of the image. The T1 relaxation time is the time, measured in milliseconds, for 63% of the hydrogen protons to return to their normal equilibrium state, while the T2 relaxation is the time for 63% of the protons to become dephased owing to interactions among nearby protons. The intensity of the signal within various tissues and image contrast can be modulated by altering acquisition parameters, such as the interval between Rf pulses (TR) and the time between the Rf pulse and the signal reception (TE). So-called T1-weighted (T1W) images are produced by keeping the TR and TE relatively short. T2-weighted (T2W) images are produced by using longer TR and TE times. Fat and subacute hemorrhage have short T1 relaxation rates and a high signal intensity on T1W images. Structures containing more water, such as CSF and edema, have long T1 and T2 relaxation rates, a low signal intensity on T1W images, and a high signal intensity on T2W images (Table 347-5). Gray matter contains 10 to 15% more water than white matter, which accounts for much of its contrast on MRI (Fig. 347-3). T2W images are more sensitive than T1W images to edema, demyelination, infarction, and chronic hemorrhage, while T1-weighted imaging is more sensitive to subacute hemorrhage and fat-containing structures.

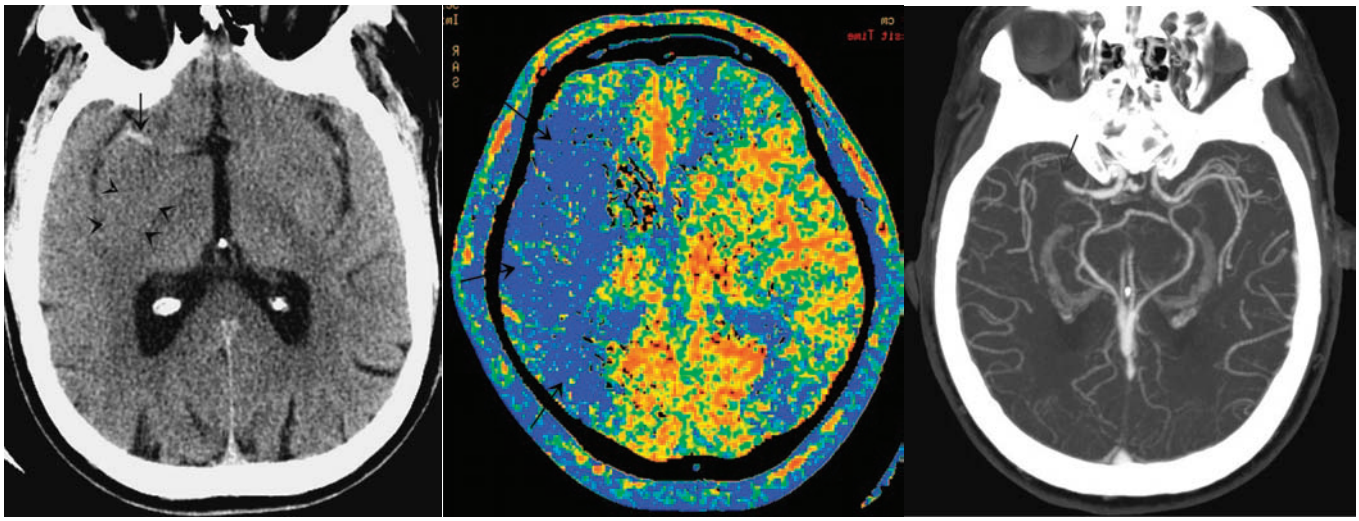

FIGURE 347-2 A 49-year-old man with acute neck pain and right hemiparesis. *A*. Axial noncontrast CT scan demonstrates high density within the right middle cerebral artery (*arrow*) associated with subtle low density involving the right putamen (*arrowheads*). *B*. Mean transit time map calculated from a CT perfusion study obtained with a 40-cc contrast injection during which 45 images were obtained at the same slice location. Prolongation of the mean transit time is visible throughout the right hemisphere (*arrows*). *C*. Axial maximum intensity projection from CTA study through the Circle of Willis demonstrates an abrupt occlusion of the proximal right middle cerebral artery (*arrow*). Reconstitution of flow via collaterals is seen distal to the occlusion, however, the patient sustained a right basal ganglia infarction. *D*. Sagittal reformation through the right internal carotid artery. Low-density lipid laden plaque (*arrows*) narrows the lumen of the internal carotid artery (*black arrows*). The internal jugular vein is shown (*white arrows*). *E*. 3D surface CTA images (different patient) demonstrate calcification and narrowing of the right internal carotid artery, consistent with atherosclerotic disease.

Many different MR pulse sequences exist, and each can be obtained in various planes (Figs. 347-3, 4, 5). The selection of a proper protocol that will best answer a clinical question depends on an accurate clinical history and indication for the examination. Fluid-attenuated inversion recovery (FLAIR) is a useful pulse sequence that produces T2W images in which the normally high signal intensity of CSF is suppressed

TABLE 347-2 *Guidelines for Use of Intravenous Contrast in Patients with Impaired Renal Function*

Serum Creatinine, μmol/L (mg/dL)[a]	Recommendation
<133 (<1.5)	Use either ionic or nonionic at 2 mL/kg to 150 mL total
133–177 (1.5–2.0)	Nonionic; hydrate diabetics 1 mL/kg per hour × 10 h
>177 (>2.0)	Consider noncontrast CT or MRI; nonionic contrast if required
177–221 (2.0–2.5)	Nonionic only if required (as above); contraindicated in diabetics
>265 (>3.0)	Nonionic IV contrast given only to patients undergoing dialysis within 24 h

[a] Risk is greatest in patients with rising creatinine levels.
Note: CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 347-3 *Indications for Use of Nonionic Contrast Media*

- Prior adverse reaction to contrast media, with the exception of heat, flushing, or an episode of nausea or vomiting
- Asthma or other serious lung disease
- History of atopic allergies (pretreatment with steroid/antihistamines recommended)
- Children under the age of 2 years
- Renal failure or creatinine >177 μmol/L (>2.0 mg/dL)
- Cardiac dysfunction, including recent or imminent cardiac decompensation, severe arrhythmias, unstable angina pectoris, recent myocardial infarction, and pulmonary hypertension
- Diabetes
- Severe debilitation

TABLE 347-4 *Guidelines for Premedication of Patients with Prior Contrast Allergy*

12 h prior to examination:
Prednisone, 40 mg PO *or* methylprednisolone, 32 mg PO
2 h prior to examination:
Prednisone, 40 mg PO *or* methylprednisolone, 32 mg PO *and*
Cimetidine, 300 mg PO *or* ranitidine, 150 mg PO
Immediately prior to examination:
Benadryl, 50 mg IV (alternatively, can be given PO 2 h prior to exam)

TABLE 347-5 *Some Common Intensities on T1- and T2-Weighted MRI Sequences*

			Signal Intensity			
Image	*TR*	*TE*	*CSF*	*Fat*	*Brain*	*Edema*
T1W	Short	Short	Low	High	Low	Low
T2W	Long	Long	High	Low	High	High

Note: TR, interval between radiofrequency (Rf) pulses; TE, interval between Rf pulse and signal reception; CSF, cerebrospinal fluid; T1W and T2W, T1- and T2-weighted.

(Fig. 347-5*A*). FLAIR images are more sensitive than standard spine echo images for the detection of lesions within or adjacent to CSF. Gradient echo imaging is most sensitive to magnetic susceptibility as seen with blood, calcium, and air, and is indicated in patients with traumatic brain injury. MR images can be generated in sagittal, coronal, axial, or oblique planes without changing the patient's position. Each plane obtained requires a separate sequence lasting 1 to 10 min. Three-dimensional volumetric imaging is also possible with MRI, resulting in a volume of data that can be reformatted in any orientation on a workstation to highlight certain disease processes.

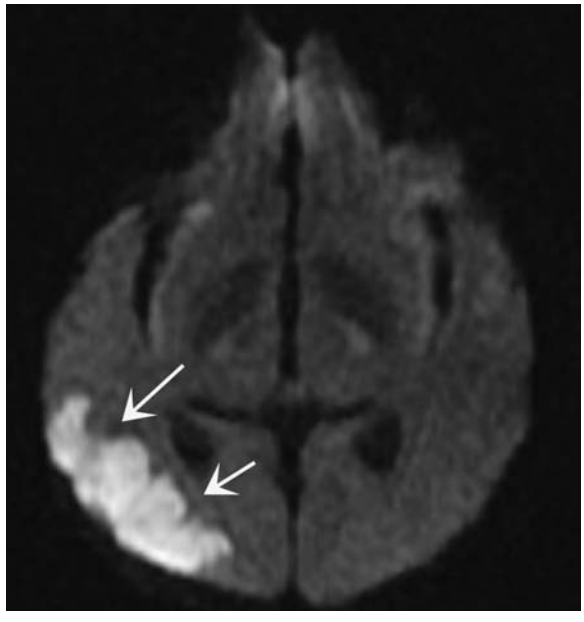
MR CONTRAST MATERIAL The heavy-metal element gadolinium forms the basis of all currently approved intravenous MR contrast agents. Gadolinium is a paramagnetic substance, which means that it reduces the T1 and T2 relaxation times of nearby water protons, resulting in a high signal on T1W images and a low signal on T2W images (the latter requires a sufficient local concentration, usually in the form of a bolus). Unlike iodinated contrast agents, the effect of MR contrast agents depends on the presence of local hydrogen protons on which it must act to achieve the desired effect. Gadolinium is chelated to DTPA (diethylenetriaminepentaacetic acid), which allows safe renal excretion. Approximately 0.2 mL/kg body weight is administered intravenously; the cost is ~$60 per dose. Gadolinium-DTPA does not cross the intact BBB but will enhance lesions lacking a BBB (Fig. 347-4*A*) and areas of the brain that normally are devoid of the BBB. The agent is well tolerated, and severe allergic reactions to gadolinium are rare but have been reported. The adverse reaction rate in patients with a prior history of atopy or asthma is 3.7%; however, the reaction rate increases to 6.3% in those patients with a prior history of unspecified allergic reaction to iodinated contrast. These agents can be administered safely to children as well as adults. Renal failure does not occur.

Complications and Contraindications From the patient's perspective, an MRI examination can be intimidating, and a higher level of cooperation is required than with CT. The patient lies on a table that is moved into a long, narrow gap within the magnet. Approximately 5% of the population experiences severe claustrophobia in the MR environment. This can be reduced by mild sedation but remains a problem for some. Unlike CT, movement of the patient during an MR sequence distorts all the images; therefore, uncooperative patients should either be sedated for the MR study or scanned with CT. Generally, children under the age of 10 years usually require conscious sedation in order to complete the MR examination without motion degradation.

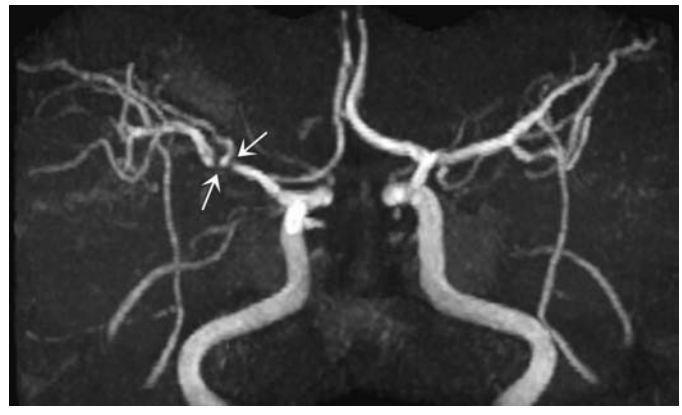
MRI is considered safe for patients, even at very high field strengths (>3 to 4 T). Serious injuries have been caused, however, by attraction of ferromagnetic objects into the magnet, which act as missiles if brought too close to the magnet. Likewise, ferromagnetic implants, such as aneurysm clips, may torque within the magnet, causing damage to vessels and even death. Metallic foreign bodies in the eye have moved and caused intraocular hemorrhage; screening for ocular metallic fragments is indicated in those with a history of metal work or ocular metallic foreign bodies. Implanted cardiac pacemakers are a contraindication to MRI owing to the risk of induced arrhythmias. All health care personnel and patients must be screened and educated thoroughly to prevent such disasters as the magnet is always "on." Table 347-6 lists common contraindications for MRI.

MAGNETIC RESONANCE ANGIOGRAPHY On routine spin echo MR sequences, moving protons (e.g., flowing blood, CSF) exhibit complex MR signals that range from high to low signal intensity relative to background stationary tissue. Fast-flowing blood returns no signal (flow void) on routine T1W or T2W spin echo MR images. Slower flowing blood, as occurs in veins or distal to arterial stenoses, may appear high in signal. However, using special pulse sequences called *gradient echo sequences*, it is possible to increase the signal intensity of moving protons in contrast to the low signal background intensity of stationary tissue. This creates angiography-like images, which can be manipulated in three dimensions to highlight vascular anatomy and relationships.

Two MRA techniques, time-of-flight (TOF) and phase-contrast, are routinely used. TOF, currently the technique used most frequently, relies on the suppression of nonmoving tissue to provide a low-intensity background for the high signal intensity of flowing blood entering the section; arterial or venous structures may be highlighted. A typical TOF angiography sequence results in a series of contiguous thin MR sections (0.9 mm thick), which can be viewed as a stack and manipulated to create an angiographic image data set that can be reformatted

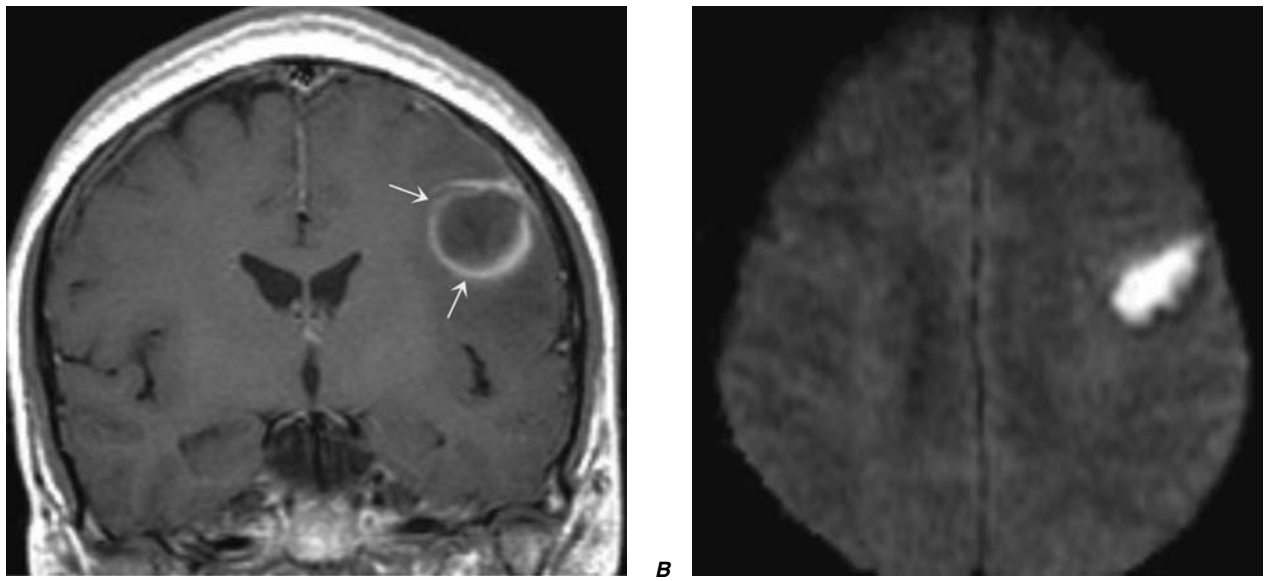


A



B

FIGURE 347-3 *A*. Axial echo-planar diffusion-weighted MR image demonstrates a large area of reduced diffusion consistent with acute cerebral ischemia (*arrows*) located in the right posterior frontotemporal lobe. Reduced diffusion is consistent with cytotoxic edema and is most commonly associated with acute cerebral infarction. *B*. Time-of-flight MR angiography through the circle of Willis demonstrates a high-grade stenosis at the left middle cerebral artery bifurcation (*arrows*).



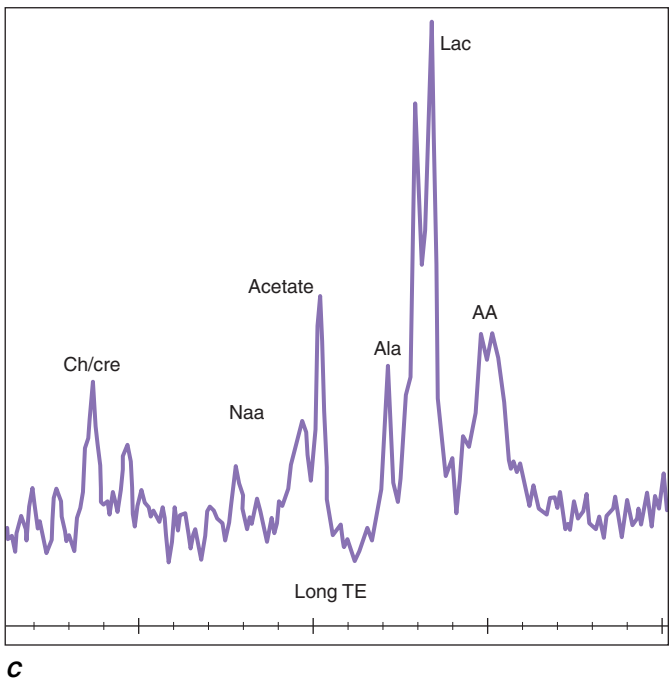


FIGURE 347-4 Middle age woman with fever and right hemiparesis. *A*. Coronal postcontrast T1-weighted image demonstrates a ring enhancing mass in the left frontal lobe (*arrows*). *B*. Axial diffusion weighted image demonstrates restricted diffusion (high signal intensity) within the lesion. Restricted diffusion in such a setting is highly suggestive of cerebral abscess. *C*. Single voxel proton spectroscopy obtained with a TE of 288 ms. In addition to the reduced Naa peak, abnormal peaks including acetate, alanine (Ala), lactate (Lac), and amino acids (AA) are visualized. These are highly suggestive of cerebral abscess. At biopsy a streptococcal abscess was identified.

and viewed in various planes and angles, much like that seen with conventional angiography (Fig. 347-3*B*). Noncontrast enhanced MRA provides a vascular flow map rather than the anatomic map shown by conventional angiography.

Phase-contrast MRA has a longer acquisition time than TOF MRA, but in addition to providing anatomic information similar to that of TOF imaging, it can be used to reveal the velocity and direction of blood flow in a given vessel. Through the selection of different imaging parameters, differing blood velocities can be highlighted; selective venous and arterial MRA images can thus be obtained. One advantage of phase-contrast MRA is the excellent suppression of high signal intensity background structures.

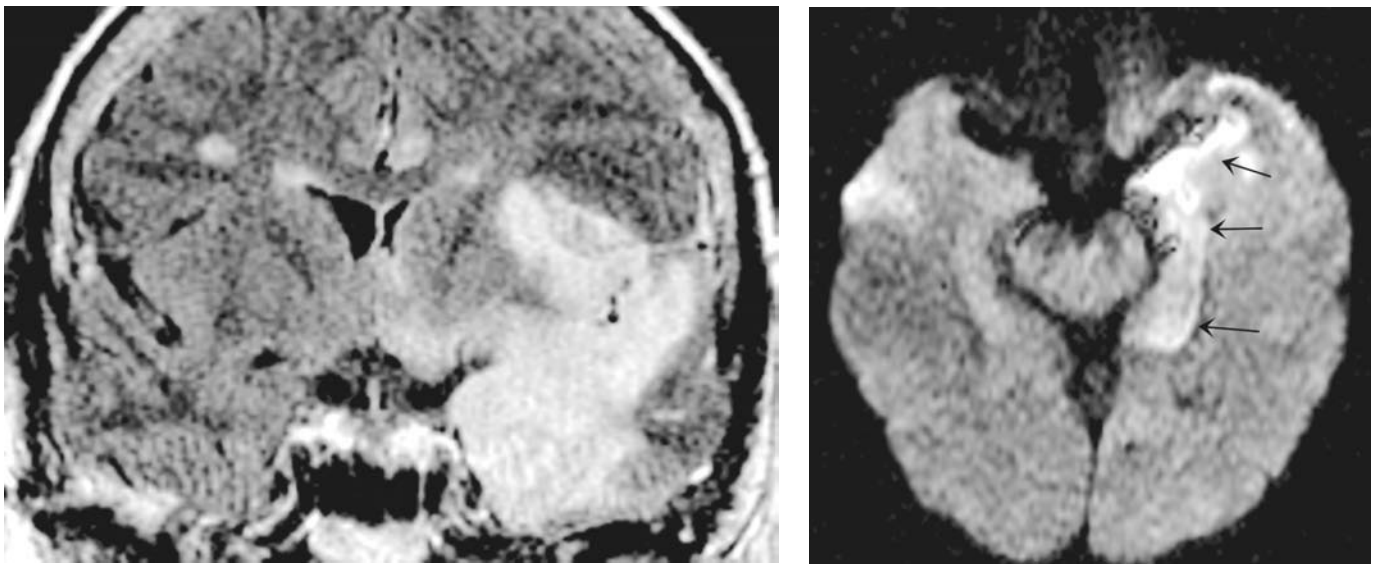
MRA can also be acquired during infusion of contrast material. Recently, contrast-enhanced MRA has become the standard for extracranial vascular MRA. This technique entails rapid imaging using coronal three-dimensional TOF sequences during a bolus infusion of 15 to 20 mL of gadolinium-DTPA. Proper technique and timing of acquisition relative to bolus arrival are critical for success. Advantages include a reduction in the time of acquisition (1 to 2 min vs. 10 min) and flow-related artifacts.

MRA is lower in spatial resolution compared with conventional film-based angiography, and therefore the detection of small-vessel detail, such as is required in the workup of vasculitis, is problematic. MRA is also less sensitive to slowly flowing blood and thus may not reliably differentiate complete from near-complete occlusions. Motion, either by the patient or by anatomic structures, may distort the MRA images, creating artifacts. These limitations notwithstanding, MRA has proved useful in evaluation of the extracranial carotid and vertebral circulation as well as of larger-caliber intracranial arteries and dural sinuses. It has also proved useful in the noninvasive detection of intracranial aneurysms and vascular malformations.

ECHO-PLANAR MR IMAGING Recent improvements in gradients, software, and high-speed computer processors now permit extremely rapid MRI of the brain. With echo-planar MRI (EPI), fast gradients are switched on and off at high speeds to create the information used to form an image. In routine spin echo imaging, images of the brain can be obtained in 5 to 10 min. With EPI, all of the information required for processing an image is accumulated in 50 to 150 ms, and the information for the entire brain is obtained in 1 to 2 min, depending on the degree of resolution required or desired. Fast MRI reduces patient and organ motion, permitting diffusion imaging (Figs. 347-3, 4, 5 and Fig. 349-13), perfusion imaging during contrast infusion fMRI, and kinematic motion studies.

Perfusion and diffusion imaging are EPI techniques that are useful in early detection of ischemic injury of the brain and may be useful together to demonstrate infarcted tissue as well as ischemic but potentially viable tissue at risk of infarction (e.g., the ischemic penumbra). Diffusion-weighted imaging (DWI) assesses microscopic motion of water; restriction of motion appears as relative high signal intensity on diffusion-weighted images. DWI is the most sensitive technique for detection of acute cerebral infarction of $<$7 days' duration and is also sensitive to encephalitis and abscess formation, all of which demonstrate reduced diffusion or high signal.

Perfusion MRI involves the acquisition of EPI images during a rapid bolus of contrast material. Relative perfusion abnormalities can be identified. The relative cerebral blood volume, mean transit time,



A **B**

FIGURE 347-5 Herpes encephalitis. A 40-year-old man presents with altered mental status and fever. *A.* Coronal T2-weighted FLAIR image demonstrates expansion and high signal intensity involving the left medial temporal lobe, insular cortex, and left cingulate gyrus. *B.* Diffusion weighted image demonstrates high signal intensity indicative of restricted diffusion involving the left medial temporal lobe and hippocampus (*arrows*). This is most consistent with neuronal destruction and can be seen in acute infarction as well as infectious and inflammatory encephalitis. PCR evaluation of the CSF confirmed Herpes encephalitis. (*Case courtesy of Howard Rowley, MD, University of Wisconsin.*)

and cerebral blood flow throughout the image can be calculated within regions of interest. Delay in mean transit time and reduction in cerebral blood volume and cerebral blood flow are typically seen in infarction. Elevated or normal cerebral blood volume in a setting of reduced blood flow may indicate tissue that is at risk of infarction. pMRI imaging can also be used in the assessment of brain tumors where it has been shown to be helpful in differentiating intraaxial primary tumors from extraaxial tumors or metastasis.

Diffusion tract imaging (DTI) is a special diffusion technique that is capable of demonstrating white matter tracts and their relationship to lesions of the brain. Preferential microscopic motion of water along white matter tracts is detected by diffusion MR, which can also indicate the direction of white matter fiber tracts. This new technique has great potential in the assessment of brain maturation as well as disease entities that undermine the integrity of the white matter architecture.

fMRI of the brain is an EPI technique that localizes regions of activity in the brain following task activation. Neuronal activity elicits an increase in the delivery of oxygenated blood flow to a specific region of the brain, resulting in a slight alteration in the balance of oxyhemoglobin and deoxyhemoglobin, which yields a 2 to 3% increase in signal intensity within draining veins. Further work will determine whether these techniques are cost effective or clinically useful, but currently preoperative somatosensory and auditory cortex localization is possible. This technique has proved useful to neuroscientists interested in interrogating the localization of certain brain functions.

MAGNETIC RESONANCE NEUROGRAPHY MR neurography is an MR technique that shows promise in detecting increased signal in irritated, inflamed, or infiltrated nerves. These images are obtained with fat-suppressed fast spin echo imaging or short inversion recovery sequences, and they may indicate nerves that are responsible for pain syndromes more precisely. Irritated or infiltrated nerves will demonstrate high signal on T2W imaging.

POSITRON EMISSION TOMOGRAPHY (PET) PET relies on the detection of positrons emitted during the decay of a radionuclide that has been injected into a patient. The most frequently used moiety is 2-[^{18}F]fluoro-2-deoxy-D-glucose (FDG), which is an analogue of glucose and is taken up by cells competitively with 2-deoxyglucose. Multiple images of glucose uptake activity are formed after 45 to 60 min. Images reveal differences in regional glucose activity among normal and pathologic brain structures. A lower activity of FDG in the parietal lobes has been associated with Alzheimer's disease. FDG PET is used primarily for the detection of extracranial metastatic disease. PET is no longer used primarily for differentiation of tumor from radiation necrosis.

MYELOGRAPHY ■ Technique Myelography involves the intrathecal instillation of specially formulated water-soluble iodinated contrast medium into the lumbar or cervical subarachnoid space. CT scanning is usually performed after myelography (*CT myelography*) to better demonstrate the spinal cord and roots, which appear as filling defects in the opacified subarachnoid space. *Low-dose CT myelography*, in which CT is performed after the subarachnoid injection of a small amount of relatively dilute contrast material, has replaced conventional myelography for many indications, thereby reducing exposure to radiation and contrast media. Newer multidetector scanners now obtain CT studies quickly so that reformations in sagittal and coronal planes, equivalent to traditional myelography projections, are now routine.

Indications Myelography has been largely replaced by CT myelography and MRI for diagnosis of diseases of the spinal canal and cord (Table 347-1). Remaining indications for conventional plain film myelography include the evaluation of suspected meningeal or arachnoid cysts and the localization of spinal dural arteriovenous or CSF fistulas. Conventional myelography and CT myelography provide the most precise information in patients with prior spinal fusion and spinal fixation hardware.

Contraindications Myelography is relatively safe; however, it should be performed with caution in any patient with elevated intracranial pressure or a history of allergic reaction to intrathecal contrast media. In patients with a suspected spinal block, MR is the preferred technique. If myelography is necessary, only a small amount of contrast medium should be instilled below the lesion in order to minimize the risk of neurologic deterioration. Lumbar puncture is to be avoided in patients with bleeding disorders, including patients receiving anticoagulant therapy, as well as in those with infections of the soft tissues.

Complications Headache, nausea, and vomiting are the most frequent complications of myelography, occurring in up to 38% of patients. These symptoms are thought to result from neurotoxic effects of the contrast agent, persistent leakage of CSF at the puncture site, or psy-

TABLE 347-6 Common Contraindications to MR Imaging

- Cardiac pacemaker or permanent pacemaker leads
- Internal defibrillatory device
- Cochlear prostheses
- Bone growth stimulators
- Spinal cord stimulators
- Electronic infusion devices
- Intracranial aneurysm clips (some but not all)
- Ocular implants (some) or ocular metallic foreign body
- McGee stapedectomy piston prosthesis
- Omniphase penile implant
- Swan-Ganz catheter
- Magnetic stoma plugs
- Magnetic dental implants
- Magnetic sphincters
- Ferromagnetic IVC filters, coils, stents—safe 6 weeks after implantation
- Tattooed eyeliner (contains ferromagnetic material and may irritate eyes)

chological reactions to the procedure. Vasovagal syncope may occur during lumbar puncture; it is accentuated by the upright position used during lumbar myelography. Adequate hydration before and after myelography will reduce the incidence of this complication. Postural headache (post–lumbar puncture headache) is generally due to leakage of CSF from the puncture site, resulting in CSF hypotension; management is discussed in Chap. 14. Hearing loss is a rare complication of myelography. It may result from a direct toxic effect of the contrast medium or from an alteration of the pressure equilibrium between CSF and perilymph in the inner ear. Puncture of the spinal cord is a rare but serious complication of cervical (C1-2) and high lumbar puncture. The risk of cord puncture is greatest in patients with spinal stenosis or conditions that reduce CSF volume. In these settings, a low-dose lumbar injection followed by thin-section CT or MRI is a safer alternative to cervical puncture. Intrathecal contrast reactions are rare, but aseptic meningitis and encephalopathy may occur. The latter is usually dose-related and associated with contrast entering the intracranial subarachnoid space. Seizures occur following myelography in 0.1 to 0.3% of patients. Risk factors include a preexisting seizure disorder and the use of a total iodine dose of >4500 mg. Other reported symptoms include hyperthermia, hallucinations, depression, and anxiety states. These side effects have been reduced by the development of nonionic, water-soluble contrast agents, as well as by head elevation and generous hydration following myelography.

SPINE INTERVENTIONS ■ Discography The evaluation of back pain and radiculopathy may require diagnostic procedures that attempt either to reproduce the patient's pain or relieve it, indicating its correct source. Discography is performed by fluoroscopic placement of a 22- to 25-gauge needle into the intervertebral disc and subsequent injection of 1 to 3 mL of contrast media. The intradiscal pressure is recorded, as is an assessment of the patient's response to the injection of contrast material. Typically little or no pain is felt during injection of a normal disc, which does not accept much more than 1 mL of contrast material, even at pressures as high as 415 to 690 kPa (60 to 100 lb/in^2). CT and plain films are obtained following the procedure.

Selective Nerve Root and Epidural Spinal Injections Percutaneous selective nerve root and epidural blocks with glucocorticoid and anesthetic mixtures may be both therapeutic as well as diagnostic, especially if a patient's pain is relieved. Typically 1 to 2 mL of an equal mixture of a long-acting glucocorticoid such as betamethasone and a long-acting anesthetic such as bupivicain 0.75% is instilled under CT or fluoroscopic guidance in the intraspinal epidural space or adjacent to an existing nerve root.

ANGIOGRAPHY ■ Technique Catheter angiography is indicated in the evaluation of patients with vascular pathology, particularly of smaller intracranial vessels. However, it carries the greatest risk of morbidity of all diagnostic imaging procedures, owing to the necessity of inserting a catheter into a blood vessel, directing the catheter to the required location, injecting contrast material to visualize the vessel, and removing the catheter while maintaining hemostasis. Therapeutic transcatheter procedures (see below) have become important options for the treatment of some cerebrovascular diseases. The decision to undertake a diagnostic or therapeutic angiographic procedure requires careful assessment of the goals of the investigation and its attendant risks.

To improve tolerance to contrast agents, patients undergoing angiography should be well hydrated before and after the procedure. Since the femoral route is used most commonly, the femoral artery must be compressed after the procedure to prevent a hematoma from developing. The puncture site and distal pulses should be evaluated carefully after the procedure; complications can include thigh hematoma or lower extremity emboli.

Indications Table 347-1 lists some of the indications for conventional angiography. Angiography has been replaced for many indications by CT/CTA or MRI/MRA; however, angiography is still used for evaluating intracranial small-vessel pathology (such as vasculitis), for assessing vascular malformations and aneurysms, and in endovascular therapeutic procedures.

Complications A common femoral arterial puncture provides retrograde access via the aorta to the aortic arch and great vessels. The most feared complication of cerebral angiography is stroke. Thrombus can form on or inside the tip of the catheter, and atherosclerotic thrombus or plaque can be dislodged by the catheter or guidewire or by the force of injection and can embolize distally in the cerebral circulation. Risk factors for ischemic complications include limited experience on the part of the angiographer, atherosclerosis, vasospasm, low cardiac output, decreased oxygen-carrying capacity, advanced age, and possibly migraine. The risk of a neurologic complication varies but is ~4% for transient ischemic attack and stroke, 1% for permanent deficit, and <0.1% for death.

Ionic contrast material injected into the cerebral vasculature can be neurotoxic if the BBB is breached, either by an underlying disease or by the injection of hyperosmolar contrast agent. Ionic contrast media are less well tolerated than nonionic media, probably because they can induce changes in cell membrane electrical potentials. Patients with dolichoectasia of the basilar artery can suffer reversible brainstem dysfunction and acute short-term memory loss during angiography, owing to the slow percolation of the contrast material and the consequent prolonged exposure of the brain. Rarely, an intracranial aneurysm ruptures during an angiographic contrast injection, causing subarachnoid hemorrhage, perhaps as a result of injection under high pressure.

Spinal Angiography Spinal angiography may be indicated to evaluate vascular malformations and tumors and to identify the artery of Adamkiewicz (Chap. 356) prior to aortic aneurysm repair. The procedure is lengthy and requires the use of relatively large volumes of contrast; the incidence of serious complications, including paraparesis, subjective visual blurring, and altered speech, is ~2%. Gadolinium-enhanced MRA has been used successfully in this setting and has promise for replacing diagnostic spinal angiography for some indications.

INTERVENTIONAL NEURORADIOLOGY This rapidly developing field is providing new therapeutic options for patients with difficult neurovascular problems. Available procedures include detachable coil therapy for aneurysms, particulate or liquid adhesive embolization of arteriovenous malformations, balloon angioplasty and stenting of arterial stenosis or vasospasm, transarterial or transvenous embolization of dural arteriovenous fistulas, balloon occlusion of carotid-cavernous and vertebral fistulas, endovascular treatment of vein-of-Galen malformations, preoperative embolization of tumors, and thrombolysis of acute arterial or venous thrombosis. Many of these disorders place the patient at high risk of cerebral hemorrhage, stroke, or death.

The highest complication rates are found with the therapies designed to treat the highest-risk diseases. In a large series of surgically difficult intracranial aneurysms treated with detachable balloons, Higashida and colleagues reported a 7.4% incidence of stroke and a 9.8% death rate. These figures must be considered in light of the high morbidity and mortality associated with untreated and surgically unap-

proachable aneurysms (Chap. 349). The advent of the electrolytically detachable coil has reduced these rates and ushered in a new era in the treatment of cerebral aneurysms. One recent double-blind trial (ISAT) found a 28% reduction of morbity and mortality at 1 year among those treated for anterior circulation aneurysm with detachable coils versus neurosurgical clipping. It remains to be determined what the role of coils will be relative to surgical options, but in many centers, coiling of aneurysms has become standard therapy for many aneurysms.

Section 2 Diseases of the Central Nervous System

348 SEIZURES AND EPILEPSY

Daniel H. Lowenstein

A *seizure* (from the Latin *sacire*, "to take possession of") is a paroxysmal event due to abnormal, excessive, hypersynchronous discharges from an aggregate of central nervous system (CNS) neurons. Depending on the distribution of discharges, this abnormal CNS activity can have various manifestations, ranging from dramatic convulsive activity to experiential phenomena not readily discernible by an observer. Although a variety of factors influence the incidence and prevalence of seizures, ~5 to 10% of the population will have at least one seizure, with the highest incidence occurring in early childhood and late adulthood.

The meaning of the term seizure needs to be carefully distinguished from that of epilepsy. *Epilepsy* describes a condition in which a person has *recurrent* seizures due to a chronic, underlying process. This definition implies that a person with a single seizure, or recurrent seizures due to correctable or avoidable circumstances, does not necessarily have epilepsy. Epilepsy refers to a clinical phenomenon rather than a single disease entity, since there are many forms and causes of epilepsy. However, among the many causes of epilepsy there are various *epilepsy syndromes* in which the clinical and pathologic characteristics are distinctive and suggest a specific underlying etiology.

Using the definition of epilepsy as two or more unprovoked seizures, the incidence of epilepsy is ~0.3 to 0.5% in different populations throughout the world, and the prevalence of epilepsy has been estimated at 5 to 10 persons per 1000.

CLASSIFICATION OF SEIZURES

Determining the type of seizure that has occurred is essential for focusing the diagnostic approach on particular etiologies, selecting the appropriate therapy, and providing potentially vital information regarding prognosis. In 1981, the International League Against Epilepsy (ILAE) published a modified version of the International Classification of Epileptic Seizures that has continued to be a useful classification system (Table 348-1). This system is based on the clinical features of seizures and associated electroencephalographic findings. Other potentially distinctive features such as etiology or cellular substrate are not considered in this classification system, although this will undoubtedly change in the future as more is learned about the pathophysiologic mechanisms that underlie specific seizure types.

TABLE 348-1 Classification of Seizures

1. Partial seizures
   a. Simple partial seizures (with motor, sensory, autonomic, or psychic signs)
   b. Complex partial seizures
   c. Partial seizures with secondary generalization
2. Primarily generalized seizures
   a. Absence (petit mal)
   b. Tonic-clonic (grand mal)
   c. Tonic
   d. Atonic
   e. Myoclonic
3. Unclassified seizures
   a. Neonatal seizures
   b. Infantile spasms

A fundamental principle is that seizures may be either partial (synonymous with focal) or generalized. *Partial seizures* are those in which the seizure activity is restricted to discrete areas of the cerebral cortex. *Generalized seizures* involve diffuse regions of the brain simultaneously. Partial seizures are usually associated with structural abnormalities of the brain. In contrast, generalized seizures may result from cellular, biochemical, or structural abnormalities that have a more widespread distribution.

PARTIAL SEIZURES Partial seizures occur within discrete regions of the brain. If consciousness is fully preserved during the seizure, the clinical manifestations are considered relatively simple and the seizure is termed a *simple partial seizure*. If consciousness is impaired, the symptomatology is more complex and the seizure is termed a *complex partial seizure*. An important additional subgroup comprises those seizures that begin as partial seizures and then spread diffusely throughout the cortex, i.e., *partial seizures with secondary generalization*.

Simple Partial Seizures Simple partial seizures cause motor, sensory, autonomic, or psychic symptoms without an obvious alteration in consciousness. For example, a patient having a partial motor seizure arising from the right primary motor cortex in the vicinity controlling hand movement will note the onset of involuntary movements of the contralateral, left hand. These movements are typically clonic (i.e., repetitive, flexion/extension movements) at a frequency of ~2 to 3 Hz; pure tonic posturing may be seen as well. Since the cortical region controlling hand movement is immediately adjacent to the region for facial expression, the seizure may also cause abnormal movements of the face synchronous with the movements of the hand. The electroencephalogram (EEG) recorded with scalp electrodes during the seizure (i.e., an ictal EEG) may show abnormal discharges in a very limited region over the appropriate area of cerebral cortex if the seizure focus involves the cerebral convexity. Seizure activity occurring within deeper brain structures is often not recorded by the standard EEG, however, and may require intracranial electrodes for its detection.

Three additional features of partial motor seizures are worth noting. First, in some patients the abnormal motor movements may begin in a very restricted region such as the fingers and gradually progress (over seconds to minutes) to include a larger portion of the extremity. This phenomenon, described by Hughlings Jackson and known as a "Jacksonian march," represents the spread of seizure activity over a progressively larger region of motor cortex. Second, patients may experience a localized paresis (Todd's paralysis) for minutes to many hours in the involved region following the seizure. Third, in rare instances the seizure may continue for hours or days. This condition, termed *epilepsia partialis continua*, is often refractory to medical therapy.

Simple partial seizures may also manifest as changes in somatic sensation (e.g., paresthesias), vision (flashing lights or formed hallucinations), equilibrium (sensation of falling or vertigo), or autonomic function (flushing, sweating, piloerection). Simple partial seizures arising from the temporal or frontal cortex may also cause alterations in hearing, olfaction, or higher cortical function (psychic symptoms). This includes the sensation of unusual, intense odors (e.g., burning rubber or kerosene) or sounds (crude or highly complex sounds), or an epigastric sensation that rises from the stomach or chest to the head. Some patients describe odd, internal feelings such as fear, a sense of

impending change, detachment, depersonalization, déjà vu, or illusions that objects are growing smaller (micropsia) or larger (macropsia). When such symptoms precede a complex partial or secondarily generalized seizure, these simple partial seizures serve as a warning, or *aura*.

Complex Partial Seizures Complex partial seizures are characterized by focal seizure activity accompanied by a transient impairment of the patient's ability to maintain normal contact with the environment. The patient is unable to respond appropriately to visual or verbal commands during the seizure and has impaired recollection or awareness of the ictal phase. The seizures frequently begin with an aura (i.e., a simple partial seizure) that is stereotypic for the patient. The start of the ictal phase is often a sudden behavioral arrest or motionless stare, which marks the onset of the period of amnesia. The behavioral arrest is usually accompanied by *automatisms*, which are involuntary, automatic behaviors that have a wide range of manifestations. Automatisms may consist of very basic behaviors such as chewing, lip smacking, swallowing, or "picking" movements of the hands, or more elaborate behaviors such as a display of emotion or running. The patient is typically confused following the seizure, and the transition to full recovery of consciousness may range from seconds up to an hour. Examination immediately following the seizure may show an anterograde amnesia or, in cases involving the dominant hemisphere, a postictal aphasia.

The routine, interictal (i.e., between seizures) EEG in patients with complex partial seizures is often normal or may show brief discharges termed *epileptiform spikes*, or *sharp waves*. Since complex partial seizures can arise from the medial temporal lobe or inferior frontal lobe, i.e., regions distant from the scalp, the EEG recorded during the seizure may be nonlocalizing. However, the seizure focus is often detected using sphenoidal or surgically placed intracranial electrodes.

The range of potential clinical behaviors linked to complex partial seizures is so broad that extreme caution is advised before concluding that stereotypic episodes of bizarre or atypical behavior are not due to seizure activity. In such cases additional, detailed EEG studies may be helpful.

Partial Seizures with Secondary Generalization Partial seizures can spread to involve both cerebral hemispheres and produce a generalized seizure, usually of the tonic-clonic variety (discussed below). Secondary generalization is observed frequently following simple partial seizures, especially those with a focus in the frontal lobe, but may also be associated with partial seizures occurring elsewhere in the brain. A partial seizure with secondary generalization is often difficult to distinguish from a primarily generalized tonic-clonic seizure, since bystanders tend to emphasize the more dramatic, generalized convulsive phase of the seizure and overlook the more subtle, focal symptoms present at onset. In some cases, the focal onset of the seizure becomes apparent only when a careful history identifies a preceding aura (i.e., simple partial seizure). Often, however, the focal onset is not clinically evident and may be established only through careful EEG analysis. Nonetheless, distinguishing between these two entities is extremely important, as there may be substantial differences in the evaluation and treatment of partial versus generalized seizure disorders.

GENERALIZED SEIZURES By definition, generalized seizures arise from both cerebral hemispheres simultaneously. However, it is currently impossible to exclude entirely the existence of a focal region of abnormal activity that initiates the seizure prior to rapid secondary generalization. For this reason, generalized seizures may be practically defined as bilateral clinical and electrographic events without any detectable focal onset. Fortunately, several types of generalized seizures have distinctive features that facilitate clinical diagnosis.

Absence Seizures (Petit Mal) Absence seizures are characterized by sudden, brief lapses of consciousness without loss of postural control. The seizure typically lasts for only seconds, consciousness returns as suddenly as it was lost, and there is no postictal confusion. Although the brief loss of consciousness may be clinically inapparent or the sole manifestation of the seizure discharge, absence seizures are usually accompanied by subtle, bilateral motor signs such as rapid blinking of the eyelids, chewing movements, or small-amplitude, clonic movements of the hands.

Absence seizures usually begin in childhood (ages 4 to 8) or early adolescence and are the main seizure type in 15 to 20% of children with epilepsy. The seizures can occur hundreds of times per day, but the child may be unaware of or unable to convey their existence. The patient may be constantly piecing together experiences that have been interrupted by the seizures. Since the clinical signs of the seizures are subtle, especially to new parents, it is not surprising that the first clue to absence epilepsy is often unexplained "daydreaming" and a decline in school performance recognized by a teacher.

The electrophysiologic hallmark of typical absence seizures is a generalized, symmetric, 3-Hz spike-and-wave discharge that begins and ends suddenly, superimposed on a normal EEG background. Periods of spike-and-wave discharges lasting more than a few seconds usually correlate with clinical signs, but the EEG often shows many more brief bursts of abnormal cortical activity than were suspected clinically. Hyperventilation tends to provoke these electrographic discharges and even the seizures themselves and is routinely used when recording the EEG.

Typical absence seizures are often associated with generalized, tonic-clonic seizures, but patients usually have no other neurologic problems and respond well to treatment with specific anticonvulsants. Although estimates vary, ~60 to 70% of such patients will have a spontaneous remission during adolescence.

Atypical Absence Seizures Atypical absence seizures have features that deviate both clinically and electrophysiologically from typical absence seizures. For example, the lapse of consciousness is usually of longer duration and less abrupt in onset and cessation, and the seizure is accompanied by more obvious motor signs that may include focal or lateralizing features. The EEG shows a generalized, slow spike-and-wave pattern with a frequency of ≤2.5/s, as well as other abnormal activity. Atypical absence seizures are usually associated with diffuse or multifocal structural abnormalities of the brain and therefore may accompany other signs of neurologic dysfunction such as mental retardation. Furthermore, the seizures are less responsive to anticonvulsants compared to typical absence seizures.

Generalized, Tonic-Clonic Seizures (Grand Mal) Primarily generalized, tonic-clonic seizures are the main seizure type in ~10% of all persons with epilepsy. They are also the most common seizure type resulting from metabolic derangements and are therefore frequently encountered in many different clinical settings. The seizure usually begins abruptly without warning, although some patients describe vague premonitory symptoms in the hours leading up to the seizure. This prodrome is distinct from the stereotypic auras associated with focal seizures that secondarily generalize. The initial phase of the seizure is usually tonic contraction of muscles throughout the body, accounting for a number of the classic features of the event. Tonic contraction of the muscles of expiration and the larynx at the onset will produce a loud moan or "ictal cry." Respirations are impaired, secretions pool in the oropharynx, and cyanosis develops. Contraction of the jaw muscles may cause biting of the tongue. A marked enhancement of sympathetic tone leads to increases in heart rate, blood pressure, and pupillary size. After 10 to 20 s, the tonic phase of the seizure typically evolves into the clonic phase, produced by the superimposition of periods of muscle relaxation on the tonic muscle contraction. The periods of relaxation progressively increase until the end of the ictal phase, which usually lasts no more than 1 min. The postictal phase is characterized by unresponsiveness, muscular flaccidity, and excessive salivation that can cause stridorous breathing and partial airway obstruction. Bladder or bowel incontinence may occur at this point. Patients gradually regain consciousness over minutes to hours, and during this transition there is typically a period of postictal confusion. Patients subsequently com-

plain of headache, fatigue, and muscle ache that can last for many hours. The duration of impaired consciousness in the postictal phase can be extremely long, i.e., many hours, in patients with prolonged seizures or underlying CNS diseases such as alcoholic cerebral atrophy.

The EEG during the tonic phase of the seizure shows a progressive increase in generalized low-voltage fast activity, followed by generalized high-amplitude, polyspike discharges. In the clonic phase, the high-amplitude activity is typically interrupted by slow waves to create a spike-and-wave pattern. The postictal EEG shows diffuse slowing that gradually recovers as the patient awakens.

There are many variants of the generalized tonic-clonic seizure, including pure tonic and pure clonic seizures. Brief tonic seizures lasting only a few seconds are especially noteworthy since they are usually associated with specific epileptic syndromes having mixed seizure phenotypes, such as the Lennox-Gastaut syndrome (discussed below).

Atonic Seizures Atonic seizures are characterized by sudden loss of postural muscle tone lasting 1 to 2 s. Consciousness is briefly impaired, but there is usually no postictal confusion. A very brief seizure may cause only a quick head drop or nodding movement, while a longer seizure will cause the patient to collapse. This can be extremely dangerous, since there is a substantial risk of direct head injury with the fall. The EEG shows brief, generalized spike-and-wave discharges followed immediately by diffuse slow waves that correlate with the loss of muscle tone. Similar to pure tonic seizures, atonic seizures are usually seen in association with known epileptic syndromes.

Myoclonic Seizures Myoclonus is a sudden and brief muscle contraction that may involve one part of the body or the entire body. A normal, common physiologic form of myoclonus is the sudden jerking movement observed while falling asleep. Pathologic myoclonus is most commonly seen in association with metabolic disorders, degenerative CNS diseases, or anoxic brain injury (Chap. 21). Although the distinction from other forms of myoclonus is imprecise, myoclonic seizures are considered to be true epileptic events since they are caused by cortical (versus subcortical or spinal) dysfunction. The EEG may show bilaterally synchronous spike-and-wave discharges synchronized with the myoclonus, although these can be obscured by movement artifact. Myoclonic seizures usually coexist with other forms of generalized seizure disorders but are the predominant feature of juvenile myoclonic epilepsy (discussed below).

UNCLASSIFIED SEIZURES Not all seizure types can be classified as partial or generalized. This appears to be especially true of seizures that occur in neonates and infants. The distinctive phenotypes of seizures at these early ages likely result, in part, from differences in neuronal function and connectivity in the immature versus mature CNS.

EPILEPSY SYNDROMES

Epilepsy syndromes are disorders in which epilepsy is a predominant feature, and there is sufficient evidence (e.g., through clinical, EEG, radiologic, or genetic observations) to suggest a common underlying mechanism. Three important epilepsy syndromes are listed below; additional examples with a known genetic basis are shown in Table 348-2.

JUVENILE MYOCLONIC EPILEPSY Juvenile myoclonic epilepsy (JME) is a generalized seizure disorder of unknown cause that appears in early adolescence and is usually characterized by bilateral myoclonic jerks that may be single or repetitive. The myoclonic seizures are most frequent in the morning after awakening and can be provoked by sleep deprivation. Consciousness is preserved unless the myoclonus is especially severe. Many patients also experience generalized tonic-clonic seizures, and up to one-third have absence seizures. The condition is otherwise benign, and although complete remission is uncommon, the seizures respond well to appropriate anticonvulsant medication. There is often a family history of epilepsy, and genetic linkage studies suggest a polygenic cause.

LENNOX-GASTAUT SYNDROME Lennox-Gastaut syndrome occurs in children and is defined by the following triad: (1) multiple seizure types (usually including generalized tonic-clonic, atonic, and atypical absence seizures); (2) an EEG showing slow (<3 Hz) spike-and-wave discharges and a variety of other abnormalities; and (3) impaired cognitive function in most but not all cases. Lennox-Gastaut syndrome is associated with CNS disease or dysfunction from a variety of causes, including developmental abnormalities, perinatal hypoxia/ischemia, trauma, infection, and other acquired lesions. The multifactorial nature of this syndrome suggests that it is a nonspecific response of the brain to diffuse neural injury. Unfortunately, many patients have a poor prognosis due to the underlying CNS disease and the physical and psychosocial consequences of severe, poorly controlled epilepsy.

MESIAL TEMPORAL LOBE EPILEPSY SYNDROME Mesial temporal lobe epilepsy (MTLE) is the most common syndrome associated with complex partial seizures and is an example of a symptomatic, partial epilepsy with distinctive clinical, electroencephalographic, and pathologic features (Table 348-3). High-resolution magnetic resonance imaging (MRI) can detect the characteristic hippocampal sclerosis that appears to be essential in the pathophysiology of MTLE for many patients (Fig. 348-1). Recognition of this syndrome is especially important because it tends to be refractory to treatment with anticonvulsants but responds extremely well to surgical intervention. Advances in the understanding of basic mechanisms of epilepsy have come through studies of experimental models of MTLE, discussed below.

THE CAUSES OF SEIZURES AND EPILEPSY

Seizures are a result of a shift in the normal balance of excitation and inhibition within the CNS. Given the numerous properties that control neuronal excitability, it is not surprising that there are many different ways to perturb this normal balance, and therefore many different causes of both seizures and epilepsy. Three clinical observations emphasize how a variety of factors determine why certain conditions may cause seizures or epilepsy in a given patient.

1. *The normal brain is capable of having a seizure under the appropriate circumstances, and there are differences between individuals in the susceptibility or threshold for seizures*. For example, seizures may be induced by high fevers in children who are otherwise normal and who never develop other neurologic problems, including epilepsy. However, febrile seizures occur only in a relatively small proportion of children. This implies there are various underlying, *endogenous factors* that influence the threshold for having a seizure. Some of these factors are clearly genetic, as it has been shown that a family history of epilepsy will influence the likelihood of seizures occurring in otherwise normal individuals. Normal development also plays an important role, since the brain appears to have different seizure thresholds at different maturational stages.

2. *There are a variety of conditions that have an extremely high likelihood of resulting in a chronic seizure disorder*. One of the best examples of this is severe, penetrating head trauma, which is associated with up to a 50% risk of subsequent epilepsy. The high propensity for severe traumatic brain injury to lead to epilepsy suggests that the injury results in a long-lasting, pathologic change in the CNS that transforms a presumably normal neural network into one that is abnormally hyperexcitable. This process is known as *epileptogenesis*, and the specific changes that result in a lowered seizure threshold can be considered *epileptogenic factors*. Other processes associated with epileptogenesis include stroke, infections, and abnormalities of CNS development. Likewise, the genetic abnormalities associated with epilepsy likely involve processes that trigger the appearance of specific sets of epileptogenic factors.

3. *Seizures are episodic*. Patients with epilepsy have seizures intermittently and, depending on the underlying cause, many patients are completely normal for months or even years between seizures. This implies there are important provocative or *precipitating factors* that

TABLE 348-2 *Examples of Genes Associated with Epilepsy Syndromes*[a]

Gene (Locus)	Function of Gene	Clinical Syndrome	Comments
CHRNA4 (20q13.2) CHRNB2 (1q21.3)	Nicotinic acetylcholine receptor subunit; mutations cause alterations in Ca^{2+} flux through the receptor; this may reduce amount of GABA release in presynaptic terminals	Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE); childhood onset; brief, nighttime seizures with prominent motor movements; often misdiagnosed as primary sleep disorder	Rare; first identified in a large Australian family; other families found to have mutations in CHRNA2 or CHRNB2, and some families appear to have mutations at other loci
KCNQ2 (20q13.3) KCNQ3 (8q24)	Voltage-gated potassium channel subunits; mutation in pore regions may cause a 20–40% reduction of potassium currents, which will lead to impaired repolarization	Benign familial neonatal convulsions (BFNC); autosomal dominant inheritance; onset in 1st week of life in infants who are otherwise normal; remission usually within weeks to months; long-term epilepsy in 10–15%	Rare; sequence and functional homology to KCNQ1, mutations of which cause long QT syndrome and a cardiac-auditory syndrome
SCN1B (19q12.1)	β-subunit of a voltage-gated sodium channel; mutation disrupts disulfide bridge that is crucial for structure of extracellular domain; mutated β-subunit leads to slower sodium channel inactivation	Generalized epilepsy with febrile seizures plus (GEFS+); autosomal dominant inheritance; presents with febrile seizures at median 1 year, which may persist >6 years, then variable seizure types not associated with fever	Incidence uncertain; GEFS+ identified in other families with mutations in other sodium channel subunits (SCN1A and SCN2A) and $GABA_A$ receptor subunit (GABRG2); significant phenotypic heterogeneity within same family, including members with febrile seizures only
LGI1 (10q24)	Leucine-rich glioma-inactivated gene; previous evidence for role in glial tumor progression; likely to be involved in nervous system development	Autosomal dominant partial epilepsy with auditory features (ADPEAF); temporal lobe epilepsy with wide range of auditory and other sensory symptoms as major manifestation; age of onset usually between 10 and 25 years	Rare; at least one family with similar syndrome has mutation(s) elsewhere; LGI1 mutation is the only known mutation identified in temporal lobe epilepsy and the only non-ion-channel gene mutation known in idiopathic epilepsy
CSTB (21q22.3)	Cystatin B, a noncaspase cysteine protease inhibitor; normal protein may block neuronal apoptosis by inhibiting caspases directly or indirectly (via cathepsins), or controlling proteolysis	Progressive myoclonus epilepsy (PME) (Unverricht-Lundborg disease); autosomal recessive inheritance; age of onset between 6–15 years, myoclonic seizures, ataxia, and progressive cognitive decline; brain shows neuronal degeneration	Overall rare, but relatively common in Finland and Western Mediterranean (>1 in 20,000); precise role of cystatin B in human disease unknown, although mice with null mutations of cystatin B have similar syndrome
EPM2A (6q24)	Laforin, a protein tyrosine phosphatase (PTP); may influence glycogen metabolism, which is known to be regulated by phosphatases	Progressive myoclonus epilepsy (Lafora's disease); autosomal recessive inheritance; onset age 6–19 years, death within 10 years; brain degeneration associated with polyglucosan intracellular inclusion bodies in numerous organs	Most common PME in Southern Europe, Middle East, Northern Africa, and Indian subcontinent; genetic heterogeneity; unknown whether seizure phenotype due to degeneration or direct effects of abnormal laforin expression.
Doublecortin (Xq21-24)	Doublecortin, expressed primarily in frontal lobes; function unknown; potentially an intracellular signalling molecule	Classic lissencephaly associated with severe mental retardation and seizures in males; subcortical band heterotopia with more subtle findings in females (presumably due to random X-inactivation); X-linked dominant	Relatively rare but of uncertain incidence, recent increased ascertainment due to improved imaging techniques; relationship between migration defect and seizure phenotype unknown

[a] The first four syndromes listed in the table (ADNFLE, BFNC, GEFS+, and ADPEAF) are examples of idiopathic generalized epilepsies associated with identified gene mutations. The last three syndromes are examples of the numerous Mendelian disorders in which seizures are one part of the phenotype.
Note: GABA, γ-aminobutyric acid.

induce seizures in patients with epilepsy. Similarly, precipitating factors are responsible for causing the single seizure in someone without epilepsy. Precipitants include those due to intrinsic physiologic processes, such as psychological or physical stress, sleep deprivation, or hormonal changes associated with the menstrual cycle. They also include exogenous factors such as exposure to toxic substances and certain medications.

These observations emphasize the concept that the many causes of seizures and epilepsy result from a dynamic interplay between endogenous factors, epileptogenic factors, and precipitating factors. The potential role of each needs to be carefully considered when determining the appropriate management of a patient with seizures. For example, the identification of predisposing factors (e.g., family history of epilepsy) in a patient with febrile seizures may increase the necessity for closer follow-up and a more aggressive diagnostic evaluation. Finding an epileptogenic lesion may help in the estimation of seizure recurrence and duration of therapy. Finally, removal or modification of a precipitating factor may be an effective and safer method for preventing further seizures than the prophylactic use of anticonvulsant drugs.

CAUSES ACCORDING TO AGE In practice, it is useful to consider the etiologies of seizures based on the age of the patient, as age is one of the most important factors determining both the incidence and likely causes of seizures or epilepsy (Table 348-4). During the *neonatal period and early infancy*, potential causes include hypoxic-ischemic encephalopathy, trauma, CNS infection, congenital CNS abnormalities, and metabolic disorders. Babies born to mothers using neurotoxic drugs such as cocaine, heroin, or ethanol are susceptible to drug-withdrawal seizures in the first few days after delivery. Hypoglycemia and hypocalcemia, which can occur as secondary complications of peri-

TABLE 348-3 Characteristics of the Mesial Temporal Lobe Epilepsy Syndrome

History	
History of febrile seizures	Seizures may remit and reappear
Family history of epilepsy	
Early onset	Seizures often intractable
Rare secondarily generalized seizures	
Clinical observations	
Aura common	Postictal disorientation, memory loss, dysphasia (with focus in dominant hemisphere)
Behavioral arrest/stare	
Complex automatisms	
Unilateral posturing	
Laboratory studies	
Unilateral or bilateral anterior temporal spikes on EEG	
Hypometabolism on interictal PET	
Hypoperfusion on interictal SPECT	
Material-specific memory deficits on intracranial amobarbital (Wada) test	
MRI findings	
Small hippocampus with increased signal on T2-weighted sequences	
Small temporal lobe	
Enlarged temporal horn	
Pathologic findings	
Highly selective loss of specific cell populations within hippocampus in most cases	

Note: EEG, electroencephalogram; PET, positron emission tomography; SPECT, single photon emission computed tomography.

FIGURE 348-1 Mesial temporal lobe epilepsy. The EEG suggested a right temporal lobe focus. Coronal high-resolution T2-weighted fast spin echo magnetic resonance image obtained through the body of the hippocampus demonstrates abnormal high signal intensity in the right hippocampus (white arrows; compare with the normal hippocampus on the left, black arrows) consistent with mesial temporal sclerosis.

natal injury, are also causes of seizures early after delivery. Seizures due to inborn errors of metabolism usually present once regular feeding begins, typically 2 to 3 days after birth. Pyridoxine (vitamin B_6) deficiency, an important cause of neonatal seizures, can be effectively treated with pyridoxine replacement. The idiopathic or inherited forms of benign neonatal convulsions are also seen during this time period.

The most common seizures arising in *late infancy and early childhood* are febrile seizures, which are seizures associated with fevers but without evidence of CNS infection or other defined causes. The overall prevalence is 3 to 5% and even higher in some parts of the world, such as Asia. Patients often have a family history of febrile seizures or epilepsy. Febrile seizures usually occur between 3 months and 5 years of age and have a peak incidence between 18 and 24 months. The typical scenario is a child who has a generalized, tonic-clonic seizure during a febrile illness in the setting of a common childhood infection such as otitis media, respiratory infection, or gastroenteritis. The seizure is likely to occur during the rising phase of the temperature curve (i.e., during the first day) rather than well into the course of the illness. A *simple* febrile seizure is a single, isolated event, brief, and symmetric in appearance. *Complex* febrile seizures are characterized by repeated seizure activity, duration >15 min, or have focal features. Approximately one-third of patients with febrile seizures will have a recurrence, but <10% have three or more episodes. Recurrences are much more likely when the febrile seizure occurs in the first year of life. Simple febrile seizures are not associated with an increase in the risk of developing epilepsy, while complex febrile seizures have a risk of 2 to 5%; other risk factors include the presence of preexisting neurologic deficits and a family history of nonfebrile seizures.

Childhood marks the age at which many of the well-defined epilepsy syndromes present. Some children who are otherwise normal develop idiopathic, generalized tonic-clonic seizures without other features that fit into specific syndromes. Temporal lobe epilepsy usually presents in childhood and may be related to mesial temporal lobe sclerosis (as part of the MTLE syndrome) or other focal abnormalities such as cortical dysgenesis. Other types of partial seizures, including those with secondary generalization, may be the relatively late manifestation of a developmental disorder, an acquired lesion such as head trauma, CNS infection (especially viral encephalitis), or very rarely a CNS tumor.

The period of *adolescence and early adulthood* is one of transition during which the idiopathic or genetically based epilepsy syndromes, including JME and juvenile absence epilepsy, become less common, while epilepsies secondary to acquired CNS lesions begin to predominate. Seizures that begin in patients in this age range may be associated with head trauma, CNS infections (including parasitic infections such as cysticercosis), brain tumors, congenital CNS abnormalities, illicit drug use, or alcohol withdrawal.

TABLE 348-4 Causes of Seizures

Neonates (<1 month)	Perinatal hypoxia and ischemia
	Intracranial hemorrhage and trauma
	Acute CNS infection
	Metabolic disturbances (hypoglycemia, hypocalcemia, hypomagnesemia, pyridoxine deficiency)
	Drug withdrawal
	Developmental disorders
	Genetic disorders
Infants and children (>1 mo and <12 years)	Febrile seizures
	Genetic disorders (metabolic, degenerative, primary epilepsy syndromes)
	CNS infection
	Developmental disorders
	Trauma
	Idiopathic
Adolescents (12–18 years)	Trauma
	Genetic disorders
	Infection
	Brain tumor
	Illicit drug use
	Idiopathic
Young adults (18–35 years)	Trauma
	Alcohol withdrawal
	Illicit drug use
	Brain tumor
	Idiopathic
Older adults (>35 years)	Cerebrovascular disease
	Brain tumor
	Alcohol withdrawal
	Metabolic disorders (uremia, hepatic failure, electrolyte abnormalities, hypoglycemia)
	Alzheimer's disease and other degenerative CNS diseases
	Idiopathic

Note: CNS, central nervous system.

Head trauma is a common cause of epilepsy in adolescents and adults. The head injury can be caused by a variety of mechanisms, and the likelihood of developing epilepsy is strongly correlated with the severity of the injury. A patient with a penetrating head wound, depressed skull fracture, intracranial hemorrhage, or prolonged posttraumatic coma or amnesia has a 40 to 50% risk of developing epilepsy, while a patient with a closed head injury and cerebral contusion has a 5 to 25% risk. Recurrent seizures usually develop within 1 year after head trauma, although intervals of ≥10 years are well known. In controlled studies, mild head injury, defined as a concussion with amnesia or loss of consciousness of <30 min, was found to be associated with only a slightly increased likelihood of epilepsy. Nonetheless, most epileptologists know of patients who have partial seizures within hours or days of a mild head injury and subsequently develop chronic seizures of the same type; such cases may represent rare examples of chronic epilepsy resulting from mild head injury.

The causes of seizures in *older adults* include cerebrovascular disease, trauma (including subdural hematoma), CNS tumors, and degenerative diseases. Cerebrovascular disease may account for ~50% of new cases of epilepsy in patients older than 65. Acute seizures (i.e., occurring at the time of the stroke) are seen more often with embolic rather than hemorrhagic or thrombotic stroke. Chronic seizures typically appear months to years after the initial event and are associated with all forms of stroke.

Metabolic disturbances such as electrolyte imbalance, hypo- or hyperglycemia, renal failure, and hepatic failure may cause seizures at any age. Similarly, endocrine disorders, hematologic disorders, vasculitides, and many other systemic diseases may cause seizures over a broad age range. A wide variety of medications and abused substances are known to precipitate seizures as well (Table 348-5).

BASIC MECHANISMS

MECHANISMS OF SEIZURE INITIATION AND PROPAGATION Partial seizure activity can begin in a very discrete region of cortex and then spread to neighboring regions, i.e., there is a *seizure initiation* phase and a *seizure propagation* phase. The initiation phase is characterized by two concurrent events in an aggregate of neurons: (1) high-frequency bursts of action potentials, and (2) hypersynchronization. The bursting activity is caused by a relatively long-lasting depolarization of the neuronal membrane due to influx of extracellular calcium (Ca^{2+}), which leads to the opening of voltage-dependent sodium (Na^+) channels, influx of Na^+, and generation of repetitive action potentials. This is followed by a hyperpolarizing afterpotential mediated by γ-aminobutyric acid (GABA) receptors or potassium (K^+) channels, depending on the cell type. The synchronized bursts from a sufficient number of neurons result in a so-called spike discharge on the EEG.

Normally, the spread of bursting activity is prevented by intact hyperpolarization and a region of surrounding inhibition created by inhibitory neurons. With sufficient activation there is a recruitment of surrounding neurons via a number of mechanisms. Repetitive discharges lead to the following: (1) an increase in extracellular K^+, which blunts hyperpolarization and depolarizes neighboring neurons; (2) accumulation of Ca^{2+} in presynaptic terminals, leading to enhanced neurotransmitter release; and (3) depolarization-induced activation of the *N*-methyl-D-aspartate (NMDA) subtype of the excitatory amino acid receptor, which causes Ca^{2+} influx and neuronal activation. The recruitment of a sufficient number of neurons leads to a loss of the surrounding inhibition and propagation of seizure activity into contiguous areas via local cortical connections, and to more distant areas via long commissural pathways such as the corpus callosum.

Many factors control neuronal excitability, and thus there are many potential mechanisms for altering a neuron's propensity to have bursting activity. Mechanisms *intrinsic* to the neuron include changes in the conductance of ion channels, response characteristics of membrane receptors, cytoplasmic buffering, second-messenger systems, and protein expression as determined by gene transcription, translation, and posttranslational modification. Mechanisms *extrinsic* to the neuron include changes in the amount or type of neurotransmitters present at the synapse, modulation of receptors by extracellular ions and other molecules, and temporal and spatial properties of synaptic and nonsynaptic input. Nonneural cells, such as astrocytes and oligodendrocytes, have an important role in many of these mechanisms as well.

Certain recognized causes of seizures are explained by these mechanisms. For example, accidental ingestion of domoic acid, which is an analogue of glutamate (the principal excitatory neurotransmitter in the brain), causes profound seizures via direct activation of excitatory amino acid receptors throughout the CNS. Penicillin, which can lower the seizure threshold in humans and is a potent convulsant in experimental models, reduces inhibition by antagonizing the effects of GABA at its receptor. The basic mechanisms of other precipitating factors of seizures, such as sleep deprivation, fever, alcohol withdrawal, hypoxia, and infection, are not as well understood but presumably involve analogous perturbations in neuronal excitability. Similarly, the endogenous factors that determine an individual's seizure threshold may relate to these properties as well.

Knowledge of the mechanisms responsible for initiation and propagation of most generalized seizures (including tonic-clonic, myoclonic, and atonic types) remains rudimentary and reflects the limited understanding of the connectivity of the brain at a systems level. Much more is understood about the origin of generalized spike-and-wave discharges in absence seizures. These appear to be related to oscillatory rhythms normally generated during sleep by circuits connecting the thalamus and cortex. This oscillatory behavior involves an interaction between $GABA_B$ receptors, T-type Ca^{2+} channels, and K^+ channels located within the thalamus. Pharmacologic studies indicate that modulation of these receptors and channels can induce absence seizures, and there is speculation that the genetic forms of absence epilepsy may be associated with mutations of components of this system.

MECHANISMS OF EPILEPTOGENESIS Epileptogenesis refers to the transformation of a normal neuronal network into one that is chronically hyperexcitable. There is often a delay of months to years between an initial CNS injury such as trauma, stroke, or infection and the first seizure. The injury appears to initiate a process that gradually lowers the seizure threshold in the affected region until a spontaneous seizure occurs. In many genetic and idiopathic forms of epilepsy, epileptogenesis is presumably determined by developmentally regulated events.

Pathologic studies of the hippocampus from patients with temporal lobe epilepsy have led to the suggestion that some forms of epileptogenesis are related to *structural changes in neuronal networks*. For example, many patients with MTLE have a highly selective loss of neurons that may contribute to inhibition of the main excitatory neurons within the dentate gyrus. There is also evidence that, in response to the loss of neurons, there is reorganization or "sprouting" of sur-

viving neurons in a way that affects the excitability of the network. Some of these changes can be seen in experimental models of prolonged electrical seizures or traumatic brain injury. Thus, an initial injury such as head injury may lead to a very focal, confined region of structural change that causes local hyperexcitability. The local hyperexcitability leads to further structural changes that evolve over time until the focal lesion produces clinically evident seizures. Similar models have also provided strong evidence for long-term alterations in *intrinsic, biochemical properties of cells* within the network, such as chronic changes in glutamate receptor function.

GENETIC CAUSES OF EPILEPSY The most important recent progress in epilepsy research has been the identification of genetic mutations associated with a variety of epilepsy syndromes (Table 348-2). Although all of the mutations identified to date cause rare forms of epilepsy, their discovery has led to extremely important conceptual advances. For example, it appears that many of the inherited, idiopathic epilepsies (i.e., the relatively "pure" forms of epilepsy in which seizures are the phenotypic abnormality and brain structure and function are otherwise normal) are due to mutations affecting ion channel function. These syndromes are therefore part of the larger group of channelopathies causing paroxysmal disorders such as cardiac arrhythmias, episodic ataxia, periodic weakness, and familial hemiplegic migraine. In contrast, gene mutations observed in symptomatic epilepsies (i.e., disorders in which other neurologic abnormalities, such as cognitive impairment, coexist with seizures) are proving to be associated with pathways influencing CNS development or neuronal homeostasis. A current challenge is to identify the multiple susceptibility genes that underlie the more common forms of idiopathic epilepsies.

MECHANISMS OF ACTION OF ANTIEPILEPTIC DRUGS Antiepileptic drugs appear to act primarily by blocking the initiation or spread of seizures. This occurs through a variety of mechanisms that modify the activity of ion channels or neurotransmitters, and in most cases the drugs have pleiotropic effects. The mechanisms include inhibition of Na^+-dependent action potentials in a frequency-dependent manner (e.g., phenytoin, carbamazepine, lamotrigine, topiramate, zonisamide), inhibition of voltage-gated Ca^{2+} channels (phenytoin), decrease of glutamate release (lamotrigine), potentiation of GABA receptor function (benzodiazepines and barbiturates), and increase in the availability of GABA (valproic acid, gabapentin, tiagabine). The two most effective drugs for absence seizures, ethosuximide and valproic acid, probably act by inhibiting T-type Ca^{2+} channels in thalamic neurons.

In contrast to the relatively large number of antiepileptic drugs that can attenuate seizure activity, there are currently no drugs known to prevent the formation of a seizure focus following CNS injury. The eventual development of such "antiepileptogenic" drugs will provide an important means of preventing the emergence of epilepsy following injuries such as head trauma, stroke, and CNS infection.

EVALUATION OF THE PATIENT WITH A SEIZURE

When a patient presents shortly after a seizure, the first priorities are attention to vital signs, respiratory and cardiovascular support, and treatment of seizures if they resume (see "Treatment"). Life-threatening conditions such as CNS infection, metabolic derangement, or drug toxicity must be recognized and managed appropriately.

When the patient is not acutely ill, the evaluation will initially focus on whether there is a history of earlier seizures (Fig. 348-2). If this is the first seizure, then the emphasis will be to (1) establish whether the reported episode was a seizure rather than another paroxysmal event, (2) determine the cause of the seizure by identifying risk factors and precipitating events, and (3) decide whether anticonvulsant therapy is required in addition to treatment for any underlying illness.

In the patient with prior seizures or a known history of epilepsy, the evaluation is directed toward (1) identification of the underlying cause and precipitating factors, and (2) determination of the adequacy of the patient's current therapy.

HISTORY AND EXAMINATION The first goal is to determine whether the event was truly a seizure. An in-depth history is essential, for *in many cases the diagnosis of a seizure is based solely on clinical grounds—the examination and laboratory studies are often normal*. Questions should be focused on the symptoms before, during, and after the episode in order to discriminate a seizure from other paroxysmal events (see "Differential Diagnosis of Seizures"). Seizures frequently occur out-of-hospital, and the patient may be unaware of the ictal and immediate postictal phases; thus witnesses to the event should be interviewed carefully.

The history should also focus on risk factors and predisposing events. Clues for a predisposition to seizures include a history of febrile seizures, earlier auras or brief seizures not recognized as such, and a family history of seizures. Epileptogenic factors such as prior head trauma, stroke, tumor, or vascular malformation should be identified. In children, a careful assessment of developmental milestones may provide evidence for underlying CNS disease. Precipitating factors such as sleep deprivation, systemic diseases, electrolyte or metabolic derangements, acute infection, drugs that lower the seizure threshold (Table 348-5), or alcohol or illicit drug use should also be identified.

The general physical examination includes a search for signs of infection or systemic illness. Careful examination of the skin may reveal signs of neurocutaneous disorders, such as tuberous sclerosis or neurofibromatosis, or chronic liver or renal disease. A finding of organomegaly may indicate a metabolic storage disease, and limb asymmetry may provide a clue to brain injury early in development. Signs of head trauma and use of alcohol or illicit drugs should be sought. Auscultation of the heart and carotid arteries may identify an abnormality that predisposes to cerebrovascular disease.

All patients require a complete neurologic examination, with particular emphasis on eliciting signs of cerebral hemispheric disease (Chap. 346). Careful assessment of mental status (including memory, language function, and abstract thinking) may suggest lesions in the anterior frontal, parietal, or temporal lobes. Testing of visual fields will help screen for lesions in the optic pathways and occipital lobes. Screening tests of motor function such as pronator drift, deep tendon reflexes, gait, and coordination may suggest lesions in motor (frontal) cortex, and cortical sensory testing (e.g., double simultaneous stimulation) may detect lesions in the parietal cortex.

LABORATORY STUDIES Routine blood studies are indicated to identify the more common metabolic causes of seizures, such as abnormalities in electrolytes, glucose, calcium, or magnesium, and hepatic or renal disease. A screen for toxins in blood and urine should also be obtained from all patients in appropriate risk groups, especially when no clear precipitating factor has been identified. A lumbar puncture is indicated if there is any suspicion of meningitis or encephalitis and is mandatory in all patients infected with HIV, even in the absence of symptoms or signs suggesting infection.

Electroencephalography All patients who have a possible seizure disorder should be evaluated with an EEG as soon as possible. The EEG measures electrical activity of the brain by recording from electrodes placed on the scalp. The potential difference between pairs of electrodes is amplified and displayed on a computer monitor, oscilloscope, or paper. The characteristics of the normal EEG depend on the patient's age and level of arousal. The recorded activity represents the postsynaptic potentials of vertically oriented pyramidal cells in the cerebral cortex and is characterized by its frequency. In normal awake adults lying quietly with the eyes closed, an 8- to 13-Hz alpha rhythm is seen posteriorly in the EEG, intermixed with a variable amount of generalized faster beta activity ($>$13 Hz), and it is attenuated when the eyes are opened (Fig. 348-3). During drowsiness, the alpha rhythm is also attenuated; with light sleep, slower activity in the theta (4 to 7 Hz) and delta ($<$4 Hz) ranges becomes more apparent.

The EEG is best recorded from several different electrode arrangements (montages) in turn, and activating procedures are usually performed in an attempt to provoke abnormalities. Such procedures com-

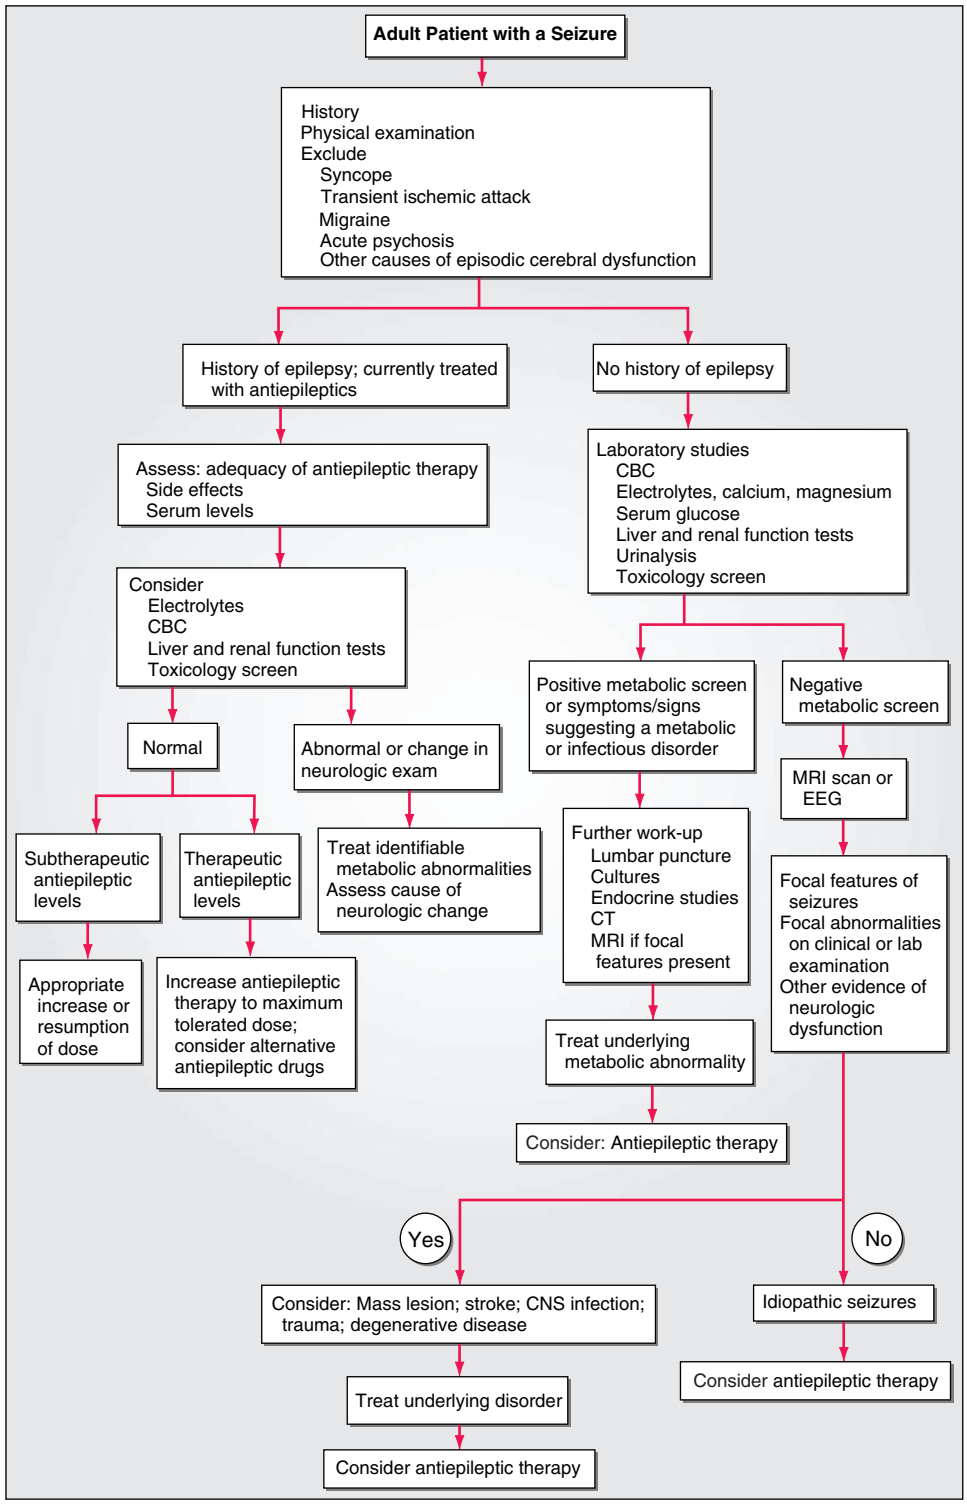

FIGURE 348-2 Evaluation of the adult patient with a seizure. CBC, complete blood count; CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalogram; CNS, central nervous system.

monly include hyperventilation (for 3 or 4 min), photic stimulation, sleep, and sleep deprivation on the night prior to the recording.

In the evaluation of a patient with suspected epilepsy, the presence of *electrographic seizure activity* during the clinically evident event, i.e., of abnormal, repetitive, rhythmic activity having an abrupt onset and termination, clearly establishes the diagnosis. The absence of electrographic seizure activity does not exclude a seizure disorder, however, because simple or complex seizures may originate from a region of cortex that is not within range of the scalp electrodes. The EEG is always abnormal during generalized tonic-clonic seizures. Since seizures are typically infrequent and unpredictable, it is often not possible to obtain the EEG during a clinical event. Continuous monitoring for prolonged periods in video-EEG telemetry units for hospitalized patients or the use of portable equipment to record the EEG continuously on cassettes for ≥24 h in ambulatory patients has made it easier to capture the electrophysiologic accompaniments of clinical events.

The EEG may also be helpful in the interictal period by showing certain abnormalities that are highly supportive of the diagnosis of epilepsy. Such *epileptiform activity* consists of bursts of abnormal discharges containing spikes or sharp waves. The presence of epileptiform activity is not specific for epilepsy, but it has a much greater prevalence in patients with epilepsy than in normal individuals. However, even in an individual who is known to have epilepsy, the initial routine interictal EEG may be normal up to 60% of the time. Thus, the EEG cannot establish the diagnosis of epilepsy in many cases.

The EEG is also used for classifying seizure disorders and aiding in the selection of anticonvulsant medications. For example, episodic generalized spike-wave activity is usually seen in patients with typical absence epilepsy and may be seen with other generalized epilepsy syndromes. Focal interictal epileptiform discharges would support the diagnosis of a partial seizure disorder such as temporal lobe epilepsy or frontal lobe seizures, depending on the location of the discharges.

The routine scalp-recorded EEG may also be used to assess the prognosis of seizure disorders; in general, a normal EEG implies a better prognosis, whereas an abnormal background or profuse epileptiform activity suggests a poor outlook. Unfortunately, the EEG has not proved to be useful in predicting which patients with predisposing conditions, such as head injury or brain tumor, will go on to develop epilepsy, because in such circumstances epileptiform activity is commonly encountered regardless of whether seizures occur.

Brain Imaging Almost all patients with new-onset seizures should have a brain imaging study to determine whether there is an underlying structural abnormality that is responsible. The only potential exception to this rule is children who have an unambiguous history and examination suggestive of a benign, generalized seizure disorder such as absence epilepsy. MRI has been shown to be superior to computed tomography (CT) for the detection of cerebral lesions associated with epilepsy. In some cases MRI will identify lesions such as tumors, vascular malformations, or other pathologies that need immediate therapy. The use of newer MRI methods, such as fluid-attenuated inversion recovery (FLAIR), has increased the sensitivity for detection of abnormalities

of cortical architecture, including hippocampal atrophy associated with mesial temporal sclerosis, and abnormalities of cortical neuronal migration. In such cases the findings may not lead to immediate therapy, but they do provide an explanation for the patient's seizures and point to the need for chronic anticonvulsant therapy or possible surgical resection.

In the patient with a suspected CNS infection or mass lesion, CT scanning should be performed emergently when MRI is not immediately available. Otherwise, it is usually appropriate to obtain an MRI study within a few days of the initial evaluation. Functional imaging procedures such as positron emission tomography (PET) and single photon emission computed tomography (SPECT) are also used to evaluate certain patients with medically refractory seizures (discussed below).

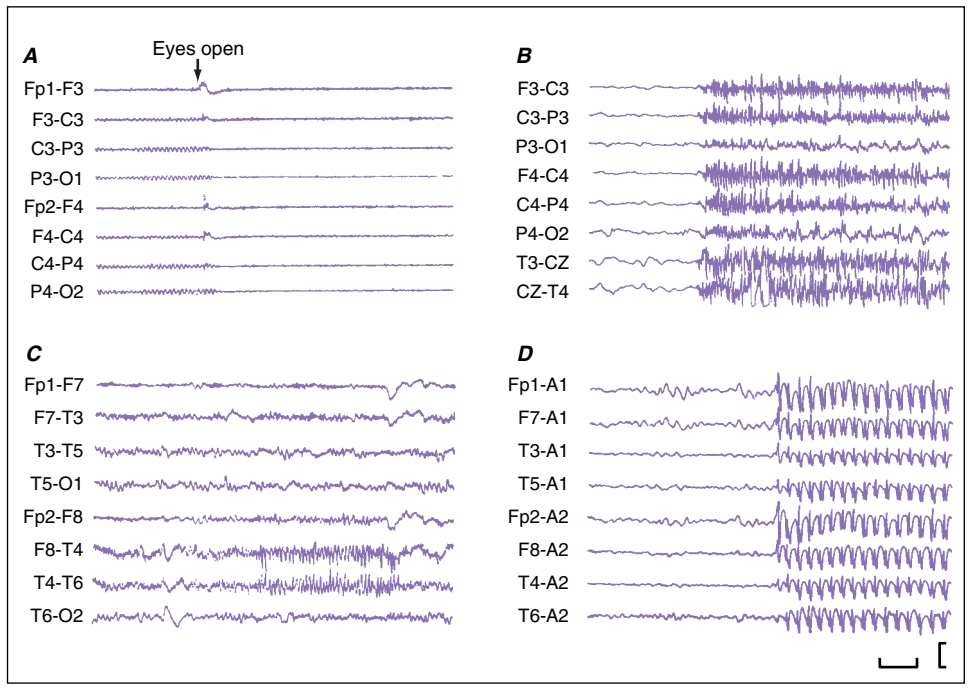

FIGURE 348-3 *A*. A normal EEG showing a posteriorly situated 9-Hz alpha rhythm that attenuates with eye opening. *B*. Onset of a tonic seizure showing generalized repetitive sharp activity with synchronous onset over both hemispheres. *C*. Burst of repetitive spikes in the right temporal region during a clinical spell suggestive of a complex partial seizure. *D*. Generalized 3-Hz spike-wave activity occurring synchronously over both hemispheres during an absence seizure. Horizontal calibration: 1s; vertical calibration: 200 μV in *A* and *C*, 400 μV in *B*, and 750 μV in *D*. Electrode placements are indicated at the left of each panel in accord with the international 10:20 system. A, earlobe; C, central; F, frontal; Fp, frontal polar; P, parietal; T, temporal; O, occipital. Right-sided placements are indicated by even numbers, left-sided placements by odd numbers, and midline placements by Z. [*From MJ Aminoff (ed): Electrodiagnosis in Clinical Neurology, 4th ed. New York, Churchill Livingstone, 1999.*]

DIFFERENTIAL DIAGNOSIS OF SEIZURES

Disorders that may mimic seizures are listed in Table 348-6. In most cases seizures can be distingished from other conditions by meticulous attention to the history and relevant laboratory studies. On occasion, additional studies, such as video-EEG monitoring, sleep studies, tilt table analysis, or cardiac electrophysiology, may be required to reach a correct diagnosis. Two of the more common nonepileptic syndromes in the differential diagnosis are detailed below.

Syncope (See also Chap. 20) The diagnostic dilemma encountered most frequently is the distinction between a generalized seizure and syncope. Observations by the patient and bystanders that can help discriminate between the two are listed in Table 348-7. Characteristics of a seizure include the presence of an aura, cyanosis, unconsciousness, motor manifestations lasting >30 s, postictal disorientation, muscle soreness, and sleepiness. In contrast, a syncopal episode is more likely if the event was provoked by acute pain or anxiety or occurred immediately after arising from the lying or sitting position. Patients with syncope often describe a stereotyped transition from consciousness to unconsciousness that includes tiredness, sweating, nausea, and tunneling of vision, and they experience a relatively brief loss of consciousness. Headache or incontinence usually suggests a seizure but may on occasion also occur with syncope. A brief period (i.e., 1 to 10 s) of convulsive motor activity is frequently seen immediately at the onset of a syncopal episode, especially if the patient remains in an upright posture after fainting (e.g., in a dentist's chair) and therefore has a sustained decrease in cerebral perfusion. Rarely, a syncopal episode can induce a full tonic-clonic seizure. In such cases the evaluation must focus on both the cause of the syncopal event as well as the possibility that the patient has a propensity for recurrent seizures.

Psychogenic Seizures Psychogenic seizures are nonepileptic behaviors that resemble seizures. They are often part of a conversion reaction precipitated by underlying psychological distress. Certain behaviors, such as side-to-side turning of the head, asymmetric and large-amplitude shaking movements of the limbs, twitching of all four extremities without loss of consciousness, and pelvic thrusting are more commonly associated with psychogenic rather than epileptic seizures. Psychogenic seizures often last longer than epileptic seizures and may wax and wane over minutes to hours. However, the distinction is sometimes difficult on clinical grounds alone, and there are many examples of diagnostic errors made by experienced epileptologists. This is especially true for psychogenic seizures that resemble complex partial seizures, since the behavioral manifestations of complex partial seizures (especially of frontal lobe origin) can be extremely unusual, and in both cases the routine surface EEG may be normal. Video-EEG monitoring is often useful when historic features are nondiagnostic. Generalized tonic-clonic seizures always produce marked EEG abnormalities during and after the seizure. For suspected complex partial seizures of temporal lobe origin, the use of additional electrodes beyond the standard scalp locations (e.g., sphenoidal electrodes) may be required to localize a seizure focus. Measurement of serum prolactin levels may also help to discriminate between organic and psychogenic seizures, since most generalized seizures and many complex partial

TABLE 348-7 *Features That Distinguish Generalized Tonic-Clonic Seizure from Syncope*

Features	Seizure	Syncope
Immediate precipitating factors	Usually none	Emotional stress, Valsalva, orthostatic hypotension, cardiac etiologies
Premonitory symptoms	None or aura (e.g., odd odor)	Tiredness, nausea, diaphoresis, tunneling of vision
Posture at onset	Variable	Usually erect
Transition to unconsciousness	Often immediate	Gradual over seconds[a]
Duration of unconsciousness	Minutes	Seconds
Duration of tonic or clonic movements	30–60 s	Never more than 15 s
Facial appearance during event	Cyanosis, frothing at mouth	Pallor
Disorientation and sleepiness after event	Many minutes to hours	<5 min
Aching of muscles after event	Often	Sometimes
Biting of tongue	Sometimes	Rarely
Incontinence	Sometimes	Sometimes
Headache	Sometimes	Rarely

[a] May be sudden with certain cardiac arrhythmias.

seizures are accompanied by rises in serum prolactin (during the immediate 30-min postictal period), whereas psychogenic seizures are not. The diagnosis of psychogenic seizures does not exclude a concurrent diagnosis of epilepsy, since the two often coexist.

TREATMENT

Therapy for a patient with a seizure disorder is almost always multimodal and includes treatment of underlying conditions that cause or contribute to the seizures, avoidance of precipitating factors, suppression of recurrent seizures by prophylactic therapy with antiepileptic medications or surgery, and addressing a variety of psychological and social issues. Treatment plans must be individualized, given the many different types and causes of seizures as well as the differences in efficacy and toxicity of antiepileptic medications for each patient. In almost all cases a neurologist with experience in the treatment of epilepsy should design and oversee implementation of the treatment strategy. Furthermore, patients with refractory epilepsy or those who require polypharmacy with antiepileptic drugs should remain under the regular care of a neurologist.

Treatment of Underlying Conditions If the sole cause of a seizure is a metabolic disturbance such as an abnormality of serum electrolytes or glucose, then treatment is aimed at reversing the metabolic problem and preventing its recurrence. Therapy with antiepileptic drugs is usually unnecessary unless the metabolic disorder cannot be corrected promptly and the patient is at risk of having further seizures. If the apparent cause of a seizure was a medication (e.g., theophylline) or illicit drug use (e.g., cocaine), then appropriate therapy is avoidance of the drug; there is usually no need for antiepileptic medications unless subsequent seizures occur in the absence of these precipitants.

Seizures caused by a structural CNS lesion such as a brain tumor, vascular malformation, or brain abscess may not recur after appropriate treatment of the underlying lesion. However, despite removal of the structural lesion, there is a risk that the seizure focus will remain in the surrounding tissue or develop de novo as a result of gliosis and other processes induced by surgery, radiation, or other therapies. Most patients are therefore maintained on an antiepileptic medication for at least 1 year, and an attempt is made to withdraw medications only if the patient has been completely seizure-free. If seizures are refractory to medication, the patient may benefit from surgical removal of the epileptic brain region (see below).

Avoidance of Precipitating Factors Unfortunately, little is known about the specific factors that determine precisely when a seizure will occur in a patient with epilepsy. Some patients can identify particular situations that appear to lower their seizure threshold; these situations should be avoided. For example, a patient who has seizures in the setting of sleep deprivation should obviously be advised to maintain a normal sleep schedule. Many patients note an association between alcohol intake and seizures, and they should be encouraged to modify their drinking habits accordingly. There are also relatively rare cases of patients with seizures that are induced by highly specific stimuli such as a video game monitor, music, or an individual's voice ("reflex epilepsy"). If there is an association between stress and seizures, stress reduction techniques such as physical exercise, meditation, or counseling may be helpful.

Antiepileptic Drug Therapy Antiepileptic drug therapy is the mainstay of treatment for most patients with epilepsy. The overall goal is to completely prevent seizures without causing any untoward side effects, preferably with a single medication and a dosing schedule that is easy for the patient to follow. Seizure classification is an important element in designing the treatment plan, since some antiepileptic drugs have different activities against various seizure types. However, there is considerable overlap between many antiepileptic drugs, such that the choice of therapy is often determined more by specific needs of the patient, especially the patient's assessment of side effects.

WHEN TO INITIATE ANTIEPILEPTIC DRUG THERAPY Antiepileptic drug therapy should be started in any patient with recurrent seizures of unknown etiology or a known cause that cannot be reversed. Whether to initiate therapy in a patient with a single seizure is controversial. Patients with a single seizure due to an identified lesion such as a CNS tumor, infection, or trauma, in which there is strong evidence that the lesion is epileptogenic, should be treated. The risk of seizure recurrence in a patient with an apparently unprovoked or idiopathic seizure is uncertain, with estimates ranging from 31 to 71% in the first 12 months after the initial seizure. This uncertainty arises from differences in the underlying seizure types and etiologies in various published epidemiologic studies. Generally accepted risk factors associated with recurrent seizures include the following: (1) an abnormal neurologic examination, (2) seizures presenting as status epilepticus, (3) postictal Todd's paralysis, (4) a strong family history of seizures, or (5) an abnormal EEG. Most patients with one or more of these risk factors should be treated. Issues such as employment or driving may influence the decision whether or not to start medications as well. For example, a patient with a single, idiopathic seizure whose job depends on driving may prefer taking antiepileptic drugs rather than risk a seizure recurrence and the potential loss of driving privileges.

SELECTION OF ANTIEPILEPTIC DRUGS Antiepileptic drugs available in the United States are shown in Table 348-8, and the main pharmacologic characteristics of commonly used drugs are listed in Table 348-9. Older medications such as phenytoin, valproic acid, carbamazepine, and ethosuximide are generally used as first-line therapy for most seizure disorders since, overall, they are as effective as recently marketed drugs and significantly less expensive. Most of the new drugs that have become available in the past decade are used as add-on or alternative therapy.

In addition to efficacy, factors influencing the choice of an initial medication include the convenience of dosing (e.g., once daily versus three or four times daily) and potential side effects. Almost all of the commonly used antiepileptic drugs can cause similar, dose-related side effects such as sedation, ataxia, and diplopia. Close follow-up is required to ensure these are promptly recognized and reversed. Most of the drugs can also cause idiosyncratic toxicity such as rash, bone marrow suppression, or hepatotoxicity. Although rare, these side effects should be considered during drug selection, and patients require laboratory tests (e.g., complete blood count and liver function tests) prior to the institution of a drug (to establish baseline values) and during initial dosing and titration of the agent.

Antiepileptic Drug Selection for Partial Seizures Carbamazepine, phenytoin, or lamotrigine is currently the initial drug of choice for the treatment of partial seizures, including those that secondarily generalize. Overall they have very similar efficacy, but differences in pharmacokinetics and toxicity are the main determinants for use in a given patient. Phenytoin has a relatively long half-life and offers the advantage of once or twice daily dosing compared to two or three times daily dosing for carbamazepine (although a more expensive, extended-release form of carbamazepine is now available) and lamotrigine. An advantage of carbamazepine is that its metabolism follows first-order pharmacokinetics, and the relationship between drug dose, serum levels, and toxicity is linear. By contrast, phenytoin shows properties of saturation kinetics, such that small increases in phenytoin doses above a standard maintenance dose can precipitate marked side effects. This is one of the main causes of acute phenytoin toxicity. Long-term use of phenytoin is associated with untoward cosmetic effects (e.g., hirsutism, coarsening of facial features, and gingival hypertrophy), and effects on bone metabolism, so it is often avoided in young patients who are likely to require the drug for many years. Carbamazepine can cause leukopenia, aplastic anemia, or hepatotoxicity and would therefore be contraindicated in patients with predispositions to these problems. A major concern with lamotrigine is the occurrence of skin rash during the initiation of therapy. This can be extremely severe and lead to Stevens-Johnson syndrome if unrecognized and if the medication is not discontinued immediately. This risk can be reduced by slow introduction and titration. Lamotrigine must be started slowly when used as add-on therapy with valproic acid, since valproic acid can inhibit its metabolism, thereby substantially prolonging its half-life.

Valproic acid is an effective alternative for some patients with partial seizures, especially when the seizures secondarily generalize. Gastrointestinal side effects are fewer when using the valproate semisodium formulation (Depakote). Valproic acid also rarely causes reversible bone marrow suppression and hepatotoxicity, and laboratory testing is required to monitor toxicity. This drug should generally be avoided in patients with preexisting bone marrow or liver disease. Irreversible, fatal hepatic failure appearing as an idiosyncratic rather than dose-related side effect is a relatively rare complication; its risk is highest in children <2 years old, especially those taking other antiepileptic drugs or with inborn errors of metabolism.

Topiramate, tiagabine, levetiracetam, zonisamide, gabapentin, and oxcarbazepine are additional drugs currently used for the treatment of partial seizures with or without secondary generalization. Until recently, phenobarbital and other barbiturate compounds were commonly used as first-line therapy for many forms of epilepsy. However, the barbiturates frequently cause sedation in adults, hyperactivity in children, and other more subtle cognitive changes; thus, their use should be limited to situations in which no other suitable treatment alternatives exist.

Antiepileptic Drug Selection for Generalized Seizures Valproic acid is currently considered the best initial choice for the treatment of primarily generalized, tonic-clonic seizures. Lamotrigine, followed by carbamazepine and phenytoin, are suitable alternatives. Valproic acid is also particularly effective in absence, myoclonic, and atonic seizures and is therefore the drug of choice in patients with generalized epilepsy syndromes having mixed seizure types. Importantly, both carbamazepine and phenytoin can worsen certain types of generalized seizures, including absence, myoclonic, tonic, and atonic seizures. Ethosuximide is a particularly effective drug for the treatment of uncomplicated absence seizures, but it is not useful for tonic-clonic or partial seizures. Ethosuximide rarely causes bone marrow suppression, so that periodic monitoring of blood cell counts is required. Although approved for use in partial seizure disorders, lamotrigine appears to be effective in epilepsy syndromes with mixed, generalized seizure types such as JME and Lennox-Gastaut syndrome. Topiramate, zonisamide, and felbamate may have similar broad efficacy. Clinical trials are underway to establish the usefulness of levetiracetam in generalized seizure syndromes.

[a] Includes simple partial, complex partial, and secondarily generalized seizures.
[b] As adjunctive therapy.

INITIATION AND MONITORING OF THERAPY Because the response to any antiepileptic drug is unpredictable, patients should be carefully educated about the approach to therapy. The goal is to prevent seizures and minimize the side effects of therapy; determination of the optimal dose is often a matter of trial and error. This process may take months or longer if the baseline seizure frequency is low. Most anticonvulsant drugs need to be introduced relatively slowly to minimize side effects, and patients should expect that minor side effects such as mild sedation, slight changes in cognition, or imbalance will typically resolve within a few days. Starting doses are usually the lowest value listed under the dosage column in Table 348-9. Subsequent increases should be made only after achieving a steady state with the previous dose (i.e., after an interval of five or more half-lives).

Monitoring of serum antiepileptic drug levels can be very useful for establishing the initial dosing schedule. However, the published therapeutic ranges of serum drug concentrations are only an approximate guide for determining the proper dose for a given patient. The key determinants are the clinical measures of seizure frequency and presence of side effects, not the laboratory values. Conventional assays of serum drug levels measure the total drug (i.e., both free and protein-bound). However, it is the concentration of free drug that reflects extracellular levels in the brain and correlates best with efficacy. Thus, patients with decreased levels of serum proteins (e.g., decreased serum albumin due to impaired liver or renal function) may have an increased ratio of free to bound drug, yet the concentration of free drug may be adequate for seizure control. These patients may have a "subtherapeutic" drug level, but the dose should be changed only if seizures remain uncontrolled, not just to achieve a "therapeutic" level. It is also useful to monitor free drug levels in such patients. In practice, other than during the initiation or modification of therapy, monitoring of antiepileptic drug levels is most useful for documenting compliance.

If seizures continue despite gradual increases to the maximum tolerated dose and documented compliance, then it becomes necessary to switch to another antiepileptic drug. This is usually done by maintaining the patient on the first drug while a second drug is added. The dose of the second drug should be adjusted to decrease seizure frequency without causing toxicity. Once this is achieved, the first drug can be gradually withdrawn (usually over weeks unless there is significant toxicity). The dose of the second drug is then further optimized based on seizure response and side effects. Monotherapy should be the goal whenever possible.

WHEN TO DISCONTINUE THERAPY Overall, about 70% of children and 60% of adults who have their seizures completely controlled with antiepi-

TABLE 348-9 *Dosage and Adverse Effects of Commonly Used Antiepileptic Drugs*

Generic Name	Trade Name	Principal Uses	Typical Dose; Dose Interval	Half-Life	Therapeutic Range	Adverse Effects		Drug Interactions
						Neurologic	Systemic	
Phenytoin (diphenyl-hydantoin	Dilantin	Tonic-clonic (grand mal) Focal-onset	300–400 mg/d (3–6 mg/kg, adult; 4–8 mg/kg, child); qd-bid	24 h (wide variation, dose-dependent)	10–20 μg/mL	Dizziness Diplopia Ataxia Incoordination Confusion	Gum hyperplasia Lymphade-nopathy Hirsutism Osteomalacia Facial coarsening Skin rash	Level increased by isoniazid, sulfonamides, fluoxetine Level decreased by enzyme-inducing drugs[a] Altered folate metabolism
Carbamaze-pine	Tegretol Carbatrol	Tonic-clonic Focal-onset	600–1800 mg/d (15–35 mg/kg, child); bid-qid	10–17 h	6–12 μg/mL	Ataxia Dizziness Diplopia Vertigo	Aplastic anemia Leukopenia Gastrointestinal irritation Hepatotoxicity Hyponatremia	Level decreased by enzyme-inducing drugs[a] Level increased by erythromy-cin, propoxy-phene, isonia-zid, cimetidine, fluoxetine
Valproic acid	Depakene Depakote	Tonic-clonic Absence Atypical absence Myoclonic Focal-onset	750–2000 mg/d (20–60 mg/kg); bid-qid	15 h	50–150 μg/mL	Ataxia Sedation Tremor	Hepatotoxicity Thrombocy-topenia Gastrointestinal irritation Weight gain Transient alopecia Hyperam-monemia	Level decreased by enzyme-inducing drugs[a]
Lamotrigine	Lamictal	Focal-onset Tonic-clonic Atypical absence Myoclonic Lennox-Gastaut syndrome	150–500 mg/d; bid	25 h 14 h (with enzyme-inducers) 59 h (with valproic acid)	Not established	Dizziness Diplopia Sedation Ataxia Headache	Skin rash Stevens-Johnson syndrome	Level decreased by enzyme-inducing drugs[a] Level increased by valproic acid
Ethosuxi-mide	Zarontin	Absence (petit mal)	750–1250 mg/d (20-40 mg/kg); qd-bid	60 h, adult 30 h, child	40–100 μg/mL	Ataxia Lethargy Headache	Gastrointestinal irritation Skin rash Bone marrow suppression	
Gabapentin	Neurontin	Focal-onset	900–2400 mg/d; tid-qid	5–9 h	Not established	Sedation Dizziness Ataxia Fatigue	Gastrointestinal irritation Weight gain Edema	No known significant interactions
Topiramate	Topamax	Focal-onset Tonic-clonic Lennox-Gastaut syndrome	200–400 mg/d; bid	20–30 h	Not established	Psychomotor slowing Sedation Speech or language problems Fatigue Paresthesias	Renal stones (avoid use with other carbonic anhydrase inhibitors) Weight loss	Level decreased by enzyme-inducing drugs[a]
Tiagabine	Gabitril	Focal-onset Tonic-clonic	32–56 mg/d; bid-qid	7–9 h	Not established	Confusion Sedation Depression Dizziness Speech or language problems Paresthesias Psychosis	Gastrointestinal irritation	Level decreased by enzyme-inducing drugs[a]

TABLE 348-9—(Continued)

Generic Name	Trade Name	Principal Uses	Typical Dose; Dose Interval	Half-Life	Therapeutic Range	Adverse Effects		Drug Interactions
						Neurologic	Systemic	
Phenobarbital	Luminol	Tonic-clonic Focal-onset	60–180 mg/d (1–4 mg/kg, adult); (3–6 mg/kg, child); qd	90 h (70 h in children)	10–40 μg/mL	Sedation Ataxia Confusion Dizziness Decreased libido Depression	Skin rash	Level increased by valproic acid, phenytoin
Primidone	Mysoline	Tonic-clonic Focal-onset	750–1000 mg/d (10–25 mg/kg); bid-tid	Primidone, 8–15 h Phenobarbital, 90 h	Primidone, 4–12 μg/mL Phenobarbital, 10–40 μg/mL	Same as phenobarbital		
Clonazepam	Klonopin	Absence Atypical absence Myoclonic	1–12 mg/d (0.1–0.2 mg/kg); qd-tid	24–48 h	10–70 ng/mL	Ataxia Sedation Lethargy	Anorexia	Level decreased by enzyme-inducing drugs[a]
Felbamate	Felbatol	Focal-onset Lennox-Gastaut syndrome	2400–3600 mg/d, (45 mg/kg, child); tid-qid	16–22 h	Not established	Insomnia Dizziness Sedation Headache	Aplastic anemia Hepatic failure Weight loss Gastrointestinal irritation	Increases phenytoin, valproic acid, active carbamazepine metabolite
Levetiracetam	Keppra	Focal-onset	1000–3000 mg/d; bid	6–8 h	Not established	Sedation Fatigue Incoordination Psychosis	Anemia Leukopenia	None known
Zonisamide	Zonegran	Focal-onset	200–400 mg/d; qd-bid	50–68 h	Not established	Sedation Dizziness Confusion Headache Psychosis	Anorexia Renal stones	Level decreased by enzyme-inducing drugs[a]
Oxcarbazepine	Trileptal	Focal-onset	900–2400 mg/d (30–45 mg/kg, child); bid	10–17 h (for active metabolite)	Not established	Fatigue Ataxia Dizziness Diplopia Vertigo Headache	See carbamazepine	Level decreased by enzyme-inducing drugs[a] May increase phenytoin

[a] Phenytoin, carbamazepine, phenobarbital.

leptic drugs can eventually discontinue therapy. The following patient profile yields the greatest chance of remaining seizure-free after drug withdrawal: (1) complete medical control of seizures for 1 to 5 years; (2) single seizure type, either partial or generalized; (3) normal neurologic examination, including intelligence; and (4) normal EEG. The appropriate seizure-free interval is unknown and undoubtedly varies for different forms of epilepsy. However, it seems reasonable to attempt withdrawal of therapy after 2 years in a patient who meets all of the above criteria, is motivated to discontinue the medication, and clearly understands the potential risks and benefits. In most cases it is preferable to reduce the dose of the drug gradually over 2 to 3 months. Most recurrences occur in the first 3 months after discontinuing therapy, and patients should be advised to avoid potentially dangerous situations such as driving or swimming during this period.

TREATMENT OF REFRACTORY EPILEPSY Approximately one-third of patients with epilepsy do not respond to treatment with a single antiepileptic drug, and it becomes necessary to try a combination of drugs to control seizures. Patients who have focal epilepsy related to an underlying structural lesion or those with multiple seizure types and developmental delay are particularly likely to require multiple drugs. There are currently no clear guidelines for rational polypharmacy, although in theory a combination of drugs with different mechanisms of action may be most useful. In most cases the initial combination therapy combines first-line drugs, i.e., carbamazepine, phenytoin, valproic acid, and lamotrigine. If these drugs are unsuccessful, then the addition of a newer drug such as topiramate or levetiracetam is indicated. Patients with myoclonic seizures resistant to valproic acid may benefit from the addition of clonazepam, and those with absence seizures may respond to a combination of valproic acid and ethosuximide. The same principles concerning the monitoring of therapeutic response, toxicity, and serum levels for monotherapy apply to polypharmacy, and potential drug interactions need to be recognized. If there is no improvement, a third drug can be added while the first two are maintained. If there is a response, the less effective or less well-tolerated of the first two drugs should be gradually withdrawn.

Surgical Treatment of Refractory Epilepsy Approximately 20% of patients with epilepsy are resistant to medical therapy despite efforts to find an effective combination of antiepileptic drugs. For some, surgery can be extremely effective in substantially reducing seizure frequency and even providing complete seizure control. Understanding the potential value of surgery is especially important when, at the time of diagnosis, a patient has an epilepsy syndrome that is considered likely to be drug-resistant. Rather than submitting the patient to years of unsuccessful medical therapy and the psychosocial trauma and increased mortality

associated with ongoing seizures, the patient should have an efficient but relatively brief attempt at medical therapy and then be referred for surgical evaluation.

The most common surgical procedure for patients with temporal lobe epilepsy involves resection of the anteromedial temporal lobe (temporal lobectomy) or a more limited removal of the underlying hippocampus and amygdala (amygdalohippocampectomy). Focal seizures arising from extratemporal regions may be abolished by a focal neocortical resection with precise removal of an identified lesion (lesionectomy). When the cortical region cannot be removed, multiple subpial transection, which disrupts intracortical connections, is sometimes used to prevent seizure spread. Hemispherectomy or multilobar resection is useful for some patients with severe seizures due to hemispheric abnormalities such as hemimegaloencephaly or other dysplastic abnormalities, and corpus callosotomy has been shown to be effective for disabling tonic or atonic seizures, usually when they are part of a mixed-seizure syndrome (e.g., Lennox-Gastaut syndrome).

Presurgical evaluation is designed to identify the functional and structural basis of the patient's seizure disorder. Inpatient video-EEG monitoring is used to define the anatomic location of the seizure focus and to correlate the abnormal electrophysiologic activity with behavioral manifestations of the seizure. Routine scalp or scalp-sphenoidal recordings are usually sufficient for localization, and advances in neuroimaging have made the use of invasive electrophysiologic monitoring such as implanted depth electrodes or subdural electrodes less common. A high-resolution MRI scan is routinely used to identify structural lesions. Functional imaging studies such as SPECT and PET are adjunctive tests that may help verify the localization of an apparent epileptogenic region. Once the presumed location of the seizure onset is identified, additional studies, including neuropsychological testing and the intracarotid amobarbital test (Wada test) may be used to assess language and memory localization and to determine the possible functional consequences of surgical removal of the epileptogenic region. In some cases, the exact extent of the resection to be undertaken is determined by performing cortical mapping at the time of the surgical procedure, allowing for a tailored resection. This involves electrocorticographic recordings made with electrodes on the surface of the brain to identify the extent of epileptiform disturbances. If the region to be resected is within or near brain regions suspected of having sensorimotor or language function, electrical cortical stimulation mapping is performed in the awake patient to determine the function of cortical regions in question in order to avoid resection of so-called eloquent cortex, and thereby minimize postsurgical deficits.

Advances in presurgical evaluation and microsurgical techniques have led to a steady increase in the success of epilepsy surgery. Clinically significant complications of surgery are $<5\%$, and the use of functional mapping procedures has markedly reduced the neurologic sequelae due to removal or sectioning of brain tissue. For example, about 70% of patients treated with temporal lobectomy will become seizure-free, and another 15 to 25% will have at least a 90% reduction in seizure frequency. Marked improvement is also usually seen in patients treated with hemispherectomy for catastrophic seizure disorders due to large hemispheric abnormalities. Postoperatively, patients generally need to remain on antiepileptic drug therapy, but the marked reduction of seizures following surgery can have a very beneficial effect on quality of life.

Vagus Nerve Stimulation (VNS) VNS is a new treatment option for patients with medically refractory epilepsy who are not candidates for resective brain surgery. The procedure involves placement of a bipolar electrode on the midcervical portion of the left vagus nerve. The electrode is connected to a small, subcutaneous generator located in the infraclavicular region, and the generator is programmed to deliver intermittent electrical pulses to the vagus nerve. Unlike medications, there may be a delay between the initiation of VNS and the appearance of antiseizure effects. The precise mechanism of action of VNS is unknown, although experimental studies have shown that stimulation of vagal nuclei leads to widespread activation of cortical and subcortical pathways and an associated increased seizure threshold. In practice, the efficacy of VNS appears to be no greater than recently introduced anticonvulsant medications. Adverse effects of the surgery are rare, and stimulation-induced side effects, including transient hoarseness, cough, and dyspnea, are usually mild and well tolerated.

STATUS EPILEPTICUS Status epilepticus refers to continuous seizures or repetitive, discrete seizures with impaired consciousness in the interictal period. The duration of seizure activity sufficient to meet the definition of status epilepticus has traditionally been specified as 15 to 30 min. However, a more practical definition is to consider status epilepticus as a situation in which the duration of seizures prompts the acute use of anticonvulsant therapy, typically when seizures last beyond 5 min.

Status epilepticus is an emergency and must be treated immediately, since cardiorespiratory dysfunction, hyperthermia, and metabolic derangements can develop as a consequence of prolonged seizures, and these can lead to irreversible neuronal injury. Furthermore, CNS injury can occur even when the patient is paralyzed with neuromuscular blockade but continues to have electrographic seizures. The most common causes of status epilepticus are anticonvulsant withdrawal or noncompliance, metabolic disturbances, drug toxicity, CNS infection, CNS tumors, refractory epilepsy, and head trauma.

Generalized status epilepticus is obvious when the patient is having overt convulsions. However, after 30 to 45 min of uninterrupted seizures, the signs may become increasingly subtle. Patients may have mild clonic movements of only the fingers, or fine, rapid movements of the eyes. There may be paroxysmal episodes of tachycardia, hypertension, and pupillary dilation. In such cases, the EEG may be the only method of establishing the diagnosis. Thus, if the patient stops having overt seizures, yet remains comatose, an EEG should be performed to rule out ongoing status epilepticus.

The first step in the management of a patient in status epilepticus is to attend to any acute cardiorespiratory problems or hyperthermia, perform a brief medical and neurologic examination, establish venous access, and send samples for laboratory studies to identify metabolic abnormalities. Anticonvulsant therapy should then begin without delay; a treatment approach is shown in Fig. 348-4.

BEYOND SEIZURES: OTHER MANAGEMENT ISSUES

Interictal Behavior The adverse effects of epilepsy often go beyond the occurrence of clinical seizures, and the extent of these effects depends largely upon the etiology of the seizure disorder, the degree to which the seizures are controlled, and the presence of side effects from antiepileptic therapy. Many patients with epilepsy are completely normal between seizures and able to live highly successful and productive lives. In contrast, patients with seizures secondary to developmental abnormalities or acquired brain injury may have impaired cognitive function and other neurologic deficits. Frequent interictal EEG abnormalities have been shown to be associated with subtle dysfunction of memory and attention. Patients with many seizures, especially those emanating from the temporal lobe, often note an impairment of short-term memory that may progress over time.

Patients with epilepsy are at risk of developing a variety of psychiatric problems including depression, anxiety, and psychosis. This risk varies considerably depending on many factors, including the etiology, frequency, and severity of seizures and the patient's age and previous history. Depression occurs in $\sim$20% of patients, and the incidence of suicide is higher in epileptic patients than in the general population. Depression should be treated through counseling or medication. The selective serotonin reuptake inhibitors typically have no effect on seizures, while the tricyclic antidepressants may lower the seizure threshold. Anxiety can appear as a manifestation of a seizure, and anxious or psychotic behavior can sometimes be observed as part of a postictal delirium. Postictal psychosis is a rare phenomenon that typically occurs after a period of increased seizure frequency. There

is usually a brief lucid interval lasting up to a week, followed by days to weeks of agitated, psychotic behavior. The psychosis will usually resolve spontaneously but may require treatment with antipsychotic or anxiolytic medications.

There is ongoing controversy as to whether some patients with epilepsy (especially temporal lobe epilepsy) have a stereotypical "interictal personality." The predominant view is that the unusual or abnormal personality traits observed in such patients are, in most cases, not due to epilepsy but result from an underlying structural brain lesion, the effects of antiepileptic drugs, or psychosocial factors related to suffering from a chronic disease.

Mortality of Epilepsy Patients with epilepsy have a risk of death that is roughly two to three times greater than expected in a matched population without epilepsy. Most of the increased mortality is due to the underlying etiology of epilepsy, e.g., tumors or strokes in older adults. However, a significant number of patients die from accidents, status epilepticus, and a syndrome known as *sudden unexpected death in epileptic patients* (SUDEP), which usually affects young people with convulsive seizures and tends to occur at night. The cause of SUDEP is unknown; it may result from brainstem-mediated effects of seizures on cardiac rhythms or pulmonary function.

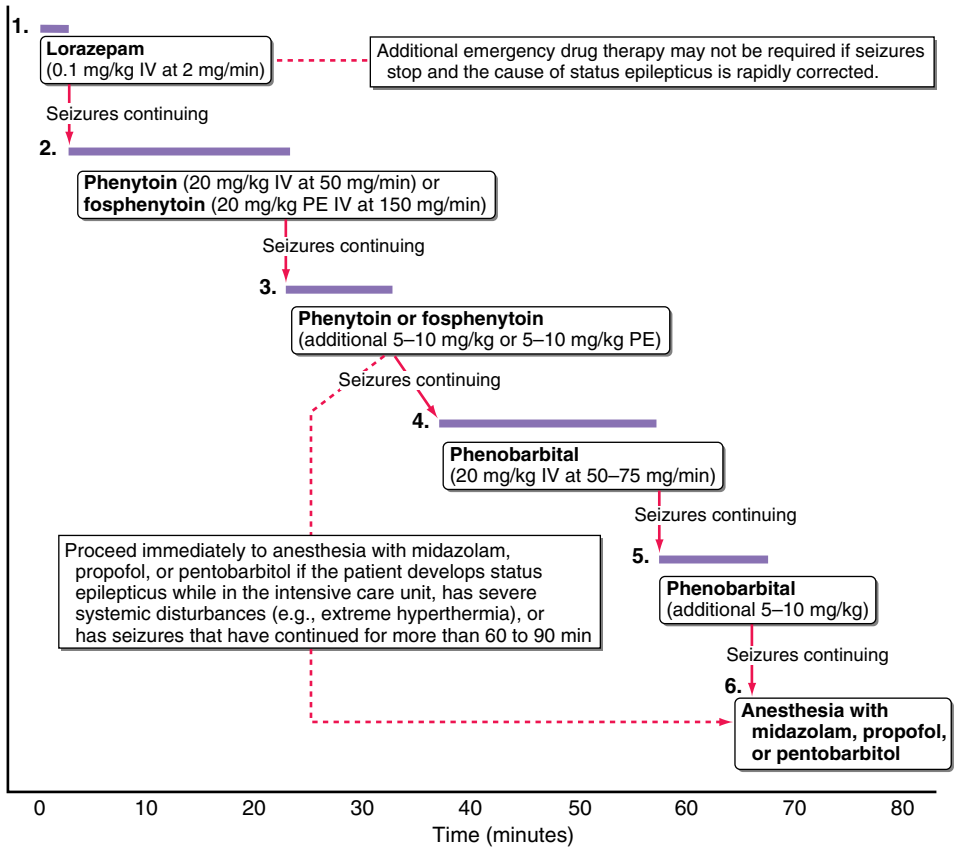

FIGURE 348-4 Pharmacologic treatment of generalized tonic-clonic status epilepticus in adults. IV, intravenous; PE, phenytoin equivalents. The horizontal bars indicate the approximate duration of drug infusions.

Psychosocial Issues There continues to be a cultural stigma about epilepsy, although it is slowly declining in societies with effective health education programs. Many patients with epilepsy harbor fears, such as the fear of becoming mentally retarded or dying during a seizure. These issues need to be carefully addressed by educating the patient about epilepsy and by ensuring that family members, teachers, fellow employees, and other associates are equally well informed. The Epilepsy Foundation of America (1-800-EFA-1000) is a patient advocacy organization and a useful source of educational material.

Employment and Driving Many patients with epilepsy face difficulty in obtaining or maintaining employment, even when their seizures are well controlled. Federal and state legislation is designed to prevent employers from discriminating against patients with epilepsy, and patients should be encouraged to understand and claim their legal rights. Patients in these circumstances also benefit greatly from the assistance of health providers who act as strong patient advocates.

Loss of driving privileges is one of the most disruptive social consequences of epilepsy. Physicians should be very clear about local regulations concerning driving and epilepsy, since the laws vary considerably among states and countries. In all cases, it is the physician's responsibility to warn patients of the danger imposed on themselves and others while driving if their seizures are uncontrolled (unless the seizures are not associated with impairment of consciousness or motor control). In general, most states allow patients to drive after a seizure-free interval (on or off medications) between 3 months and 2 years.

SPECIAL ISSUES RELATED TO WOMEN AND EPILEPSY

Catamenial Epilepsy Some women experience a marked increase in seizure frequency around the time of menses. This is thought to reflect either the effects of estrogen and progesterone on neuronal excitability or changes in antiepileptic drug levels due to altered protein binding. Acetazolamide (250 to 500 mg/d) may be effective as adjunctive therapy in some cases when started 7 to 10 days prior to the onset of menses and continued until bleeding stops. Some patients may benefit from increases in antiepileptic drug dosages during this time or from control of the menstrual cycle through the use of oral contraceptives. Natural progestins may be of benefit to a subset of women.

Pregnancy Most women with epilepsy who become pregnant will have an uncomplicated gestation and deliver a normal baby. However, epilepsy poses some important risks to a pregnancy. Seizure frequency during pregnancy will remain unchanged in ~50% of women, increase in 30%, and decrease in 20%. Changes in seizure frequency are attributed to endocrine effects on the CNS, variations in antiepileptic drug pharmacokinetics (such as acceleration of hepatic drug metabolism or effects on plasma protein binding), and changes in medication compliance. It is useful to see patients at frequent intervals during pregnancy and monitor serum antiepileptic drug levels. Measurement of the unbound drug concentrations may be useful if there is an increase in seizure frequency or worsening of side effects of antiepileptic drugs.

The overall incidence of fetal abnormalities in children born to mothers with epilepsy is 5 to 6%, compared to 2 to 3% in healthy women. Part of the higher incidence is due to teratogenic effects of antiepileptic drugs, and the risk increases with the number of medications used (e.g., 10% risk of malformations with three drugs). A syndrome comprising facial dysmorphism, cleft lip, cleft palate, cardiac defects, digital hypoplasia, and nail dysplasia was originally ascribed to phenytoin therapy, but it is now known to occur with other first-line antiepileptic drugs (i.e., valproic acid and carbamazepine) as well. Also, valproic acid and carbamazepine are associated with a 1 to 2% incidence of neural tube defects compared with a baseline of 0.5 to 1%. Little is currently known about the safety of newer drugs.

Since the potential harm of uncontrolled seizures on the mother and fetus is considered greater than the teratogenic effects of antiepileptic drugs, it is currently recommended that pregnant women be maintained on effective drug therapy. When possible, it seems prudent to have the patient on monotherapy at the lowest effective dose, especially during the first trimester. Patients should also take folate (1

to 4 mg/d), since the antifolate effects of anticonvulsants are thought to play a role in the development of neural tube defects, although the benefits of this treatment remain unproved in this setting.

Enzyme-inducing drugs such as phenytoin, phenobarbital, and primidone cause a transient and reversible deficiency of vitamin K–dependent clotting factors in ~50% of newborn infants. Although neonatal hemorrhage is uncommon, the mother should be treated with oral vitamin K (20 mg daily) in the last 2 weeks of pregnancy, and the infant should receive vitamin K (1 mg) at birth.

Contraception Special care should be taken when prescribing antiepileptic medications for women who are taking oral contraceptive agents. Drugs such as carbamazepine, phenytoin, phenobarbital, and topiramate can significantly antagonize the effects of oral contraceptives via enzyme induction and other mechanisms. Patients should be advised to consider alternative forms of contraception, or their contraceptive medications should be modified to offset the effects of the antiepileptic medications.

Breast Feeding Antiepileptic medications are excreted into breast milk to a variable degree. The ratio of drug concentration in breast milk relative to serum is ~80% for ethosuximide, 40 to 60% for phenobarbital, 40% for carbamazepine, 15% for phenytoin, and 5% for valproic acid. Given the overall benefits of breast feeding and the lack of evidence for long-term harm to the infant by being exposed to antiepileptic drugs, mothers with epilepsy can be encouraged to breast feed. This should be reconsidered, however, if there is any evidence of drug effects on the infant, such as lethargy or poor feeding.

349 CEREBROVASCULAR DISEASES

Wade S. Smith, S. Claiborne Johnston, J. Donald Easton

Cerebrovascular diseases include some of the most common and devastating disorders: ischemic stroke, hemorrhagic stroke, and cerebrovascular anomalies such as intracranial aneurysms and arteriovenous malformations (AVMs). They cause ~200,000 deaths each year in the United States and are a major cause of disability. The incidence of cerebrovascular diseases increases with age, and the number of strokes is projected to increase as the elderly population grows, with a doubling in stroke deaths in the United States by 2030. Most cerebrovascular diseases are manifest by the abrupt onset of a focal neurologic deficit, as if the patient was "struck by the hand of God". A stroke, or cerebrovascular accident, is defined by this abrupt onset of a neurologic deficit that is attributable to a focal vascular cause. Thus, the definition of stroke is clinical, and laboratory studies including brain imaging are used to support the diagnosis. The clinical manifestations of stroke are highly variable because of the complex anatomy of the brain and its vasculature. *Cerebral ischemia* is caused by a reduction in blood flow that lasts longer than several seconds. Neurologic symptoms are manifest within seconds because neurons lack glycogen, so energy failure is rapid. When blood flow is quickly restored, brain tissue can recover fully and the patient's symptoms are only transient: this is called a *transient ischemic attack* (TIA). Typically the neurologic signs and symptoms of a TIA last for 5 to 15 min but, by definition, must last <24 h. If the cessation of flow lasts for more than a few minutes, *infarction* or death of brain tissue results. Stroke has occurred if the neurologic signs and symptoms last for >24 h. A generalized reduction in cerebral blood flow due to systemic hypotension (e.g., cardiac arrhythmia, myocardial infarction, or hemorrhagic shock) usually produces syncope (Chap. 20). If low cerebral blood flow persists for a longer duration, then infarction in the border zones between the major cerebral artery distributions may develop. In more severe instances, *global hypoxia-ischemia* causes widespread brain injury; the constellation of cognitive sequelae that ensue is called *hypoxic-ischemic encephalopathy* (Chap. 258). *Focal ischemia* or infarction, on the other hand, is usually caused by thrombosis of the cerebral vessels themselves or by emboli from a proximal arterial source or the heart. *Cerebral hemorrhage* produces neurologic symptoms by producing a mass effect on neural structures or from the toxic effects of blood itself.

APPROACH TO THE PATIENT

Patients with acute stroke often do not seek medical assistance on their own, both because they are rarely in pain, as well as because they may lose the appreciation that something is wrong **(anosagnosia)**. It is often a family member or a bystander who calls for help. The rapid evaluation of patients is essential for use of time-sensitive treatments such as thrombolysis. Patients at risk for stroke should be counseled to call emergency medical services immediately if they experience the sudden onset of any of the following: loss of sensory and/or motor function on one side of the body (nearly 85% of ischemic stroke patients have hemiparesis); change in vision, gait, or ability to speak or understand; or if they experience a sudden, severe headache.

There are several common causes of sudden-onset neurologic symptoms that may mimic stroke. An adequate history from an observer that no convulsive activity occurred at the onset reasonably excludes seizure. Tumors may present with acute neurologic symptoms due to hemorrhage, seizure, or hydrocephalus. Surprisingly, migraine can mimic cerebral ischemia, even in patients without a significant migraine history. When it develops without head pain (*acephalgic migraine*), the diagnosis may remain elusive. Patients without any prior history of complicated migraine may develop acephalgic migraine even after age 65. A sensory disturbance is often prominent, and the sensory deficit, as well as any motor deficits, tends to migrate slowly across a limb over minutes. The diagnosis of migraine becomes more secure as the cortical disturbance begins to cross vascular boundaries or if typical visual symptoms are present, such as scintillating scotomata (Chap. 14). At times it may be difficult to make the diagnosis until multiple episodes have occurred leaving behind no residual stroke or magnetic resonance imaging (MRI) changes consistent with stroke. Classically, metabolic encephalopathies produce fluctuating mental status without focal neurologic findings. However, in the setting of prior stroke or brain injury, a patient with fever or sepsis may manifest hemiparesis, which clears rapidly when the infection is remedied. The metabolic process serves to "unmask" a prior deficit. Once the diagnosis of stroke is made, a brain imaging study is necessary to determine if the cause of stroke is ischemia or hemorrhage (Fig. 349-1). Computed tomography (CT) imaging of the brain is the standard imaging modality to detect the presence or absence of intracranial hemorrhage (see "Imaging Studies," below). If the stroke is ischemic, administration of tissue plasminogen activator

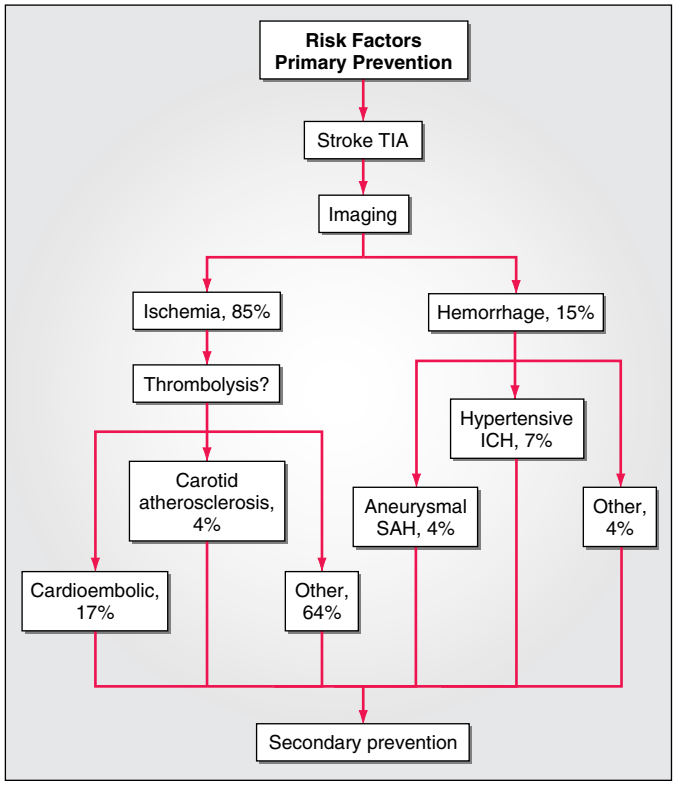

FIGURE 349-1 Schematic approach to acute stroke. Numbers are percentage of all strokes. Abbreviations: TIA, transient ischemic attack; SAH, subarachnoid hemorrhage; ICH, intracerebral hemorrhage.

(tPA) may be beneficial in restoring cerebral perfusion (see "Treatment" below). Medical management to reduce the risk of complications becomes the next priority, followed by plans for secondary prevention. For ischemic stroke, several strategies can reduce the risk of subsequent stroke in all patients, while other strategies are effective for patients with specific causes of stroke such as cardiac embolus and carotid atherosclerosis. For hemorrhagic stroke, aneurysmal subarachnoid hemorrhage (SAH) is the most important treatable condition followed by hypertensive intracranial hemorrhage.

ISCHEMIC STROKE

PATHOPHYSIOLOGY OF ISCHEMIC STROKE Acute occlusion of an intracranial vessel causes reduction in blood flow to the brain region it supplies. The magnitude of flow reduction is a function of collateral blood flow and this depends on individual vascular anatomy and the site of occlusion. A fall in cerebral blood flow to zero causes death of brain tissue within 4 to 10 min; values <16 to 18 mL/100 g tissue per min cause infarction within an hour; and values <20 mL/100 g tissue per min cause ischemia without infarction unless prolonged for several hours or days. If blood flow is restored prior to a significant amount of cell death, the patient may experience only transient symptoms, i.e., a TIA. Tissue surrounding the core region of infarction is ischemic but reversibly dysfunctional and is referred to as the *ischemic penumbra*. The penumbra may be imaged by using perfusion-diffusion imaging with MRI (see below and Fig. 349-13). The ischemic penumbra will eventually infarct if no change in flow occurs, and hence saving the ischemic penumbra is the goal of thrombolytic therapy and newer therapies under investigation.

The complex processes that are involved in focal cerebral infarction are summarized in Fig. 349-2. Cellular death occurs via two distinct pathways: (1) a necrotic pathway in which cellular cytoskeletal breakdown is rapid, due principally to energy failure of the cell; and (2) an apoptotic pathway in which cells become programmed to die. Ischemia produces necrosis by starving neurons of glucose which in turn results in failure of mitochondria to produce ATP. Without ATP, membrane ion pumps stop functioning and neurons depolarize, allowing intracellular calcium to rise. Cellular depolarization also causes glutamate release from synaptic terminals; excess extracellular glutamate produces neurotoxicity by agonizing postsynaptic glutamate receptors that increase neuronal calcium influx. Free radicals are produced by membrane lipid degradation and mitochondrial dysfunction. Free radicals cause catalytic destruction of membranes and likely damage other vital functions of cells. Lesser degrees of ischemia, as are seen within the ischemic penumbra, favor apoptotic cellular death causing cells to die days to weeks later. There are no clinically proven strategies that alter these ischemic cascades despite extensive clinical study. It is clear, however, that fever dramatically worsens ischemia, as does hyperglycemia [glucose > 11.1 to 16.7 mmol/L (200 to 300 mg/dL)], so it is reasonable to suppress fever and prevent hyperglycemia as much as possible. Hypothermia and other neuroprotective strategies are subjects of continuing clinical research.

TREATMENT

Acute Ischemic Stroke After the clinical diagnosis of stroke is made, an orderly process of evaluation and treatment should follow (Table 349-1). The first goal is to prevent or reverse brain injury. After initial stabilization, an emergency noncontrast head CT scan should be performed to differentiate ischemic from hemorrhagic stroke; there are no reliable clinical findings that conclusively separate ischemia from hemorrhage, although a more depressed level of consciousness and higher initial blood pressure favor hemorrhage, and a deficit that remits suggests ischemia. Treatments designed to reverse or lessen the amount of tissue infarction fall within five categories: (1) medical support, (2) thrombolysis, (3) anticoagulation, (4) antiplatelet agents, and (5) neuroprotection.

TABLE 349-1 Clinical Management of Acute Stroke

New onset of neurologic deficit: Stroke or TIA?	Differential diagnosis of new focal deficit Stroke or TIA Seizure with postictal Todd's paresis Tumor Migraine Metabolic encephalopathy Fever/infection and old stroke Hyperglycemia Hypercalcemia Hepatic encephalopathy
Initial assessment and management	ABCs, serum glucose Noncontrast head CT Hemorrhage Medical and surgical management Tumor or other CNS process Treat as indicated Normal or hypodense area consistent with acute ischemic stroke Consider thrombolysis, aspirin Maintain blood pressure and hydrate Admit patient to appropriate level of care depending on concomitant medical problems and airway
Subsequent hospital management	Establish cause of stroke and risk factors Plan for secondary prophylaxis (drugs, risk factor modifications) Obtain physical, occupational, and speech therapy consultation and social work as appropriate Provide nutrition Plan for discharge, including prescriptions for risk factor reduction, including when to institute antihypertensive treatment, and antithrombotic medication prophylaxis

Note: ABCs, airway management, breathing, cardiac status; CNS, central nervous system; CT, computed tomography; TIA, transient ischemic attack.

MEDICAL SUPPORT When cerebral infarction occurs, the immediate goal is to optimize cerebral perfusion in the surrounding ischemic penumbra. Attention is also directed toward preventing the common complications of bedridden patients—infections (pneumonia, urinary tract, and skin) and deep venous thrombosis (DVT) with pulmonary embolism. Many physicians use pneumatic compression stockings to prevent DVT; subcutaneous heparin appears to be safe as well.

Because collateral blood flow within the ischemic brain is blood pressure dependent, there is controversy about whether blood pressure should be lowered acutely. Blood pressure should be lowered if there is malignant hypertension (Chap. 230) or concomitant myocardial ischemia or if blood pressure is >185/110 mmHg and thrombolytic therapy is anticipated. When faced with the competing demands of myocardium and brain, lowering the heart rate with a β_1-adrenergic blocker (such as esmolol or labetolol) can be a first step to decrease cardiac work and maintain blood pressure. Fever is detrimental and should be treated with antipyretics. Serum glucose should be monitored and kept at <11.1 mmol/L (200 mg/dL).

Between 5 and 10% of patients develop enough cerebral edema to cause obtundation or brain herniation. Edema peaks on the second or third day but can cause mass effect for ~10 days. The larger the infarct, the greater the likelihood that clinically significant edema will develop. Special vigilance is warranted for patients with cerebellar infarction. Even small amounts of cerebellar edema can acutely increase intracranial pressure (ICP) in the posterior fossa or directly compress the brainstem. The resulting brainstem compression can result in coma and respiratory arrest and require emergency surgical decompression. Water restriction and intravenous mannitol may be used to raise the serum osmolarity, but hypovolemia should be avoided as this may contribute to hypotension and worsening infarction. Trials are under way to test the clinical benefits of craniotomy and temporary removal of part of the skull (hemicraniectomy) for large hemispheric infarcts with marked cerebral edema.

THROMBOLYSIS The National Institute of Neurological Disorders and Stroke (NINDS) recombinant tPA (rtPA) Stroke Study showed a clear benefit for intravenous rtPA in selected patients with acute stroke. The NINDS study used intravenous rtPA (0.9 mg/kg to a 90-mg max; 10% as a bolus, then the remainder over 60 min) vs. placebo in patients with ischemic stroke within 3 h of onset. Half of the patients were treated within 90 min. Symptomatic intracerebral hemorrhage occurred in 6.4% of patients on rtPA and 0.6% on placebo. There was a nonsignificant 4% reduction in mortality in patients on rtPA (21% on placebo and 17% on rtPA); there was a significant 12% absolute increase in the number of patients with only minimal disability (32% on placebo and 44% on rtPA.) Thus, despite an increased incidence of symptomatic intracerebral hemorrhage, treatment with intravenous rtPA within 3 h of the onset of ischemic stroke improved clinical outcome.

Results of other trials of rtPA have been negative, perhaps because of the dose of rtPA and timing of its delivery. The European Cooperative Acute Stroke Study (ECASS) I used a higher dose of rtPA (1.2 mg/kg), and ECASS-II tested the NINDS dose of rtPA (0.9 mg/kg; maximum dose, 90 mg) but allowed patients to receive drug up to the sixth hour. No significant benefit was found, but improvement was found in post hoc analyses. ATLANTIS tested the NINDS dosing of rtPA between 3 and 5 h and found no benefit. Three major trials using streptokinase reported increased mortality for patients receiving streptokinase. Early administration of the fibrinolytic agent ancrod appears to improve outcomes for patients with acute ischemic stroke; although the drug has not been approved for clinical use, its efficacy provides further evidence that thrombolytics should have a role in treatment of acute ischemic stroke.

Because of the marked differences in trial design, including drug and dose used, time to thrombolysis, and severity of stroke, the precise efficacy of intravenous thrombolytics for acute ischemic stroke remains unclear. The risk of intracranial hemorrhage appears to rise with larger strokes, longer times from onset of symptoms, and higher doses of rtPA administered. The established dose of 0.9 mg/kg administered intravenously within 3 h of stroke onset appears safe. Many hospitals have developed expert stroke teams to facilitate this treatment. The drug is now approved in the United States, Canada, and Europe for acute stroke when given within 3 h from the time the stroke symptoms began, and efforts should be made to give it as early in this 3-h window as possible. The time of stroke onset is defined as the time the patient's symptoms began or the time the patient was last seen as normal. A patient who awakens with stroke has the onset defined as when they went to bed. Table 349-2 summarizes eligibility criteria and instructions for administration of rtPA.

There is growing interest in using thrombolytics via an intraarterial route to increase the concentration of drug at the clot and minimize systemic bleeding complications. The Prolyse in Acute Cerebral Thromboembolism (PROACT) II trial found benefit for intraarterial pro-urokinase for acute middle cerebral artery (MCA) occlusions up to the sixth hour following onset of stroke. Intraarterial treatment of basilar artery occlusions may also be beneficial for selected patients. Intraarterial administration of a thrombolytic agent for acute ischemic stroke is not approved by the U.S. Food and Drug Administration (FDA); however, many stroke centers offer this treatment based on these data.

ANTIPLATELET AGENTS Aspirin is the only antiplatelet agent that has been prospectively studied for the treatment of acute ischemic stroke. The recent large trials, the International Stroke Trial (IST) and the Chinese Acute Stroke Trial (CAST), found that the use of aspirin within 48 h of stroke onset reduced both stroke recurrence risk and mortality minimally. Among 19,435 patients in IST, those allocated to aspirin, 300 mg/d, had slightly fewer deaths within 14 days (9.0 vs. 9.4%), signif-

TABLE 349-2 *Administration of Intravenous Recombinant Tissue Plasminogen Activator (rtPA) for Acute Ischemic Stroke*[a]

Indication	Contraindication
Clinical diagnosis of stroke	Sustained BP > 185/110 despite treatment
Onset of symptoms to time of drug administration ≤3 h	Platelets < 100,000; HCT < 25%; glucose < 50 or > 400 mg/dL
CT scan showing no hemorrhage or edema of > $\frac{1}{3}$ of the MCA territory	Use of heparin within 48 h and prolonged PTT, or elevated INR
Age ≥18 years	Rapidly improving symptoms
Consent by patient or surrogate	Prior stroke or head injury within 3 months; prior intracranial hemorrhage
	Major surgery in preceding 14 days
	Minor stroke symptoms
	Gastrointestinal bleeding in preceding 21 days
	Recent myocardial infarction
	Coma or stupor

Administration of rtPA

- Intravenous access with two peripheral IV lines (avoid arterial or central line placement)
- Review eligibility for rtPA
- Administer 0.9 mg/kg intravenously (maximum 90 mg) IV as 10% of total dose by bolus, followed by remainder of total dose over 1 h
- Frequent cuff blood pressure monitoring
- No other antithrombotic treatment for 24 h
- For decline in neurologic status or uncontrolled blood pressure, stop infusion, give cryoprecipitate, and reimage brain emergently
- Avoid urethral catheterization for ≥2 h

[a] See Activase (tissue plasminogen activator) package insert for complete list of contraindications and dosing.

Note: BP, blood pressure; CT, computed tomography; HCT, hematocrit; INR, international normalized ratio; MCA, middle cerebral artery; PTT, partial thromboplastin time.

icantly fewer recurrent ischemic strokes (2.8 vs. 3.9%), no excess of hemorrhagic strokes (0.9 vs. 0.8%), and a trend towards a reduction in death or dependence at 6 months (61.2 vs. 63.5%). In CAST, 21,106 patients with ischemic stroke received 160 mg/d of aspirin or a placebo for up to 4 weeks. There were very small reductions in the aspirin group in early mortality (3.3 vs. 3.9%), recurrent ischemic strokes (1.6 vs. 2.1%), and dependency at discharge or death (30.5 vs. 31.6%). These trials demonstrate that the use of aspirin in the treatment of acute ischemic stroke is safe and produces a small net benefit. For every 1000 acute strokes treated with aspirin, about 9 deaths or nonfatal stroke recurrences will be prevented in the first few weeks and ~13 fewer patients will be dead or dependent at 6 months.

Agents that act at the glycoprotein IIb/IIIa receptor are undergoing clinical trials in acute stroke treatment. Early results show that intravenous abciximab can be used safely within 6 h of stroke onset and suggest that it may be effective.

Anticoagulation The role of anticoagulation in atherothrombotic cerebral ischemia is uncertain. Several trials have investigated antiplatelet versus anticoagulant medications given within 12 to 24 h of the initial event. The U.S. Trial of Organon 10172 in Acute Stroke Treatment (TOAST), an investigational low-molecular-weight heparin, failed to show any benefit over aspirin. Use of subcutaneous unfractionated heparin versus aspirin was tested in IST. Heparin given subcutaneously afforded no additional benefit over aspirin and increased bleeding rates. Several trials of low-molecular-weight heparins have also shown no consistent benefit in acute ischemic stroke. Therefore, trials do not support the use of heparin or other anticoagulants for patients with atherothrombotic stroke.

In spite of the absence of evidence, heparin is still used frequently to treat stroke and TIA, primarily based on beliefs about its impact on pathophysiology. Theoretically, heparin may prevent propagation of clot within a thrombosed vessel or may prevent more emboli from occurring. Heparin is widely used for crescendo TIAs (TIAs that increase in frequency), despite the absence of data from controlled studies regarding this indication. In ~20% of patients with acute stroke, deficits will progress over several hours to 1 to 2 days. Some physicians heparinize all patients with recent mild ischemic stroke in order to prevent some of this worsening, but this practice is discouraged. The bleeding complication rate for 7 days of heparin is about 10%, with a serious bleed rate of ~2%. Clearly the value of this approach must be clarified. Heparinization is generally accomplished by beginning an infusion without bolus and is monitored to maintain the activated partial thromboplastin time (PTT) at approximately twice normal.

Neuroprotection Neuroprotection is the concept of providing a treatment that prolongs the brain's tolerance to ischemia. Hypothermia is a powerful neuroprotective treatment in patients with cardiac arrest, but it has not been adequately studied in patients with stroke. Drugs that block the excitatory amino acid pathways have been shown to protect neurons and glia in animals, but despite multiple clinical trials, they have not yet been proven to be beneficial in humans. Even so, interest in neuroprotection continues because of the potential for agents to have limited risk, even when administered in the pre-hospital setting or in conjunction with thrombolytic agents.

Stroke Centers and Rehabilitation Patient care in comprehensive stroke units followed by rehabilitation services improves neurologic outcomes and reduces mortality. Use of clinical pathways and staff dedicated to the stroke patient can improve care. Stroke teams that provide emergency 24-h evaluation of acute stroke patients for acute medical management and consideration of thrombolysis are important.

Proper rehabilitation of the stroke patient includes early physical, occupational, and speech therapy. It is directed toward educating the patient and family about the patient's neurologic deficit, preventing the complications of immobility (e.g., pneumonia, DVT and pulmonary embolism, pressure sores of the skin, and muscle contractures), and providing encouragement and instruction in overcoming the deficit. The goal of rehabilitation is to return the patient to home and to maximize recovery by providing a safe, progressive regimen suited to the individual patient. Additionally, the use of restraint therapy has been shown to improve hemiparesis following stroke, even years following the stroke, suggesting that physical therapy can recruit unused neural pathways. This finding suggests that the human nervous system is more adaptable than originally thought and has stimulated active research into physical and pharmacologic strategies that can enhance long-term neural recovery.

ETIOLOGY OF ISCHEMIC STROKE (Table 349-3) Although the initial management of acute ischemic stroke often does not depend on the etiology, establishing a cause is essential in reducing the risk of recurrence. The clinical presentation and examination findings often establish the cause of stroke or narrow the possibilities to a few. Judicious use of laboratory testing and imaging studies completes the initial evaluation. Nevertheless, nearly 30% of strokes remain unexplained despite extensive evaluation.

Clinical examination should be focused on the peripheral and cervical vascular system (carotid auscultation for bruits, blood pressure, and pressure comparison between arms), the heart (dysrhythmia, murmurs), extremities (peripheral emboli), and retina [effects of hypertension and cholesterol emboli (Hollenhorst plaques)]. A complete neurologic examination is performed to localize the site of stroke. An imaging study of the brain is nearly always performed and is required for patients being considered for thrombolysis. A chest x-ray, electrocardiogram (ECG), urinalysis, complete blood count, erythrocyte sedimentation rate, serum electrolytes, blood urea nitrogen, creatinine, blood sugar, serologic test for syphilis, serum lipid profile, prothrombin time, and PTT are often useful and should be considered in all patients. An ECG may demonstrate conduction abnormalities and arrhythmias or reveal evidence of recent myocardial infarction (MI).

Cardioembolic Stroke Cardioembolism is responsible for ~20% of all ischemic strokes. Stroke caused by heart disease is primarily due to embolism of thrombotic material forming on the atrial or ventricular

TABLE 349-3 *Causes of Ischemic Stroke*

Common Causes	Uncommon Causes
Thrombosis	Hypercoagulable disorders
Lacunar stroke (small vessel)	Protein C deficiency
Large vessel thrombosis	Protein S deficiency
Dehydration	Antithrombin III deficiency
Embolic occlusion	Antiphospholipid syndrome
Artery-to-artery	Factor V Leiden mutation[a]
Carotid bifurcation	Prothrombin G20210 mutation[a]
Aortic arch	Systemic malignancy
Arterial dissection	Sickle cell anemia
Cardioembolic	β-Thalassemia
Atrial fibrillation	Polycythemia vera
Mural thrombus	Systemic lupus erythematosus
Myocardial infarction	Homocysteinemia
Dilated cardiomyopathy	Thrombotic thrombocytopenic purpura
Valvular lesions	Disseminated intravascular coagulation
Mitral stenosis	Dysproteinemias
Mechanical valve	Nephrotic syndrome
Bacterial endocarditis	Inflammatory bowel disease
Paradoxical embolus	Oral contraceptives
Atrial septal defect	Venous sinous thrombosis[b]
Patent foramen ovale	Fibromuscular dysplasia
Atrial septal aneurysm	Vasculitis
Spontaneous echo contrast	Systemic vasculitis (PAN, Wegner's, Takayasu's, giant cell arteritis)
	Primary CNS vasculitis
	Meningitis (syphilis, tuberculosis, fungal, bacterial, zoster
	Cardiogenic
	Mitral valve calcification
	Atrial myxoma
	Intracardiac tumor
	Marantic endocarditis
	Libman-Sacks endocarditis
	Subarachnoid hemorrhage vasospasm
	Drugs: cocaine, amphetamine
	Moyamoya disease
	Eclampsia

[a] Chiefly cause venous sinus thrombosis.
[b] May be associated with any hypercoagulable disorder.
Note: CNS, central nervous system; PAN, polyarteritis nodosa.

wall or the left heart valves. These thrombi then detach and embolize into the arterial circulation. The thrombus may fragment or lyse quickly, producing only TIA. Alternatively, the arterial occlusion may last longer, producing stroke. Embolic strokes tend to be sudden in onset, with maximum neurologic deficit at once. With reperfusion following more prolonged ischemia, petechial hemorrhage can occur within the ischemic territory. This is usually of no clinical significance and should be distinguished from frank intracranial hemorrhage into a region of ischemic stroke where the mass effect from the hemorrhage can cause a decline in neurologic function.

Emboli from the heart most often lodge in the MCA, the posterior cerebral artery (PCA), or one of their branches; infrequently, the anterior cerebral artery (ACA) territory is involved. Emboli large enough to occlude the stem of the MCA (3 to 4 mm) lead to large infarcts that involve both deep gray and white matter and some portions of the cortical surface and its underlying white matter. A smaller embolus may occlude a small cortical or penetrating arterial branch. The location and size of an infarct within a vascular territory depend on the extent of the collateral circulation.

The most significant causes of cardioembolic stroke in most of the world are nonrheumatic (often called nonvalvular) atrial fibrillation, MI, prosthetic valves, rheumatic heart disease, and ischemic cardiomyopathy (Table 349-3). Cardiac disorders causing brain embolism are discussed in the respective chapters on heart diseases. A few pertinent aspects are highlighted here.

Nonrheumatic atrial fibrillation is the most common cause of cerebral embolism overall. The presumed stroke mechanism is thrombus formation in the fibrillating atrium or atrial appendage, with subsequent embolization. Patients with atrial fibrillation have an average annual risk of stroke of ~5%. The risk varies according to the presence of certain risk factors, including older age, hypertension, poor left ventricular function, prior cardioembolism, diabetes, and thyrotoxicosis. Patients younger than 60 with none of these risk factors have an annual risk for stroke of ~0.5%, while those with most of the factors have a rate of ~15% per year. Left atrial enlargement and congestive heart failure are additional risk factors for formation of atrial thrombi. Rheumatic heart disease usually causes ischemic stroke when there is prominent mitral stenosis or atrial fibrillation. Guidelines for the use of warfarin and aspirin for secondary prevention are based on risk factors (Table 349-4).

Recent MI may be a source of emboli, especially when transmural and involving the anteroapical ventricular wall, and prophylactic anticoagulation following MI has been shown to reduce stroke risk. Mitral valve prolapse is not usually a source of emboli unless the prolapse is severe.

Paradoxical embolization occurs when venous thrombi migrate to the arterial circulation, usually via a patent foramen ovale or atrial septal defect. Bubble-contrast echocardiography (intravenous injection of agitated saline coupled with either transthoracic or transesophageal echocardiography) can demonstrate a cardiac right-to-left shunt, revealing the conduit for paradoxical embolization. Alternatively, a right-to-left shunt is implied if immediately following intravenous injection of agitated saline, high-intensity transients are observed during transcranial Doppler insonation of the MCA. Both techniques are highly sensitive for detection of right-to-left shunts. Besides venous clot, fat and tumor emboli, bacterial endocarditis, intravenous air, and amniotic fluid emboli associated with delivery may occasionally be responsible for paradoxical embolization. The importance of right-to-left shunt as a cause of stroke is debated, particularly because such shunts occur in ~15% of the general population. Some studies have suggested that the risk is only elevated in the presence of a coexisting atrial septal aneurysm. The presence of a venous source of embolus, most commonly a deep venous thrombus, may provide confirmation of the importance of a right-to-left shunt in a particular case.

Bacterial endocarditis can cause valvular vegetations that can give rise to multiple septic emboli (Chap. 109). The appearance of multifocal symptoms and signs in a patient with stroke makes bacterial endocarditis more likely. Infarcts of microscopic size occur, and large septic infarcts may evolve into brain abscesses or cause hemorrhage into the infarct, which generally precludes use of anticoagulation or thrombolytics. Mycotic aneurysms caused by septic emboli give rise to SAH or intracerebral hemorrhage.

Artery-to-Artery Embolic Stroke Thrombus formation on atherosclerotic plaques may embolize to intracranial arteries producing an artery-to-artery embolic stroke. Alternatively, a diseased vessel may acutely thrombose; the resulting blockage causes stroke by producing ischemia within the region of brain it supplied. Unlike the myocardial vessels, artery-to-artery embolism appears to be the dominant vascular mech-

TABLE 349-4 *Consensus Recommendation for Antithrombotic Prophylaxis in Atrial Fibrillation*

Age	Risk Factors[a]	Recommendation
Age ≤65	≥1	Warfarin INR 2–3
	0	Aspirin or no treatment
Age 65–75	≥1	Warfarin INR 2–3
	0	Warfarin INR 2–3 or aspirin
Age >75		Warfarin INR 2–3

[a] Risk factors include previous transient ischemic attack or stroke, hypertension, heart failure, diabetes, clinical coronary artery disease, mitral stenosis, prosthetic heart valves, or thyrotoxicosis.
Source: Modified from GW Albers et al: Antithrombotic therapy in atrial fibrillation. Chest 119:194S, 2001; with permission.

anism causing ischemia rather than thrombosis. The most common source of embolism is the carotid bifurcation, but any diseased vessel may be a source, including the aortic arch and common carotid, internal carotid, vertebral, and basilar arteries. Carotid bifurcation atherosclerosis is the most common source of artery-to-artery embolus, and specific treatments have proven efficacy in reducing risk.

TABLE 349-5 Risk Factors for Stroke

Risk Factor	Relative Risk	Relative Risk Reduction with Treatment	Number Needed to Treat[a]	
			Primary Prevention	Secondary Prevention
Hypertension	2–5	38%	100–300	50–100
Atrial fibrillation	1.8–2.9	68% warfarin, 21% aspirin	20–83	13
Diabetes	1.8–6	No proven effect		
Smoking	1.8	50% at 1 year, baseline risk at 5 years post cessation		
Hyperlipidemia	1.8–2.6	10–29%		—
Asymptomatic carotid stenosis	2.0	53%	85	N/A
Symptomatic carotid stenosis (70–99%)		65% at 2 years	N/A	12
Symptomatic carotid stenosis (50–69%)		29% at 5 years	N/A	77

[a] Number needed to treat to prevent one stroke annually. Prevention of other cardiovascular outcomes is not considered here.
Note: N/A, not applicable.

CAROTID ATHEROSCLEROSIS Atherosclerosis within the carotid artery occurs most frequently within the common carotid bifurcation and proximal internal carotid artery. Additionally, the carotid siphon (portion within the cavernous sinus) is also vulnerable to atherosclerosis. Male gender, older age, smoking, hypertension, diabetes, and hypercholesterolemia are risk factors for carotid disease, as they are for stroke in general (Table 349-5). Carotid atherosclerosis produces an estimated 5% of ischemic stroke, and the risk of stroke rises the higher the degree of carotid narrowing. →***For further discussion of the pathogenesis of atherosclerosis, see Chap. 224.***

Carotid disease can be classified by whether the stenosis is symptomatic or asymptomatic and by the degree of stenosis (percent narrowing of the narrowest segment compared to a more distal internal carotid segment). Symptomatic carotid disease implies that the patient has experienced a stroke or TIA within the vascular distribution of the artery, and it is associated with a greater risk of subsequent stroke than asymptomatic stenosis, in which the patient is symptom free and the stenosis is detected through screening. Greater degrees of arterial narrowing are generally associated with a greater risk of stroke.

TREATMENT

Surgical Therapy Surgery for atherosclerotic occlusive disease is largely limited to *carotid endarterectomy* for plaques located at the origin of the internal carotid artery in the neck.

Symptomatic carotid stenosis was studied in the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). Both showed a substantial benefit for surgery in patients with a stenosis of >70%. In NASCET, the average cumulative ipsilateral stroke risk at 2 years was 26% for patients treated medically and 9% for those receiving the same medical treatment plus a carotid endarterectomy. This 17% *absolute* reduction in the surgical group is a 65% *relative* risk reduction favoring surgery (Table 349-5). NASCET also showed a significant benefit for patients with 50 to 70% stenosis, although less robust. ECST found harm for patients with stenosis in the 0 to 30% range treated surgically.

A patient's risk of stroke and possible benefit from surgery are related to the presence of retinal versus hemispheric symptoms, degree of arterial stenosis, extent of associated medical conditions, institutional surgical morbidity and mortality, and other factors. A patient with multiple atherosclerosis risk factors, symptomatic hemispheric ischemia, high-grade stenosis in the appropriate internal carotid artery, and an institutional perioperative morbidity and mortality rate of ≤6% generally should undergo carotid endarterectomy. If the perioperative stroke rate is >6% for any particular surgeon, however, the benefits of carotid endarterectomy are questionable.

The indications for surgical treatment of *asymptomatic carotid disease* have been clarified by the results of the Asymptomatic Carotid Atherosclerosis Study (ACAS), which randomized patients with ≥60% stenosis to medical treatment with aspirin or the same medical treatment plus carotid endarterectomy. The surgical group had a risk over 5 years for ipsilateral stroke (and any perioperative stroke or death) of 5.1%, compared to a risk in the medical group of 11%. While this demonstrates a 53% *relative* risk reduction, the *absolute* risk reduction is only 5.9% over 5 years, or 1.2% annually (Table 349-5). The perioperative complication rate was higher in women, so they received only a 17% relative risk reduction over 5 years. Nearly half of the strokes in the surgery group were caused by preoperative angiograms.

The natural history of asymptomatic stenosis is an ~2% per year stroke rate, while symptomatic patients experience a 13% per year risk of stroke. Whether to recommend carotid revascularization for an asymptomatic patient remains controversial and depends on many factors including patient preference, age, and comorbidities. Medical therapy for reduction of atherosclerosis risk factors, including statins and aspirin, is generally recommended for patients with asymptomatic carotid stenosis. As with atrial fibrillation, it is imperative to counsel the patient about TIAs so their therapy can be revised if they become symptomatic.

Balloon angioplasty coupled with stenting is being used with increasing frequency to open stenotic carotid arteries and maintain their patency. This method has not yet been compared prospectively with endarterectomy, except in high-risk patients where one small trial suggested less morbidity with stenting compared with endarterectomy. Concern exists about distal embolization of plaque during vessel dilation, and many new devices designed to prevent distal embolization are undergoing clinical trials. Extracranial to intracranial (EC-IC) bypass surgery has been proven ineffective for atherosclerotic stenoses that are inaccessible to conventional carotid endarterectomy. However, using more functional techniques [positron emission tomography (PET) imaging] to select patients who may benefit from EC-IC bypass is currently being studied.

OTHER CAUSES OF ARTERY-TO-ARTERY EMBOLIC STROKE *Intracranial atherosclerosis* produces stroke either by an embolic mechanism or by in-situ thrombosis of a diseased vessel and is more common in patients of Asian and African-American descent. It is estimated that following a stroke or TIA from intracranial atherosclerosis the risk of a second stroke is ~15% per year. There is no proven superior treatment for stroke prevention in this disorder. Warfarin sodium and aspirin are being compared in a U.S. based prospective trial. Many neurointerventional centers are using intracranial angioplasty coupled with intracranial stenting, but this has not been compared with antithrombotic strategies for stroke prevention.

Dissection of the internal carotid or vertebral arteries or even vessels beyond the circle of Willis is a common source of embolic stroke in young (age <60 years) patients. The dissection is usually painful and precedes the stroke by several hours or days. Extracranial dissections rarely cause hemorrhage because of the tough adventitia of these vessels. Intracranial dissections, on the other hand, may produce SAH because the adventitia of intracranial vessels is thin and pseudoaneu-

rysms may form, requiring treatment to prevent rerupture. The cause of dissection is usually unknown and recurrence is rare. Ehlers-Danlos type IV, Marfan's disease, cystic medial necrosis, and fibromuscular dysplasia are associated with dissections. Trauma (usually a motor vehicle accident or a sports injury) can cause carotid and vertebral artery dissections. Spinal manipulative therapy is independently associated with vertebral artery dissection and stroke. Most dissections heal spontaneously, and stroke or TIA is uncommon beyond 2 weeks. Although there are no trials comparing anticoagulation to antiplatelet agents, many physicians treat with anticoagulants for 3 to 6 months then convert to antiplatelet therapy after demonstration of vascular recanalization.

Small-Vessel Stroke The term *lacunar infarction* refers to infarction following atherothrombotic or lipohyalinotic occlusion of a small artery (30 to 300 μm) in the brain. The term *small-vessel stroke* denotes occlusion of such a small penetrating artery and is now the preferred term. Small-vessel strokes account for ~20% of all strokes.

PATHOPHYSIOLOGY The MCA stem, the arteries comprising the circle of Willis (A1 segment, anterior and posterior communicating arteries, and P1 segment), and the basilar and vertebral arteries all give rise to 30- to 300-μm branches that penetrate the deep gray and white matter of the cerebrum or brainstem (Fig. 349-3). Each of these small branches can occlude either by atherothrombotic disease at its origin or by the development of lipohyalinotic thickening. Thrombosis of these vessels causes small infarcts that are referred to as *lacunes* (Latin for "lake" of fluid noted at autopsy). They range in size from 3 mm to 2 cm. Hypertension and age are the principal risk factors.

CLINICAL MANIFESTATIONS The most common *lacunar syndromes* are the following: (1) Pure motor hemiparesis from an infarct in the posterior limb of the internal capsule or basis pontis; the face, arm, and leg are almost always involved; (2) pure sensory stroke from an infarct in the ventrolateral thalamus; (3) ataxic hemiparesis from an infarct in the base of the pons; (4) dysarthria and a clumsy hand or arm due to infarction in the base of the pons or in the genu of the internal capsule; and (5) pure motor hemiparesis with "motor (Broca's) aphasia" due to thrombotic occlusion of a lenticulostriate branch supplying the genu and anterior limb of the internal capsule and adjacent white matter of the corona radiata.

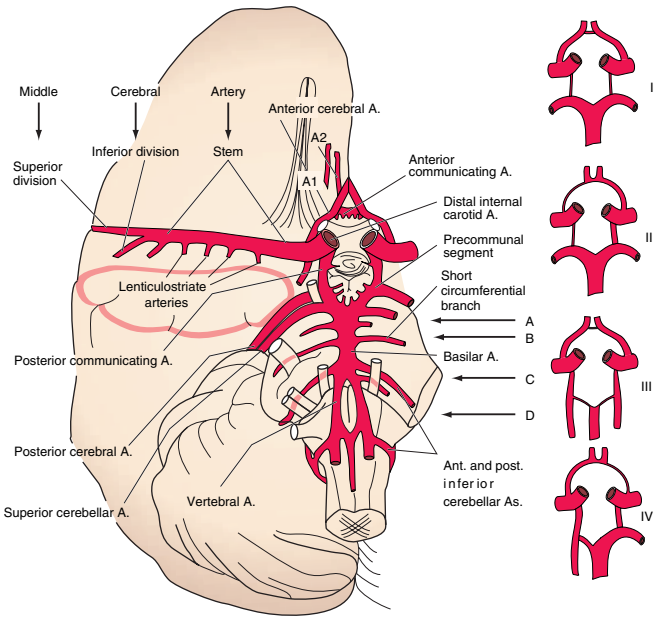

FIGURE 349-3 Diagram of the brainstem, cerebellum, inferior right frontal lobe, and transected temporal lobe. Principal branches of the vertebral basilar arterial system are pictured. The stem of the middle cerebral artery with its small, deep penetrating lenticulostriate arteries and the circle of Willis with its small, deep penetrating branches are shown. Roman numerals I, II, III, and IV represent some of the possible variations of the circle of Willis. *A*, *B*, *C*, and *D* arrows indicate the four levels of the brainstem diagrammed below (*A*, Fig. 349-11; *B*, Fig. 349-10; *C*, Fig. 349-9; *D*, Fig. 349-8). Although typical vascular syndromes of the pons and medulla have been designated by the shaded areas in Figs. 349-8 to 349-11, the shading is approximate only. Great variability in infarct size and location occurs when the basilar or vertebral arteries or one of their penetrating branches becomes occluded. This variability is because of variation in arterial anatomic location and available collateral circulation. Thus the stroke syndromes produced are often atypical, incomplete, or merge with one another. *(Courtesy of CM Fisher, MD.)*

Transient symptoms (small vessel TIAs) may herald a small-vessel infarct; they may occur several times a day and last only a few minutes. Recovery from a small-vessel stroke often begins within hours or days, and over weeks or months may be nearly complete; in some cases, however, there is severe permanent disability. Often, institution of combined antithrombotic treatments does not prevent eventual stroke in "stuttering lacunes."

A large-vessel source (either thrombosis or embolism) may manifest initially as a lacunar syndrome with small-vessel infarction. Therefore, the search for embolic sources (carotid and heart) should not be completely abandoned in the evaluation of these patients. Secondary prevention of lacunar stroke involves risk factor modification, specifically reduction in blood pressure (see "Primary and Secondary Prevention," below).

LESS COMMON CAUSES OF STROKE (Table 349-3) *Hypercoagulable disorders* (Chap. 53) primarily cause increased risk of venous thrombosis and therefore may cause venous sinus thrombosis. Protein S deficiency and homocysteinemia may cause arterial thromboses as well. Systemic lupus erythematosus with Liebman-Sacks endocarditis can be a cause of embolic stroke. These conditions overlap with the antiphospholipid syndrome, which probably requires long-term anticoagulation to prevent further stroke.

Venous sinus thrombosis of the lateral or sagittal sinus or of small cortical veins (cortical vein thrombosis) occurs as a complication of pregnancy and the postpartum period, sepsis, and intracranial infections (meningitis). It is also seen with increased incidence in patients with laboratory-confirmed thrombophilia (Table 349-3) including polycythemia, sickle cell anemia, proteins C and S deficiency, factor V Leiden mutation (resistance to activated protein C), antithrombin III deficiency, homocysteinemia, and the prothrombin G20210 mutation. Women who take oral contraceptives and have the prothrombin G20210 mutation may be at high risk for sinus thrombosis. Patients present with headache, focal neurologic signs (especially paraparesis), and seizures. Often, CT imaging is normal unless an intracranial venous hemorrhage has occurred, but the venous sinus occlusion is readily visualized using magnetic resonance (MR) venography or conventional x-ray angiography. With greater degrees of sinus thrombosis, the patient may develop signs of increased ICP and coma. Intravenous heparin, regardless of the presence of intracranial hemorrhage, has been shown to reduce morbidity and mortality, and the long-term outcome is generally good. Heparin prevents further thrombosis and reduces venous hypertension and ischemia. If an underlying hypercoagulable state is not found, many physicians treat with warfarin sodium for 3 to 6 months then convert to aspirin, depending on the degree of resolution of the venous sinus thrombus. Anticoagulation is often continued indefinitely if thrombophilia is diagnosed.

Fibromuscular dysplasia affects the cervical arteries and occurs mainly in women. The carotid or vertebral arteries show multiple rings of segmental narrowing alternating with dilatation. Occlusion is usually incomplete. The process is often asymptomatic but occasionally is associated with an audible bruit, TIAs, or stroke. The cause and natural history of fibromuscular dysplasia is unknown (Chap. 232). TIA or stroke generally occurs only when the artery is severely narrowed or dissects. Anticoagulation or antiplatelet therapy may be helpful.

Temporal (giant cell) arteritis (Chap. 306) is a relatively common affliction of elderly persons in which the external carotid system, particularly the temporal arteries, becomes the site of a subacute granu-

lomatous inflammation with giant cells. Occlusion of posterior ciliary arteries derived from the ophthalmic artery results in blindness in one or both eyes and can be prevented with glucocorticoids. It rarely causes stroke as the internal carotid artery is usually not inflamed. Idiopathic giant cell arteritis involving the great vessels arising from the aortic arch (*Takayasu's arteritis*) may cause carotid or vertebral thrombosis; it is rare in the western hemisphere.

Necrotizing (or granulomatous) arteritis, occurring alone or in association with generalized polyarteritis nodosa or Wegener's granulomatosis, involves the distal small branches (<2 mm diameter) of the main intracranial arteries and produces small ischemic infarcts in the brain, optic nerve, and spinal cord. The cerebrospinal fluid often shows pleocytosis, and the protein level is elevated. *Primary central nervous system vasculitis* is rare; small or medium-sized vessels are usually affected. Brain biopsy or high-resolution conventional x-ray angiography is usually required to make the diagnosis. Patients with any form of vasculitis may present with insidious progression of combined white and gray matter infarctions, prominent headache, and cognitive decline. Aggressive immunosuppression with glucocorticoids, and often cyclophosphamide, is usually necessary to prevent progression. Depending upon the duration of the disease, many patients can make an excellent recovery.

Drugs, in particular amphetamines and perhaps cocaine, may cause stroke on the basis of acute hypertension and drug-induced vasculitis. Abstinence appears to be the best treatment, as no data exist on use of any treatment. Phenylpropanolamine has been linked with intracranial hemorrhage as has cocaine, perhaps related to a drug-induced vasculitis. Arteritis can also occur as a consequence of bacterial, tuberculous, and syphilitic meningitis.

Moyamoya disease is a poorly understood occlusive disease involving large intracranial arteries, especially the distal internal carotid artery and the stem of the middle and anterior cerebral arteries. Vascular inflammation is absent. The lenticulostriate arteries develop a rich collateral circulation around the occlusive lesion, which gives the impression of a "puff of smoke" (*moyamoya* in Japanese) on conventional x-ray angiography. Other collaterals include transdural anastomoses between the cortical surface branches of the meningeal and scalp arteries. The disease occurs mainly in Asian children or young adults, but the appearance may be identical in adults who have atherosclerosis. The etiology of the childhood form is unknown. Because of the occurrence of intracranial hemorrhage from rupture of the transdural and pial anastomotic channels, anticoagulation is risky. Breakdown of dilated lenticulostriate arteries may produce parenchymal hemorrhage, and progressive occlusion of large surface arteries can occur, producing large-artery distribution strokes. Bypass of extracranial carotid arteries to the dura or MCAs may prevent stroke and hemorrhage.

Reversible posterior leukoencephalopathy can occur in head injury, migraine, sympathomimetic drug use, eclampsia, and the postpartum period. The etiology is unclear but likely involves widespread cerebral segmental vasoconstriction. Patients complain of headache and manifest fluctuating neurologic symptoms and signs, especially visual symptoms. Sometimes cerebral infarction ensues. Conventional x-ray angiography is the only means of establishing the diagnosis, but because angiography itself can cause spasm of vessels, even the existence of this vascular entity is debated.

Binswanger's disease (chronic progressive subcortical encephalopathy) is a rare condition in which infarction of the subcortical white matter occurs subacutely. CT or MRI scans detect periventricular white matter infarcts and gliosis. There is lipohyalinosis in the small arteries of the deep white matter, as in hypertension. There are usually associated lacunar infarcts. Binswanger's disease may represent a type of border zone ischemic infarction in the deep white matter between the penetrating arteries of the circle of Willis and of the cortex. The pathophysiologic basis of the disease is unclear, but it typically occurs in older patients with severe long-standing hypertension.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is an inherited disorder that presents as small-vessel strokes, progressive dementia, and extensive symmetric white matter changes visualized by MRI. Approximately 40% of patients have migraine with aura, often manifest as transient motor or sensory deficits. Onset is usually in the fourth or fifth decade of life. This autosomal dominant condition is caused by one of several mutations in Notch-3, a member of a highly conserved gene family characterized by epidermal growth factor repeats in its extracellular domain. CADASIL is the only monogenic ischemic stroke syndrome so far described. Genetic testing is available.

TRANSIENT ISCHEMIC ATTACKS TIAs are episodes of stroke symptoms that last only briefly; the current definition of duration is <24 h, but the average duration of a TIA is ~12 min. The causes of TIA are similar to all causes of stroke, but because TIAs may herald stroke they are an important risk factor that should be considered separately. TIAs may arise from emboli to the brain or from in situ thrombosis of an intracranial vessel. With a TIA, the occluded blood vessel reopens and neurologic function is restored. However, infarcts of the brain do occur in 15 to 40% of TIAs even though neurologic signs and symptoms are absent.

In addition to the stroke syndromes discussed below, there are a few specific TIA symptoms that should receive special notice. *Amaurosis fugax*, or transient monocular blindness, occurs from emboli to the central retinal artery of one eye. This may indicate carotid stenosis as the cause or local ophthalmic artery disease.

The risk of stroke after a TIA is ~10% in the first 3 months, with most events occurring in the first 2 days. Therefore, urgent evaluation and treatment are justified. Since etiologies for stroke and TIA are identical, evaluation for TIA should parallel that of stroke (Tables 349-1 and 349-3). The improvement characteristic of TIA is a contraindication to thrombolysis. Acute antiplatelet therapy has not been tested specifically after TIA but is likely to be effective and is recommended. No large-scale trial has evaluated acute anticoagulation after TIA, a setting in which the risk of hemorrhage may be lower.

RISK FACTORS FOR ISCHEMIC STROKE Identification and control of modifiable risk factors is the best strategy to reduce the burden of stroke, as the total number of strokes could be reduced substantially by these means (Table 349-5).

PRIMARY AND SECONDARY PREVENTION ■ General Principles A number of medical and surgical interventions, as well as life-style modifications, are available for preventing stroke. Some of these can be widely applied because of their low cost and minimal risk; others are expensive and carry substantial risk but may be valuable for selected high-risk patients.

Evaluation of a patient's *clinical risk profile* can help determine which preventive treatments to offer. In addition to known risk factors for ischemic stroke (above), certain clinical characteristics also contribute to an increased risk of stroke (Table 349-5). NASCET found that even in patients with the same degree of carotid artery stenosis, specifically 70 to 99%, nine prospectively selected risk factors predicted the risk of vascular outcomes in the medically treated patients. The overall risk of stroke was much greater in a high-risk group (those with more than six risk factors) than in a low-risk group (those with fewer than six risk factors). Fully 39% of patients in the high-risk group treated medically experienced an ipsilateral stroke within 2 years. The rate for the low-risk group was less than half that but was still 17%.

Atherosclerosis Risk Factors The relationship of various factors to the risk of atherosclerosis is described in Chap. 225. Older age, family history of thrombotic stroke, diabetes mellitus, hypertension, tobacco smoking, abnormal blood cholesterol [particularly, low high-density lipoprotein (HDL) and/or high low-density lipoprotein (LDL), and other factors are either proven or probable risk factors for ischemic stroke, largely by their link to atherosclerosis. Risk of second stroke is strongly influenced by prior stroke or TIA, depending on cause.

Many cardiac conditions predispose to stroke, including atrial fibrillation and recent MI. Oral contraceptives may increase stroke risk, and certain inherited and acquired hypercoagulable states predispose to stroke. Hypertension is the most significant of the risk factors; in general, all hypertension should be treated. The presence of known cerebrovascular disease is not a contraindication to treatment aimed at achieving normotension. Also, the value of treating systolic hypertension in older patients has been clearly established. Lowering blood pressure to levels below those traditionally defining hypertension appears to reduce the risk of stroke even further. Data are particularly strong in support of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers.

Several trials have confirmed that statin drugs reduce the risk of stroke even in patients without elevated LDL or low HDL. Although studies specifically targeting prevention of second stroke are still underway, results for patients with cardiovascular risk factors or dyslipidemia have been compelling, with a 20 to 30% relative risk reduction for stroke. Therefore, a statin should be considered in all patients with prior ischemic stroke. Tobacco smoking should be discouraged in all patients (Chap. 375). Whether or not tight control of blood sugar in patients with diabetes lowers stroke risk is uncertain.

Antiplatelet Agents *Platelet antiaggregation agents* can prevent atherothrombotic events, including TIA and stroke, by inhibiting the formation of intraarterial platelet aggregates. These can form on diseased arteries, induce thrombus formation, and occlude the artery or embolize into the distal circulation. Aspirin, clopidogrel, and the combination of aspirin plus extended-release dipyridamole are the antiplatelet agents most commonly used for this purpose. Ticlopidine has been largely abandoned because of its adverse effects.

Aspirin is the most widely studied antiplatelet agent. Aspirin acetylates platelet cyclooxygenase, which irreversibly inhibits the formation in platelets of thromboxane A_2, a platelet aggregating and vasoconstricting prostaglandin. This effect is permanent and lasts for the usual 8-day life of the platelet. Paradoxically, aspirin also inhibits the formation in endothelial cells of prostacyclin, an antiaggregating and vasodilating prostaglandin. This effect is transient. As soon as aspirin is cleared from the blood, the nucleated endothelial cells again produce prostacyclin. Aspirin in low doses given once daily inhibits the production of thromboxane A_2 in platelets without substantially inhibiting prostacyclin formation. The FDA recommends 50 to 325 mg of aspirin daily for stroke prevention.

Ticlopidine and clopidogrel block the ADP receptor on platelets and thus prevent the cascade resulting in activation of the glycoprotein IIb/IIIa receptor that leads to fibrinogen binding to the platelet and consequent platelet aggregation. Ticlopidine is more effective than aspirin; however, it has the disadvantage of causing diarrhea, skin rash, a low incidence of neutropenia, and thrombotic thrombocytopenic purpura. Clopidogrel is not associated with these important side effects. However, the CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial, which led to FDA approval, found that it was only marginally more effective than aspirin in reducing risk of stroke. Studies of clopidogrel in combination with aspirin are in progress in both cerebrovascular and cardiovascular patients.

Dipyridamole is an antiplatelet agent that inhibits the uptake of adenosine by a variety of cells, including those of the vascular endothelium. The accumulated adenosine is an inhibitor of aggregation. At least in part through its effects on platelet and vessel wall phosphodiesterases, dipyridamole also potentiates the antiaggregatory effects of prostacyclin and nitric oxide produced by the endothelium and acts by inhibiting platelet phosphodiesterase, which is responsible for the breakdown of cyclic AMP. The resulting elevation in cyclic AMP inhibits aggregation of platelets. Dipyridamole has a controversial history in stroke prevention. The European Stroke Prevention Study-2 showed efficacy of both 50 mg daily of aspirin and extended-release dipyridamole in preventing stroke, and a significantly better risk reduction when the two agents were combined. A combination capsule of extended-release dipyridamole and aspirin is approved for prevention of stroke.

Many large clinical trials have demonstrated clearly that most antiplatelet agents reduce the risk of all important vascular atherothrombotic events (i.e., ischemic stroke, MI, and death due to all vascular causes) in patients at risk for these events. The overall *relative* reduction in risk of nonfatal stroke is about 25 to 30% and of all vascular events is about 25%. The *absolute* reduction varies considerably depending on the particular patient's risk. Individuals at very low risk for stroke seem to experience the same relative reduction, but their risk may be so low that the "benefit" is meaningless. On the other hand, individuals with a 10 to 15% risk of vascular events per year experience a reduction to about 7.5 to 11%.

Aspirin is inexpensive, can be given in low doses, and could be recommended for all adults to prevent both stroke and MI. However, it causes epigastric discomfort, gastric ulceration, and gastrointestinal hemorrhage, which may be asymptomatic or life-threatening. Consequently, not every 40- or 50-year-old should be advised to take aspirin regularly because the risk of atherothrombotic stroke is extremely low and is outweighed by the risk of adverse side effects. Conversely, every patient who has experienced an atherothrombotic stroke or TIA and has no contraindication should be taking an antiplatelet agent regularly because the average annual risk of another stroke is 8 to 10%; another few percent will experience a MI or vascular death. Clearly, the likelihood of benefit far outweighs the risks of treatment.

The choice of antiplatelet agent and dose must balance the risk of stroke, the expected benefit, and the risk and cost of treatment. However, there are no definitive data, and opinions vary. Many authorities believe low-dose (30 to 75 mg daily) and high-dose (650 to 1300 mg daily) aspirin are about equally effective. Some advocate very low doses to avoid adverse effects, and still others advocate very high doses to be sure the benefit is maximal. Most physicians in North America recommend 81 to 325 mg daily, while most Europeans recommend 50 to 100 mg. Similarly, the choice of aspirin, clopidogrel, or dipyridamole plus aspirin must balance the fact that the latter are more effective than aspirin but the cost is higher.

Anticoagulation Therapy and Noncardiogenic Stroke There are few data to support the use of long-term warfarin for preventing atherothrombotic stroke, either intracranially or extracranially. The WARSS study found no benefit of warfarin sodium (INR, 2 to 3) over aspirin, 325 mg, for secondary prevention of stroke but did find a slightly higher bleeding rate in the warfarin group. A prospective trial is ongoing to study warfarin versus aspirin in secondary stroke prevention for intracranial atherosclerosis.

Anticoagulation Therapy and Embolic Stroke Several trials have shown that anticoagulation (INR range, 2 to 3) in patients with chronic nonvalvular (nonrheumatic) atrial fibrillation prevents cerebral embolism and is safe. For primary prevention and for patients who have experienced stroke or TIA, anticoagulation with warfarin reduces the risk by about 67% which clearly outweighs the 1% risk per year of a major bleeding complication.

The decision to use anticoagulation for primary prevention is based primarily on risk factors (Table 349-4). The presence of any risk factor tips the balance in favor of anticoagulation.

Because of the high annual stroke risk in untreated rheumatic heart disease, primary prophylaxis against stroke has not been studied in a double-blind fashion. These patients generally receive long-term anticoagulation.

Anticoagulation also reduces the risk of embolism in acute MI. Most clinicians recommend a 3-month course of anticoagulation when there is anterior Q-wave infarction, substantial left ventricular dysfunction, congestive heart failure, mural thrombosis, or atrial fibrillation. Warfarin is recommended long-term if atrial fibrillation persists. Warfarin is currently being studied in patients with congestive heart failure.

Thromboembolism is one of the most serious complications of

prosthetic heart valve implantation. Anticoagulation has been proven effective for preventing strokes in this situation, while antiplatelet therapy alone has not. However, coupled with warfarin anticoagulation, aspirin adds substantial benefit. A greater degree of anticoagulation (INR of 3 to 4, depending on valve type) is recommended for some patients with prosthetic heart valves.

If the embolic source cannot be eliminated, anticoagulation should in most cases be continued indefinitely. Many neurologists recommend combining antiplatelet agents with anticoagulants for patients who "fail" one form of therapy (i.e., have another stroke or TIA). This empirical approach subjects the patient to an increased bleeding risk.

Other Causes of Stroke ■ *CAROTID DISEASE* Surgical or endovascular repair of carotid atherosclerosis is preferred over medical therapy for symptomatic carotid artery disease (see section above). Anticoagulation has not been directly compared with antiplatelet therapy for carotid disease.

DURAL SINUS THROMBOSIS Limited evidence exists to support short-term usage of anticoagulants, regardless of the presence of intracranial hemorrhage for venous infarction following sinus thrombosis.

STROKE SYNDROMES A careful history and neurologic examination can often localize the region of brain dysfunction; if this region corresponds to a particular arterial distribution, the possible causes responsible for the syndrome can be narrowed. This is of particular importance when the patient presents with a TIA and a normal examination. For example, if a patient develops language loss and a right homonymous hemianopia, a search for causes of left middle cerebral emboli should be performed. A finding of an isolated stenosis of the right internal carotid artery in that patient, for example, suggests an asymptomatic carotid stenosis, and the search for other causes of stroke should continue. The following sections describe the clinical findings of cerebral ischemia associated with cerebral vascular territories depicted in Figs. 349-3 through 349-11. Stroke syndromes are divided into: (1) large-vessel stroke within the anterior circulation, (2) large-vessel stroke within the posterior circulation, and (3) small-vessel disease of either vascular bed.

Stroke Within the Anterior Circulation The internal carotid artery and its branches comprise the anterior circulation of the brain. These vessels can be occluded by intrinsic disease of the vessel (e.g., atherosclerosis or dissection) or by embolic occlusion from a proximal source as discussed above. Occlusion of each major intracranial vessel has distinct clinical manifestations.

MIDDLE CEREBRAL ARTERY Occlusion of the proximal MCA or one of its major branches is most often due to an embolus (artery-to-artery, cardiac, or of unknown source) rather than intracranial atherothrombosis. Atherosclerosis of the proximal MCA may cause distal emboli to the middle cerebral territory or, less commonly, may produce low-flow TIAs. Collateral formation via leptomeningeal vessels often prevents MCA stenosis from becoming symptomatic.

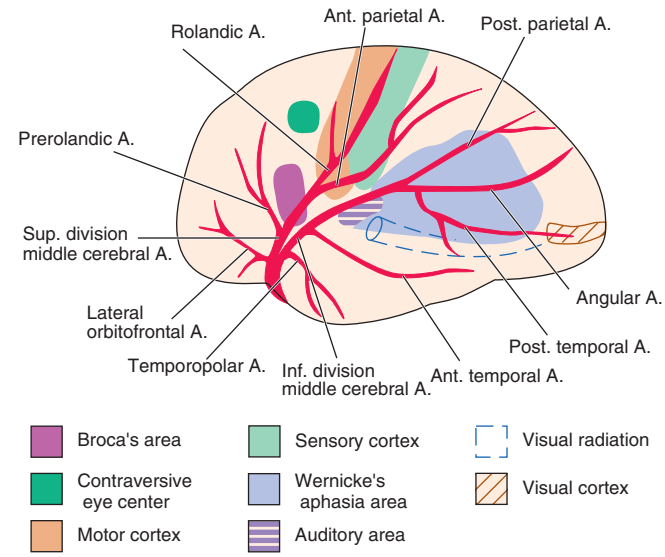

FIGURE 349-5 Diagram of a cerebral hemisphere, lateral aspect, showing the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization. Note the bifurcation of the middle cerebral artery into a superior and inferior division. *(Courtesy of CM Fisher, MD.)*

Signs and symptoms: *Structures involved*

Paralysis of the contralateral face, arm, and leg; sensory impairment over the same area (pinprick, cotton touch, vibration, position, two-point discrimination, stereognosis, tactile localization, barognosis, cutaneographia): *Somatic motor area for face and arm and the fibers descending from the leg area to enter the corona radiata and corresponding somatic sensory system*

Motor aphasia: *Motor speech area of the dominant hemisphere*

Central aphasia, word deafness, anomia, jargon speech, sensory agraphia, acalculia, alexia, finger agnosia, right-left confusion (the last four comprise the Gerstmann syndrome): *Central, suprasylvian speech area and parietooccipital cortex of the dominant hemisphere*

Conduction aphasia: *Central speech area (parietal operculum)*

Apractognosia of the nondominant hemisphere, anosognosia, hemiasomatognosia, unilateral neglect, agnosia for the left half of external space, dressing "apraxia," constructional "apraxia," distortion of visual coordinates, inaccurate localization in the half field, impaired ability to judge distance, upside-down reading, visual illusions (e.g., it may appear that another person walks through a table): *Nondominant parietal lobe (area corresponding to speech area in dominant hemisphere); loss of topographic memory is usually due to a nondominant lesion, occasionally to a dominant one*

Homonymous hemianopia (often homonymous inferior quadrantanopia): *Optic radiation deep to second temporal convolution*

Paralysis of conjugate gaze to the opposite side: *Frontal contraversive field or projecting fibers*

The cortical branches of the MCA supply the lateral surface of the hemisphere except for (1) the frontal pole and a strip along the superomedial border of the frontal and parietal lobes supplied by the ACA, and (2) the lower temporal and occipital pole convolutions supplied by the PCA (Figs. 349-4, 349-6, and 349-7).

The proximal MCA (M1 segment) gives rise to penetrating branches (termed *lenticulostriate arteries*) that supply the putamen, outer globus pallidus, posterior limb of the internal capsule, the adjacent corona radiata, and most of the caudate nucleus. In the sylvian fissure, the MCA in most patients divides into *superior* and *inferior* divisions (M2 branches). Branches of the inferior division supply the inferior parietal and temporal cortex, and those from the superior division supply the frontal and superior parietal cortex (Fig. 349-5).

If the entire MCA is occluded at its origin (blocking both its penetrating and cortical branches) and the distal collaterals are limited, the clinical findings are contralateral hemiplegia, hemianesthesia, homonymous hemianopia, and a day or two of gaze preference to the ipsilateral side. Dysarthria is common because of facial weakness.

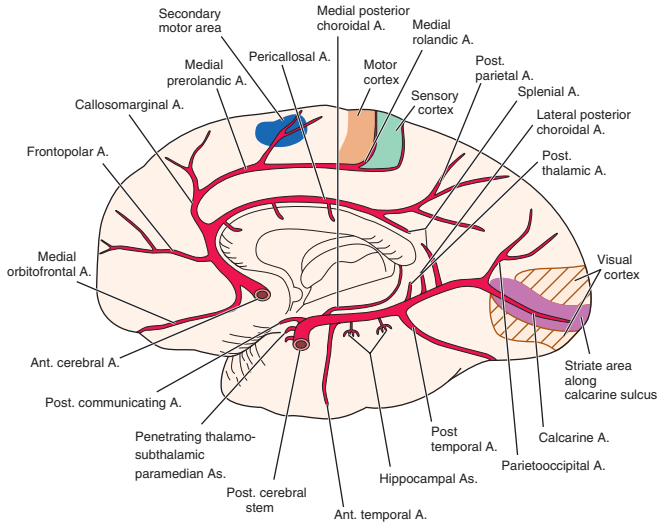

FIGURE 349-6 Diagram of a cerebral hemisphere, medial aspect, showing the branches and distribution of the anterior cerebral artery and the principal regions of cerebral localization. (*Courtesy of CM Fisher, MD.*)

Signs and symptoms: ***Structures involved***

Paralysis of opposite foot and leg: *Motor leg area*

A lesser degree of paresis of opposite arm: *Arm area of cortex or fibers descending to corona radiata*

Cortical sensory loss over toes, foot, and leg: *Sensory area for foot and leg*

Urinary incontinence: *Sensorimotor area in paracentral lobule*

Contralateral grasp reflex, sucking reflex, gegenhalten (paratonic rigidity): *Medial surface of the posterior frontal lobe (?) supplemental motor area*

Abulia (akinetic mutism), slowness, delay, intermittent interruption, lack of spontaneity, whispering, reflex distraction to sights and sounds: *Uncertain localization—probably cingulate gyrus and medial inferior portion of frontal, parietal, and temporal lobes*

Impairment of gait and stance (gait apraxia): *Frontal cortex near leg motor area*

Dyspraxia of left limbs, tactile aphasia in left limbs: *Corpus callosum*

When the dominant hemisphere is involved, global aphasia is present also, and when the nondominant hemisphere is affected, anosognosia, constructional apraxia, and neglect are found (Chap. 23).

Complete MCA syndromes occur most often when an embolus occludes the stem of the artery. Cortical collateral blood flow and differing arterial configurations are probably responsible for the development of many partial syndromes. Partial syndromes may also be due to emboli that enter the proximal MCA without complete occlusion, occlude distal MCA branches, or fragment and move distally.

Partial syndromes due to embolic occlusion of a single branch include hand, or arm and hand, weakness alone (brachial syndrome) or facial weakness with nonfluent (Broca) aphasia (Chap. 23), with or without arm weakness (frontal opercular syndrome). A combination of sensory disturbance, motor weakness, and nonfluent aphasia suggests that an embolus has occluded the proximal superior division and infarcted large portions of the frontal and parietal cortices (Fig. 349-5). If a fluent (Wernicke's) aphasia occurs without weakness, the inferior division of the MCA supplying the posterior part (temporal cortex) of the dominant hemisphere is probably involved. Jargon speech and an inability to comprehend written and spoken language are prominent features, often accompanied by a contralateral, homonymous superior quadrantanopia. Hemineglect or spatial agnosia without weakness indicates that the inferior division of the MCA in the nondominant hemisphere is involved.

Occlusion of a lenticulostriate vessel produces small-vessel (lacunar) stroke within the internal capsule. This produces pure motor stroke or sensory-motor stroke contralateral to the lesion. Ischemia within the genu of the internal capsule causes primarily facial weakness followed by arm then leg weakness as the ischemia moves posterior within the capsule. Alternatively, the contralateral hand may become ataxic and dysarthria will be prominent (clumsy hand, dysarthria lacunar syndrome). Lacunar infarction affecting the globus pallidus and putamen often has few clinical signs, but parkinsonism and hemiballismus have been reported.

ANTERIOR CEREBRAL ARTERY The ACA is divided into two segments: the precommunal (A1) circle of Willis, or stem, which connects the internal carotid artery to the anterior communicating artery, and the postcommunal (A2) segment distal to the anterior communicating artery (Figs. 349-3 and 349-7). The A1 segment gives rise to several deep penetrating branches that supply the anterior limb of the internal capsule, the anterior perforate substance, amygdala, anterior hypothalamus, and the inferior part of the head of the caudate nucleus (Fig. 349-4).

Occlusion of the proximal ACA is usually well tolerated because of collateral flow through the anterior communicating artery and collaterals through the MCA and PCA. Occlusion of a single A2 segment results in the contralateral symptoms noted in Fig. 349-6. If both A2 segments arise from a single anterior cerebral stem (contralateral A1

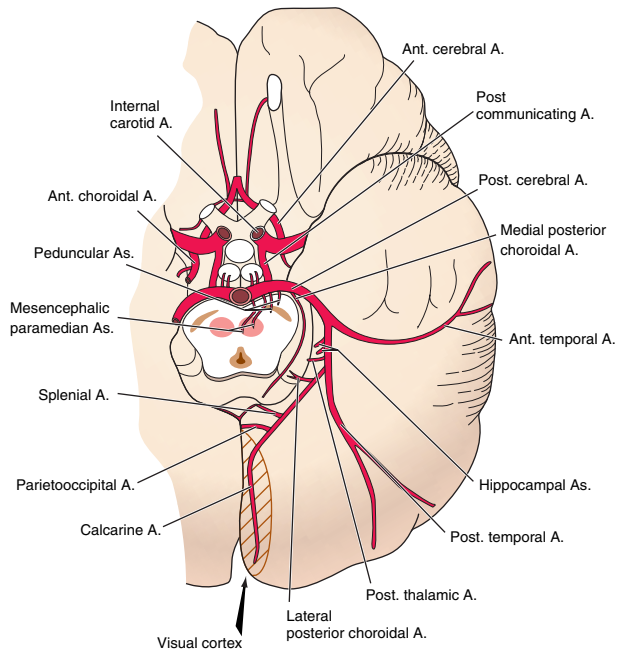

FIGURE 349-7 Inferior aspect of the brain with the branches and distribution of the posterior cerebral artery and the principal anatomic structures shown. (*Courtesy of CM Fisher, MD.*)

Signs and symptoms: ***Structures involved***

Peripheral territory (see also Fig. 349-11). Homonymous hemianopia (often upper quadrantic): *Calcarine cortex or optic radiation nearby*. Bilateral homonymous hemianopia, cortical blindness, awareness or denial of blindness; tactile naming, achromatopia (color blindness), failure to see to-and-fro movements, inability to perceive objects not centrally located, apraxia of ocular movements, inability to count or enumerate objects, tendency to run into things that the patient sees and tries to avoid: *Bilateral occipital lobe with possibly the parietal lobe involved*. Verbal dyslexia without agraphia, color anomia: *Dominant calcarine lesion and posterior part of corpus callosum*. Memory defect: *Hippocampal lesion bilaterally or on the dominant side only*. Topographic disorientation and prosopagnosia: *Usually with lesions of nondominant, calcarine, and lingual gyrus*. Simultagnosia, hemivisual neglect: *Dominant visual cortex, contralateral hemisphere*. Unformed visual hallucinations, peduncular hallucinosis, metamorphopsia, teleopsia, illusory visual spread, palinopsia, distortion of outlines, central photophobia: *Calcarine cortex*. Complex hallucinations: *Usually nondominant hemisphere*.

Central territory. Thalamic syndrome: sensory loss (all modalities), spontaneous pain and dysesthesias, choreoathetosis, intention tremor, spasms of hand, mild hemiparesis: *Posteroventral nucleus of thalamus; involvement of the adjacent subthalamus body or its afferent tracts*. Thalamoperforate syndrome: crossed cerebellar ataxia with ipsilateral third nerve palsy (Claude's syndrome): *Dentatothalamic tract and issuing third nerve*. Weber's syndrome: third nerve palsy and contralateral hemiplegia: *Third nerve and cerebral peduncle*. Contralateral hemiplegia: *Cerebral peduncle*. Paralysis or paresis of vertical eye movement, skew deviation, sluggish pupillary responses to light, slight miosis and ptosis (retraction nystagmus and "tucking" of the eyelids may be associated): *Supranuclear fibers to third nerve, interstitial nucleus of Cajal, nucleus of Darkschewitsch, and posterior commissure*. Contralateral rhythmic, ataxic action tremor; rhythmic postural or "holding" tremor (rubral tremor): *Dentatothalamic tract (?)*.

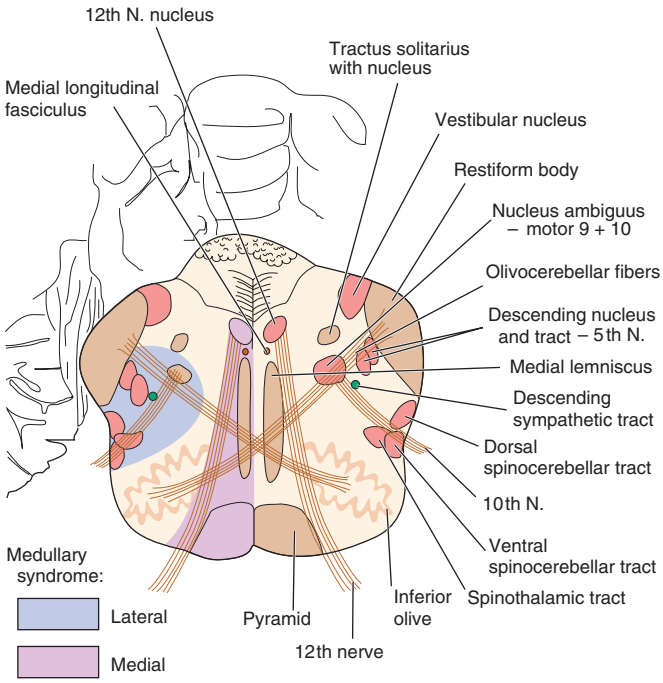

FIGURE 349-8 *(Courtesy of CM Fisher, MD.)*
Signs and symptoms: *Structures involved*

1. Medial medullary syndrome (occlusion of vertebral artery or of branch of vertebral or lower basilar artery)
   On side of lesion
   Paralysis with atrophy of half the tongue: *Ipsilateral twelfth nerve*
   On side opposite lesion
   Paralysis of arm and leg, sparing face; impaired tactile and proprioceptive sense over half the body: *Contralateral pyramidal tract and medial lemniscus*
2. Lateral medullary syndrome (occlusion of any of five vessels may be responsible—vertebral, posterior inferior cerebellar, superior, middle, or inferior lateral medullary arteries)
   On side of lesion
   Pain, numbness, impaired sensation over half the face: *Descending tract and nucleus fifth nerve*
   Ataxia of limbs, falling to side of lesion: *Uncertain—restiform body, cerebellar hemisphere, cerebellar fibers, spinocerebellar tract (?)*
   Nystagmus, diplopia, oscillopsia, vertigo, nausea, vomiting: *Vestibular nucleus*
   Horner's syndrome (miosis, ptosis, decreased sweating): *Descending sympathetic tract*
   Dysphagia, hoarseness, paralysis of palate, paralysis of vocal cord, diminished gag reflex: *Issuing fibers ninth and tenth nerves*
   Loss of taste: *Nucleus and tractus solitarius*
   Numbness of ipsilateral arm, trunk, or leg: *Cuneate and gracile nuclei*
   On side opposite lesion
   Impaired pain and thermal sense over half the body, sometimes face: *Spinothalamic tract*
3. Total unilateral medullary syndrome (occlusion of vertebral artery): Combination of medial and lateral syndromes
4. Lateral pontomedullary syndrome (occlusion of vertebral artery): Combination of lateral medullary and lateral inferior pontine syndrome
5. Basilar artery syndrome (the syndrome of the lone vertebral artery is equivalent): A combination of the various brainstem syndromes plus those arising in the posterior cerebral artery distribution.
   Bilateral long tract signs (sensory and motor; cerebellar and peripheral cranial nerve abnormalities): *Bilateral long tract; cerebellar and peripheral cranial nerves*
   Paralysis or weakness of all extremities, plus all bulbar musculature: *Corticobulbar and corticospinal tracts bilaterally*

segment atresia), the occlusion may affect both hemispheres. Profound abulia (a delay in verbal and motor response) and bilateral pyramidal signs with paraparesis and urinary incontinence result.

ANTERIOR CHOROIDAL ARTERY This artery arises from the internal carotid artery and supplies the posterior limb of the internal capsule and the white matter posterolateral to it, through which pass some of the geniculocalcarine fibers (Figs. 349-4 and 349-7). The complete syndrome of anterior choroidal artery occlusion consists of contralateral hemiplegia, hemianesthesia (hypesthesia), and homonymous hemianopia. However, because this territory is also supplied by penetrating vessels of the proximal MCA and the posterior communicating and posterior choroidal arteries, minimal deficits may occur, and patients frequently recover substantially. Anterior choroidal strokes are usually the result of in situ thrombosis of the vessel, and the vessel is particularly vulnerable to iatrogenic occlusion during surgical clipping of aneurysms arising from the internal carotid artery.

INTERNAL CAROTID ARTERY The clinical picture of internal carotid occlusion varies depending on whether the cause of ischemia is propagated thrombus, embolism, or low flow. The cortex supplied by the MCA territory is affected most often. With a competent circle of Willis, occlusion may go unnoticed. If the thrombus propagates up the internal carotid artery into the MCA or embolizes it, symptoms are identical to proximal MCA occlusion (see above). Sometimes there is massive infarction of the entire deep white matter and cortical surface. When the origins of both the ACA and MCA are occluded at the top of the carotid artery, abulia or stupor occurs with hemiplegia, hemianes-

Signs and symptoms: *Structures involved*

1. Medial inferior pontine syndrome (occlusion of paramedian branch of basilar artery)
   On side of lesion
   Paralysis of conjugate gaze to side of lesion (preservation of convergence): *Center for conjugate lateral gaze*
   Nystagmus: *Vestibular nucleus*
   Ataxia of limbs and gait: *Middle cerebellar peduncle (?)*
   Diplopia on lateral gaze: *Abducens nerve*
   On side opposite lesion
   Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract in lower pons*
   Impaired tactile and proprioceptive sense over half of the body: *Medial lemniscus*
2. Lateral inferior pontine syndrome (occlusion of anterior inferior cerebellar artery)
   On side of lesion
   Horizontal and vertical nystagmus, vertigo, nausea, vomiting, oscillopia: *Vestibular nerve or nucleus*
   Facial paralysis: *Seventh nerve*
   Paralysis of conjugate gaze to side of lesion: *Center for conjugate lateral gaze*
   Deafness, tinnitus: *Auditory nerve or cochlear nucleus*
   Ataxia: *Middle cerebellar peduncle and cerebellar hemisphere*
   Impaired sensation over face: *Descending tract and nucleus fifth nerve*
   On side opposite lesion
   Impaired pain and thermal sense over half the body (may include face): *Spinothalamic tract*

Signs and symptoms: ***Structures involved***

1. Medial midpontine syndrome (paramedian branch of midbasilar artery)
   On side of lesion
   Ataxia of limbs and gait (more prominent in bilateral involvement): *Pontine nuclei*
   On side opposite lesion
   Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract*
   Variable impaired touch and proprioception when lesion extends posteriorly: *Medial lemniscus*
2. Lateral midpontine syndrome (short circumferential artery)
   On side of lesion
   Ataxia of limbs: *Middle cerebellar peduncle*
   Paralysis of muscles of mastication: *Motor fibers or nucleus of fifth nerve*
   Impaired sensation over side of face: *Sensory fibers or nucleus of fifth nerve*
   On side opposite lesion
   Impaired pain and thermal sense on limbs and trunk: *Spinothalamic tract*

thesia, and aphasia or anosognosia. When the PCA arises from the internal carotid artery (a configuration called a *fetal posterior cerebral artery*), it may also become occluded and give rise to symptoms referable to its peripheral territory (Figs. 349-6 and 349-7).

In addition to supplying the ipsilateral brain, the internal carotid artery perfuses the optic nerve and retina via the ophthalmic artery. In about 25% of symptomatic internal carotid disease, recurrent transient monocular blindness (amaurosis fugax) warns of the lesion. Patients typically describe a horizontal shade that sweeps down or up across the field of vision. They may also complain that their vision was blurred in that eye or that the upper or lower half of vision disappeared. In most cases, these symptoms last only a few minutes. Rarely, ischemia or infarction of the ophthalmic artery or central retinal arteries occurs at the time of cerebral TIA or infarction.

A high-pitched prolonged carotid bruit fading into diastole is often associated with tightly stenotic lesions. As the stenosis grows tighter and flow distal to the stenosis becomes reduced, the bruit becomes fainter and may disappear when occlusion is imminent.

COMMON CAROTID ARTERY All symptoms and signs of internal carotid occlusion may also be present with occlusion of the common carotid artery. Bilateral common carotid artery occlusions at their origin may occur in Takayasu's arteritis (Chap. 306).

Stroke Within the Posterior Circulation The posterior circulation is composed of the paired vertebral arteries, the basilar artery, and the paired posterior cerebral arteries. The vertebral arteries join to form the basilar artery at the pontomedullary junction. The basilar artery divides into two posterior cerebral arteries in the interpeduncular fossa (Fig. 349-3). These major arteries give rise to long and short circumferential branches and to smaller deep penetrating branches that supply the cerebellum, medulla, pons, midbrain, subthalamus, thalamus, hippocampus, and medial temporal and occipital lobes. Occlusion of each vessel produces its own distinctive syndrome.

POSTERIOR CEREBRAL ARTERY In 75% of cases, both PCAs arise from the bifurcation of the basilar artery; in 20%, one has its origin from the ipsilateral internal carotid artery via the posterior communicating artery; in 5%, both originate from the respective ipsilateral internal carotid arteries (Fig. 349-3). The precommunal, or P1, segment of the true posterior cerebral artery is atretic in such cases.

PCA syndromes usually result from atheroma formation or emboli that lodge at the top of the basilar artery; posterior circulation disease may also be caused by dissection of either vertebral artery and fibromuscular dysplasia.

Two clinical syndromes are commonly observed with occlusion of the PCA: (1) *P1 syndrome*: midbrain, subthalamic, and thalamic signs, which are due to disease of the proximal P1 segment of the PCA or its penetrating branches (thalamogeniculate, Percheron, and posterior choroidal arteries); and (2) *P2 syndrome*: cortical temporal and occipital lobe signs, due to occlusion of the P2 segment distal to the junction of the PCA with the posterior communicating artery.

P1 Syndromes Infarction usually occurs in the ipsilateral subthalamus and medial thalamus and in the ipsilateral cerebral peduncle and midbrain (Fig. 349-7). A third nerve palsy with contralateral ataxia (Claude's syndrome) or with contralateral hemiplegia (Weber's syndrome) may result. The ataxia indicates involvement of the red nucleus or dentatorubrothalamic tract; the hemiplegia is localized to the cerebral peduncle. If the subthalamic nucleus is involved, contralateral

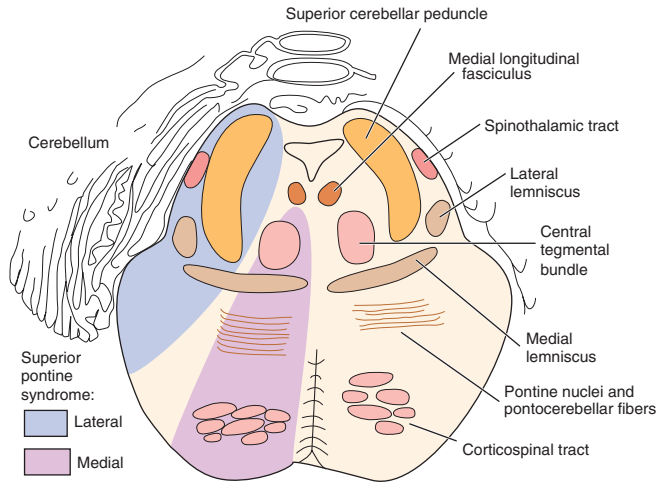

FIGURE 349-11 *(Courtesy of CM Fisher, MD.)*
Signs and symptoms: *Structures involved*

1. Medial superior pontine syndrome (paramedian branches of upper basilar artery)
   On side of lesion
   Cerebellar ataxia (probably): *Superior and/or middle cerebellar peduncle*
   Internuclear ophthalmoplegia: *Medial longitudinal fasciculus*
   Myoclonic syndrome, palate, pharynx, vocal cords, respiratory apparatus, face, oculomotor apparatus, etc.: *Localization uncertain—central tegmental bundle (?), dentate projection (?), inferior olivary nucleus (?)*
   On side opposite lesion
   Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract*
   Rarely touch, vibration, and position are affected: *Medial lemniscus*
2. Lateral superior pontine syndrome (syndrome of superior cerebellar artery)
   On side of lesion
   Ataxia of limbs and gait, falling to side of lesion: *Middle and superior cerebellar peduncles, superior surface of cerebellum, dentate nucleus*
   Dizziness, nausea, vomiting; horizontal nystagmus: *Vestibular nucleus*
   Paresis of conjugate gaze (ipsilateral): *Pontine contralateral gaze*
   Skew deviation: *Uncertain*
   Miosis, ptosis, decreased sweating over face (Horner's syndrome): *Descending sympathetic fibers*
   Tremor: *Dentate nucleus (?), superior cerebellar peduncle (?)*
   On side opposite lesion
   Impaired pain and thermal sense on face, limbs, and trunk: *Spinothalamic tract*
   Impaired touch, vibration, and position sense, more in leg than arm (there is a tendency to incongruity of pain and touch deficits): *Medial lemniscus (lateral portion)*

hemiballismus may occur. Occlusion of the artery of Percheron produces paresis of upward gaze and drowsiness, and often abulia. Extensive infarction in the midbrain and subthalamus occurring with bilateral proximal PCA occlusion presents as coma, unreactive pupils, bilateral pyramidal signs, and decerebrate rigidity.

Occlusion of the penetrating branches of thalamic and thalamogeniculate arteries produces less extensive thalamic and thalamocapsular lacunar syndromes. The *thalamic Déjerine-Roussy syndrome* consists of contralateral hemisensory loss followed later by an agonizing, searing or burning pain in the affected areas. It is persistent and responds poorly to analgesics. Anticonvulsants (carbamazepine or gabapentin) or tricyclic antidepressants may be beneficial.

P2 Syndromes (See also Fig. 349-7) Occlusion of the distal PCA causes infarction of the medial temporal and occipital lobes. Contralateral homonymous hemianopia with macula sparing is the usual manifestation. Occasionally, only the upper quadrant of visual field is involved. If the visual association areas are spared and only the calcarine cortex is involved, the patient may be aware of visual defects. Medial temporal lobe and hippocampal involvement may cause an acute disturbance in memory, particularly if it occurs in the dominant hemisphere. The defect usually clears because memory has bilateral representation. If the dominant hemisphere is affected and the infarct extends to involve the splenium of the corpus callosum, the patient may demonstrate alexia without agraphia. Visual agnosia for faces, objects, mathematical symbols, and colors and anomia with paraphasic errors (amnestic aphasia) may also occur in this setting, even without callosal involvement. Occlusion of the posterior cerebral artery can produce *peduncular hallucinosis* (visual hallucinations of brightly colored scenes and objects).

Bilateral infarction in the distal PCAs produces cortical blindness (blindness with preserved pupillary light reaction). The patient is often unaware of the blindness or may even deny it (*Anton's syndrome*). Tiny islands of vision may persist, and the patient may report that vision fluctuates as images are captured in the preserved portions. Rarely, only peripheral vision is lost and central vision is spared, resulting in "gun-barrel" vision. Bilateral visual association area lesions may result in *Balint's syndrome*, a disorder of the orderly visual scanning of the environment (Chap. 23), usually resulting from infarctions secondary to low flow in the "watershed" between the distal posterior and middle cerebral artery territories, as occurs after cardiac arrest. Patients may experience persistence of a visual image for several minutes despite gazing at another scene (*palinopia*). Embolic occlusion of the top of the basilar artery can produce any or all of the central or peripheral territory symptoms. The hallmark is the sudden onset of bilateral signs, including ptosis, pupillary asymmetry or lack of reaction to light, and somnolence.

VERTEBRAL AND POSTERIOR INFERIOR CEREBELLAR ARTERIES The vertebral artery, which arises from the innominate artery on the right and the subclavian artery on the left, consists of four segments. The first (V1) extends from its origin to its entrance into the sixth or fifth transverse vertebral foramen. The second segment (V2) traverses the vertebral foramina from C6 to C2. The third (V3) passes through the transverse foramen and circles around the arch of the atlas to pierce the dura at the foramen magnum. The fourth (V4) segment courses upward to join the other vertebral artery to form the basilar artery; only the fourth segment gives rise to branches that supply the brainstem and cerebellum. The posterior inferior cerebellar artery (PICA) in its proximal segment supplies the lateral medulla and, in its distal branches, the inferior surface of the cerebellum.

Atherothrombotic lesions have a predilection for V1 and V4 segments of the vertebral artery. The first segment may become diseased at the origin of the vessel and may produce posterior circulation emboli; collateral flow from the contralateral vertebral artery or the ascending cervical, thyrocervical, or occipital arteries is usually sufficient to prevent low-flow TIAs or stroke. When one vertebral artery is atretic and an atherothrombotic lesion threatens the origin of the other, the collateral circulation, which may also include retrograde flow down the basilar artery, is often insufficient (Figs. 349-3 and 349-7). In this setting, low-flow TIAs may occur, consisting of syncope, vertigo, and alternating hemiplegia; this state also sets the stage for thrombosis. Disease of the distal fourth segment of the vertebral artery can promote thrombus formation manifest as embolism or with propagation as basilar artery thrombosis. Stenosis proximal to the origin of the posterior inferior cerebellar artery can threaten the lateral medulla and posterior inferior surface of the cerebellum.

If the subclavian artery is occluded proximal to the origin of the vertebral artery, there is a reversal in the direction of blood flow in the ipsilateral vertebral artery. Exercise of the ipsilateral arm may increase demand on vertebral flow, producing posterior circulation TIAs, or "subclavian steal."

Although atheromatous disease rarely narrows the second and third segments of the vertebral artery, this region is subject to dissection, fibromuscular dysplasia, and, rarely, encroachment by osteophytic spurs within the vertebral foramina.

Embolic occlusion or thrombosis of a V4 segment causes ischemia of the lateral medulla. The constellation of vertigo, numbness of the ipsilateral face and contralateral limbs, diplopia, hoarseness, dysarthria, dysphagia, and ipsilateral Horner's syndrome is called the lateral medullary (or Wallenberg's) syndrome (Fig. 349-8). Most cases result from ipsilateral vertebral artery occlusion; in the remainder, PICA occlusion is responsible. Occlusion of the medullary penetrating branches of the vertebral artery or PICA results in partial syndromes. *Hemiparesis is not a feature of vertebral artery occlusion.*

Rarely, a *medial medullary syndrome* occurs with infarction of the pyramid and contralateral hemiparesis of the arm and leg, sparing the face. If the medial lemniscus and emerging hypoglossal nerve fibers are involved, contralateral loss of joint position sense and ipsilateral tongue weakness occur.

Cerebellar infarction with edema can lead to *sudden respiratory arrest* due to raised ICP in the posterior fossa. Drowsiness, Babinski signs, dysarthria, and bifacial weakness may be absent, or present only briefly, before respiratory arrest ensues. Gait unsteadiness, headache, dizziness, nausea, and vomiting may be the only early symptoms and signs and should arouse suspicion of this impending complication, which may require neurosurgical decompression, often with an excellent outcome. Separating these symptoms from those of viral labyrinthitis can be a challenge, but headache, neck stiffness, and unilateral dysmetria favor stroke.

BASILAR ARTERY Branches of the basilar artery supply the base of the pons and superior cerebellum and fall into three groups: (1) paramedian, 7 to 10 in number, which supply a wedge of pons on either side of the midline; (2) short circumferential, 5 to 7 in number, which supply the lateral two-thirds of the pons and middle and superior cerebellar peduncles; and (3) bilateral long circumferential (superior cerebellar and anterior inferior cerebellar arteries), which course around the pons to supply the cerebellar hemispheres.

Atheromatous lesions can occur anywhere along the basilar trunk but are most frequent in the proximal basilar and distal vertebral segments. Typically, lesions occlude either the proximal basilar and one or both vertebral arteries. The clinical picture varies depending on the availability of retrograde collateral flow from the posterior communicating arteries. Rarely, dissection of a vertebral artery may involve the basilar artery and, depending on the location of true and false lumen, may produce multiple penetrating artery strokes.

Although atherothrombosis occasionally occludes the distal portion of the basilar artery, emboli from the heart or proximal vertebral or basilar segments are more commonly responsible for "top of the basilar" syndromes.

Because the brainstem contains many structures in close apposition, a diversity of clinical syndromes may emerge with ischemia, reflecting involvement of the corticospinal and corticobulbar tracts, ascending sensory tracts, and cranial nerve nuclei (Figs. 349-9, 349-10, and 349-11).

The symptoms of transient ischemia or infarction in the territory of the basilar artery often do not indicate whether the basilar artery itself or one of its branches is diseased, yet this distinction has important implications for therapy. *The picture of complete basilar occlusion, however, is easy to recognize as a constellation of bilateral long tract signs (sensory and motor) with signs of cranial nerve and cerebellar dysfunction*. A "locked-in" state of preserved consciousness with quadriplegia and cranial nerve signs suggests complete pontine and lower midbrain infarction. The therapeutic goal is to identify *impending* basilar occlusion before devastating infarction occurs. A series of TIAs and a slowly progressive, fluctuating stroke are extremely significant as they often herald an atherothrombotic occlusion of the distal vertebral or proximal basilar artery.

TIAs in the proximal basilar distribution may produce dizziness (often described by patients as "swimming," "swaying," "moving," "unsteadiness" or "light-headedness"). Other symptoms that warn of basilar thrombosis include diplopia, dysarthria, facial or circumoral numbness, and hemisensory symptoms. In general, symptoms of basilar branch TIAs affect one side of the brainstem, whereas symptoms of basilar artery TIAs usually affect both sides, though a "herald" hemiparesis has been emphasized as an initial symptom of basilar occlusion. Most often TIAs, whether due to impending occlusion of the basilar artery or a basilar branch, are short-lived (5 to 30 min) and repetitive, occurring several times a day. The pattern suggests intermittent reduction of flow. Many neurologists treat with heparin to prevent clot propagation.

Atherothrombotic occlusion of the basilar artery with infarction usually causes *bilateral* brainstem signs. A gaze paresis or internuclear ophthalmoplegia associated with ipsilateral hemiparesis may be the only manifestation of bilateral brainstem ischemia. More often, unequivocal signs of bilateral pontine disease are present. Complete basilar thrombosis carries a high mortality.

Occlusion of a branch of the basilar artery usually causes *unilateral* symptoms and signs involving motor, sensory, and cranial nerves. As long as symptoms remain unilateral, concern over pending basilar occlusion should be reduced.

Occlusion of the superior cerebellar artery results in severe ipsilateral cerebellar ataxia, nausea and vomiting, dysarthria, and contralateral loss of pain and temperature sensation over the extremities, body, and face (spino- and trigeminothalamic tract). Partial deafness, ataxic tremor of the ipsilateral upper extremity, Horner's syndrome, and palatal myoclonus may occur rarely. Partial syndromes occur frequently (Fig. 349-11). With large strokes, swelling and mass effects may compress the midbrain or produce hydrocephalus; these symptoms may evolve rapidly. Neurosurgical intervention may be lifesaving in such cases.

Occlusion of the anterior inferior cerebellar artery produces variable degrees of infarction because the size of this artery and the territory it supplies vary inversely with those of the PICA. The principal symptoms include: (1) ipsilateral deafness, facial weakness, vertigo, nausea and vomiting, nystagmus, tinnitus, cerebellar ataxia, Horner's syndrome, and paresis of conjugate lateral gaze; and (2) contralateral loss of pain and temperature sensation. An occlusion close to the origin of the artery may cause corticospinal tract signs (Fig. 349-9).

Occlusion of one of the short circumferential branches of the basilar artery affects the lateral two-thirds of the pons and middle or superior cerebellar peduncle, whereas occlusion of one of the paramedian branches affects a wedge-shaped area on either side of the medial pons (Figs. 349-9 through 349-11).

IMAGING STUDIES (See also Chap. 347) ■ **Computed Tomographic Scans** CT radiographic images identify or exclude hemorrhage as the cause of stroke, and they identify extraparenchymal hemorrhages, neoplasms, abscesses, and other conditions masquerading as stroke. Scans obtained in the first several hours after an infarction generally show no abnormality, and the infarct may not be seen reliably for 24 to 48 h. CT may fail to show small ischemic strokes in the posterior fossa because of bone artifact; small infarcts on the cortical surface may also be missed.

Contrast-enhanced CT scans add specificity by showing contrast enhancement of subacute infarcts and allow visualization of venous structures. Coupled with newer generation scanners, CT angiography (CTA) can be performed with administration of intravenous iodinated contrast allowing visualization of the cervical and intracranial arteries. Carotid disease and intracranial vascular occlusions are readily identified with this method (Fig. 349-12). After an intravenous bolus of contrast, deficits in brain perfusion produced by vascular occlusion can also be demonstrated (Fig. 349-12 *C*). CT imaging is also sensitive for detecting subarachnoid hemorrhage, and CTA can readily identify intracranial aneurysms (see below). Because of its speed and wide availability, noncontrast head CT is the imaging modality of choice in patients with acute stroke (Fig. 349-1), and CTA and CT perfusion imaging may also be useful and convenient adjuncts.

Magnetic Resonance Imaging (MRI) MRI reliably documents the extent and location of infarction in all areas of the brain, including the posterior fossa and cortical surface. It also identifies intracranial hemorrhage and other abnormalities but is less sensitive than CT for detecting acute blood. MRI scanners with magnets of higher field strength produce more reliable and precise images. Diffusion-weighted imaging is more sensitive for early brain infarction than standard MR sequences (Fig. 349-13), as is FLAIR (fluid-attenuated inversion recovery) imaging (Chap. 347). Using intravenous administration of gadolinium contrast, MR perfusion studies can be performed. Brain regions showing poor perfusion but no abnormality on diffusion are considered equivalent to the ischemic penumbra (see "Pathophysiol-

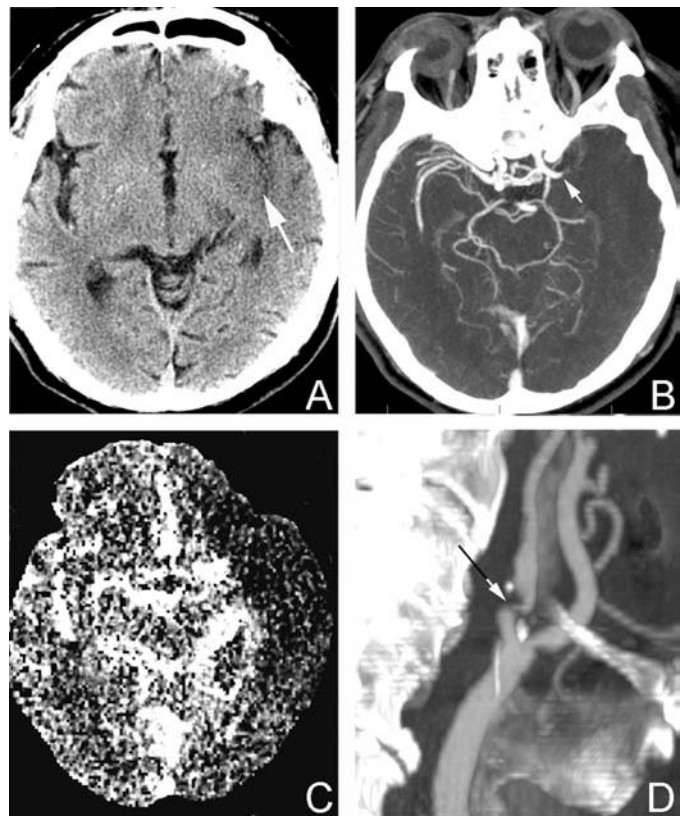

FIGURE 349-12 *A*. Computed tomography (CT) scan of the brain of a patient with a left middle cerebral artery (MCA) stroke of 3 h duration. As an earliest indicator of infarction, the "insular ribbon sign" is caused by edema (darker signal) within the left insular cortex and basal ganglia (*arrow*). *B*. Embolic occlusion of the MCA imaged with CT angiography during the acute stroke (*arrow*). *C*. Cerebral blood flow measured with CT perfusion; blood flow is reduced over a wider region of brain than appeared edematous in *A*. *D*. CT angiogram of a carotid artery showing high-grade stenosis (*arrow*) from atheroma in another patient.

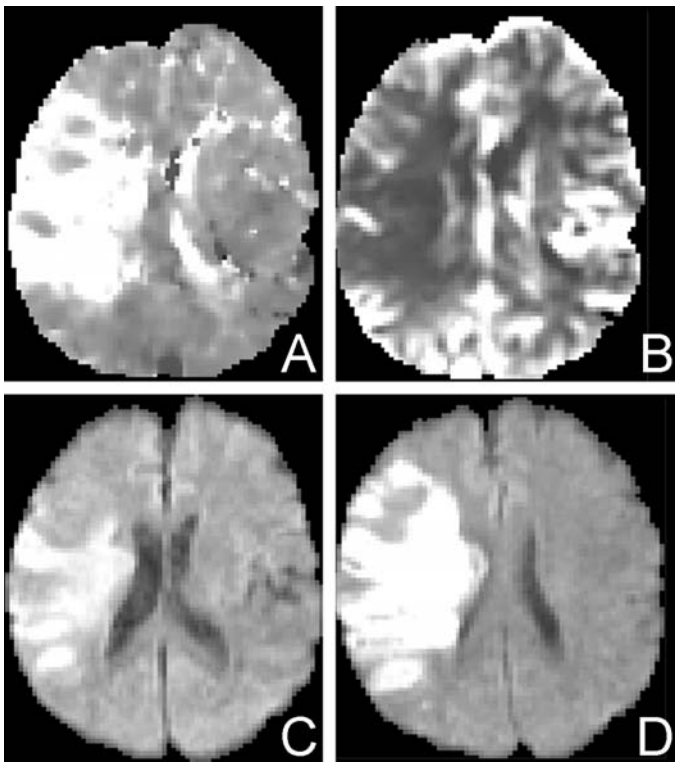

FIGURE 349-13 Magnetic resonance imaging of acute stroke. *A*. Perfusion defect within this right hemisphere (bright signal) imaged after administration of an intravenous bolus of gadolinium contrast. *B*. Cerebral blood flow measured at the same time as in *A*; darker signal reflects decreased blood flow. C. Diffusion-weighted image obtained 5 h after onset of a right middle cerebral artery stroke; bright signal indicates regions of restricted diffusion that will progress to infarction. The discrepancy between the region of poor perfusion shown in *A* and *B* and the diffusion deficit, is called *diffusion-perfusion mismatch* and is a measure of the ischemic penumbra. Without specific therapy the region of infarction expands to match the perfusion deficit, as shown in the diffusion weighted image in *D* obtained 5 days later. *(Courtesy of Gregory Albers and Vincent Thijs, MD, Stanford University)*

ogy of Ischemic Stroke," above), and patients showing large regions of mismatch may be better candidates for acute revascularization. MR angiography is highly sensitive for stenosis of extracranial internal carotid arteries and of large intracranial vessels. With higher degrees of stenosis, MR angiography tends to overestimate the degree of stenosis when compared to conventional x-ray angiography. MRI with fat saturation is an imaging sequence used to visualize extra- or intracranial arterial dissection. This sensitive technique images clotted blood within the dissected vessel wall.

MRI is less sensitive for acute blood products than CT and is more expensive and time consuming and less readily available. Claustrophobia also limits its application. Most acute stroke protocols use CT because of these limitations. However, MRI may be useful outside the acute period by more clearly defining the extent and possible source of a stroke.

Cerebral Angiography Conventional x-ray cerebral angiography is the "gold standard" for identifying and quantifying atherosclerotic stenoses of the cerebral arteries and for identifying and characterizing other pathologies, including aneurysm, vasospasm, intraluminal thrombi, fibromuscular dysplasia, arteriovenous fistula, vasculitis, and collateral channels of blood flow. Endovascular techniques, which are evolving rapidly, can be used to deploy stents within delicate intracranial vessels, to perform balloon angioplasty of stenotic lesions, and to treat intracranial aneurysms by embolization. Recent studies have documented that intraarterial delivery of thrombolytic agents to patients with acute MCA stroke can effectively recanalize vessels and improve clinical outcomes. Although its use is investigational in many centers, cerebral angiography coupled with endovascular techniques for cerebral revascularization may become routine in the near future. Conventional angiography carries risks of arterial damage, groin hemorrhage, embolic stroke, and renal failure from contrast nephropathy, so it should be reserved for situations where less invasive means are inadequate.

Ultrasound Techniques Stenosis at the origin of the internal carotid artery can be identified and quantified reliably by ultrasonography that combines a B-mode ultrasound image with a Doppler ultrasound assessment of flow velocity ("duplex" ultrasound). Transcranial Doppler (TCD) assessment of middle, anterior, and posterior cerebral artery flow and of vertebrobasilar flow is also useful. This latter technique can detect stenotic lesions in the large intracranial arteries because such lesions increase systolic flow velocity. In many cases, MR angiography combined with carotid and transcranial ultrasound studies eliminates the need for conventional x-ray angiography in evaluating vascular stenosis. Alternatively, CT angiography of the entire head and neck can be performed during the initial imaging of acute stroke. Because this images the entire arterial system relevant to stroke, with the exception of the heart, much of the clinician's stroke workup can be completed with one imaging study.

Perfusion Techniques Both xenon techniques (principally xenon-CT) and PET can quantify cerebral blood flow. These tools are generally used for research (Chap. 347) but can be useful for determining the significance of arterial stenosis and planning for revascularization surgery. Single photon emission tomography (SPECT), CT perfusion, and MR perfusion techniques report relative cerebral blood flow. Since CT imaging is used as the initial imaging modality for acute stroke, many centers now combine both CT angiography and CT perfusion imaging together with the noncontrast CT scan. CT perfusion imaging increases the sensitivity and improves accuracy in imaging ischemic brain. Alternatively, MR perfusion can be combined with MR diffusion imaging to identify the ischemic penumbra as the mismatch between these two imaging sequences (Fig. 349-13). The ability to image the ischemic penumbra allows more judicious selection of patients who may or may not benefit from acute interventions such as thrombolysis or investigational neuroprotective strategies.

INTRACRANIAL HEMORRHAGE

Hemorrhages are classified by their location and the underlying vascular pathology. Bleeding into subdural and epidural spaces is principally produced by trauma (Chap. 357). Intraparenchymal, intraventricular, and subarachnoid hemorrhage will be considered here.

DIAGNOSIS Intracranial hemorrhage is often discovered on noncontrast CT imaging of the brain during the acute evaluation of stroke. Since CT is more sensitive than routine MRI for acute blood, CT imaging is the preferred method for acute stroke evaluation (Fig. 349-1). The location of the hemorrhage narrows the differential diagnosis to a few entities. Table 349-6 lists the causes and anatomic spaces involved in hemorrhages.

EMERGENCY MANAGEMENT Close attention should be paid to airway management since a reduction in the level of consciousness is common. The initial blood pressure should be maintained until the results of the CT scan are reviewed. Patients with acute SAH should have blood pressure lowered to a normal range with nonvasodilating agents such as nicardipine, labetalol, or esmolol. Patients with cerebellar hemorrhages or with depressed mental status and radiographic evidence of hydrocephalus should undergo urgent neurosurgical evaluation. Based on the clinical examination and CT findings, further imaging studies may be necessary, including MRI or conventional x-ray angiography. Stuporous or comatose patients generally are treated presumptively for elevated ICP, with tracheal intubation and hyperventilation, mannitol administration, and elevation of the head of the bed while surgical consultation is obtained (Chap. 258).

SUBARACHNOID HEMORRHAGE Excluding head trauma, the most common cause of SAH is rupture of a saccular aneurysm. Other causes

TABLE 349-6 *Causes of Intracranial Hemorrhage*

Cause	Location	Comments
Head trauma	Intraparenchymal: frontal lobes, anterior temporal lobes; subarachnoid	Coup and contracoup injury during brain deceleration
Hypertensive hemorrhage	Putamen, globus pallidus, thalamus, cerebellar hemisphere, pons	Chronic hypertension produces hemorrhage from small (~100 μm) vessels in these regions
Transformation of prior ischemic infarction	Basal ganglion, subcortical regions, lobar	Occurs in 1–6% of ischemic strokes with predilection for large hemispheric infarctions
Metastatic brain tumor	Lobar	Lung, choriocarcinoma, melanoma, renal cell carcinoma, thyroid, atrial myxoma
Coagulopathy	Any	Uncommon cause; often associated with prior stroke or underlying vascular anomaly
Drug	Lobar, subarachnoid	Cocaine, amphetamine, phenylpropranolamine
Arteriovenous malformation	Lobar, intraventricular, subarachnoid	Risk is ~2–4% per year for bleeding
Aneurysm	Subarachnoid, intraparenchymal, rarely subdural	Mycotic and nonmycotic forms of aneurysms
Amyloid angiopathy	Lobar	Degenerative disease of intracranial vessels; linkage to Alzheimer's disease, rare in patients <60
Cavernous angioma	Intraparenchymal	Multiple cavernous angiomas linked to chromosome 7q
Dural arteriovenous fistula	Lobar, rarely subarachnoid	Produces bleeding by venous hypertension
Capillary telangiectasias	Usually brainstem	Rare cause of hemorrhage

include bleeding from a vascular anomaly and extension into the subarachnoid space from a primary intracerebral hemorrhage. Some idiopathic SAHs are localized to the perimesencephalic cisterns and are benign; they probably have a venous or capillary source, and angiography is unrevealing.

Saccular ("Berry") Aneurysm Autopsy and angiography studies have found that about 2% of adults harbor intracranial aneurysms, for a prevalence of 4 million persons in the United States; the aneurysm will rupture, producing SAH, in 25,000 to 30,000 cases per year. For patients who arrive alive at hospital, the mortality rate over the next month is about 45%. Of those who survive, more than half are left with major neurologic deficits as a result of the initial hemorrhage, cerebral vasospasm with infarction, or hydrocephalus. If the patient survives but the aneurysm is not obliterated, the rate of rebleeding is about 20% in the first 2 weeks and about 3% per year afterwards. Given these alarming figures, the major therapeutic emphasis is on preventing the predictable early complications of the SAH.

Unruptured, asymptomatic aneurysms are much less dangerous than a recently ruptured aneurysm. The annual risk of rupture for aneurysms <10 mm in size is ~0.1%, and for aneurysms ≥10 mm in size is ~0.5 to 1%; the surgical morbidity far exceeds these percentages. As more data become available, a true risk-benefit analysis for treating these aneurysms will result.

Giant aneurysms, those >2.5 cm in diameter, occur at the same sites (see below) as small aneurysms and account for 5% of cases. The three most common locations are the terminal internal carotid artery, MCA bifurcation, and top of the basilar artery. Their risk of rupture is about 6% in the first year after identification and may remain high indefinitely. They often cause symptoms by compressing the adjacent brain or cranial nerves.

Mycotic aneurysms are usually located distal to the first bifurcation of major arteries of the circle of Willis. Most result from infected emboli due to bacterial endocarditis causing septic degeneration of arteries and subsequent dilatation and rupture. Whether these lesions should be sought and repaired prior to rupture, or left to heal spontaneously, is controversial.

PATHOPHYSIOLOGY Saccular aneurysms occur at the bifurcations of the large to medium-sized intracranial arteries; rupture is into the subarachnoid space in the basal cisterns and often into the parenchyma of the adjacent brain. Approximately 85% of aneurysms occur in the anterior circulation, mostly on the circle of Willis. About 20% of patients have multiple aneurysms, many at mirror sites bilaterally. As an aneurysm develops, it typically forms a neck with a dome. The length of the neck and the size of the dome vary greatly and are factors that are important in planning neurosurgical obliteration or endovascular embolization. The arterial internal elastic lamina disappears at the base of the neck. The media thins, and connective tissue replaces smooth-muscle cells. At the site of rupture (most often the dome) the wall thins, and the tear that allows bleeding is often no more than 0.5 mm long. Aneurysm size and site are important in predicting risk of rupture. Those >7 mm in diameter and those at the top of the basilar artery and at the origin of the posterior communicating artery are at greater risk of rupture.

CLINICAL MANIFESTATIONS Most unruptured intracranial aneurysms are completely asymptomatic. Symptoms are usually due to rupture and resultant SAH. At the moment of aneurysmal rupture with major SAH, the ICP suddenly rises. This may account for the sudden transient loss of consciousness that occurs in nearly half of patients. Sudden loss of consciousness may be preceded by a brief moment of excruciating headache, but most patients first complain of headache upon regaining consciousness. In 10% of cases, aneurysmal bleeding is severe enough to cause loss of consciousness for several days. In about 45% of cases, severe headache associated with exertion is the presenting complaint. The patient often calls the headache "the worst headache of my life." Occasionally these ruptures may present as headache of only moderate intensity or as a change in the patient's usual headache pattern. The headache is usually generalized, often with neck stiffness, and vomiting is common.

Although sudden headache in the absence of focal neurologic symptoms is the hallmark of aneurysmal rupture, focal neurologic deficits may occur. Anterior communicating artery or MCA bifurcation aneurysms may rupture into the adjacent brain or subdural space and form a hematoma large enough to produce mass effect. The common deficits that result include hemiparesis, aphasia, and abulia.

Occasionally, prodromal symptoms suggest the location of a progressively enlarging unruptured aneurysm. A third cranial nerve palsy, particularly when associated with pupillary dilatation, loss of ipsilateral (but retained contralateral) light reflex, and focal pain above or behind the eye, may occur with an expanding aneurysm at the junction of the posterior communicating artery and the internal carotid artery. A sixth nerve palsy may indicate an aneurysm in the cavernous sinus, and visual field defects can occur with an expanding supraclinoid carotid or anterior cerebral artery aneurysm. Occipital and posterior cervical pain may signal a posterior inferior cerebellar artery or anterior inferior cerebellar artery aneurysm. Pain in or behind the eye and in the low temple can occur with an expanding MCA aneurysm. Thunderclap headache is a variant of migraine that simulates a SAH. Before concluding that a patient with sudden, severe headache has thunderclap migraine, a definitive workup for aneurysm or other intracranial pathology is required.

Aneurysms can undergo small ruptures and leaks of blood into the subarachnoid space, so-called sentinel bleeds. Sudden unexplained headache at any location should raise suspicion of SAH and be investigated, because a major hemorrhage may be imminent.

DELAYED NEUROLOGIC DEFICITS There are four major causes of delayed neurologic deficits: rerupture, hydrocephalus, vasospasm, and hyponatremia.

1. *Rerupture*. The incidence of rerupture of an untreated aneurysm in the first month following SAH is ~30%, with the peak in the first 7 days. Rerupture is associated with a 60% mortality and poor outcome. Early treatment eliminates this risk.

2. *Hydrocephalus*. Acute hydrocephalus can cause stupor and coma. More often, subacute hydrocephalus develops over a few days or weeks and causes progressive drowsiness or slowed mentation (abulia) with incontinence. Hydrocephalus is differentiated from cerebral vasospasm with a CT scan, TCD ultrasound, or conventional x-ray angiography. Hydrocephalus may clear spontaneously or require temporary ventricular drainage. Chronic hydrocephalus may develop weeks to months after SAH and manifest as gait difficulty, incontinence, or impaired mentation. Subtle signs may be a lack of initiative in conversation or a failure to recover independence.

3. *Vasospasm*. Narrowing of the arteries at the base of the brain following SAH causes symptomatic ischemia and infarction in ~30% of patients and is the major cause of delayed morbidity and death. Signs of ischemia appear 4 to 14 days after the hemorrhage, most often at 7 days. The severity and distribution of vasospasm determine whether infarction will occur.

Delayed vasospasm is believed to result from direct effects of clotted blood and its breakdown products on the artery. In general, the more blood that surrounds the arteries, the greater the chance of symptomatic vasospasm. Spasm of major arteries produces symptoms referable to the appropriate vascular territory (see "Stroke Syndromes," above). All of these focal symptoms may present abruptly, fluctuate, or develop over a few days. In most cases, focal spasm is preceded by a decline in mental status.

Vasospasm can be detected reliably with conventional x-ray angiography, but this invasive procedure is expensive and carries risk of stroke and other complications. TCD ultrasound is based on the principle that the velocity of blood flow within an artery will rise as the lumen diameter is narrowed. By directing the probe along the MCA and proximal ACA, carotid terminus, vertebral, and basilar arteries on a daily or every-other-day basis, vasospasm can be reliably detected and treatments initiated to prevent cerebral ischemia (see below). CT angiography is another method that can reliably detect vasospasm.

Severe cerebral edema in patients with infarction from vasospasm may increase the ICP enough to reduce cerebral perfusion pressure. Treatment is with mannitol and hyperventilation (Chap. 258).

4. *Hyponatremia*. Hyponatremia may be profound and develop quickly in the first 2 weeks following SAH. It usually results from inappropriate secretion of vasopressin (Chap. 319) and secretion of atrial and brain natriuretic factors, which produce a natriuresis. This "cerebral salt-wasting syndrome" clears over the course of 1 to 2 weeks and, in the setting of SAH, should not be treated with free-water restriction as this may increase the risk of stroke (see below).

LABORATORY EVALUATION AND IMAGING (Fig. 349-14) The hallmark of aneurysmal rupture is blood in the cerebrospinal fluid (CSF). More than 95% of cases have enough blood to be visualized on a high-quality noncontrast CT scan obtained within 72 h. If the scan fails to establish the diagnosis of SAH and no mass lesion or obstructive hydrocephalus is found, a lumbar puncture should be performed to establish the presence of subarachnoid blood. Lysis of the red blood cells and subsequent conversion of hemoglobin to bilirubin stains the spinal fluid yellow within 6 to 12 h of SAH. This xanthochromic spinal fluid peaks in intensity at 48 h and lasts for 1 to 4 weeks, depending on the amount of subarachnoid blood.

The extent and location of subarachnoid blood on noncontrast CT scan help locate the underlying aneurysm, identify the cause of any neurologic deficit, and predict delayed vasospasm. A high incidence of symptomatic vasospasm in the MCA and ACA has been found when early CT scans show subarachnoid clots $>5 \times 3$ mm in the basal cisterns or layers of blood >1 mm thick in the cerebral fissures. CT scans less reliably predict vasospasm in the vertebral, basilar, or posterior cerebral arteries.

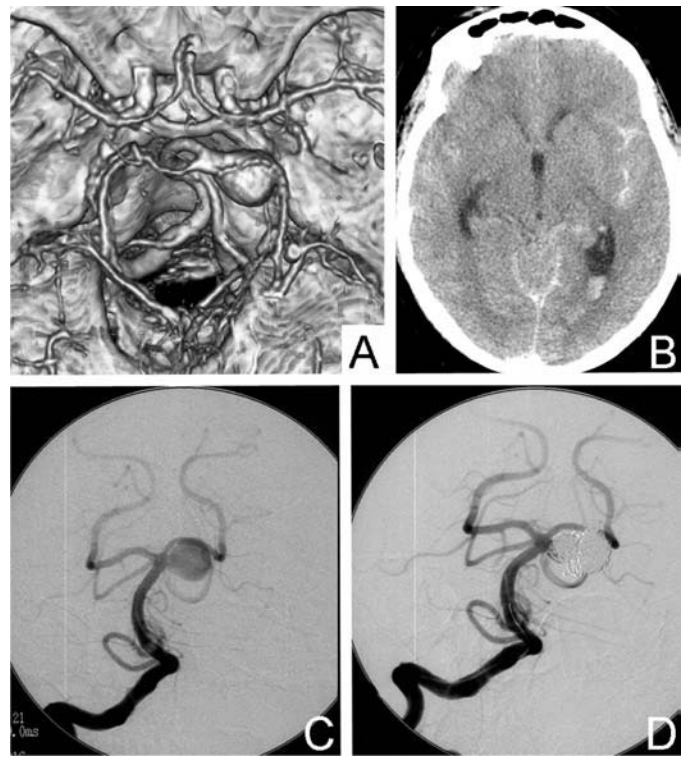

FIGURE 349-14 Subarachnoid hemorrhage. *A*. Computed tomography (CT) angiography revealing an aneurysm of the left superior cerebellar artery. *B*. Noncontrast CT scan at the level of the third ventricle revealing subarachnoid blood in the left sylvian fissue (bright) and within the left lateral ventricle. *C*. Conventional anteroposterior x-ray angiogram of the right vertebral and basilar artery showing the large aneurysm. *D*. Conventional angiogram following coil embolization of the aneurysm, whereby the aneurysm body is filled with platinum delivered through a microcatheter navigated from the femoral artery into the aneurysm neck.

Lumbar puncture prior to an imaging procedure is indicated only if a CT scan is not available at the time of the suspected SAH. Once the diagnosis of hemorrhage from a ruptured saccular aneurysm is suspected, four-vessel conventional x-ray angiography (both carotids and both vertebrals) is generally performed to localize and define the anatomic details of the aneurysm and to determine if other unruptured aneurysms exist (Fig. 349-14). CT angiography is an alternative method for locating the aneurysm and may be sufficient to plan definitive therapy. At some centers, the ruptured aneurysm can be treated using endovascular techniques at the time of the initial angiogram (see below).

The ECG frequently shows ST-segment and T-wave changes similar to those associated with cardiac ischemia. Prolonged QRS complex, increased QT interval, and prominent "peaked" or deeply inverted symmetric T waves are usually secondary to the intracranial hemorrhage. There is evidence that structural myocardial lesions produced by circulating catecholamines may occur after SAH, causing reversible cardiomyopathy sufficient to cause shock or congestive heart failure. Serious ventricular dysrhythmias are unusual.

Close monitoring (daily or twice daily) of electrolytes is important because hyponatremia can occur precipitously during the first 2 weeks following SAH (see above).

TREATMENT

Early aneurysm repair prevents rerupture and allows the safe application of techniques to improve blood flow (e.g., induced hypertension and hypervolemia) should symptomatic vasospasm develop. An aneurysm can be "clipped" by a neurosurgeon or "coiled" by a neurointerventional radiologist. Surgical repair involves placing a metal clip across the aneurysm neck, thereby immediately eliminating the risk of

rebleeding. This approach requires craniotomy and brain retraction, which is associated with neurologic morbidity. The newer endovascular technique involves placing platinum coils within the aneurysm via a catheter that is passed from the femoral artery. The aneurysm is packed tightly to enhance thrombosis and over time is walled-off from the circulation (Fig. 349-14). The only prospective randomized trial of surgery versus endovascular treatment for ruptured aneurysm, the International Study of Aneurysm Treatment (ISAT), was terminated early when 24% of patients treated with endovascular therapy were dead or dependent at 1 year compared to 31% treated with surgery, a 23% relative reduction. However, some aneurysms have a morphology that is not amenable to coiling, and only a few endovascular centers are available world-wide. Thus, surgery remains an important treatment option.

The medical management of SAH centers on protecting the airway, managing blood pressure before and after aneurysm treatment, preventing rebleeding prior to treatment, managing vasospasm, treating hydrocephalus, treating hyponatremia, and preventing pulmonary embolus.

Intracranial hypertension following aneurysmal rupture occurs secondary to subarachnoid blood, parenchymal hematoma, acute hydrocephalus, or loss of vascular autoregulation. Patients who are stuporous should undergo emergent ventriculostomy to prevent cerebral ischemia from high ICP. Medical therapies designed to combat raised ICP (e.g., mild hyperventilation, mannitol, and sedation) can also be used as needed (Chap. 258). High ICP refractory to treatment is a poor prognostic sign.

Prior to definitive treatment of the ruptured aneurysm, care is required to maintain adequate cerebral perfusion pressure while avoiding excessive elevation of arterial pressure. Occasionally an intracranial hematoma causing neurologic deterioration requires removal.

Because rebleeding is common, all patients who are not candidates for early aneurysm repair are put on bed rest in a quiet room and are given stool softeners to prevent straining. If headache or neck pain is severe, mild sedation and analgesia are prescribed. Extreme sedation is avoided because it can obscure changes in neurologic status. Adequate hydration is necessary to avoid a decrease in blood volume predisposing to brain ischemia.

Seizures are uncommon at the onset of aneurysmal rupture. The quivering, jerking, and extensor posturing that often accompany loss of consciousness are probably related to the sharp rise in ICP or, perhaps, acute generalized vasospasm. However, phenytoin is often given as prophylactic therapy since a seizure may promote rebleeding.

Glucocorticoids may help reduce the head and neck ache caused by the irritative effect of the subarachnoid blood. There is no good evidence that they reduce cerebral edema, are neuroprotective, or reduce vascular injury, and their routine use therefore is not recommended.

Antifibrinolytic agents are not routinely prescribed but may be considered in patients in whom aneurysm treatment cannot proceed immediately. They are associated with a reduced incidence of aneurysmal rerupture but are also associated with an increased incidence of delayed cerebral infarction and DVT.

Vasospasm remains the leading cause of morbidity and mortality following aneurysmal SAH and treatment of the aneurysm. Treatment with the calcium channel antagonist nimodipine (60 mg orally every 4 h) improves outcome, perhaps by preventing ischemic injury rather than reducing the risk of vasospasm. Nimodipine can cause significant hypotension in some patients, which may worsen cerebral ischemia in patients with vasospasm. Symptomatic cerebral vasospasm can also be treated by increasing the cerebral perfusion pressure by raising mean arterial pressure through plasma volume expansion and the judicious use of vasopressor agents, usually phenylephrine or dopamine. Raised perfusion pressure has been associated with clinical improvement in many patients, but high arterial pressure may promote rebleeding in unprotected aneurysms. Treatment with induced hypertension and hypervolemia generally requires monitoring of arterial and central venous pressures. Volume expansion helps prevent hypotension, augments cardiac output, and reduces blood viscosity by reducing the hematocrit. This method is called "triple-H" (hypertension, hemodilution, and hypervolemic) therapy.

If symptomatic vasospasm persists despite optimal medical therapy, intraarterial vasodilators and percutaneous transluminal angioplasty are considered. Vasodilatation following angioplasty appears to be permanent, allowing triple-H therapy to be tapered sooner. The pharmacologic vasodilators (verapamil and nicardipine) do not last more than 8 to 24 h, and therefore multiple treatments may be required until the subarachnoid blood is reabsorbed.

Acute hydrocephalus can cause stupor or coma. It may clear spontaneously or require temporary ventricular drainage. When chronic hydrocephalus develops, ventricular shunting is the treatment of choice.

Free-water restriction is contraindicated in patients with SAH at risk for vasospasm because hypovolemia and hypotension may occur and precipitate cerebral ischemia. Many patients continue to experience a decline in serum sodium despite receiving parenteral fluids containing normal saline. Frequently, supplemental oral salt coupled with normal saline will mitigate hyponatremia, but often patients also require hypertonic saline. Care must be taken not to correct serum sodium too quickly in patients with marked hyponatremia of several days' duration, as central pontine myelinolysis (Chap. 258) may occur.

All patients should have pneumatic compression stockings applied to prevent pulmonary embolism. Systemic heparin is contraindicated in patients with ruptured and untreated aneurysms; it is a relative contraindication following craniotomy, and it may delay thrombosis of a coiled aneurysm.

INTRAPARENCHYMAL HEMORRHAGE Intraparenchymal hemorrhage is the most common type of intracranial hemorrhage. It accounts for about 10% of all strokes and is associated with a 50% case fatality rate. Incidence rates are particularly high in Asians and African Americans. Hypertension, trauma, and cerebral amyloid angiopathy cause the majority of these hemorrhages. Advanced age and heavy alcohol consumption increase the risk, and cocaine use is one of the most important causes in the young.

Hypertensive Intraparenchymal Hemorrhage ■ *PATHOPHYSIOLOGY* Hypertensive intraparenchymal hemorrhage (hypertensive hemorrhage or hypertensive intracerebral hemorrhage) usually results from spontaneous rupture of a small penetrating artery deep in the brain. The most common sites are the basal ganglia (putamen, thalamus, and adjacent deep white matter), deep cerebellum, and pons. When hemorrhages occur in other brain areas or in nonhypertensive patients, greater consideration should be given to hemorrhagic disorders, neoplasms, vascular malformations, and other causes. The small arteries in these areas seem most prone to hypertension-induced vascular injury. The hemorrhage may be small or a large clot may form and compress adjacent tissue, causing herniation and death. Blood may dissect into the ventricular space, which substantially increases morbidity and may cause hydrocephalus.

Most hypertensive intraparenchymal hemorrhages develop over 30 to 90 min, whereas those associated with anticoagulant therapy may evolve for as long as 24 to 48 h. Within 48 h macrophages begin to phagocytize the hemorrhage at its outer surface. After 1 to 6 months, the hemorrhage is generally resolved to a slitlike orange cavity lined with glial scar and hemosiderin-laden macrophages.

CLINICAL MANIFESTATIONS Although not particularly associated with exertion, intracerebral hemorrhages almost always occur while the patient is awake and sometimes when stressed. The hemorrhage generally presents as the abrupt onset of focal neurologic deficit. Seizures are uncommon. The focal deficit typically worsens steadily over 30 to 90 min and is associated with a diminishing level of consciousness and signs of increased ICP, such as headache and vomiting.

The putamen is the most common site for hypertensive hemorrhage, and the adjacent internal capsule is invariably damaged (Fig.

FIGURE 349-15 Transaxial noncontrast computed tomography scan through the region of the basal ganglia reveals a hematoma involving the left putamen in a patient with rapidly progressive onset of right hemiparesis. This is a typical hypertensive hemorrhage.

349-15). Contralateral hemiparesis is therefore the sentinel sign. When mild, the face sags on one side over 5 to 30 min, speech becomes slurred, the arm and leg gradually weaken, and the eyes deviate away from the side of the hemiparesis. The paralysis may worsen until the affected limbs become flaccid or extend rigidly. When hemorrhages are large, drowsiness gives way to stupor as signs of upper brainstem compression appear. Coma ensues, accompanied by deep, irregular, or intermittent respiration, a dilated and fixed ipsilateral pupil, and decerebrate rigidity. In milder cases, edema in adjacent brain tissue may cause progressive deterioration over 12 to 72 h.

Thalamic hemorrhages also produce a contralateral hemiplegia or hemiparesis from pressure on, or dissection into, the adjacent internal capsule. A prominent sensory deficit involving all modalities is usually present. Aphasia, often with preserved verbal repetition, may occur after hemorrhage into the dominant thalamus, and apractognosia or mutism occurs in some cases of nondominant hemorrhage. There may also be a homonymous visual field defect. Thalamic hemorrhages cause several typical ocular disturbances by virtue of extension medially into the upper midbrain. These include deviation of the eyes downward and inward so that they appear to be looking at the nose, unequal pupils with absence of light reaction, skew deviation with the eye opposite the hemorrhage displaced downward and medially, ipsilateral Horner's syndrome, absence of convergence, paralysis of vertical gaze, and retraction nystagmus. Patients may later develop a chronic, contralateral pain syndrome (Déjerine-Roussy syndrome).

In pontine hemorrhages, deep coma with quadriplegia usually occurs over a few minutes. There is often prominent decerebrate rigidity and "pin-point" (1 mm) pupils that react to light. There is impairment of reflex horizontal eye movements evoked by head turning (doll's-head or oculocephalic maneuver) or by irrigation of the ears with ice water (Chap. 257). Hyperpnea, severe hypertension, and hyperhidrosis are common. Death often occurs within a few hours, but small hemorrhages are compatible with survival.

Cerebellar hemorrhages usually develop over several hours and are characterized by occipital headache, repeated vomiting, and ataxia of gait. In mild cases there may be no other neurologic signs other than gait ataxia. Dizziness or vertigo may be prominent. There is often paresis of conjugate lateral gaze toward the side of the hemorrhage, forced deviation of the eyes to the opposite side, or an ipsilateral sixth nerve palsy. Less frequent ocular signs include blepharospasm, involuntary closure of one eye, ocular bobbing, and skew deviation. Dysarthria and dysphagia may occur. As the hours pass, the patient often becomes stuporous and then comatose from brainstem compression or obstructive hydrocephalus; immediate surgical evacuation before brainstem compression occurs may be lifesaving. Hydrocephalus from fourth ventricle compression can be relieved by external ventricular drainage, but definitive hematoma evacuation is essential for survival. If the deep cerebellar nuclei are spared, full recovery is common.

Lobar Hemorrhage Symptoms and signs appear over several minutes. Most lobar hemorrhages are small and cause a restricted clinical syndrome that simulates an embolus to an artery supplying one lobe. For example, the major neurologic deficit with an occipital hemorrhage is hemianopia; with a left temporal hemorrhage, aphasia and delirium; with a parietal hemorrhage, hemisensory loss; and with frontal hemorrhage, arm weakness. Large hemorrhages may be associated with stupor or coma if they compress the thalamus or midbrain. Most patients with lobar hemorrhages have focal headaches, and more than half vomit or are drowsy. Stiff neck and seizures are uncommon.

Other Causes of Intracerebral Hemorrhage *Cerebral amyloid angiopathy* is a disease of the elderly in which arteriolar degeneration occurs and amyloid is deposited in the walls of the cerebral arteries. Amyloid angiopathy causes both single and recurrent lobar hemorrhages and is probably the most common cause of lobar hemorrhage in the elderly. It accounts for some intracranial hemorrhages associated with intravenous thrombolysis given for MI. This disorder can be suspected in patients who present with multiple hemorrhages (and infarcts) over several months or years, or in patients with "micro-bleeds" seen on brain MRI sequences sensitive for hemosiderin, but it is definitively diagnosed by demonstration of Congo red staining of amyloid in cerebral vessels. There is no specific therapy.

Cocaine is a frequent cause of stroke in young (age < 45) patients. Intracerebral hemorrhage, ischemic stroke, and SAH are all associated with cocaine use. Angiographic findings vary from completely normal arteries to large-vessel occlusion or stenosis, vasospasm, or changes consistent with vasculitis. The mechanism of cocaine-related stroke is not known, but cocaine enhances sympathetic activity causing acute, sometimes severe, hypertension, and this may lead to hemorrhage. Slightly more than half of cocaine-related intracranial hemorrhages are intracerebral, and the rest are subarachnoid. In cases of SAH, a saccular aneurysm is usually identified. Presumably, acute hypertension causes aneurysmal rupture.

Head injury often causes intracranial bleeding. The common sites are intracerebral (especially temporal and inferior frontal lobes) and into the subarachnoid, subdural, and epidural spaces. Trauma must be considered in any patient with an unexplained acute neurologic deficit (hemiparesis, stupor, or confusion), particularly if the deficit occurred in the context of a fall (Chap. 357).

Intracranial hemorrhages associated with *anticoagulant therapy* can occur at any location; they are often lobar or subdural. Anticoagulant-related intracerebral hemorrhages may evolve slowly, over 24 to 48 h. Coagulopathy should be reversed with fresh-frozen plasma or factor replacement and vitamin K to limit the volume of hemorrhage. When intracerebral hemorrhage is associated with thrombocytopenia (platelet count $< 50{,}000/\mu L$), transfusion of fresh platelets is indicated. Intracerebral hemorrhage associated with *hematologic disorders* (leukemia, aplastic anemia, thrombocytopenic purpura) can occur at any site and may present as multiple intracerebral hemorrhages. Skin and mucous membrane bleeding is usually evident and offers a diagnostic clue.

Hemorrhage into a *brain tumor* may be the first manifestation of neoplasm. Choriocarcinoma, malignant melanoma, renal cell carcinoma, and bronchogenic carcinoma are among the most common metastatic tumors associated with intracerebral hemorrhage. Glioblastoma multiforme in adults and medulloblastoma in children may also have areas of intracerebral hemorrhage.

Hypertensive encephalopathy is a complication of malignant hypertension. In this acute syndrome, severe hypertension is associated with headache, nausea, vomiting, convulsions, confusion, stupor, and

coma. Focal or lateralizing neurologic signs, either transitory or permanent, may occur but are infrequent and therefore suggest some other vascular disease (hemorrhage, embolism, or atherosclerotic thrombosis). There are retinal hemorrhages, exudates, papilledema (hypertensive retinopathy), and evidence of renal and cardiac disease. In most cases ICP and CSF protein levels are elevated. The hypertension may be essential or due to chronic renal disease, acute glomerulonephritis, acute toxemia of pregnancy, pheochromocytoma, or other causes. Lowering the blood pressure reverses the process, but stroke can occur, especially if blood pressure is lowered too rapidly. Neuropathologic examination reveals multifocal to diffuse cerebral edema and hemorrhages of various sizes from petechial to massive. Microscopically, there are necrosis of arterioles, minute cerebral infarcts, and hemorrhages. The term *hypertensive encephalopathy* should be reserved for this syndrome and not for chronic recurrent headaches, dizziness, recurrent TIAs, or small strokes that often occur in association with high blood pressure.

Primary intraventricular hemorrhage is rare. It usually begins within the substance of the brain and dissects into the ventricular system without leaving signs of intraparenchymal hemorrhage. Alternatively, bleeding can arise from periependymal veins. Vasculitis, usually polyarteritis nodosa or lupus erythematosus, can produce hemorrhage into any region of the central nervous system; most hemorrhages are associated with hypertension, but the arteritis itself may cause bleeding by disrupting the vessel wall. *Sepsis* can cause small petechial hemorrhages throughout the cerebral white matter. *Moyamoya disease*, mainly an occlusive arterial disease that causes ischemic symptoms, may on occasion produce intraparenchymal hemorrhage, particularly in the young. Hemorrhages into the spinal cord are usually the result of an AVM or metastatic tumor. *Epidural spinal hemorrhage* produces a rapidly evolving syndrome of spinal cord or nerve root compression (Chap. 356). Spinal hemorrhages usually present with sudden back pain and some manifestation of myelopathy.

Laboratory and Imaging Evaluation The CT scan reliably detects acute focal hemorrhages in the supratentorial space. Small pontine hemorrhages may not be identified because of motion and bone-induced artifact that obscure structures in the posterior fossa. After the first 2 weeks, x-ray attenuation values of clotted blood diminish until they become isodense with surrounding brain. Mass effect and edema may remain. In some cases, a surrounding rim of contrast enhancement appears after 2 to 4 weeks and may persist for months. MRI, though more sensitive for delineating posterior fossa lesions, is generally not necessary in most instances. Images of flowing blood on MRI scan may identify AVMs as the cause of the hemorrhage. MRI, CT angiography, and conventional x-ray angiography are used when the cause of intracranial hemorrhage is uncertain, particularly if the patient is young or not hypertensive and the hematoma is not in one of the four usual sites for hypertensive hemorrhage. For example, hemorrhage into the temporal lobe suggests rupture of a MCA saccular aneurysm.

Since patients typically have focal neurologic signs and obtundation, and often show signs of increased ICP, a lumbar puncture should be avoided as it may induce cerebral herniation.

TREATMENT

Acute Management Nearly 50% of patients with a hypertensive intracerebral hemorrhage die, but others may have a good to complete recovery if they survive the initial hemorrhage. The volume and location of the hematoma determine the prognosis. In general, supratentorial hematomas with volumes <30 mL have a good prognosis; 30 to 60 mL, an intermediate prognosis; and >60 mL, a poor prognosis during initial hospitalization. Extension into the ventricular system worsens the prognosis. Except in patients who are on therapeutic anticoagulation or who have a bleeding disorder, little can be done about the hemorrhage itself. Hematomas may expand for several hours following the initial hemorrhage, so treating severe hypertension seems reasonable to prevent hematoma progression.

Evacuation of the hematoma is usually not helpful, except in cerebellar hemorrhages. For cerebellar hemorrhages, a neurosurgeon should be consulted immediately to assist with the evaluation; most cerebellar hematomas >3 cm in diameter will require surgical evacuation. If the patient is alert without focal brainstem signs and if the hematoma is <1 cm in diameter, surgical removal is usually unnecessary. Patients with hematomas between 1 and 3 cm require careful observation for signs of impaired consciousness and precipitous respiratory failure.

Tissue surrounding hematomas is displaced and compressed but not necessarily infarcted. Hence, in survivors, major improvement commonly occurs as the hematoma is reabsorbed and the adjacent tissue regains its function. Careful management of the patient during the acute phase of the hemorrhage can lead to considerable recovery.

Surprisingly, despite large intraparenchymal hemorrhages, ICP is often not elevated. However, if the hematoma causes marked midline shift of structures with consequent obtundation, coma, or hydrocephalus, osmotic agents coupled with induced hyperventilation can be instituted to lower ICP (Chap. 258). These maneuvers will provide enough time to place a ventriculostomy or ICP monitor. Once ICP is recorded, further hyperventilation and osmotic therapy can be tailored to the individual patient. For example, if ICP is found to be high, CSF can be drained from the ventricular space and osmotic therapy continued; persistent or progressive elevation in ICP may prompt surgical evacuation of the clot or withdrawal of support. Alternately, if ICP is normal or only mildly elevated, induced hyperventilation can be reversed and osmotic therapy tapered. Since hyperventilation may actually produce ischemia by cerebral vasoconstriction, induced hyperventilation should be limited to acute resuscitation of the patient with presumptive high ICP and eliminated once other treatments (osmotic therapy or surgical treatments) have been instituted. Glucocorticoids are not helpful for the edema from intracerebral hematoma.

Prevention Hypertension is the leading cause of primary intracerebral hemorrhage. Prevention is aimed at reducing hypertension, excessive alcohol use, and use of illicit drugs such as cocaine and amphetamines.

VASCULAR ANOMALIES

Vascular anomalies can be divided into congenital vascular malformations and acquired vascular lesions.

CONGENITAL VASCULAR MALFORMATIONS True *arteriovenous malformations*, venous anomalies, and capillary telangiectasias are lesions that usually remain clinically silent through life. Although most AVMs are congenital, cases of acquired lesions have been reported.

True AVMs are congenital shunts between the arterial and venous systems that may present as headache, seizures, and intracranial hemorrhage. AVMs consist of a tangle of abnormal vessels across the cortical surface or deep within the brain substance. AVMs vary in size from a small blemish a few millimeters in diameter to a large mass of tortuous channels composing an arteriovenous shunt of sufficient magnitude to raise cardiac output. The blood vessels forming the tangle interposed between arteries and veins are usually abnormally thin and do not have a normal structure. AVMs occur in all parts of the cerebral hemispheres, brainstem, and spinal cord, but the largest ones are most frequently in the posterior half of the hemispheres, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle.

Although the lesion is present from birth, bleeding or other symptoms are most common between the ages of 10 and 30, occasionally as late as the fifties. AVMs are more frequent in men, and rare familial cases have been described.

Headache (without bleeding) may be hemicranial and throbbing, like migraine, or diffuse. Focal seizures, with or without generalization, occur in about 30% of cases. Half of AVMs become evident as intracerebral hemorrhages. In most, the hemorrhage is mainly intraparenchymal with extension into the subarachnoid space in some cases. Blood is usually not deposited in the basal cisterns, and symp-

tomatic cerebral vasospasm is rare. The risk of rerupture is about 18% per year and is particular high in the first few weeks. Hemorrhages may be massive, leading to death, or may be as small as 1 cm in diameter, leading to minor focal symptoms or no deficit. The AVM may be large enough to steal blood away from adjacent normal brain tissue or to increase venous pressure significantly to produce venous ischemia locally and in remote areas of the brain. This is seen most often with large AVMs in the territory of the MCA.

Large AVMs of the anterior circulation may be associated with a systolic and diastolic bruit (sometimes self-audible) over the eye, forehead, or neck and a bounding carotid pulse. Headache at the onset of AVM rupture is not generally as explosive as with aneurysmal rupture. MRI is better than CT for diagnosis, although contrast CT scanning sometimes detects calcification of the AVM.

Surgical treatment of symptomatic AVMs, often with preoperative embolization to reduce operative bleeding, is usually indicated for accessible lesions. Stereotaxic radiation, an alternative to surgery, can produce a slow sclerosis of arterial channels over 2 to 3 years.

Patients with asymptomatic AVMs have about a 2% per year risk for hemorrhage. Several angiographic features of the AVM can be used to help predict future bleeding risk. Paradoxically, smaller lesions seem to have a higher hemorrhage rate. The mortality rate with each bleed is about 15%. Given this natural history, surgical treatment is probably indicated for most AVMs that can be treated with reasonable surgical risk.

Venous anomalies are the result of development of anomalous cerebral, cerebellar, or brainstem drainage. These structures, unlike AVMs, are functional venous channels. They are of little clinical significance and should be ignored if found incidentally on brain imaging studies. Surgical resection of these anomalies may result in venous infarction and hemorrhage. Venous anomalies may be associated with cavernous malformations (see below), which do carry some bleeding risk. If resection of a cavernous malformation is attempted, the venous anomaly should not be disturbed.

Capillary telangiectasias are true capillary malformations that often form extensive vascular networks through an otherwise normal brain structure. The pons and deep cerebral white matter are typical locations, and these capillary malformations can be seen in patients with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber) syndrome. If bleeding does occur, it rarely produces mass effect or significant symptoms. No treatment options exist.

ACQUIRED VASCULAR LESIONS *Cavernous angiomas* are tufts of capillary sinusoids that form within the deep hemispheric white matter and brainstem with no normal intervening neural structures. The pathogenesis is unclear. Familial cavernous angiomas have been mapped to several different chromosomal loci; the gene responsible for the 7q-linked form encodes a protein that interacts with a member of the RAS family of GTPases. Cavernous angiomas are typically <1 cm in diameter and are often associated with a venous anomaly. Bleeding is usually of small volume, causing slight mass effect only. The bleeding risk for single cavernous malformations is 0.7 to 1.5% per year and may be higher for patients with prior clinical hemorrhage or multiple malformations. Seizures may occur if the malformation is located near the cerebral cortex. Surgical resection eliminates bleeding risk and may reduce seizure risk, but it is reserved for those malformations that form near the brain surface. Radiation treatment has not been shown to be of benefit.

Dural arteriovenous fistulas are acquired connections usually from a dural artery to a dural sinus. Patients may complain of a pulse-synchronous cephalic bruit ("pulsatile tinnitus") and headache. Depending on the magnitude of the shunt, venous pressures may rise high enough to cause cortical ischemia or venous hypertension and hemorrhage. Surgical and endovascular techniques are usually curative. These fistulas may form because of trauma, but most are idiopathic. There is an association between fistulas and dural sinus thrombosis. Fistulas have been observed to appear months to years following venous sinus thrombosis, suggesting that angiogenesis factors elaborated from the thrombotic process may cause these anomalous connections to form. Alternatively, dural arteriovenous fistulas can produce venous sinus occlusion over time, perhaps from the high pressure and high flow through a venous structure.

350 ALZHEIMER'S DISEASE AND OTHER DEMENTIAS

Thomas D. Bird, Bruce L. Miller

Dementia, a syndrome of many causes, affects >4 million Americans and results in a total health care cost of $>\$100$ billion annually. It is defined as an acquired deterioration in cognitive abilities that impairs the successful performance of activities of daily living. Memory is the most common cognitive ability lost with dementia; 10% of persons over age 70 and 20 to 40% of individuals over age 85 have clinically identifiable memory loss. In addition to memory, other mental faculties are also affected in dementia, such as language, visuospatial ability, calculation, judgment, and problem solving. Neuropsychiatric and social deficits develop in many dementia syndromes resulting in depression, withdrawal, hallucinations, delusions, agitation, insomnia, and disinhibition. The common forms of dementia are progressive, but some dementing illnesses are static or fluctuate dramatically from day to day.

MEMORY

Memory is a complex function of the brain that uses several storage buffers of differing capacity and duration. It can be divided into three major types: working, episodic, and long-term, or remote, memory. Working memory lasts for <30 s and has a limited storage capacity. Normal individuals can hold seven (plus or minus two) bits of information in working memory where these bits can be manipulated and

either discarded or retained as a more permanent memory store. Working memory is highly vulnerable to distraction, requiring attention and vigilance for its maintenance. It is tested by asking the patient to recall digits backwards. The reticular activating system and prefrontal and parietal lobe networks are activated during working memory tasks.

Episodic memory lasts for minutes to many months or even years and binds information about "what," "where," and "when." Normal individuals lay down multiple episodic memories throughout the day, which allow them to move through life connected to previous experiences. On entering this memory buffer, information undergoes a process of consolidation. Significant events are more likely to be consolidated as a more permanent trace. Episodic memory is commonly tested by asking a patient to recall three words after 3 to 5 min. Other simple ways to test episodic memory include determining whether patients can remember what they had for breakfast, how they got to the office, or who examined them earlier in the day. The hippocampal complex is critical for episodic memory, and physiologic changes in synapses in this brain region accompany new episodic memories. Eventually episodic memories become independent of the hippocampal complex and move to neocortex.

Remote, or long-term, memory stores information lasting weeks to a lifetime and contains most of our personal experiences and knowledge. Some information appears to be stored accurately for an indefinite time, whereas other items fade or become distorted. More permanent stores of words, dates, historic facts, or names require the left anterior temporal cortex. The specific localization of other types of long-term memories is unknown, although the neocortex appears to be particularly important. Animal experiments have shown that long-term memory requires new protein synthesis, and the stabilization process probably involves physical changes at neuronal synapses.

Memory function includes *registration* (encoding or acquisition), *retention* (storage or consolidation), *stabilization* (consolidation), and *retrieval* (decoding or recall). Registration and retrieval are conscious processes. The process of encoding is dependent upon the frontal lobes and hippocampal complex, while the process of retrieval requires the frontal lobes. The hippocampal complex is vulnerable to metabolic insults such as seizures, hypoglycemia, hypoxia, and neurodegenerative processes, which explains why episodic memory deficits are the most common cognitive deficits that follow these varied disorders.

Several additional terms for memory types are sometimes used. *Amnesia* is a term used to describe an impairment in memory function. *Semantic memory* contains unchanging facts, principles, associations, and rules (for example, the number of days in a week). Injury to the anterior temporal neocortex will lead to loss of semantic memory. *Declarative (explicit) memory* refers to facts about the world and past personal events that must be consciously retrieved to be remembered. Episodic memory is the prototypical declarative, or explicit, memory. *Procedural (implicit) memory* is involved in learning and retaining a skill or procedure such as riding a bicycle, getting dressed, or driving a car. Abilities stored in procedural memory become automatic and do not require conscious implementation.

Finally, the term *executive function* refers to mental activity involved in planning, initiating, and regulating behavior. It is considered the central organizing function of the brain that results in systematic, goal-directed activity and is highly dependent upon working memory. Executive functions are active in situations where reflex or automatic behavior is not adequate. Executive functions are presumed to involve the frontal lobes (Chap. 23). Deficits in executive function occur frequently in patients with dementia.

FUNCTIONAL ANATOMY OF THE DEMENTIAS

Dementia results from disorders of cerebral neuronal circuits and is a result of the total quantity of neuronal loss combined with the specific location of such loss (Chap. 23). Episodic memory requires the dorsomedial nucleus of the thalamus (damaged in Korsakoff's syndrome due to thiamine deficiency) and the medial temporal lobes. Unilateral temporal lobe lesions produce mild to moderate amnesia for either verbal or nonverbal material, while bilateral lesions produce a severe anterograde learning disorder, i.e., an inability to store new memories, often with retained ability to recall old ones.

The components of the medial temporal lobe memory system include the hippocampus and adjacent cortex, including the entorhinal, perirhinal, and parahippocampal regions (Fig. 350-1). This includes a circular pathway of neurons from the entorhinal cortex to the dentate gyrus, CA3 and CA1 neurons of the hippocampus to the subiculum, and back to the entorhinal cortex; this pathway is heavily damaged in Alzheimer's disease (AD). This system is fast, has limited capacity, and performs a crucial function at the time of learning and establishing declarative memory and semantic associations. Its role continues after learning during a lengthy period of reorganization and consolidation, whereby memory stored in neocortex eventually becomes independent of the medial temporal lobe memory system. This process, by which the burden of long-term (permanent) memory storage is gradually assumed by neocortex, ensures that the medial temporal lobe system is constantly available for the acquisition of new information.

Functional imaging studies indicate that learning and memory involve many of the same regions of the cortex that process sensory information and control motor output. The forms of perceptual and motor learning that can occur without conscious recollections are mediated in part by contractions and expansions of representations in the sensory and motor cortex. One study, for example, has shown that the cortical representation of the fingers of the left hand of musical string players is larger than that in controls, suggesting that the representation of different parts of the body in the primary somatosensory cortex of humans depends on use and changes to conform to the current needs and experiences of the individual. Discrete cortical regions exist in the anterior temporal lobes in which object knowledge (such as words related to color, animals, tools, or action) is organized as a distributed system. Here the attributes of an object are stored close to the regions of the cortex that mediate perception of those attributes.

Procedural (implicit) memory appears to involve centers outside the hippocampus such as amygdala, basal ganglia, cerebellum, and sensory cortex. Different frontal regions are activated for different kinds of memory storage. Functional magnetic resonance imaging (MRI) studies show that the magnitude of focal activation in left prefrontal-temporal regions and right prefrontal-bilateral parahippocampal regions predicts how well verbal or visual stimuli, respectively, will be remembered.

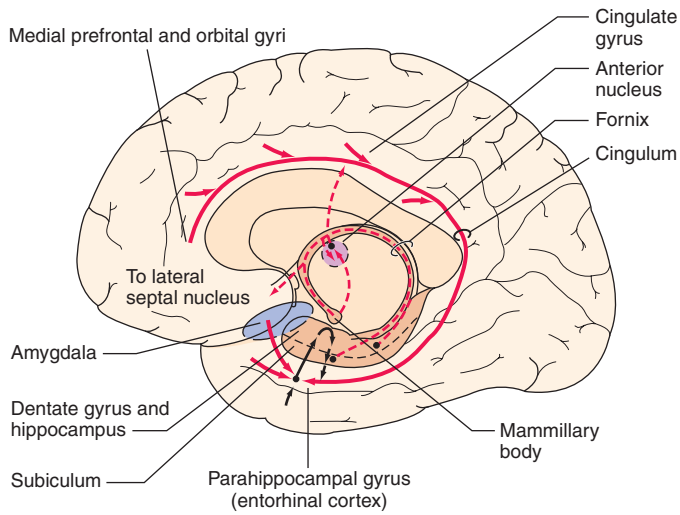

FIGURE 350-1 The principal connections of the hippocampus. Afferent connections (*red arrows*) from the cingulate gyrus (cortical association fibers) and amygdala converge on the entorhinal cortex (part of the parahippocampal gyrus) and connect with the hippocampus via a polysynaptic circuit (*black arrows*) from dentate to CA3, CA1, and subiculum neurons with output back to the entorhinal cortex. Efferent connections (*broken arrows*) are principally via the fornix to the anterior nucleus of the thalamus, septal nucleus, and mammillary body.

The cholinergic system plays an important role in memory, and anticholinergic agents such as atropine and scopolamine interfere with memory. Choline acetyltransferase (the enzyme catalyzing the formation of acetylcholine) and cholinergic receptors are known to be deficient in the cortex of patients with AD. The brains of AD patients show severe neuronal loss in the nucleus basalis of Meynert, the major source of cholinergic input to the cerebral cortex. These findings form the basis for the use of cholinesterase inhibitors in the treatment of AD, with benefits thought to arise from increased available levels of acetylcholine. Behavior and mood are modulated by noradrenergic, serotonergic, and dopaminergic pathways, and norepinephrine has been shown to be reduced in the brainstem locus coeruleus in AD. Neurotrophins (Chap. 345) are also postulated to play a role in memory in part by preserving cholinergic neurons.

Long-term potentiation (LTP), which refers to a long-lasting enhancement of synaptic transmission resulting from repetitive stimulation of excitatory synapses, is presumed to be involved in memory acquisition and storage. LTP occurs in the hippocampus and is mediated by *N*-methyl-D-aspartate (NMDA) receptors as well as cyclic AMP-responsive element-binding (CREB) protein. Dementias have anatomically specific patterns of neuronal degeneration, which dictate the clinical symptomatology. AD begins in the entorhinal cortex, spreads to the hippocampus, then moves to posterior temporal and parietal neocortex and eventually causes a relatively diffuse degeneration throughout the cerebral cortex. Multi-infarct dementia is associated with focal damage in a random patchwork of cortical regions. Diffuse white matter damage may disrupt intracerebral connections and cause dementia syndromes similar to those associated with leukodystrophies, multiple sclerosis, and Binswanger's disease (see below). Subcortical structures including the caudate, putamen, thalamus, and substantia nigra also modulate cognition and behavior in ways that are not yet well understood. AD primarily presents as memory loss and is often associated with aphasia or other disturbance of language. In contrast, patients with frontal lobe or subcortical dementias such as frontotemporal dementia (FTD) or Huntington's disease are less likely to begin with memory and language problems and more likely to have difficulties with attention, judgment, awareness, and behavior.

Lesions of specific cortical-subcortical pathways will have important effects on behavior (Chap. 23). The dorsolateral prefrontal cortex has connections with the dorsolateral caudate, globus pallidus, and thalamus. Lesions of these pathways result in poor organization and planning, decreased cognitive flexibility, and impaired judgment. The lateral orbital frontal cortex connects with the ventromedial caudate, globus pallidus, and thalamus. Lesions of these connections cause irritability, impulsiveness, and distractibility. The anterior cingulate cortex connects with the nucleus accumbens, globus pallidus, and thalamus. Interruption of these connections produces apathy and poverty of speech or even akinetic mutism.

TABLE 350-1 Differential Diagnosis of Dementia

MOST COMMON CAUSES OF DEMENTIA	
Alzheimer's disease	Alcoholism[a]
Vascular dementia	Parkinson's disease
Multi-infarct	Drug/medication intoxication[a]
Diffuse white matter disease (Binswanger's)	
LESS COMMON CAUSES OF DEMENTIA	
Vitamin deficiencies	Toxic disorders
Thiamine (B_1): Wernicke's encephalopathy[a]	Drug, medication, and narcotic poisoning[a]
B_{12} (pernicious anemia)[a]	Heavy metal intoxication[a]
Nicotinic acid (pellagra)[a]	Dialysis dementia (aluminum)
Endocrine and other organ failure	Organic toxins
Hypothyroidism[a]	Psychiatric
Adrenal insufficiency and Cushing's syndrome[a]	Depression (pseudodementia)[a]
Hypo- and hyperparathyroidism[a]	Schizophrenia[a]
Renal failure[a]	Conversion reaction[a]
Liver failure[a]	Degenerative disorders
Pulmonary failure[a]	Huntington's disease
Chronic infections	Pick's disease
HIV	Dementia with Lewy bodies
Neurosyphilis[a]	Progressive supranuclear palsy (Steel-Richardson syndrome)
Papovavirus (progressive multifocal leukoencephalopathy)	Multisystem degeneration (Shy-Drager syndrome)
Prion (Creutzfeldt-Jakob and Gerstmann-Sträussler-Scheinker diseases)	Hereditary ataxias (some forms)
Tuberculosis, fungal, and protozoal[a]	Motor neuron disease [amyotrophic lateral sclerosis (ALS); some forms]
Sarcoidosis[a]	Frontotemporal dementia
Whipple's disease[a]	Cortical basal degeneration
Head trauma and diffuse brain damage	Multiple sclerosis
Dementia pugilistica	Adult Down's syndrome with Alzheimer's
Chronic subdural hematoma[a]	ALS–Parkinson's–Dementia complex of Guam
Postanoxia	Miscellaneous
Postencephalitis	Vasculitis[a]
Normal-pressure hydrocephalus[a]	CADASIL
Neoplastic	Acute intermittent porphyria[a]
Primary brain tumor[a]	Recurrent nonconvulsive seizures[a]
Metastatic brain tumor[a]	Additional conditions in children or adolescents
Paraneoplastic limbic encephalitis	Hallervorden-Spatz disease
	Subacute sclerosing panencephalitis
	Metabolic disorders (e.g., Wilson's and Leigh's diseases, leukodystrophies, lipid storage diseases, mitochondrial mutations)

[a] Potentially reversible dementia.

THE CAUSES OF DEMENTIA

The many causes of dementia are listed in Table 350-1. The frequency of each condition depends on the age group under study, the access of the group to medical care, the country of origin, and perhaps racial or ethnic background. AD is the most common cause of dementia in western countries, representing more than half of demented patients. Vascular disease is the second most common cause of dementia in the United States, representing 10 to 20%. In populations with limited access to medical care, where vascular risk factors are undertreated, the prevalence of vascular dementia can be much higher. Dementia associated with Parkinson's disease is the next most common category, and in many instances these patients suffer from dementia with Lewy bodies (DLB). Chronic intoxications including those resulting from alcohol and prescription drugs are an important, often treatable cause of dementia. Other disorders listed in the table are uncommon but important because many are reversible. The classification of dementing illnesses into two broad groups of reversible and irreversible disorders is a useful approach to the differential diagnosis of dementia.

In a study of 1000 persons attending a memory disorders clinic, 19% had a potentially reversible cause of the cognitive impairment and 23% had a potentially reversible concomitant condition. The three most common potentially reversible diagnoses were depression, hydrocephalus, and alcohol dependence.

The single strongest risk factor for dementia is increasing age. The prevalence of disabling memory loss increases with each decade over age 50 and is associated most often with the microscopic changes of AD at autopsy. Slow accumulation of mutations in neuronal mitochondria is also hypothesized to contribute to the increasing prevalence of dementia with age. Nonetheless, some centenarians have

TABLE 350-2 *Evaluation of the Patient with Dementia*

Routine Evaluation	*Optional Focused Tests*	*Occasionally Helpful Tests*
History	HIV	EEG
Physical examination	Chest x-ray	Parathyroid function
Laboratory tests	Lumbar puncture	Adrenal function
Thyroid function (TSH)	Liver function	Urine heavy metals
Vitamin B_{12}	Renal function	RBC sedimentation rate
Complete blood count	Urine toxin screen	Angiogram
Electrolytes	Psychometric testing	Brain biopsy
VDRL	Apolipoprotein E	SPECT
CT/MRI		

DIAGNOSTIC CATEGORIES *Reversible Causes*	*Irreversible/Degenerative Dementias*	*Psychiatric Disorders*
Examples	Examples	Depression
Hypothyroidism	Alzheimer's	Schizophrenia
Thiamine deficiency	Frontotemporal dementia	Conversion reaction
Vitamin B_{12} deficiency	Huntington's	
Normal-pressure hydrocephalus	Dementia with Lewy bodies	
Chronic infection	Multi-infarct	
Brain tumor	Leukoencephalopathies	
Drug intoxication	Parkinson's	

Associated Treatable Conditions	
Depression	Agitation
Seizures	Caregiver "burnout"
Insomnia	Drug side effects

intact memory function and no evidence of clinically significant dementia. Whether dementia is an inevitable consequence of normal human aging remains controversial.

Subtle cumulative decline in episodic memory is a natural part of aging. This frustrating experience, often the source of jokes and humor, is referred to as *benign forgetfulness of the elderly*. Benign means that it is not so progressive or serious that it impairs reasonably successful and productive daily functioning, although the distinction between benign and more significant memory loss can be difficult to make. At age 85 years the average person is able to remember approximately one-half the number of words that he or she could at age 18. A mild cognitive problem that has subtly begun to interfere with daily activities is referred to as *mild cognitive impairment* (MCI). A sizeable proportion of persons with MCI will progress to frank dementia, usually caused by AD. The conversion rate from MCI to AD is ~12% per year. It remains unclear why some individuals show progression and others do not. Factors that predict progression from MCI to AD include a memory deficit >1.5 standard deviations from the norm, family history of dementia, the presence of an apolipoprotein ε4 (Apo ε4) allele, and small hippocampal volumes.

The major degenerative dementias include AD, FTD and related disorders, DLB, and prion disorders including Creutzfeldt-Jakob disease (CJD). These disorders are all associated with the abnormal aggregation of a specific protein: Aβ_{42} in AD, tau in FTD, α-synuclein in DLB, and PrP in CJD.

APPROACH TO THE PATIENT

(Tables 350-1 and 350-2) Three major issues should be kept in the forefront: (1) What is the most accurate diagnosis? (2) Is there a treatable or reversible component to the dementia? (3) Can the physician help to alleviate the burden on caregivers? The major degenerative dementias can usually be distinguished by the initial symptoms; neuropsychological, neuropsychiatric, and neurologic findings; and neuroimaging features (Table 350-3).

History The history should focus on the onset, duration, and tempo of progression of the dementia. An acute or subacute onset of confusion may represent delirium and should trigger the search for intoxication, infection, or metabolic derangement. An elderly person with slowly progressive memory loss over several years is likely to suffer from AD. Nearly 75% of AD patients begin with memory symptoms, but other early symptoms include difficulty with managing money, driving, shopping, following instructions, finding words, or navigating. A change in personality, disinhibition, gain of weight, or food obsession suggests FTD, not AD. FTD is also suggested by the finding of apathy, loss of executive function, progressive abnormalities in speech, or by a relative sparing of memory or spatial abilities. The diagnosis of DLB is suggested by the early presence of visual hallucinations, parkinsonism, delirium, rapid-eye-movement (REM) sleep disorder (the merging of dream states into wakefulness), or *Capgras syndrome*, the delusion that a familiar person has been replaced by an impostor.

A history of sudden stroke with an irregular stepwise progression suggests multi-infarct dementia. Multi-infarct dementia is also commonly seen in the setting of hyper-

TABLE 350-3 *Clinical Differentiation of the Major Dementias*

Disease	*Initial Symptom*	*Mental Status*	*Neuropsychiatry*	*Neurology*	*Imaging*
AD	Memory loss	Episodic memory loss	Initially normal	Initially normal	Entorhinal and hippocampal atrophy
Vascular	Often sudden; variable initial symptoms; apathy, falls, focal weakness	Frontal/executive cognitive slowing; can spare memory	Apathy, delusions, anxiety	Usually motor slowing, spasticity; can be normal	Cortical and/or subcortical infarctions, confluent white matter disease
FTD	Apathy; reduced judgment/ insight/speech/ language; hyperorality	Frontal/executive, language; spares drawing	Apathy, disinhibition, hyperorality, euphoria, depression	Vertical gaze palsy, axial rigidity, dystonia, alien hand (due to PSP/CBD overlap)	Frontal and/or temporal atrophy; spares posterior parietal lobe
DLB	Visual hallucinations, REM-sleep disorder, delirium, Capgras syndrome, parkinsonism	Drawing and frontal/ executive; spares memory; delirium prone	Visual hallucinations, depression, sleep disorder, delusions	Parkinsonism	Posterior parietal; hippocampi larger than in AD
Prion	Dementia, mood changes, anxiety, movement disorder	Variable, frontal/ executive, focal cortical, memory	Depression, anxiety	Myoclonus, rigidity, parkinsonism	Cortical ribboning and basal ganglia hyperintensities on diffusion/flare MRI

Note: AD, Alzheimer's disease; FTD, frontotemporal dementia; PSP, progressive supranuclear palsy; CBD, cortical basal degeneration; DLB, dementia with Lewy bodies; MRI, magnetic resonance imaging.

tension, atrial fibrillation, peripheral vascular disease, and diabetes. In patients suffering from cerebrovascular disease it can be difficult to determine whether the dementia is due to AD, multi-infarct dementia, or a mixture of the two. Rapid progression of the dementia in association with motor rigidity and myoclonus suggests a prion disease. Seizures may indicate strokes or neoplasm. Gait disturbance is commonly seen with multi-infarct dementia, Parkinson's disease, or normal-pressure hydrocephalus. Multiple sex partners or intravenous drug use should trigger a search for a central nervous system (CNS) infection, especially in persons with HIV. A history of recurrent head trauma could indicate chronic subdural hematoma, dementia pugilistica, or normal-pressure hydrocephalus. Alcoholism may suggest malnutrition and thiamine deficiency. A remote history of gastric surgery may result in loss of intrinsic factor and vitamin B_{12} deficiency. Certain occupations such as working in a battery or chemical factory might indicate heavy metal intoxication. A careful review of medications, especially of sedatives and tranquilizers, may raise the issue of chronic drug intoxication. A family history of dementia is found in Huntington's disease, familial AD, or familial FTD. Depressive signs such as insomnia or weight loss are often seen with pseudodementia due to depression, which can also be caused by the recent death of a loved one.

Physical and Neurologic Examination A thorough examination is essential to document the dementia, look for other signs of nervous system involvement, and search for clues of a systemic disease that might be responsible for the cognitive disorder. AD does not affect motor systems until late in the course. In contrast, FTD patients often develop axial rigidity, supranuclear gaze palsy, or features of amyotrophic lateral sclerosis (ALS). In DLB, initial symptoms may be the new onset of a parkinsonian syndrome (resting tremor, cogwheel rigidity, bradykinesia, and festinating gait) with the dementia following later, or vice-versa. Corticobasal degeneration (CBD) is associated with dystonia and alien hand (unilateral involuntary movements of the upper limb resembling purposeful actions) and with asymmetric motor deficits or myoclonus. A presentation with unexplained falls, axial rigidity, and gaze deficits suggests progressive supranuclear palsy (PSP). CJD is suggested by diffuse rigidity, an akinetic state, and myoclonus.

Hemiparesis or other focal neurologic deficits may occur in multi-infarct dementia or brain tumor. Dementia with a myelopathy and peripheral neuropathy suggests vitamin B_{12} deficiency. A peripheral neuropathy could also indicate an underlying vitamin deficiency or heavy metal intoxication. Dry cool skin, hair loss, and bradycardia suggest hypothyroidism. Confusion associated with repetitive stereotyped movements may indicate ongoing seizure activity. Hearing impairment or visual loss may produce confusion and disorientation misinterpreted as dementia. Such sensory deficits are common in the elderly.

Cognitive and Neuropsychiatric Examination Brief screening tools such as the mini-mental status examination (MMSE) help to confirm the presence of cognitive impairment and to follow the progression of dementia (Table 350-4). The MMSE is an easily administered 30-point test of cognitive function and contains tests of orientation, working and episodic memory, language comprehension, naming, and copying. In most patients with MCI and some with clinically apparent AD, the MMSE may be normal and a more rigorous set of neuropsychological tests will be required. Additionally, when the etiology for the dementia syndrome remains in doubt, a specially tailored evaluation should be performed that includes tasks of working and episodic memory, frontal executive tasks, language, visuospatial function, and perception. In AD the deficits involve episodic memory, category generation ("name as many animals as you can in one minute"), and visuoconstructive ability. Deficits in verbal or visual episodic memory are often the first neuropsychological abnormalities seen with AD, and tasks that require the patient to recall a long list of words or pictures after a predetermined

delay will demonstrate deficits in most AD patients. In FTD the earliest deficits often involve frontal executive function or language (speech or naming). DLB patients have more severe deficits in visuospatial function but do better on episodic memory tasks than do patients with AD. Patients with vascular dementia often demonstrate a mixture of frontal executive and visuospatial deficits. In delirium, deficits tend to occur in the areas of attention, working memory, and frontal tasks.

A functional assessment should also be performed. The physician should determine the day-to-day impact of the disorder on the patient's memory, community affairs, hobbies, judgment, dressing, and eating. Knowledge of the patient's day-to-day function will help to organize a therapeutic approach with the family.

Neuropsychiatric assessment is important for diagnosis, prognosis, and treatment. In the early stages of AD mild depressive features, social withdrawal, and denial of illness are the most prominent psychiatric changes. However, patients often maintain their social skills into the middle stages of the illness when delusions, agitation, and sleep disturbance become more common. In FTD dramatic personality change, apathy, overeating, repetitive compulsions, disinhibition, euphoria, and loss of empathy are common. DLB shows visual hallucinations, delusions related to personal identity, and day-to-day fluctuation. Vascular dementia can present with psychiatric symptoms such as depression, delusions, disinhibition, or apathy.

Laboratory Tests The choice of laboratory tests in the evaluation of dementia is not straightforward. A reversible or treatable cause must not be missed, yet no single etiology is common; thus a screen must employ multiple tests, each of which has a low yield. Cost/benefit ratios are difficult to assess, and many laboratory screening algorithms for dementia discourage multiple tests. Nevertheless, even a test with only a 1 to 2% positive rate is probably worth undertaking if the alternative is missing a treatable cause of dementia. The algorithm in Table 350-2 lists most screening tests for dementia. Recently the American Academy of Neurology recommended the routine measurement of thyroid function tests, a vitamin B_{12} level, and a neuroimaging study [computed tomography (CT) or MRI].

Neuroimaging studies will identify primary and secondary ne-

oplasms, locate areas of infarction, reveal subdural hematomas, and suggest normal-pressure hydrocephalus or diffuse white matter disease. They also lend support to the diagnosis of AD, especially if there is hippocampal atrophy in addition to diffuse cortical atrophy. Focal frontal and/or anterior temporal atrophy suggest FTD. There is no specific pattern yet determined for DLB, although these patients tend to have less hippocampal atrophy than is seen in AD. Diffusion-weighted MRI will detect abnormalities in the cortical-ribbon and basal ganglia in the vast majority of patients with CJD. Large white matter abnormalities correlate with a vascular etiology for dementia. The role of functional imaging in the diagnosis of dementia is still under study. Single photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning reveal temporal-parietal hypoperfusion or hypometabolism in AD, and frontotemporal hypoperfusion or hypometabolism in FTD, but most of these changes reflect atrophy. Recently, amyloid imaging has shown promise for the diagnosis of AD. Similarly, MRI perfusion and brain activation studies using functional MRI are under study as diagnostic tools.

Lumbar puncture need not be done routinely in the evaluation of dementia but is indicated if CNS infection is a serious consideration. Cerebrospinal fluid (CSF) levels of tau protein are increased and $A\beta_{42}$ amyloid decreased in some AD patients; however, the sensitivity and specificity of these measures are not sufficiently high to warrant routine measurement. Formal psychometric testing is not necessary in every patient but helps to document the severity of dementia, suggest psychogenic causes, and provide a semiquantitative method for following the disease course. An electroencephalogram (EEG) is rarely helpful except to suggest CJD (repetitive bursts of diffuse high-voltage sharp waves) or an underlying nonconvulsive seizure disorder (epileptiform discharges). Brain biopsy (including meninges) is not advised except to diagnose vasculitis, potentially treatable neoplasms, unusual infections, or systemic disorders such as vasculitis or sarcoid or in young persons where the diagnosis is uncertain. Angiography should be considered when cerebral vasculitis is a possible cause of the dementia.

SPECIFIC DEMENTIAS

ALZHEIMER'S DISEASE AD is the most common cause of dementia in western countries. Approximately 10% of all persons over the age of 70 have significant memory loss, and in more than half the cause is AD. AD can occur, however, in any decade of adulthood. The annual cost of caring for a single AD patient in an advanced stage of the disease is estimated at $50,000. The disease also exacts a heavy emotional toll on family members and caregivers. AD most often presents with subtle onset of memory loss followed by a slowly progressive dementia that has a course of several years. Pathologically there is diffuse atrophy of the cerebral cortex with secondary enlargement of the ventricular system. Microscopically there are neuritic plaques containing $A\beta$ amyloid, silver-staining neurofibrillary tangles (NFTs) in neuronal cytoplasm, and accumulation of $A\beta$ amyloid in arterial walls of cerebral blood vessels. The identification of four different susceptibility genes has provided a foundation for rapid progress in understanding the biologic basis of AD.

Clinical Manifestations The cognitive changes with AD tend to follow a characteristic pattern, beginning with memory impairment and spreading to language and visuospatial deficits. However, ~20% of AD patients present with nonmemory complaints such as word-finding, organizational, or navigational difficulty. In the early stages of the disease, the memory loss may go unrecognized or may be ascribed to benign forgetfulness. Once the memory loss begins to affect day-to-day activities or falls to <1.5 standard deviations from normal on standardized memory tasks, the disease is defined as MCI. Slowly the cognitive problems begin to interfere with daily activities, such as keeping track of finances, following instructions on the job, driving, shopping, and housekeeping. Some patients are unaware of these difficulties (*anosognosia*), while others have considerable insight. Change of environment may be bewildering, and the patient may become lost on walks or while driving an automobile. In the middle stages of AD, the patient is unable to work, is easily lost and confused, and requires daily supervision. Social graces, routine behavior, and superficial conversation may be surprisingly retained. Language becomes impaired: first naming, then comprehension, and finally fluency. In some patients, *aphasia* is an early and prominent feature. Word-finding difficulties and circumlocution may be a problem even when formal testing demonstrates intact naming and fluency. *Apraxia* emerges and patients have trouble carrying out sequential motor tasks. Visuospatial deficits begin to interfere with dressing, eating, solving simple puzzles, and copying geometric figures. Patients may be unable to perform simple calculations or tell time.

In the late stages of the disease, some persons remain ambulatory but wander aimlessly. Loss of judgment, reason, and cognitive abilities occurs. Delusions are common, usually simple in quality, involving delusions of theft, infidelity, or misidentification. Approximately 10% of AD patients develop the Capgras syndrome, believing that a caregiver has been replaced by an impostor. In contrast to DLB where the Capgras syndrome is an early feature, in AD this syndrome emerges later in the course of the illness. Loss of inhibitions and aggression may alternate with passivity and withdrawal. Sleep-wake patterns are prone to disruption, and nighttime wandering becomes disturbing to the household. Some patients develop a shuffling gait, with generalized muscle rigidity associated with slowness and awkwardness of movement. Patients often look parkinsonian (Chap. 351) but rarely have tremor. In end-stage AD, patients become rigid, mute, incontinent, and bedridden. Help may be needed with the simplest tasks, such as eating, dressing, and toilet function. Hyperactive tendon reflexes may be noted. Myoclonic jerks (sudden brief contractions of various muscles or the whole body) may occur spontaneously or in response to physical or auditory stimulation. Myoclonus raises the possibility of a prion disease (Chap. 362), but the course of AD is much more prolonged. Generalized seizures may also occur. Often, death results from malnutrition, secondary infections, pulmonary emboli, or heart disease. The typical duration of AD is 8 to 10 years, but the course can range from 1 to 25 years. For unknown reasons, some AD patients show a steady downhill decline in function, while others have prolonged plateaus without major deterioration.

Diagnosis Early in the disease course, other etiologies of dementia should be excluded (see above). Neuroimaging studies (CT and MRI) do not show a single specific pattern with AD and may be normal early in the course of the disease. As AD progresses, diffuse cortical atrophy becomes apparent, and MRI scans show atrophy of the hippocampus (Fig. 350-2*A*, *B*). Functional imaging studies in AD reveal hypoperfusion or hypometabolism in the posterior temporal-parietal cortex (Fig. 350-2*C*, *D*). The EEG is normal or shows nonspecific slowing. Routine spinal fluid examination is also normal. The use of blood Apo ε genotyping is discussed under "Genetic Considerations" below.

Slowly progressive decline in memory and orientation, normal results on laboratory tests, and an MRI or CT scan showing only diffuse or posteriorly predominant cortical and hippocampal atrophy are highly suggestive of AD. A clinical diagnosis of AD, reached after careful evaluation, is confirmed at autopsy ~90% of the time, with misdiagnosed cases usually representing one of the other dementing disorders (Table 350-3).

Epidemiology The most important risk factors for AD are old age and a positive family history. The frequency of AD increases with each decade of adult life, reaching 20 to 40% of the population over the age of 85. A positive family history of dementia suggests a genetic cause of AD. Female gender may also be a risk factor independent of the greater longevity of women. Some AD patients have a past history of head trauma with concussion, but this appears to be a relatively minor risk factor. AD is more common in groups with lower educa-

tional attainment, but education influences test-taking ability, and it is clear that AD can affect persons of all intellectual levels. One study found that the capacity to express complex written language in early adulthood correlated with a decreased risk for AD. Numerous environmental factors, including aluminum, mercury, and viruses, have been proposed as causes of AD, but none has been demonstrated to play a significant role. Several studies suggest that the use of nonsteroidal anti-inflammatory agents is associated with a decreased risk of AD, but this has not been confirmed in large prospective studies. Vascular disease does not seem to be a direct cause of AD, but amyloid angiopathy can lead to ischemic infarctions or hemorrhages. Elevated homocysteine and cholesterol levels, hypertension, and insufficient exercise are all being explored as potential risk factors for AD.

Pathology The most severe pathology is usually found in the hippocampus, temporal cortex, and nucleus basalis of Meynert (lateral septum). The most important microscopic findings are neuritic "senile" plaques and NFTs. These lesions accumulate in small numbers during normal aging of the brain but occur in excess in AD. Neuritic plaques contain a central core that includes Aβ amyloid, proteoglycans, Apo ε4, α_1 antichymotrypsin, and other proteins. Aβ amyloid is a protein of 39 to 42 amino acids that is derived proteolytically from a larger transmembrane protein, amyloid precursor protein (APP), which has neurotrophic and neuroprotective activity. The normal function of Aβ amyloid is unknown. Soluble amyloid fibrils may represent the initial pathologic event in AD leading to formation of neuritic plaques. The plaque core is surrounded by the debris of degenerating neurons, microglia, and macrophages. The accumulation of Aβ amyloid in cerebral arterioles, termed *amyloid angiopathy*, may lead to cerebral lobar hemorrhages. NFTs are silver-staining, twisted neurofilaments in neuronal cytoplasm that represent abnormally phosphorylated tau protein and appear as paired helical filaments by electron microscopy. Tau is a microtubule-associated protein that may function to assemble and stabilize the microtubules that convey cell organelles, glycoproteins, and other important materials through the neuron. A hyperphosphorylated state of tau impairs its capacity to bind to microtubules. AD is also associated with decreased levels of several proteins and neurotransmitters in the cerebral cortex, especially acetylcholine, its synthetic enzyme choline acetyltransferase, and nicotinic cholinergic receptors. Reduction of acetylcholine may result from degeneration of cholinergic neurons in the nucleus basalis of Meynert that project to many areas of the cortex. There is also reduction in norepinephrine levels in brainstem nuclei such as the locus coeruleus.

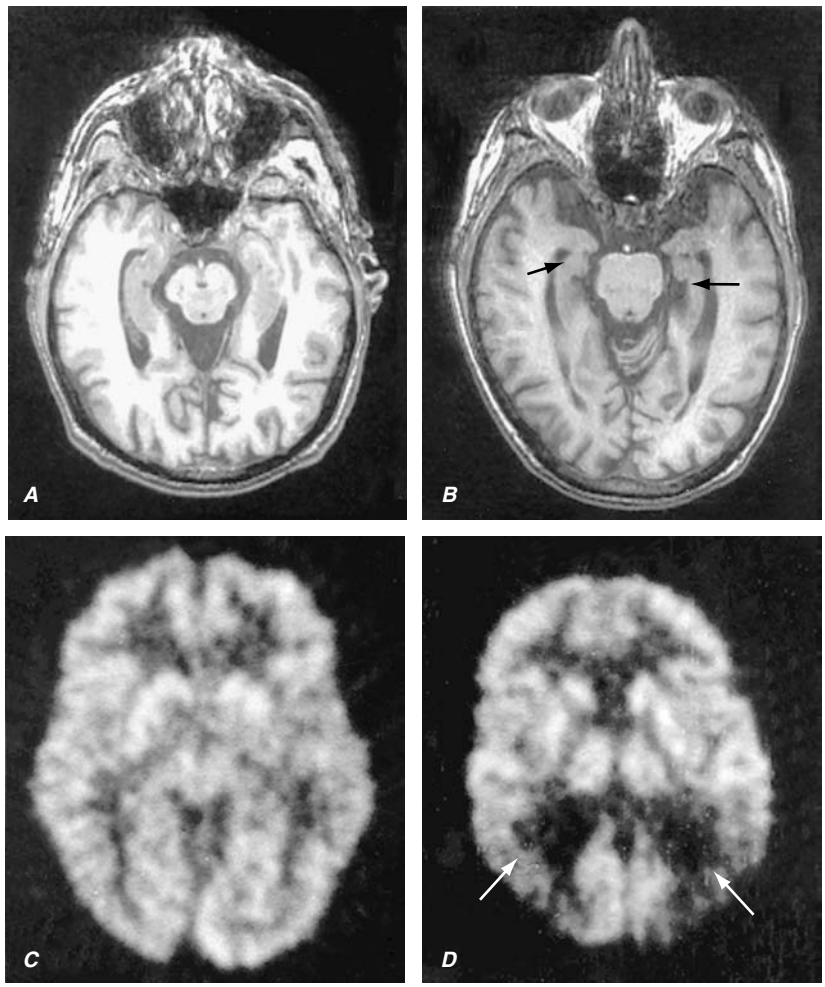

FIGURE 350-2 Alzheimer's disease. Axial T1-weighted MR images through the midbrain of a normal 86-year-old athletic individual (*A*) and a 77-year-old male (*B*) with Alzheimer's disease. Note that both individuals have prominent sulci and slight dilatation of the lateral ventricles. However, there is a reduction in the volume of the hippocampus of the patient with Alzheimer's disease (*arrows*) compared with that of the normal-for-age hippocampus of the older individual. Fluorodeoxyglucose positron emission tomographic scans of a normal control (*C*) and a patient with Alzheimer's disease (*D*). Note that the patient with Alzheimer's disease has decreased activity in the parietal lobes bilaterally (*arrows*), a typical finding in this condition. *(Images courtesy of TF Budinger, University of California.)*

GENETIC CONSIDERATIONS Several genes have been found to play important roles in the pathogenesis of at least some cases of AD. The first to be identified was the *APP* gene on chromosome 21. Point mutations in *APP* produce early-onset, autosomal dominant AD. APP is a membrane-spanning protein that is subsequently processed into smaller units, including Aβ amyloid that is deposited in neuritic plaques. Aβ peptide results from cleavage of APP by β- and γ-secretases (Fig. 350-3). Only very rare families with AD-producing *APP* mutations have been identified. However, adults with trisomy 21 (Down's syndrome) who survive beyond age 40 consistently develop a progressive dementia superimposed upon their baseline mental retardation and accompanied by typical neuropathologic changes of AD. Presumably the extra dose of the *APP* gene on chromosome 21 is the initiating cause of AD in adult Down's syndrome and results in an excess of cerebral amyloid.

Investigation of large families with multigenerational familial AD led to the discovery of two additional AD genes, termed the *presenilins*. Presenilin-1 (*PS-1*) is on chromosome 14 and encodes a protein called S182. Mutations in this gene cause an early-onset AD (onset before age 60 and often before age 50) transmitted in an autosomal dominant, highly penetrant fashion. More than 50 different mutations have been found in the *PS-1* gene in families from a wide range of ethnic backgrounds. Presenilin-2 (*PS-2*) is on chromosome 1 and encodes a protein called STM2. The two genes (*PS-1* and *PS-2*) are highly homologous and encode similar proteins that at first appeared to have seven transmembrane domains (hence the designation *STM*), but subsequent studies have suggested eight such domains with a ninth submembrane region. Both S182 and STM2 are cytoplasmic neuronal proteins that are widely expressed throughout the nervous system. They are homologous to a cell-trafficking protein, sel 12, found in the nematode *Coenorhabditis elegans*. Patients with mutations in these genes have elevated plasma levels of Aβ_{42} amyloid, suggesting a possible link between the presenilins and APP. There is evidence that *PS-1* is involved in the cleavage of APP at the γ-secretase site, and mutations in either gene (*PS-1* or *PS-2*) may disturb this function. Mutations in *PS-1* have thus far proved to be the most common cause of early-onset familial AD, representing 40 to 70% of this relatively rare syndrome. Mutations in *PS-1* tend to produce AD with an earlier age of onset (mean onset, 45 years) and a shorter, more rapidly pro-

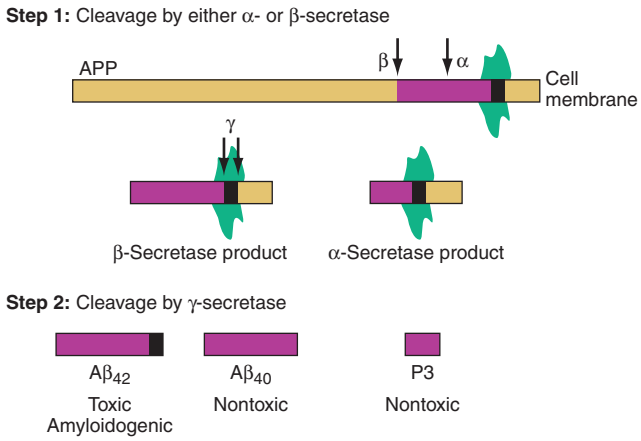

FIGURE 350-3 Amyloid precursor protein (APP) is catabolized by β-, α-, and γ-secretases. A key initial step is the digestion by either β-secretase (BASE) or α-secretase [(ADAM10 or ADAM17 (TACE))], producing smaller nontoxic products. Cleavage of the β-secretase product by γ-secretase (step 2) results in either the toxic $A\beta_{42}$ or the nontoxic $A\beta_{40}$ peptide; cleavage of the α-secretase product by γ-secretase produces the nontoxic P3 peptide. Excess production of $A\beta_{42}$ is a key initiator of cellular damage in Alzheimer's disease. Current AD research is focused on developing therapies designed to reduce accumulation of $A\beta_{42}$ by antagonizing β- or γ-secretases; promoting α-secretase; or clearing $A\beta_{42}$ that has already formed by use of specific antibodies.

gressive course (mean duration 6 to 7 years) than the disease caused by mutations in *PS-2* (mean onset 53 years; duration 11 years). Some carriers of uncommon *PS-2* mutations have had onset of dementia after the age of 70. Mutations in the *presenilins* are rarely involved in the more common sporadic cases of late-onset AD occurring in the general population. DNA testing for these uncommon mutations is now possible on a research basis, and mutation analysis of *PS-1* is commercially available. Such testing is likely to be positive only in early-onset familial cases of AD. Any testing of asymptomatic at-risk individuals should be done only in the context of formal genetic counseling.

A discovery of great importance has implicated the *Apo* ε gene on chromosome 19 in the pathogenesis of late-onset familial and sporadic forms of AD. *Apo* ε is involved in cholesterol transport (Chap. 335) and has three alleles, designated 2, 3, and 4. The Apo ε4 allele has a strong association with AD in the general population, including sporadic and late-onset familial cases. Approximately 40 to 65% of AD patients, compared to 24 to 30% of the nondemented Caucasian population, has at least one ε4 allele. Many AD patients have no ε4 allele, however, and individuals with ε4 may never develop AD. Nevertheless, it is clear that the Apo ε4 allele, especially in the homozygous 4/4 state, is an important risk factor for AD. It appears to act as a dose-dependent modifier of age of onset, with the earliest onset associated with the ε4/4 homozygous state. Apo ε may be involved with the clearance of amyloid; clearance is least efficient with Apo ε4. Apo ε is present in the neuritic amyloid plaques of AD, and it may be involved in NFT formation, because it binds to tau. Apo ε4 decreases neurite outgrowth in cultures of dorsal root ganglion neurons, perhaps indicating a deleterious role in the brain's response to injury. Some cognitively normal ε4 heterozygotes and homozygotes have also been found by PET to have decreased cerebral cortical metabolic rates, suggesting possible presymptomatic abnormalities compatible with the earliest stage of AD. Finally, there is suggestive evidence that the ε2 allele may be "protective."

Apo ε testing is not indicated as a predictive test for AD in normal persons. In demented persons who meet clinical criteria for AD, the finding of an ε4 allele increases the reliability of diagnosis; however, its absence does not eliminate the diagnosis of AD. Furthermore, all patients with dementia, including those with an ε4 allele, require a search for reversible causes of their cognitive impairment. The ε4 allele is not associated with FTD, DLB, or CJD.

Additional genes are also likely to be involved in AD. Potential candidate genes have been described on chromosomes 12 (α_2-macroglobulin) and 10.

TREATMENT

AD cannot be cured, and no highly effective drug exists. The focus is on judicious use of cholinesterase inhibitor drugs; symptomatic management of behavioral problems; and building rapport with the patient, family members, and other caregivers.

Tacrine (tetrahydroaminoacridine), donepezil, rivastigmine, and galantamine are approved by the U.S. Food and Drug Administration (FDA) for treatment of AD. Their pharmacologic action is presumed to be inhibition of cholinesterase, with a resulting increase in cerebral levels of acetylcholine. Controlled studies indicate that cholinesterase inhibitors improve caregiver ratings of patients' functioning and decrease the rate of decline in cognitive test scores over periods of up to 3 years. The average patient on an anticholinesterase compound maintains his or her MMSE score at 1 year, whereas a placebo-treated patient declines two to three points over the same time period. Nevertheless, these compounds are only modestly efficacious and offer little or no benefit in the late stages of AD. Tacrine is expensive and may cause hepatotoxicity, thus it is rarely used. Donepezil avoids liver toxicity and can be administered once daily (5 to 10 mg), offering an advantage over the other cholinesterase inhibitors.

In a prospective observational study, the use of estrogen-replacement therapy appeared to protect—by ~50%—against development of AD in women. This study appeared to confirm the results of two earlier case-controlled studies. However, a prospective placebo-controlled study of a combined estrogen-progesterone therapy for asymptomatic postmenopausal women appeared to increase the prevalence of dementia. This study has markedly dampened enthusiasm for hormone treatments for the prevention of dementia. Additionally, no benefit has been found in the treatment of established AD with estrogen.

In patients with moderately advanced AD, a prospective trial of the antioxidants selegiline (Chap. 351), α-tocopherol (vitamin E), or both slowed institutionalization and progression to death. Because vitamin E has less potential for toxicity than selegiline and is inexpensive, the doses used in this study of 1000 IU twice daily are offered to many patients with AD. However, the beneficial effects of vitamin E are likely to be small.

A controlled trial of an extract of *Ginkgo biloba* found modest improvement in cognitive function in subjects with AD and vascular dementia. This study requires confirmation before *Ginkgo biloba* is considered an effective treatment for dementia because there was a high subject dropout rate and no improvement on a clinician's judgment scale.

One study of AD subjects in the mid-stages of disease showed a slowing of progression over a 28-week course in patients treated with memantine, an NMDA receptor antagonist.

There has been considerable enthusiasm for a strategy involving vaccination against the Aβ protein. This approach was highly effective in mouse models of AD; amyloid deposits were effectively cleared, and cognitive decline was arrested. The mechanism appears to involve generation of antibodies against Aβ, which cross the blood-brain barrier and eliminate neuritic plaques. Unfortunately, in human trials this approach led to life-threatening meningoencephalitis in some vaccinated individuals. Modifications of the vaccine approach are under development.

Several retrospective studies have suggested that nonsteroidal anti-inflammatory agents and statins (HMG-CoA reductase inhibitors) may protect against dementia. Controlled prospective studies are under way. Other prospective studies designed to lower serum homocysteine levels are in progress, based upon epidemiologic studies that revealed an association of elevated homocysteine levels with dementia progression.

Mild to moderate depression, common in the early stages of AD, may respond to antidepressant or cholinesterase inhibitors. Selective serotonin reuptake inhibitors (SSRIs) are commonly used due to their

low anticholinergic side effects. Generalized seizures should be treated with an appropriate anticonvulsant, such as phenytoin or carbamazepine. For management of behavioral disturbances and suggestions for caregivers, see "General Symptomatic Treatment of the Patient with Dementia," below.

VASCULAR DEMENTIA Dementia associated with cerebrovascular disease can be divided into two general categories: multi-infarct dementia and diffuse white matter disease (also called subcortical arteriosclerotic encephalopathy, or Binswanger's disease). Cerebrovascular disease appears to be a more common cause of dementia in Asia than in Europe and North America. Individuals who have had several strokes may develop chronic cognitive deficits, commonly called *multi-infarct dementia*. The strokes may be large or small (sometimes lacunar) and usually involve several different brain regions. The occurrence of dementia appears to depend partly on the total volume of damaged cortex, but it is also more common in individuals with left-hemisphere lesions, independent of any language disturbance. Patients typically report a history of discrete episodes of sudden neurologic deterioration. Many multi-infarct dementia patients have a history of hypertension, diabetes, coronary artery disease, or other manifestations of widespread atherosclerosis. Physical examination usually shows focal neurologic deficits such as hemiparesis, a unilateral Babinski reflex, a visual field defect, or pseudobulbar palsy. The recurrent strokes result in a stepwise progression of disease. Neuroimaging studies show multiple areas of infarction. Thus, the history and neuroimaging findings differentiate this condition from AD. However, both AD and multiple infarctions are common and sometimes occur together. With normal aging, there is also an accumulation of amyloid in cerebral blood vessels, leading to a condition called *cerebral amyloid angiopathy of aging* (not associated with dementia), which predisposes older persons to hemorrhagic lobar stroke. AD patients with amyloid angiopathy may be at increased risk of cerebral infarction.

Some individuals with dementia are discovered on MRI to have bilateral subcortical white matter abnormalities, termed *diffuse white matter disease* (or leukoaraiosis), often occurring in association with lacunar infarctions (Fig. 350-4). The dementia may be insidious in onset and progress slowly, features that distinguish it from multi-infarct dementia, although other patients can show a stepwise deterioration more typical of multi-infarct dementia. Early symptoms are mild confusion, apathy, changes in personality, depression, psychosis, and memory or executive deficits. Marked difficulties in judgment and orientation and dependence on others for daily activities develop later. Euphoria, elation, depression, or aggressive behaviors are common. Both pyramidal and cerebellar signs may be present in the same patient. A gait disorder appears in at least half of affected patients. With advanced disease, urinary incontinence and dysarthria with or without other pseudobulbar features (e.g., dysphagia, emotional lability) are frequent. Seizures and myoclonic jerks appear in a minority of patients. This disorder is a microangiopathy due to occlusive disease of small penetrating cerebral arteries and arterioles. The patients usually, but not always, have a history of hypertension, but any disease causing stenosis of small cerebral vessels may be the critical underlying factor. The term *Binswanger's disease* should be used with caution, because it does not really identify a single entity.

FIGURE 350-4 Diffuse white matter disease (Binswanger's disease). Axial T2-weighted MR image through the lateral ventricles reveals multiple areas of abnormal high signal intensity involving the periventricular white matter as well as the corona radiata and lentiform nuclei (*arrows*). While seen in some individuals with normal cognition, this appearance is more pronounced in patients with dementia of a vascular etiology.

A dominantly inherited form of diffuse white matter disease is known as *cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy* (CADASIL). Clinically there is a progressive dementia developing in the fifth to seventh decades in multiple family members who may also have a history of migraine and recurrent stroke without hypertension. Skin biopsy may show characteristic dense bodies in the media of arterioles. The disease is caused by mutations in the notch 3 gene, and there is a commercially available genetic test. The frequency of this disorder is unknown, and there are no known treatments. Mitochondrial disorders can present with strokelike episodes and can selectively injure basal ganglia or cortex. Many such patients show other findings suggestive of a neurologic or systemic disorder such as ophthalmoplegia, retinal degeneration, deafness, myopathy, neuropathy, or diabetes. Diagnosis is difficult, but serum, and especially CSF, levels of lactate and pyruvate may be abnormal, and biopsy of affected tissue is often diagnostic.

Treatment of vascular dementia must be focused on the underlying causes, such as hypertension, atherosclerosis, and diabetes. Recovery of lost cognitive function is not likely to occur, although fluctuations with periods of improvement are common. Anticholinesterase compounds appear to be useful, as in AD (see above).

FRONTOTEMPORAL DEMENTIA AND RELATED DISORDERS ■ **Frontotemporal Dementia** FTD often begins between 50 and 70 years of age, and in this age group its prevalence may approach that of AD. Men and women are equally affected. Unlike AD, behavioral symptoms often predominate in the early stages of FTD. FTD can be sporadic or familial. The clinical heterogeneity is remarkable; patients demonstrate combinations of disinhibition, dementia, apraxia, parkinsonism, and motor neuron disease. In many families with an autosomal dominant pattern of inheritance, mutations in the tau gene on chromosome 17 have been found; in others, the dementia has been linked to 17 but does not involve tau. In still other families, chromosomes 3 and 9 have been linked to FTD.

Early symptoms are divided between cognitive, behavioral, and sometimes motor abnormalities, reflecting degeneration of the anterior frontal and temporal regions, basal ganglia, and motor neurons. Cognitive presentations typically spare memory and involve planning, judgment, or language. Poor business decisions, difficulty organizing work plans, and speech and language deficits emerge. Insight into the disorder is often severely impaired. Common behavioral deficits associated with FTD include apathy, disinhibition, weight gain, food fetishes, compulsions, and euphoria.

Findings at the bedside are dictated by the anatomic localization of the disorder. Asymmetric left frontal cases present with nonfluent aphasias, while left anterior temporal degeneration is characterized by loss of words and concepts related to language (semantic dementia). Nonfluent patients quickly progress to mutism, while those with semantic dementia develop features of visual agnosia, losing the ability to recognize faces, objects, and words (Chap. 23). Copying, calculating, and navigation often remain normal into later in the illness. These left hemisphere presentations of FTD have been called *primary pro-*

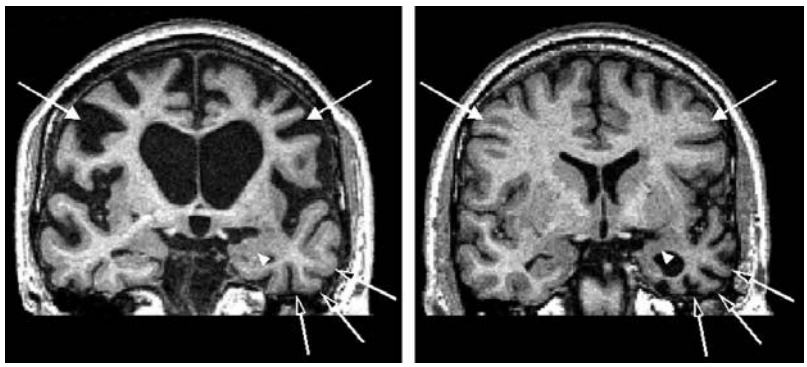

FIGURE 350-5 Frontotemporal dementia (FTD). Coronal MRI sections from one patient with frontally predominant FTD (*left*) and another with temporally predominant FTD (*right*). Prominent atrophy affecting the frontal gyri (*white arrows*) is present in frontally predominant FTD, particularly affecting the right frontal region; note also the thinning of the corpus callosum superior to the lateral ventricles. This patient presented with dysinhibition and antisocial behavior. In the temporally predominant patient, severe atrophy in the left temporal lobe (*open arrows*) and amygdala (*white arrowheads*) is present; this patient presented with progressive aphasia. *(Images courtesy of H Rosen and G Schauer, University of California at San Francisco.)*

gressive aphasia. In contrast, right frontal or temporal cases show profound alterations in social conduct with loss of empathy, disinhibition, and antisocial behaviors predominating. Memory and visuospatial skills are relatively spared in most FTD patients. There is a striking overlap between FTD and PSP, CBD, and motor neuron disease; ophthalmoplegia, dystonia, swallowing symptoms, and fasciculations are common at presentation of FTD or emerge during the course of the illness.

The anatomic hallmark of FTD is a marked atrophy of the temporal and/or frontal lobes, which can be visualized by neuroimaging studies (Figs. 350-5 and 350-6). The atrophy is sometimes remarkably asymmetric. A variety of pathologies have been associated with the clinical syndrome. The most consistent microscopic findings include gliosis and neuronal loss, and many cases show swollen or ballooned neurons containing cytoplasmic inclusions that in the majority of cases stain for tau. These aggregates sometimes resemble those found in PSP and CBD; tau is accepted as playing a major role in the pathogenesis of all three conditions. A toxic gain of function related to tau underlies the pathogenesis of many familial cases and is presumed to play a role in sporadic cases as well. Finally, many patients show no cellular inclusions, and the pathology remains bland with frontal and temporal gliosis, vacuolar changes, and neuronal loss the only evidence for disease. Nearly 80% of FTD patients show involvement of the basal ganglia at autopsy, and 15% go on to develop motor neuron disease, indicating the multisystem nature of this illness. Depletion of serotonergic and glutamatergic neurons is present in many patients. In contrast to AD, the cholinergic system is relatively spared in FTD.

Pick's disease was historically described as a progressive degenerative disorder of the anterior frontal and temporal neocortex accompanied by intracellular inclusions (*Pick's bodies*) that stain positive with silver (argyrophilic) and tau. Many of the τ-positive inclusions in FTD cases, however, are not labeled with silver stains. Although the nomenclature for these patients has remained controversial, the term *FTD* is increasingly used for all patients with frontotemporal degenerations, whereas Pick's disease is used to classify pathologically the subset of FTD cases that show Pick's bodies at autopsy.

The burden on caregivers of FTD patients is extremely high. Treatment is symptomatic, and there are currently no therapies known to slow progression or improve cognitive symptoms. Many of the behaviors that accompany FTD such as depression, hyperorality, compulsions, and irritability can be ameliorated with serotonin-modifying antidepressants. The co-association with motor disorders necessitates the careful use antipsychotics, which can exacerbate this problem.

Progressive Supranuclear Palsy PSP is a degenerative disease that usually begins with falls and a vertical supranuclear gaze paresis and progresses to symmetric rigidity and dementia. A stiff, unstable posture with hyperextension of the neck and slow gait with frequent falls is characteristic. Early in the disease, patients have difficulty with downgaze and lose vertical opticokinetic nystagmus on downward movement of a target. Although patients have very limited voluntary eye movements, oculocephalic reflexes (doll's head maneuver) are retained; thus, the eye movement disorder is supranuclear. Frequent unexplained and sometimes spectacular falls are common secondary to a combination of axial rigidity, inability to look down, and bad judgment. The dementia is similar to FTD with apathy, frontal/executive dysfunction, poor judgment, slowed thought processes, impaired verbal fluency, and difficulty with sequential actions and with shifting from one task to another. These cognitive deficits are usually evident at the time of presentation and often precede the motor syndrome.

PSP is often confused with Parkinson's disease. Dementia does occur in ~20% of Parkinson's disease patients, often secondary to DLB. Furthermore, the behavioral syndromes seen with DLB differ from those of PSP (see below). The occurrence of dementia in Parkinson's disease is more likely with increasing age, increasing severity of extrapyramidal signs, a long duration of disease, and the presence of depression. Cortical atrophy is usually present on brain imaging studies. Neuropathologically, there may be Alzheimer changes in the cortex (amyloid plaques and NFTs), neuronal Lewy body inclusions in both the substantia nigra and the cortex, or no specific microscopic changes other than gliosis and neuronal loss. →***PSP and Parkinson's disease are discussed in detail in Chap. 351.***

Cortical Basal Degeneration CBD is a slowly progressive dementing illness that typically presents with a unilateral onset with rigidity, dystonia, and apraxia of one arm and hand, sometimes called the "alien hand." Eventually the condition becomes bilateral and includes dysarthria, slow gait, action tremor, and dementia. →***CBD is discussed in detail in Chap. 351.***

DEMENTIA WITH LEWY BODIES This syndrome is characterized by visual hallucinations, parkinsonism, fluctuating alertness, and falls. Dementia can precede or follow the appearance of parkinsonism. DLB may present in a patient with longstanding Parkinson's disease without cognitive impairment who slowly develops dementia associated with visual hallucinations, parkinsonism, and fluctuating alertness. In other patients the dementia and neuropsychiatric syndrome precede the parkinsonism. DLB patients are highly susceptible to metabolic perturbations, and in some the first manifestation of illness is a delirium,

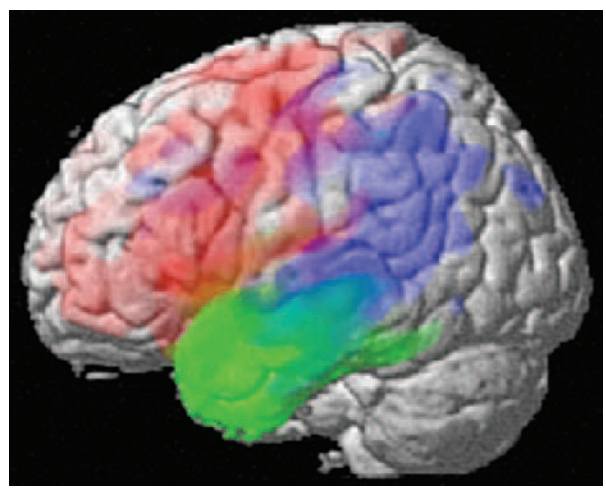

FIGURE 350-6 Voxel-based morphometry (VBM) analysis showing differing patterns of brain atrophy in the frontal variant of frontotemporal dementia (red), temporal variant of frontotemporal dementia (green), and Alzheimer's disease (blue). This technique allows comparison of MRI gray matter volumes between groups of subjects. *(Image courtesy of Marilu Gorno-Tempini, University of California at San Francisco.)*

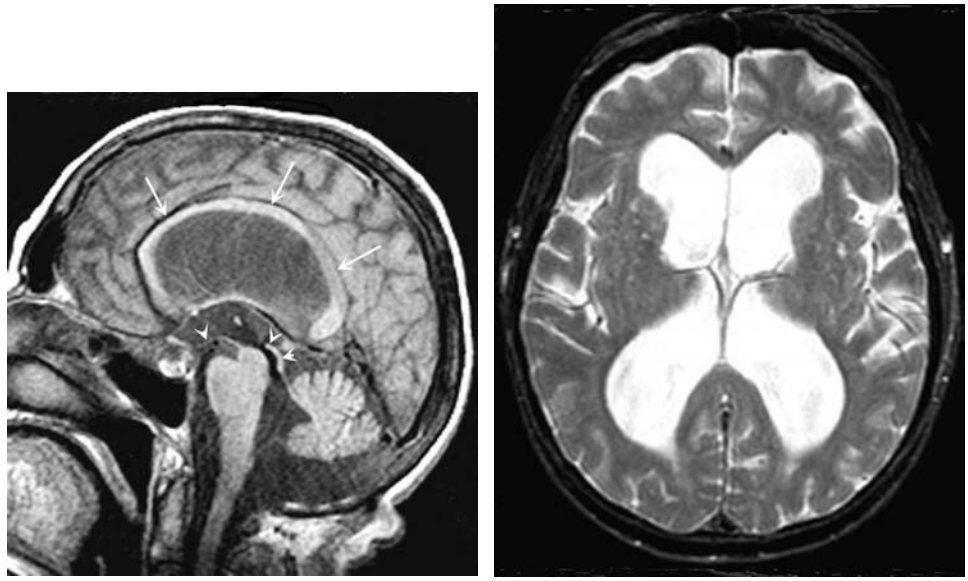
often precipitated by an infection or other systemic disturbance. A delirium induced by L-dopa, prescribed for parkinsonian symptoms attributed to Parkinson's disease, may be the initial clue that the correct diagnosis is DLB. Even without an underlying precipitant, fluctuations can be marked in DLB patients, with the occurrence of episodic confusion admixed with lucid intervals. However, despite the fluctuating pattern, the clinical features persist over a long period of time, unlike delirium, which resolves following correction of the underlying precipitant. Cognitively, DLB patients tend to have relatively better memory, but more severe visuospatial deficits, than individuals with AD.

The key neuropathologic feature is the presence of Lewy bodies throughout the cortex, amygdala, cingulated cortex, and substantia nigra. Lewy bodies are intraneuronal cytoplasmic inclusions that stain with periodic acid–Schiff (PAS) and ubiquitin. They are composed of straight neurofilaments 7 to 20 nm long with surrounding amorphous material. They are recognized by antibodies against phosphorylated and nonphosphorylated neurofilament proteins, ubiquitin, and a presynaptic protein called α-synuclein. Lewy bodies are traditionally found in the substantia nigra of patients with idiopathic Parkinson's disease. A profound cholinergic deficit is present in many patients with DLB and may be a factor responsible for the fluctuations and visual hallucinations present in these patients. In patients without other pathologic features, the condition is referred to as *diffuse Lewy body disease*. In patients whose brains also contain excessive amounts of amyloid plaques and NFTs, the condition is called the *Lewy body variant of AD*. The quantity of Lewy bodies required to establish the diagnosis is not agreed on, but a definite diagnosis requires pathologic confirmation. At autopsy, 10 to 30% of demented patients show cortical Lewy bodies.

Due to the overlap with AD and the cholinergic deficit in DLB, anticholinesterase compounds may be helpful. Exercise programs are also helpful to maximize the motor function of these patients. Antidepressants are often necessary to treat depressive syndromes that accompany DLB. Atypical antipsychotics in low doses are sometimes needed to alleviate psychosis, although even low doses can increase extrapyramidal syndromes, which rarely may be life-threatening. As noted above, patients with DLB are extremely sensitive to dopaminergic medications, which must be carefully titrated; tolerability may be improved by concomitant use of cholinesterase inhibitors.



A **B**

FIGURE 350-7 Normal pressure hydrocephalus. *A*. Sagittal T1-weighted MR image demonstrates dilatation of the lateral ventricle and stretching of the corpus callosum (*arrows*), depression of the floor of the third ventricle (*single arrowhead*), and enlargement of the aqueduct (*double arrowheads*). Note the diffuse dilatation of the lateral, third, and fourth ventricles with a patent aqueduct, typical of communicating hydrocephalus. *B*. Axial T2-weighted MR images demonstrate dilatation of the lateral ventricles without generalized cortical atrophy. This patient underwent successful ventriculoperitoneal shunting.

OTHER CAUSES OF DEMENTIA *Huntington's disease (HD)* (Chap. 351) is an autosomal dominant, degenerative brain disorder. A DNA repeat expansion (CAG repeat) of the gene encoding huntingtin on chromosome 4 forms the basis of a diagnostic blood test for the disease gene. The clinical hallmarks of the disease are chorea, behavioral disturbance, and a frontal/executive disorder. Onset is usually in the fourth or fifth decade, but there is a wide range in age of onset, from childhood to >70 years. Memory is frequently not impaired until late in the disease, but attention, judgment, awareness, and executive functions may be seriously deficient at an early stage. Depression, apathy, social withdrawal, irritability, and intermittent disinhibition are common. Delusions and obsessive-compulsive behavior may occur. The disease duration is typically about 15 years but is quite variable. There is no specific treatment, but the adventitious movements and behavioral changes may partially respond to phenothiazines, haloperidol, or benzodiazepines. Asymptomatic adult children at risk for HD should receive careful genetic counseling prior to DNA testing, because a positive result may have serious emotional and social consequences.

Normal-pressure hydrocephalus (NPH) is a relatively uncommon syndrome consisting of an abnormal gait (ataxic or apractic), dementia (usually mild to moderate), and urinary incontinence. Historically, many individuals who have been treated as having NPH have suffered from other dementias, particularly AD, multi-infarct dementia, and DLB. Neuroimaging findings in NPH are those of a communicating hydrocephalus with a patent aqueduct of Sylvius (Fig. 350-7). In many cases periventricular edema is present. Lumbar puncture findings include an opening pressure in the high-normal range and normal CSF protein, sugar concentrations, and cell count. NPH is presumed to be caused by obstruction to normal flow of CSF over the cerebral convexity and delayed absorption into the venous system. The indolent nature of the process results in enlarged lateral ventricles but relatively little increase in CSF pressure. There is presumably stretching and distortion of white matter tracts in the corona radiata, but the exact physiologic cause of the clinical syndrome is unclear. Some patients have a history of conditions producing scarring of the basilar meninges (blocking upward flow of CSF) such as previous meningitis, subarachnoid hemorrhage, or head trauma. Others with longstanding but asymptomatic congenital hydrocephalus may have an adult-onset deterioration in gait or memory that is confused with NPH; in these patients, the aqueduct of Sylvius is small, in contrast to patients with NPH. Unlike in AD, the NPH patient has an early and prominent gait disturbance and no evidence of cortical or hippocampal atrophy on neuroimaging studies. A number of attempts have been made to use various special studies to improve the diagnosis of NPH and predict the success of ventricular shunting. These include radionuclide cisternography (showing a delay in CSF absorption over the convexity) and various attempts to monitor and alter CSF flow dynamics. None has proved to be specific or consistently useful. There is sometimes a transient improvement in gait or cognition following lumbar puncture (or serial punctures) with removal of ≥30 mL of CSF, but this finding is not a reliable predictor of post-shunt improvement. Approximately 30 to 50% of patients identified by careful diagnosis as having NPH will show improvement with a ventricular shunting procedure. Gait may improve more than memory. Transient, short-lasting improvement is common. Patients should be carefully selected for this operation, because subdural hematoma and infection are known complications.

Prion diseases such as CJD are rapidly progressive disorders associated with dementia, focal cortical signs, rigidity, and myoclonus. The rapidity of progression seen with CJD is uncommon in AD so that distinction between the two disorders is usually straightforward. CBD and DLB progress more rapidly than AD and are associated with prominent disorders of movement and so are more likely to be mistaken for CJD. Abnormal periodic EEG discharges and cortical and basal ganglia abnormalities on diffusion-weighted MRI are unique diagnostic features of CJD. →***Prion diseases are discussed in detail in Chap. 362.***

Dementia can accompany *chronic alcoholism* (Chap. 372). This may be a result of associated malnutrition, especially of B vitamins and particularly thiamine. However, other as yet poorly defined aspects of chronic alcohol ingestion may also produce cerebral damage. A rare syndrome of dementia and seizures with degeneration of the corpus callosum has been reported primarily in male Italian drinkers of red wine (Marchiafava-Bignami disease).

Thiamine (vitamin B_1) deficiency causes Wernicke's encephalopathy (Chap. 258). The clinical presentation is a malnourished individual (frequently but not necessarily alcoholic) with confusion, ataxia, and diplopia from ophthalmoplegia. Thiamine deficiency damages the thalamus, mammillary bodies, midline cerebellum, periaqueductal gray matter of the midbrain, and peripheral nerves. Damage to the dorsomedial thalamic regions correlates most closely with memory loss. Prompt administration of parenteral thiamine may reverse the disease if given in the first few days of symptom onset. However, prolonged untreated thiamine deficiency can result in an irreversible dementia/amnestic syndrome known as *Korsakoff's syndrome*. Here, the patient is unable to recall new information despite normal immediate memory, attention span, and level of consciousness. Memory for new events is seriously impaired, whereas memory of knowledge prior to the illness is relatively intact. Patients are easily confused, disoriented, and incapable of recalling new information for more than a brief interval. Superficially, they may be conversant, entertaining, able to perform simple tasks, and follow immediate commands. Confabulation is common, although not always present, and may result in obviously erroneous statements and elaborations. There is no specific treatment because the previous thiamine deficiency has produced irreversible damage to the medial thalamic nuclei and mammillary bodies. Mammillary body atrophy may be visible on high-resolution MRI (Fig. 258-6).

Vitamin B_{12} deficiency, as can occur in pernicious anemia, causes a macrocytic anemia and may also damage the nervous system (Chaps. 92 and 356). Neurologically it most commonly produces a spinal cord syndrome (myelopathy) affecting the posterior columns (loss of position and vibratory sense) and corticospinal tracts (hyperactive tendon reflexes with Babinski responses); it also damages peripheral nerves, resulting in sensory loss with depressed tendon reflexes. Damage to cerebral myelinated fibers may also cause dementia. The mechanism of neurologic damage is unclear but may be related to a deficiency of *S*-adenosylmethionine (required for methylation of myelin phospholipids) due to reduced methionine synthase activity or accumulation of methylmalonate, homocysteine, and propionate, providing abnormal substrates for fatty acid synthesis in myelin. The neurologic signs of vitamin B_{12} deficiency are usually associated with macrocytic anemia, but on occasion may occur in its absence. Treatment with parenteral vitamin B_{12} stops progression of the disease if instituted promptly, but reversal of advanced nervous system damage will not occur.

Deficiency of nicotinic acid (pellagra) is associated with sun-exposed skin rash, glossitis, and angular stomatitis (Chap. 61). Severe dietary deficiency of nicotinic acid along with other B vitamins such as pyridoxine may result in spastic paraparesis, peripheral neuropathy, fatigue, irritability, and dementia. This syndrome has been seen in prisoner-of-war and concentration camps. Low serum folate levels appear to be a rough index of malnutrition, but isolated folate deficiency has not been proved to be a specific cause of dementia.

Infections of the CNS usually cause delirium and other acute neurologic syndromes (Chap. 258). However, some chronic CNS infections, particularly those associated with chronic meningitis (Chap. 361), may produce a dementing illness. The possibility of chronic infectious meningitis should be suspected in patients presenting with a dementia or behavioral syndrome who also have headache, meningismus, cranial neuropathy, and/or radiculopathy. Between 20 and 30% of patients in the advanced stages of infection with HIV become demented (Chap. 173). Cardinal features include psychomotor retardation, apathy, and impaired memory. This may result from secondary opportunistic infections but can also be caused by direct infection of CNS neurons with HIV. Neurosyphilis (Chap. 153) was a common cause of dementia in the preantibiotic era; it is now uncommon but can still be encountered in patients with multiple sex partners. Characteristic CSF changes consist of pleocytosis, increased protein, and a positive Venereal Disease Research Laboratory (VDRL) test.

Primary and metastatic neoplasms of the CNS (Chap. 358) usually produce focal neurologic findings and seizures rather than dementia. However, if tumor growth begins in the frontal or temporal lobes, the initial manifestations may be memory loss or behavioral changes. A paraneoplastic syndrome of dementia associated with occult carcinoma (often small cell lung cancer) is termed *limbic encephalitis* (Chap. 87). In this syndrome, confusion, agitation, seizures, poor memory, movement disorders, and dementia occur in association with sensory neuropathy.

A nonconvulsive seizure disorder may underlie a syndrome of confusion, clouding of consciousness, and garbled speech. Psychiatric disease is often suspected, but an EEG demonstrates the seizure discharges. If recurrent or persistent, the condition may be termed *complex partial status epilepticus*. The cognitive disturbance often responds to anticonvulsant therapy. The etiology may be previous small strokes or head trauma; some cases are idiopathic.

It is important to recognize systemic diseases that indirectly affect the brain and produce chronic confusion or dementia. Such conditions include hypothyroidism; vasculitis; and hepatic, renal, or pulmonary disease. Hepatic encephalopathy may begin with irritability and confusion and slowly progress to agitation, lethargy, and coma (Chap. 258).

Isolated vasculitis of the CNS (CNS granulomatous vasculitis) (Chaps. 306 and 349) occasionally causes a chronic encephalopathy with confusion, disorientation, and clouding of consciousness. Headache is common, and strokes and cranial neuropathies may occur. Brain imaging studies may be normal or nonspecifically abnormal. CSF studies reveal a mild pleocytosis or elevation in the protein level. Cerebral angiography often shows multifocal stenosis and narrowing of vessels. A few patients have only small-vessel disease that is not revealed on angiography. The angiographic appearance is nonspecific and may be mimicked by atherosclerosis, infection, or other causes of vascular disease. Brain or meningeal biopsy demonstrates abnormal arteries with endothelial cell proliferation and infiltrates of mononuclear cells. The prognosis is often poor; however, the disorder may remit spontaneously. Some patients respond to glucocorticoids or chemotherapy.

Chronic metal exposure may produce a dementing syndrome. The key to diagnosis is to elicit a history of exposure at work, home, or even as a consequence of a medical procedure such as dialysis. Chronic lead poisoning may present as fatigue, depression, and confusion and may be associated with episodic abdominal pain and peripheral neuropathy. Inadequately fired glazed pottery has been reported as a cause. Gray lead lines appear in the gums. There is usually an anemia with basophilic stippling of red cells. The clinical presentation can resemble that of acute intermittent porphyria, including elevated levels of urine porphyrins as a result of the inhibition of δ-aminolevulinic acid dehydrase. The treatment is chelation therapy with agents such as ethylenediamine tetraacetic acid (EDTA). Chronic mercury poisoning produces dementia, peripheral neuropathy, ataxia, and tremulousness that may progress to choreoathetosis. Chronic arsenic intoxication can produce confusion and memory loss associated with nausea, weight

loss, peripheral neuropathy, pigmentation and scaling of the skin, and transverse white lines of the fingernails (Mee's lines). Treatment is chelation therapy with dimercaprol (BAL). Aluminum poisoning has been best documented with the dialysis dementia syndrome in which water used during renal dialysis was contaminated with excessive amounts of aluminum. A progressive encephalopathy ensued, associated with confusion, aphasia, memory loss, agitation, and, later, lethargy and stupor. Speech arrest and myoclonic jerks were common and associated with severe and generalized EEG changes. The condition has been eliminated by the use of deionized water for dialysis.

Recurrent head trauma in professional boxers may lead to dementia, sometimes called the "punch drunk" syndrome or *dementia pugilistica*. The symptoms can be progressive, beginning late in a boxer's career or even long after retirement. The severity of the syndrome correlates with the length of the boxing career and number of bouts. Early on, a personality change associated with social instability and sometimes paranoia and delusions occurs. Later, memory loss progresses to full dementia, often associated with parkinsonian signs and ataxia or intention tremor. At autopsy, the cerebral cortex may show changes similar to those in AD, although NFTs are usually more prominant than amyloid plaques (which are usually diffuse rather than neuritic). There may also be loss of neurons in the substantia nigra. Chronic subdural hematoma (Chap. 357) is also occasionally associated with dementia, often in the context of underlying cortical atrophy from conditions such as AD or Huntington's disease. In these latter cases, evacuation of the subdural hematoma will not alter the underlying degenerative process.

Transient global amnesia (TGA) is characterized by the sudden onset of a severe episodic memory deficit, usually occurring in persons over age 50. Often, the memory loss occurs in the setting of an emotional stimulus or physical exertion. During the attack the individual is alert and communicative, general cognition seems intact, and there are no other neurologic signs or symptoms. The patient may seem confused and repeatedly ask about present events. The ability to form new memories returns after a period of hours, and the individual returns to normal with no recall for the period of the attack. Frequently no cause is determined, but cerebrovascular disease, epilepsy (7% in one study), migraine, or cardiac arrhythmia have all been implicated. A Mayo Clinic review of 277 patients with TGA found a past history of migraine in 14% and cerebrovascular disease in 11%, but these conditions were not temporally related to the TGA episodes. Approximately one-quarter of the patients had recurrent attacks, but they were not at increased risk for subsequent stroke. Rare instances of permanent memory loss after sudden onset have been reported, usually representing ischemic infarction of the hippocampi or medial thalamic nuclei bilaterally.

The ALS/parkinsonian/dementia complex of Guam is a rare degenerative disease that has occurred in the Chamorro natives on the island of Guam. Any combination of parkinsonian features, dementia, and motor neuron disease may occur. The most characteristic pathologic features are the presence of NFTs in degenerating neurons of the cortex and substantia nigra and loss of motor neurons in the spinal cord. Epidemiologic evidence supports a possible environmental cause, such as exposure to a neurotoxin with a long latency period. One interesting but unproven candidate neurotoxin occurs in the seed of the false palm tree, which Guamanians traditionally used to make flour. The ALS syndrome is decreasing in frequency on Guam, but a dementing illness with rigidity continues to be seen.

Rarely adult-onset leukodystrophies, neuronal storage diseases, and other genetic disorders can cause dementia late in life. Adult metachromatic leukodystrophy (arylsulfatase A deficiency) can present as a dementia associated with large frontal white matter lesions. Adult presentations of adrenaleukodystrophy have been reported, and in these cases involvement of the spinal cord and posterior white matter is common. This is diagnosed with measurement of medium- and long-chain fatty acids (Chap. 356). The neuronal cerebrolipofuscinoses are a genetically heterogeneous group of disorders associated with myoclonus, seizures, and progressive dementia. Diagnosis is made by finding curvilinear inclusions within white blood cells or neuronal tissue.

Psychogenic amnesia for personally important memories is common, although whether this results from deliberate avoidance of unpleasant memories or from unconscious repression is currently unknown. The event-specific amnesia is more likely to occur after violent crimes such as homicide of a close relative or friend or sexual abuse. It may also develop in association with drug or alcohol intoxication and sometimes with schizophrenia. More prolonged psychogenic amnesia occurs in fugue states that also commonly follow severe emotional stress. The patient with a fugue state suffers from a sudden loss of personal identity and may be found wandering far from home. In contrast to organic amnesia, fugue states are associated with amnesia for personal identity and events closely associated with the personal past. At the same time, memory for other recent events and the ability to learn and use new information are preserved. The episodes usually last hours or days and occasionally weeks or months while the patient takes on a new identity. On recovery, there is a residual amnesia for the period of the fugue. Very rarely, selective loss of autobiographical information represents a focal injury in the brain areas involved with these functions.

Psychiatric diseases may mimic dementia. Severely depressed individuals may appear demented, a phenomenon called *pseudodementia*. Memory and language are usually intact when carefully tested in depressed persons, and a significant memory disturbance usually suggests an underlying dementia, even if the patient is depressed. The patient with pseudodementia may feel confused and unable to accomplish routine tasks. Vegetative symptoms are common, such as insomnia, lack of energy, poor appetite, and concern with bowel function. The onset is often abrupt, and the psychosocial milieu may suggest prominent reasons for depression. Such patients respond to treatment of the depression. Schizophrenia is usually not difficult to distinguish from dementia, but occasionally the distinction can be problematic. Schizophrenia usually has a much earlier age of onset (second and third decades) than most dementing illnesses and is associated with intact memory. The delusions and hallucinations of schizophrenia are usually more complex and bizarre than those of dementia. Some chronic schizophrenics develop an unexplained progressive dementia late in life that is not related to AD. Conversely, FTD, HD, vascular dementia, DLB, AD, or leukoencephalopathy can begin with schizophrenia-like features, leading to the misdiagnosis of a psychiatric condition. The later age of onset, presence of significant deficits on cognitive testing, and neuroimaging findings point toward a degenerative condition. Memory loss may also be part of a conversion reaction. In this situation, patients commonly complain bitterly of memory loss, but careful cognitive testing either does not confirm the deficits or demonstrates inconsistent or unusual patterns of cognitive problems. The patient's behavior and "wrong" answers to questions often indicate that he or she understands the question and knows the correct answer.

Clouding of cognition by chronic drug or medication use, often prescribed by physicians, is an important cause of dementia. Sedatives, tranquilizers, and analgesics used to treat insomnia, pain, anxiety, or agitation may cause confusion, memory loss, and lethargy, especially in the elderly. Discontinuation of the offending medication often improves mentation.

GENERAL SYMPTOMATIC TREATMENT OF THE PATIENT WITH DEMENTIA

The major goals of management are to treat any correctable causes of the dementia and to provide comfort and support to the patient and caregivers. Removal of sedating or cognition-impairing drugs and medications is often beneficial. If the patient is depressed rather than demented, the depression should be vigorously treated. Patients with degenerative diseases may also be depressed, and that portion of their condition may respond to antidepressant therapy. Antidepressants that are low in cognitive side effects, such as SSRIs (Chap. 371), are ad-

visable when treatment is necessary. Anticonvulsants are used to control seizures.

Agitation, hallucinations, delusions, and confusion are difficult to treat. These behavioral problems represent major causes for nursing home placement and institutionalization. Before treating these behaviors with medications, a thorough search for potentially modifiable environmental or metabolic factors should be sought. Hunger, lack of exercise, toothache, constipation, urinary tract infection, or drug toxicity all represent easily correctable factors that can be treated without psychoactive drugs. Medications that may calm agitation and insomnia without worsening dementia include low-dose haloperidol (0.5 to 2 mg), trazodone, buspirone, or propranolol. The new atypical antipsychotics including risperidone, olanzapine, and quetiapine are increasingly used for patients with difficult behaviors. When patients do not respond it is usually a mistake to advance to higher doses or to use anticholinergics or sedatives (such as barbiturates or benzodiazepines). The few controlled studies comparing drugs with behavioral intervention in the treatment of agitation suggest that both approaches are effective. However, careful, daily, nondrug behavior management is often not available, rendering medication necessary. Sometimes, apathy, visual hallucinations, and other psychiatric symptoms respond to the cholinesterase inhibitors, obviating the need for other therapies.

A proactive strategy has been shown to reduce the occurrence of delirium in hospitalized patients. This includes frequent orientation, cognitive activities, sleep-enhancement measures, vision and hearing aids, and correction of dehydration.

Nondrug behavior therapy has an important place in the management of dementia. The primary goal is to make the demented patient's life comfortable, uncomplicated, and safe. Memory aids such as notebooks, lists, and posted daily reminders are frequently helpful. It is also useful to stress familiar routines, short-term tasks, walks, and simple physical exercises. For many demented patients, the memory for facts is worse than that for routine activities, and they still may be able to take part in remembered physical activities such as walking, bowling, dancing, and golf. Demented patients usually object to losing control over familiar tasks such as driving, cooking, and handling finances. Attempts to help or take over may be greeted with complaints, depression, or anger. Hostile responses on the part of the caretaker are useless and sometimes harmful. Explanation, reassurance, distraction, and calm statements are more productive responses in this setting. Eventually, tasks such as finances and driving must be assumed by others, and the patient will conform and adjust. Safety is an important issue that includes not only driving but the environment of the kitchen, bathroom, and sleeping area. These areas need to be monitored, supervised, and made as safe as possible. A move to a retirement home, assisted-living center, or nursing home can initially increase confusion and agitation. Repeated reassurance, reorientation, and careful introduction to the new personnel will help to smooth the process. Provision of activities that are known to be enjoyable to the patient can be of considerable benefit. Attention should also be paid to frustration and depression in family members and caregivers. Caregiver guilt and burn-out are common, often resulting in nursing home placement of the patient. Family members often feel overwhelmed and helpless and may vent their frustrations on the patient, each other, and health care providers. Caregivers should be encouraged to take advantage of day-care facilities and respite breaks. Education and counseling about dementia are important. Local and national support groups, such as the Alzheimer's Disease and Related Disorders Association, can be of considerable help.

351 PARKINSON'S DISEASE AND OTHER MOVEMENT DISORDERS

Mahlon R. DeLong, Jorge L. Juncos

PARKINSON'S DISEASE

Parkinson's disease (PD) is the most common example of a family of neurodegenerative disorders characterized by a neuronal accumulation of the presynaptic protein α-synuclein and by variable degrees of *parkinsonism*, defined as a paucity and slowness of movement (*bradykinesia*), tremor at rest, rigidity, shuffling gait, and flexed posture. Nearly all forms of parkinsonism result from a reduction of dopaminergic transmission within the basal ganglia. Sporadic and idiopathic PD account for ~75% of all cases of parkinsonism; the remaining 25% result from genetically defined etiologies and other causes including other neurodegenerative disorders, cerebrovascular disease, and drugs.

Epidemiology PD afflicts >1 million individuals in the United States (~1% of those >55 years). Its peak age of onset is in the 60s (range is 35 to 85 years), and the course of the illness ranges between 10 and 25 years. Familial clusters of autosomal dominant and recessive forms of PD comprise ~5% of cases (Table 351-1). These are characterized by an earlier age of onset (typically before age 50 years) and a longer course than the more typical "sporadic" PD. Although most patients with PD appear to have no strong genetic determinant, epidemiologic evidence points to a complex interaction between genetic vulnerability and environmental factors (Fig. 351-1). Risk factors include a positive family history, male gender, head injury, exposure to pesticides, consumption of well water, and rural living. Factors linked to a reduced incidence of PD include coffee drinking, smoking, use of nonsteroidal anti-inflammatory drugs, and estrogen replacement in postmenopausal women.

TABLE 351-1 Familial Parkinson's Disease

Locus	Gene	Inheritance
PARK1	*α-Synuclein*	AD
PARK2	*Parkin*	AR
PARK4	*α-Synuclein* triplication	AD
PARK5	UCHL1	AD
PARK7	DJ-1	AR
PARK3,4,6,8,9	Unknown	AD and AR mutations
PARK10	Unknown	Late-onset susceptibility gene

Clinical Features A diagnosis of PD can be made with some confidence in patients who present with at least two of the three cardinal signs—rest tremor, rigidity, and bradykinesia. Tremor is particularly important, as it is present in 85% of patients with true PD; a diagnosis of PD is particularly difficult when tremor is absent. A unilateral and gradual onset of symptoms further supports the diagnosis. Masked facies, decreased eye blinking, stooped posture, and decreased arm swing complete the early picture. The onset may also be heralded by

vague feelings of weakness and fatigue, incoordination, aching, and discomfort.

Motor Features The most disabling feature of PD is bradykinesia, which interferes with all aspects of daily living such as walking, rising from a chair, turning in bed, dressing. Fine motor control is also impaired as evidenced by decreased manual dexterity and handwriting (*micrographia*). Soft speech (*hypophonia*) and sialorrhea are other troubling manifestations of (bulbar) bradykinesia. Rest tremor, at a frequency of 4 to 6 Hz, typically appears unilaterally, first distally, involving the digits and wrist where it may have a "pill-rolling" character. Tremor usually spreads proximally, ipsilaterally, and occasionally to the leg before crossing to the other side after a year or more. It may appear later in the lips, tongue, and jaw but spares the head. Rigidity is felt as a uniform resistance to passive movement about a joint throughout the full range of motion, giving rise to a characteristic "plastic" quality. Brief, regular interruptions of resistance during passive movement, corresponding to subclinical tremor, may give rise to a "cogwheeling" sensation. Dystonia involving the distal arm or leg may occur early in the disease, unrelated to treatment, especially in younger patients. It can also be provoked by antiparkinsonian drug therapy.

Gait disturbance with shuffling short steps and a tendency to turn en bloc is a prominent feature of PD. Festinating gait, a classic parkinsonian sign, results from the combination of flexed posture and loss of postural reflexes, which cause the patient to accelerate in an effort to "catch up" with the body's center of gravity. Freezing of gait, a feature of more advanced PD, occurs commonly at the onset of locomotion (start hesitation), when attempting to change direction or turn around, and upon entering a narrow space such as a doorway.

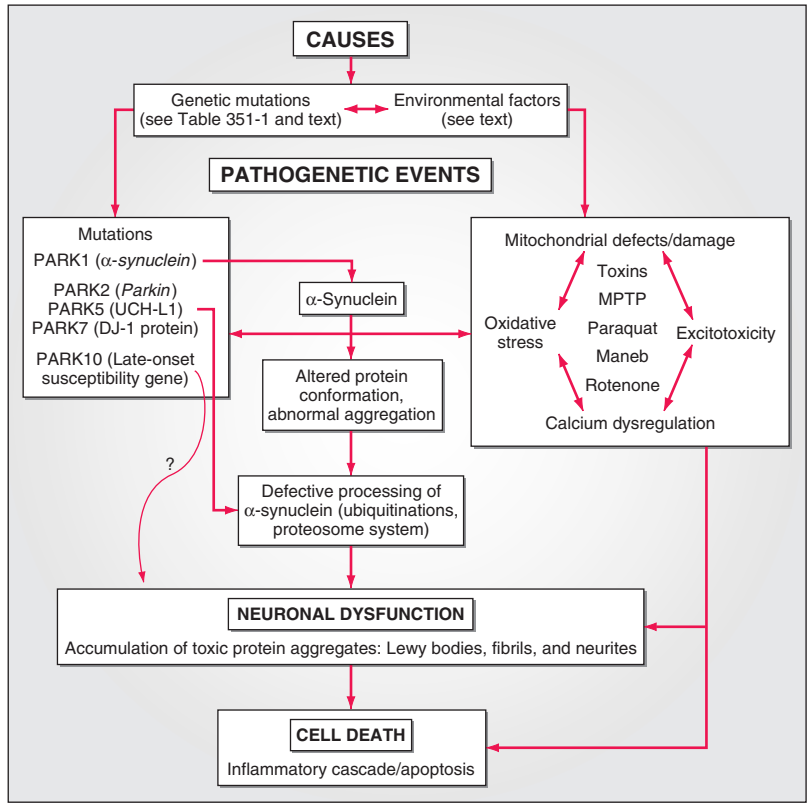

FIGURE 351-1 Possible cascade of pathogenic events leading to neuronal cell death in Parkinson's disease.

Abnormalities of balance and posture tend to increase in prominence as the disease progresses. Flexion of the head, stooping and tilting of the upper trunk, and a tendency to hold the arm in a flexed posture while walking are common, as are changes in the posture of the fingers and hands. Postural instability is one of the most disabling features of advanced PD, contributing to falls and injuries and leading to major morbidity and mortality. Significant postural instability and falls in the first years of the illness, however, strongly suggest a diagnosis other than PD.

Non-Motor Features Non-motor aspects of PD include depression and anxiety, cognitive impairment, sleep disturbances, sensory abnormalities and pain, loss of smell (*anosmia*), and disturbances of autonomic function. Together they may contribute as much to the burden of the disease as the more obvious motor abnormalities. Some of these (e.g., anosmia, depression, and sleep disorders) may be present long before the onset of motor signs. The physiologic basis of the non-motor signs and symptoms are explained in part by widespread involvement of brainstem, olfactory, thalamic, and cortical structures, as discussed below.

Sensory symptoms most often manifest as a distressing sensation of inner restlessness presumed to be a form of akathisia. Aching pain and discomfort in the extremities can be a prominent presenting symptom or develop when antiparkinson medications are wearing off. Other patients develop a subjective shortness of breath in the absence of any underlying cardiorespiratory pathology.

Sleep disorders are common in PD. Daytime drowsiness and frequent napping are typical signs of sleep disruption. Factors that disrupt sleep include nighttime reemergence of bradykinesia and rigidity, with difficulty turning in bed, as well as tremor and involuntary movements (e.g., myoclonic jerks or periodic leg movements). Restless legs and rapid eye movement–behavioral disorder (RBD) are present in considerable numbers of patients, often preceding the onset of PD. Vivid dreams and hallucinations related to dopaminomimetic therapy may also contribute to sleep disruption. Finally, sleep apnea and other sleep disturbances can occur.

Autonomic dysfunction can produce diverse manifestations, including orthostatic hypotension, constipation, urinary urgency and frequency, excessive sweating, and seborrhea. Orthostatic hypotension is present in many patients resulting from sympathetic denervation of the heart or as a side effect of dopaminomimetic therapy. This rarely leads to syncope unless the patient has developed true autonomic failure or has an unrelated cardiac problem. Drenching sweats may occur in advanced PD, often related to wearing off of medication.

Neuropsychiatric Symptoms Changes in mood, cognition, and behavior are common accompaniments of the later stages of PD and may be the direct result of PD or its comorbid pathologies [e.g., Alzheimer's disease (AD), cortical dementia with Lewy bodies (DLB)], or occur as a side effect of its pharmacotherapy.

Depression affects approximately half of patients with PD and can occur at any phase of the illness. It is often difficult to diagnose due to the overlap between the somatic and vegetative symptoms of PD and depression. As a consequence, depression often goes unrecognized and untreated. There is compelling evidence that depression in PD is an intrinsic part of the illness and not simply a reaction to disability. Recognizing even mild depression is particularly important since it can account for otherwise unexplained worsening parkinsonian motor symptoms, new somatic symptoms, and sleep disruption. Depression can also be induced or aggravated iatrogenically by antiparkinsonian and psychotropic agents used to treat other symptoms. Finally, other causes for depressive symptoms and refractory depression should always be considered, including hypothyroidism, hypogonadism, and vitamin B_{12} deficiency.

Anxiety disorders in PD can appear in isolation or as an accompaniment of depression or progressive cognitive impairment. They can also be due to an akathisia equivalent mediated by "dopamine hunger" due to undertreatment of motor symptoms. The development of drug-induced motor fluctuations can compound the problem by precipitating fluxes in anxiety during the off periods that mimic panic attacks.

Cognitive abnormalities affect many patients with PD. Most are mild to moderate in severity. Difficulties with complex tasks, long-term planning, and memorizing or retrieving new information are common. Although some of these symptoms represent *bradyphrenia* (the cognitive equivalent of bradykinesia), it is now clear that the dysfunction also includes working memory, attention, mental flexibility, visuospatial function, word fluency, and executive functions. Iatrogenic contributors include the indiscriminate use of amantadine or psychotropic, anticholinergic, and dopaminomimetic medications. Depression and intercurrent medical illnesses, such as urinary tract or other infections, are reversible causes of cognitive symptoms in PD.

Whether these nondementing abnormalities form a continuum with the dementias that affect a subset of patients in later stages of the disease is unknown. The incidence of dementia in PD may be as high as six times that in age-matched controls. The presence of significant cognitive impairment may limit therapeutic options and contribute more to overall disability than the motor symptoms in PD. Predictors of dementia include late age of onset, akinetic rigid phenotype, presence of severe depression, persistent hallucinations, and advanced stages of disease. In most instances accumulating amyloid and α-synuclein pathologies in the frontal lobes, basal forebrain, hippocampus, and amygdala account for the progression of symptoms (see "Pathology," below).

Psychotic symptoms affect 6 to 40% of patients with PD, depending on the age and prevalence of dementia in the population surveyed. Early symptoms include formed visual hallucinations (usually people and animals) with retained insight. Although depression and dementia are the most important risk factors for psychotic symptoms in PD, the symptoms are often triggered by drug therapy and are dose-dependent. Dopaminomimetics, anticholinergics, amantadine, and selegiline are the chief offenders. Delusions are more disturbing than hallucinations because they place an even heavier burden on the family and caregivers. The prodrome to these psychotic symptoms includes subtle erratic behaviors with temperamental and sometimes unreasonable outbursts.

Differential Diagnosis The differential diagnosis of parkinsonian syndromes requires a careful history and physical examination (Table 351-2). Neuroimaging with magnetic resonance imaging (MRI) is useful to rule out disorders such as normal pressure hydrocephalus, vascular disease, or mass lesions. Positron emission tomography (PET) is helpful in confirming suspected atypical forms (see "Corticobasal Degeneration," below). Essential tremor (ET) is sometimes confused with rest tremor in PD, but the absence of other signs of parkinsonism and the bilaterality, higher frequency (8 to 10 Hz), and postural dependency of ET plus significant relief with even a small amount of alcohol help differentiate this from the rest tremor of PD. In individuals under 40 it is important to rule out Wilson's disease (Chap. 339). In younger individuals Huntington's disease (HD) sometimes presents with prominent parkinsonian features. Although parkinsonian features are often present in AD, they are greatly outweighed by the cognitive and behavioral disturbances. In DLB, the parkinsonian features are compounded by the early appearance of hallucinations and disturbances in arousal and behavior. Parkinsonism may also develop following exposure to certain neurotoxins such as carbon monoxide or manganese.

The differentiation of sporadic PD from atypical parkinsonism (see below) is the most difficult task, since early in their course these atypical forms often meet diagnostic criteria for PD. Accordingly, it is important not to settle on a definite diagnosis at the first visit. The development of early imbalance and falls suggests progressive supranuclear palsy (PSP); early urinary incontinence, orthostatic hypotension, and dysarthria suggest multiple system atrophy (MSA). The

TABLE 351-2 Differential Diagnosis of Parkinsonism

PRIMARY PARKINSONISM	SECONDARY PARKINSONISM
I. Familial ("primary") PD (rare; see Table 351-1)	I. Repeated head trauma ("dementia pugilistica" with parkinsonian features)
II. Idiopathic ("sporadic") PD (most common form) Phenotype may be influenced by vulnerability genes and environmental factors	II. Infectious and postinfectious diseases A. Postencephalitic PD B. Neurosyphillis
III. Other neurodegenerative disorders A. Disorders associated with α-synuclein pathology 1. Multiple systems atrophies (glial and neuronal inclusions) a. Striatonigral degeneration b. Olivopontocerebellar atrophy c. Shy-Drager syndrome d. Motor neuron disease with PD features 2. Dementia with Lewy bodies (cortical and brainstem neuronal inclusions) B. Disorders associated with primary tau pathology ("tauopathies") 1. Progressive supranuclear palsy 2. Corticobasal degeneration 3. Frontotemporal dementia C. Disorders associated with primary amyloid pathology ("amyloidopathies") 1. Alzheimer's disease with parkinsonism	III. Metabolic conditions A. Hypoparathyroidism or pseudohypoparathyroidism with basal ganglia calcifications B. Non-Wilsonian hepatolenticular degeneration
IV. Genetically mediated disorders with occasional parkinsonian features A. Wilson's disease B. Hallervorden-Spatz disease C. Chédiak-Higashi disease D. SCA-3 spinocerebellar ataxia E. X-linked dystonia-parkinsonism (DYT3) F. Fragile X premutation associated ataxia-tremor-parkinsonism syndrome G. Huntington's disease (Westphalt variant) H. Prion disease	IV. Drugs A. Neuroleptics (typical antipsychotics) B. Selected atypical antipsychotics (see text) C. Antiemetics (e.g., compazine, metoclopramide) D. Dopamine-depleting agents (reserpine, tetrabenazine) E. ∝-Methyldopa F. Lithium carbonate G. Valproic acid H. Fluoxetine
V. Miscellaneous acquired conditions A. Vascular parkinsonism B. Normal pressure hydrocephalus C. Catatonia D. Cerebral Palsy	V. Toxins A. 1-Methyl-1,2,4,6 tetrahydropyridine (MPTP) B. Manganese C. Cyanide D. Methanol E. Carbon monoxide F. Carbon disulfide G. *N*-hexane?

Note: PD, Parkinson's disease.

early appearance of drug-induced hallucinations strongly favors the diagnosis of DLB. As a rule the different forms of atypical parkinsonism can be reliably differentiated from sporadic PD within the first 3 to 4 years.

Pathology Gross pathologic examination of the brain in PD reveals mild frontal atrophy with loss of the normal dark melanin pigment of the midbrain. Microscopically there is degeneration of the dopaminergic cells with the presence of Lewy bodies (LBs) in the remaining neurons and processes of the substantia nigra pars compacta (SNpc), other brainstem nuclei, and regions such as the medial temporal, limbic, and frontal cortices. LBs have a high concentration of α-synuclein and are the pathologic hallmark of the disorder. Mutations in the α-synuclein gene can cause familial PD by promoting the formation of α-synuclein-positive filaments that aggregate into LBs and Lewy neurites (Fig. 351-2). This pathology may begin in the anterior olfactory nuclei and lower brainstem (glossopharyngeal and vagal nerve nuclei), with ascending brainstem involvement of the locus coeruleus, n. gigantocellularis, and the raphe, before extending to the magnocellular nuclei of the basal forebrain, the central nucleus of the amygdala, and the SNpc. Involvement of these nuclei may play a role in the non-motor (e.g., autonomic, sleep, emotional, and cognitive) and refractory motor aspects (e.g., postural instability, gait, and bulbar disturbances) of PD.

The biochemical consequence of dopaminergic cell loss in the SNpc is gradual denervation of the striatum, the main target projection for the SNpc neurons. Other target regions of these neurons include the intralaminar and parafascicular nuclei of the thalamus, the globus pallidus, and the subthalamic nucleus (STN). Dopamine denervation of the striatum leads to many of the motor symptoms of PD. Symptoms develop when striatal dopamine depletion reaches 50 to 70% of normal. Pharmacologic restoration of dopamine transmission is the basis for symptomatic drug treatment of PD.

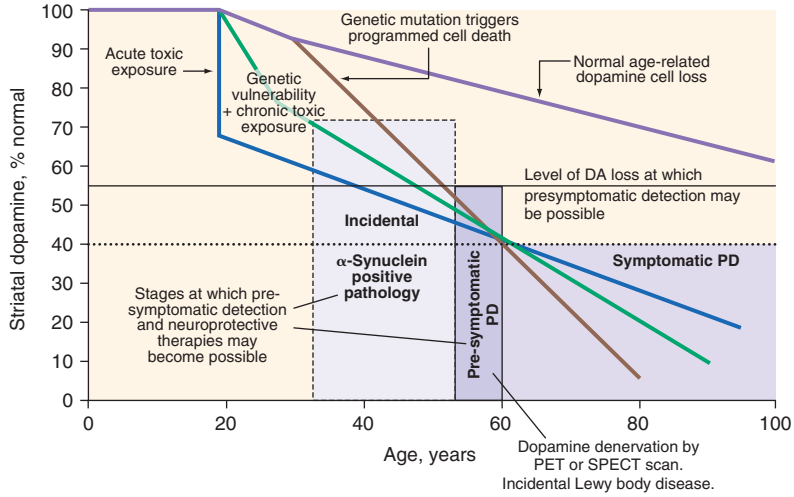

FIGURE 351-2 Proposed stages of Parkinson's disease (PD) based on extrapolations from epidemiologic field studies and on brain imaging data using PET and SPECT technology. At presymptomatic stages the patient would not meet criteria for the clinical diagnosis of PD but may instead exhibit striatal dopamine denervation on PET scan or, in familial cases, have a positive genetic test. This stage is thought to last about 5 years. The presence of incidental α-synuclein positive pathology (Lewy neurites or LBs) at autopsy may be the earliest recognizable stage of PD. PET, positron emission tomography using 18-F fluorodopa; SPECT, single proton emission computerized tomography using β-CIT, both presynaptic markers of presynaptic dopamine innervation.

GENETIC CONSIDERATIONS Although >90% of cases of idiopathic PD appear to be sporadic, increasing evidence indicates that genetic factors play an important role in many forms PD. Much of this evidence comes from studies of the concordance rates for PD among monozygotic and dizygotic twins. These studies suggest that heredity plays an important role in cases with age of onset <50 years and a less important role in older patients. Four genes have been clearly linked to familial forms of PD (Table 351-1), and a number of other candidate genes or genetic loci have been identified as possibly causative of PD. Among the former, PARK1 and PARK5 lead to an autosomal dominant form of PD with atypical features such as early age of onset and rapid progression of symptoms. PARK1 encodes α-synuclein, leading to its abnormal aggregation. PARK2 and PARK7 lead to autosomal recessive disorders also with atypical features, including juvenile forms of parkinsonism. PARK2 encodes *parkin*, an E3 ubiquitin protein ligase. Mutations in *parkin* appear to be the major cause of autosomal recessive PD. Remarkably, PARK5 codes for the ubiquitin carboxy-terminal hydroxylase L1 (UCH-L1), another component of the ubiquitin proteosomal system. Because ubiquitination of proteins targets them for degradation in the proteosome, these findings suggest that abnormal proteosomal processing is important in the pathogenesis of PD. Other mutations with yet-to-be identified genes include PARK10, a late-onset PD susceptibility gene. All these mutations are thought to affect α-synuclein or its biochemical processing, either directly or indirectly. The identification of these and other mutations are proving invaluable in refining the correlation between genotypes and phenotypes, in generating animal models to study pathogenesis, and in identifying target pathways for possible therapeutic intervention.

Pathogenesis (Fig. 351-1) In PD dopaminergic and other cells die due to a combination of factors including: (1) genetic vulnerability, (2) oxidative stress, (3) proteosomal dysfunction, and (4) environmental factors, most of which have yet to be identified.

Oxidative stress appears to play an important role in the sporadic forms of PD. Endogenous sources of oxidative stress include the free-radicals produced by the metabolism of dopamine and melanin. Additional stress may come from defects in mitochondrial complex I of the oxidative phosphorylation chain in patients with PD. This defect has been detected in platelets and muscle and in postmortem tissue from the substantia nigra. Several toxins have been shown to cause oxidative toxicity and dopamine cell death in animal models of PD, further strengthening the above hypothesis. The most important of these are MPTP, a meperidine derivative, and rotenone, a commonly used insecticide. Both cause oxidative damage by inhibiting complex I. In vitro, oxidative stress can lead to aggregation of α-synuclein and proteosomal dysfunction. Proteosomal system abnormalities have also been described in the substantia nigra from sporadic cases of PD. The other factors of the selective dopamine neuron degeneration in PD are microglial activation, low-grade inflammation, and apoptosis, each a potential target for therapeutic intervention.

TREATMENT

General Considerations The goals of therapy in PD are to maintain function and quality of life and to avoid drug-induced complications. Bradykinesia, tremor, rigidity, and abnormal posture respond well to symptomatic therapy early in the course of the illness. In contrast, cognitive symptoms, hypophonia, autonomic dysfunction, and balance difficulties respond poorly. Primary motor disability in PD is often aggravated by secondary disability resulting from physical deconditioning following a sedentary life-style. Prevention of secondary disability requires a consistent program of physical activity, thus regular activity is strongly encouraged. Remaining mentally active is probably equally important.

A current priority is to move beyond symptom control to neuroprotective therapies. Unfortunately, no such therapy is yet available, although selegiline (deprenyl) may, in addition to a mild symptomatic effect, have a neuroprotective function. High doses of coenzyme Q_{10} and intrastriatal infusion of neurotrophic factors show promise in early clinical trials. Animal studies have shown that exercise can promote neuroprotection against neurotoxins.

TABLE 351-3 *Guide to the Use of Levodopa Formulations and Dopamine Agonists in Parkinson's Disease*

		LD Dose Equivalency, mg	Available Strengths, mg	Initial Dose	Other Considerations
CARBIDOPA/LEVODOPA (TYPICAL INITIAL STRENGTH)					
Carbidopa/levodopa IR 25/100	→	100 (anchor dose)	10/100 25/100 25/250	25/100; 0.5 tab tid	Target dose = 3–6 25/100 tabs/d
Carbidopa/levodopa CR 50/200	→	150	25/100 50/200	50/200; one tab bid to tid	Increased bioavailability with food; splitting the tablet negates the CR property
Carbidopa/levodopa/entacapone 25/100/200	→	120	12.5/50/200 25/100/200 37.5/150/200	25/100/200; one tab bid to tid	Do not split tablets

	DA Equivalent to LD Anchor Dose Above, mg[a]	Available Strengths, mg	Approximate Target Doses: Initial Dose, mg	Approximate Target Doses: As Monotherapy, mg/d	Approximate Target Doses: As Adjuncts to LD, mg/d	Other Considerations
DOPAMINE AGONISTS						
Non-ergot alkaloids						
Ropinirole	5	0.25, 0.5, 1, 2, 3, 4, 5	0.25 tid	12–24	6–16	Hepatic metabolism; potential drug-drug interactions Occasionally associated with "sleep attacks"
Pramipexole	1	0.125, 0.25, 1, 1.5	0.125 tid	1.5–4.5	0.375–3.0	Renal metabolism; dose adjustments needed in renal insufficiency Occasionally associated with "sleep attacks"
Ergot alkaloids						
Pergolide	1	0.05, 0.25, 1.0	0.05 tid	1.5–6	0.3–3	Rare reports of valvular heart disease; fewer reports of sleep attacks compared to non-ergots
Bromocriptine	2	2.5, 5.0	1.25 bid to tid	7.5–15	3.75–7.5	Rare reports of pulmonary and retroperitoneal fibrosis Relative incidence of sleep attacks not well studied

[a] Equivalency doses are approximations based on clinical experience and may not correlate with the relative in vitro binding properties of these compounds.

Note: LD, levodopa (with carbidopa); IR, immediate release; CR, controlled release; DA, dopamine agonist. Carbidopa/levodopa/entacapone, Stalevo.

Initiation of Therapy From a practical standpoint, dopaminomimetic therapy should be initiated as soon as the patient's symptoms begin to interfere with quality of life. The ideal agent for initiation of symptomatic therapy depends on the age and cognitive status of the patient and, to a lesser extent, the patient's clinical type and finances. The choices consist of either a levodopa preparation or a dopamine agonist. Controlled studies support the view that, in early PD, dopamine agonist monotherapy is well tolerated and significantly reduces the risk of later treatment-related complications such as motor fluctuations and dyskinesias. *Motor fluctuations* are the exaggerated ebb and flow of parkinsonian signs experienced by many patients between doses of antiparkinsonian medications. *Dyskinesias* refer to choreiform and dystonic movements that can occur as a peak dose effect or at the beginning or end of the dose (diphasic dyskinesias). More than 50% of patients with PD treated over five years with levodopa will develop these complications.

Successful dopamine agonist monotherapy requires a higher dose of the agonist than is typically needed when the agonist is used to supplement levodopa (Table 351-3). In both cases titration has to be slow and cautious to avoid unnecessary side effects. Patients benefit greatly from education and support during this titration. Most patients will require the addition of levodopa or another agent within 1 to 3 years of initiating dopamine agonist monotherapy. Preclinical studies suggest that the advantages of dopamine agonist monotherapy can be maintained with agonist-dominant therapy. In this case dopamine agonists continue to provide the bulk of dopaminomimetic therapy, with levodopa playing a supplementary role.

Although dopamine agonist monotherapy is considered the initial treatment of choice for most patients with PD, the long-term benefits noted above must be balanced against a higher incidence of non-motor side effects and a slightly higher level of motor disability than with levodopa. These recommendations may need to be modified in patients with psychotic symptoms or severe daytime sleep disturbances. Older patients and those with akinetic rigid phenotypes of PD have a lower risk of motor complications and dyskinesias compared to the average PD patient and may be satisfactorily treated with levodopa.

Pharmacotherapy of Motor Symptoms

The above advances in the initiation of therapy notwithstanding, levodopa remains the most effective treatment for PD. It significantly improves motor symptoms and increases quality of life and independence. The aim of all dopaminomimetic strategies is to restore dopamine transmission in the striatum. This is accomplished by stimulating postsynaptic receptors (directly with dopamine agonists), increasing dopamine precursor availability (levodopa), blocking the metabolism of levodopa in the periphery and in the brain, and blocking the catabolism of dopamine at the presynaptic terminal.

DOPAMINE AGONISTS Dopamine agonists readily cross the blood-brain barrier and act directly on postsynaptic dopamine receptors (primarily D_2 type). Compared to levodopa, they are longer acting and thus provide a more uniform stimulation of dopamine receptors. They are effective as monotherapeutic agents and as adjuncts to carbidopa/levodopa therapy. They can also be used in combination with anticholinergics and amantadine. Table 351-3 provides a guide to the doses and uses of these agents.

Available agents include two ergot alkaloids, pergolide and bromocriptine, and two non-ergot alkaloids, pramipexole and ropinirole. Apomorphine has been available for subcutaneous infusion and injection in Europe and Canada for many years and will soon become available in the United States as "rescue therapy" to help control motor

fluctuations ("off" spells) in patients with moderate to advanced disease. These agents are particularly effective in treating bradykinesia and gait disturbances, but they are less effective in treating tremor. Side effects include nausea, postural hypotension, psychiatric symptoms, daytime sedation, and occasional sleep attacks. These can be managed using the above strategies and, in severe cases, through the introduction of peripheral dopamine blockers such as domperidone (not available in the United States) or short courses of trimethobenzamide or dronabinol until the symptoms subside. Patients need to be warned against the potential for sleep attacks, which can occur without warning and have resulted in traffic accidents. This phenomenon has been most often associated with agonists and less so with carbidopa/levodopa. Pergolide has recently been shown to be associated with valvular disease. When used as adjuncts to levodopa therapy these agents can aggravate dyskinesias if the doses of carbidopa/levodopa are not adjusted accordingly, and they are more expensive than carbidopa/levodopa, which is now available in generic form.

CARBIDOPA/LEVODOPA FORMULATIONS Carbidopa/levodopa is available in regular, immediate release (IR) formulations (Sinemet, Atamet and others; 10/100 mg, 25/100 mg, and 25/250 mg), controlled release (CR) formulations (Sinemet CR 25/100 mg, 50/200 mg), and more recently as Stalevo (Table 351-3). The latter combines IR carbidopa/levodopa with 200 mg of entacapone (see below). In most individuals, at least 75 mg/d of carbidopa is necessary to block peripheral levodopa decarboxylation into dopamine and thus symptoms of nausea and orthostasis often associated with the initiation of levodopa. Initial target doses of these medications are summarized in the table. Individualized and gradual escalation of these doses is recommended. Initiation of dosing at mealtimes will reduce the incidence and severity of nausea. As patients develop tolerance to nausea and other side effects, these medications can be administered on an empty stomach, which generally leads to a more brisk and predictable absorption.

LEVODOPA AUGMENTATION Selegiline is a selective and irreversible monoamine oxidase (MAO) B inhibitor with a weak symptomatic effect when used as monotherapy or as an adjunct to carbidopa/levodopa. Typically, selegiline is used as initial therapy or is added to alleviate tremor or levodopa-associated wearing-off. The usual dose is 5 mg with breakfast and lunch. At this dose there is no need for dietary restrictions, as is the case with non-selective and MAO-A inhibitors. A significant side-effect of selegiline is insomnia. Older individuals, and those with significant cardiac abnormalities, may benefit from doses as low as 2.5 mg/d. The potential role of selegiline (or desmethylselegiline) as neuroprotective therapy remains controversial.

The catechol *O*-methyltransferase (COMT) inhibitors entacapone and tolcapone offer yet another strategy to augment the effects of levodopa by blocking the enzymatic degradation of levodopa and dopamine. Entacapone is preferred to tolcapone because of the low but potentially serious incidence of hepatic and hematologic side effects of the latter. When used in conjunction with carbidopa/levodopa, these agents increase the area under the curve of plasma levodopa by >30%. They alleviate wearing-off symptoms and increase by 1 to 2 h the time a patient remains "on" (i.e., well medicated) during the day. The more common side effects are gastrointestinal and hyperdopaminergic, including increased dyskinesias that may require reductions in the dose of carbidopa/levodopa. The dose of entacapone is 200 mg coadministered with each dose of carbidopa/levodopa. The dose of tolcapone is 50 to 200 mg tid.

Anticholinergics and amantadine are appropriate adjuncts to dopaminomimetic therapy. Anticholinergics are particularly useful for controlling rest tremor and dystonia, and amantadine can reduce drug-induced dyskinesias by up to 70%. The mechanisms of action of amantadine are unknown, although there is evidence it has both anticholinergic and dopaminomimetic properties. Recently amantadine has been shown to have weak glutamate antagonist properties, a mechanism thought responsible for reducing drug-induced dyskinesias. The side-effects of amantadine are nausea, headaches, edema, erythema, and livedo reticularis. In older patients, it may aggravate confusion and psychosis. Doses need to be adjusted in patients with renal failure.

Therapy of Non-Motor Symptoms Patients with frequent nighttime awakenings due to nocturnal akinesia or tremor can be treated with supplemental doses of carbidopa/levodopa at night. A bedtime dose of dopamine agonists helps restless leg symptoms and urinary urgency. Treatment of other bladder symptoms will improve sleep for many elderly patients. Depression typically responds to antidepressants [e.g., tricyclics, selective serotonin reuptake inhibitors (SSRIs)]. The combination of SSRIs and selegiline carries an exceedingly low risk of a hyperserotonergic syndrome (delirium with myoclonus and hyperpyrexia). Electroconvulsive therapy (ECT) is highly effective in drug-refractory cases or in patients intolerant of oral antidepressants. There are several reports indicating that ECT, in addition, has short-term benefit for parkinsonian motor symptoms.

In patients with psychotic symptoms or confusion, anticholinergics and amantadine should be eliminated first. In severe cases not responding to the above approach, some dopaminomimetics may have to be reduced or eliminated. Further drug simplification and dose reductions should proceed in the following order: selegiline, nocturnal doses of dopamine agonists, Sinemet CR, daytime doses of dopamine agonists, and finally, daytime doses of carbidopa/levodopa. If the patient improves after only a modest reduction of antiparkinsonian therapy, the overall impact on the parkinsonian motor symptoms will be negligible. If in the process parkinsonian symptoms worsen, most specialists initiate treatment with an atypical antipsychotic with a low incidence of extrapyramidal side effects rather than continuing to lower dopaminomimetic therapy. Quetiapine is recommended first because, although not as well studied in PD as clozapine, it has proved to be effective in open-label studies and lacks the small risk of agranulocytosis associated with clozapine. Typical doses of quetiapine are 12.5 to 100 mg/d, and for clozapine 12.5 to 100 mg/d. Both are dosed at night to promote sleep and minimize daytime sedation and orthostasis. Other atypical antipsychotics, such as risperidone and olanzapine, are not well tolerated by most patients with PD because they are associated with dose-dependent parkinsonism. Early evidence suggests that the use of acetylcholinesterase inhibitors may be well tolerated and capable of treating hallucinations and delusions in patients with PD and dementia.

Given the complexity of the above polypharmacy, the management of non-motor symptoms is best carried out in an interdisciplinary setting, coordinated by a neurologist who specializes in PD together with a psychiatrist and the patient's primary care physician.

Neuroprotective Therapy Reducing the progression of PD through neuroprotective or restorative therapy is a major focus of research. Epidemiologic studies suggest that the chronic use of nonsteroidal anti-inflammatory agents or the use of estrogen replacement in postmenopausal women may delay or prevent the onset of PD through yet unclear mechanisms. From a pharmacologic standpoint, current strategies involve interrupting the cascade of biochemical events that leads to death of dopaminergic cells (Fig. 351-2). The first such clinical trial in PD was the large multicenter DATATOP study in which selegiline monotherapy delayed the need for levodopa therapy by 9 to 12 months in newly diagnosed patients. Most evidence indicates that this delay was due to a mild symptomatic effect of selegiline. Long-term follow-up of the DATATOP cohort revealed that patients who remained on selegiline for 7 years experienced slower motor decline compared to those who were changed to placebo after 5 years. The 7-year patient group was more likely to develop dyskinesias but less likely to develop freezing gait. Finally, the metabolite of selegiline, desmethylselegiline, has been shown in laboratory studies to have powerful neuroprotective effects, possibly through interactions of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and other cellular protective (antiapoptotic) factors. Clinical trials to test this agent are under way.

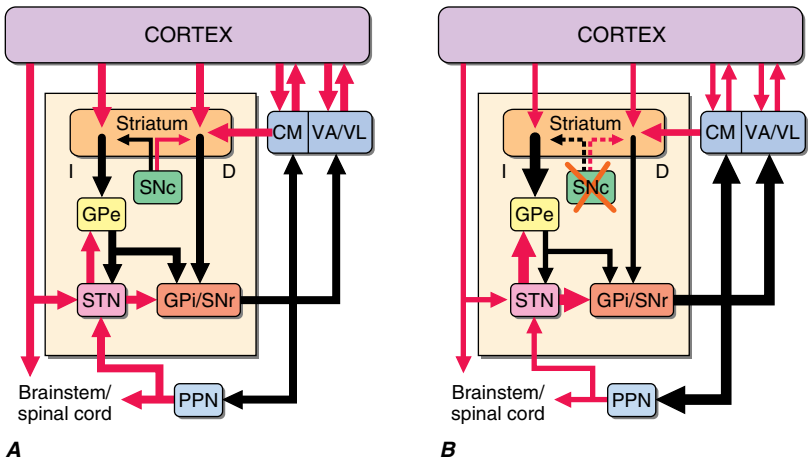

FIGURE 351-3 Schematic diagram of the basal ganglia–thalamocortical circuitry under normal conditions and in Parkinson's disease (PD). Inhibitory connections are shown as black arrows and excitatory connections as red arrows. Note that in PD, striatal dopamine denervation results in increased traffic in the indirect pathway and decreased traffic in the direct pathway. The downstream consequence of this is increased activity in striatal outflow stemming from the increased activity of STN and ultimately GPi/SNr neurons. Because striatal outflow is inhibitory to the thalamus (main neurotransmitter = γ-aminobutyric acid), there is a decrease in the ability of the thalamus to activate the frontal cortex leading to signs of parkinsonism. As discussed, changes in discharge pattern are also a major factor. D, direct pathway; I, indirect pathway; GPe, external segment of the globus pallidus; GPi, internal segment of the globus pallidus; SNr, substantia nigra, pars reticulata; SNc, substantia nigra, pars compacta; STN, subthalamic nucleus; VA/VL, ventral anterior and ventrolateral thalamus; CM, centromedian nucleus; PPN, pedunculopontine nucleus. *(Courtesy of T Wichmann, MD, Emory University School of Medicine.)*

In a recent trial, coenzyme Q_{10}, an antioxidant and a cofactor of complex I of the mitochondrial oxidative chain, appeared to delay progression of early disability in PD. Other potentially neuroprotective agents under investigation are acetyl-levo-carnitine and creatine monohydrate. A large controlled study of the antiglutamatergic agent riluzole (Chap. 353) was prematurely discontinued after a futility analysis revealed little effect on progression of symptoms. Dopamine agonists are also under investigation as putative agents to slow disease progression in PD, based on their possible antioxidant properties resulting in part from their ability in vitro to decrease dopamine turnover, scavenge free radicals, and interfere with proapoptotic cell signals. Other promising agents include nitric oxide synthetase inhibitors, antiapoptotic agents such as Jun N-terminal kinase inhibitors, and the antibiotic minocycline. Minocycline can inhibit microglial activation in vitro and interrupt apoptosis by inhibiting caspase 1 and 3, which are involved in the enzymatic processing of α-synuclein.

Surgical Treatments Over the past decade there has been a renaissance in the surgical treatment of PD and other movement disorders. Although both pallidotomy and thalmotomy were performed widely in the 1950s, the introduction of levodopa in the 1960s led to the virtual abandonment of surgery. The resurgence in the use of surgery has been motivated by the fact that after ≥5 years of treatment, many patients develop significant drug-induced motor fluctuations and dyskinesias. Second, advances in understanding of the functional organization of the basal ganglia and the pathophysiologic basis of parkinsonism have provided a clearer rationale for the effectiveness of these procedures and guidance for targeting specific structures (Fig. 351-3). The demonstration, in animal models of PD, that ablation of the STN (subthalamotomy) resulted in a dramatic reduction in all of the cardinal features of parkinsonism was a critical finding.

The selection of suitable patients for surgery is most important, since in general patients with atypical Parkinson's do not have a favorable response. The major indications for surgery are (1) a diagnosis of idiopathic PD, (2) a clear response to levodopa, (3) significant intractable symptoms of PD, and/or (4) drug-induced dyskinesias and wearing-off. Contraindications to surgery include atypical forms of PD, cognitive impairment, major psychiatric illness, substantial medical comorbidities, and advanced age (a relative factor). Signs and symptoms not responding to levodopa, such as postural instability and falling, hypophonia, micrographia, drooling, and autonomic dysfunction, are unlikely to benefit from surgery. As a rule of thumb, the benefits from surgery are unlikely to exceed the benefits of antiparkinson medication. In general, the decision for surgery should be made by a movement disorder neurologist who is part of a team including a neurosurgeon trained in functional neurosurgery, a psychiatrist, a neuropsychologist, and trained technicians.

ABLATION VERSUS DEEP BRAIN STIMULATION (DBS) The use of ablation (e.g., pallidotomy or thalamotomy) has decreased greatly since the introduction of DBS and is generally reserved for individuals who for medical or economic reasons cannot have DBS. Major advantages of DBS are that it is somewhat less invasive and more reversible than ablation, and in addition may be adjusted to best effect following implantation. Although the choice between the STN and the internal segment of the globus pallidus for DBS has shifted toward the STN, the data to support this are lacking. Several clinical trials are now under way to compare these two targets. The available evidence suggests that both are effective for all the cardinal features of PD as well as for dyskinesias and motor fluctuations. Unilateral stimulation is appropriate for patients with asymmetric disease, although bilateral surgery is generally necessary for patients with more advanced disease and for those with significant bilateral manifestations. Reductions in drug dosages appear to be easier with STN than globus pallidus procedures.

The mechanism of action of DBS remains controversial. Since clinically it appears that ablation and stimulation of a given target have a similar effect, it has been assumed that stimulation caused a functional blockade. It is likely, however, that multiple factors are involved. The basis for improvement may be the replacement of abnormal neural activity by a more tolerable pattern of activity. Following ablation or DBS, the remaining motor systems in the brainstem, thalamus, and cortex are able to compensate more effectively for the abnormal activity associated with the parkinsonian state. Whatever the mechanism, it is clear that these approaches can offer impressive results in properly selected patients.

NEUROTRANSPLANTATION AND OTHER SURGICAL APPROACHES Despite highly encouraging open-label pilot studies of fetal cell transplantation, this approach has suffered considerable disappointment with the recent publication of the results from two large, well-controlled clinical trials. The first, using sham surgery, showed only modest benefit in patients under 60 and no benefit in those over 60. An unexpected complication in a number of patients was the development of symptomatic dyskinesias, occurring off medication. The second study has shown similar findings with regard to benefit and the development of dyskinesias. A puzzling feature of these studies is the apparent successful grafting observed by PET and autopsy. Because of these disappointing results, the considerable obstacles to obtaining sufficient fetal tissue, and opposition to the use of fetal tissue on ethical grounds, this approach is now viewed as purely investigational. It is hoped that these issues can be addressed with the development of other strategies to enhance dopaminergic cell function (e.g., carotid body cells; stem cells; encapsulated and genetically engineered cells capable of producing levodopa, dopamine, and/or trophic factors). The favorable response from direct infusion of glial cell–derived neurotrophic factor (GDNF) to the putamen in a small number of patients with PD has raised hopes that this approach, or the use of gene-transfer of trophic factors such as GDNF, will succeed. Preliminary studies in primate models of PD have been encouraging in this regard.

DEMENTIA IN PARKINSON'S DISEASE As noted above, the incidence of dementia in PD may be as high as six times that in the general non-PD population. Approximately a quarter of patients will develop de-

mentia of the Alzheimer type simply due to the overlap of these two common age-related disorders. Pathologically, the incidence of AD-type findings in postmortem tissue from patients dying with PD is as high as 40%. Conversely, 25% of AD patients have at least mild clinical parkinsonian features such as rigidity and bradykinesia, and ≥60% have coexistent α-synuclein pathology in the cortex. Patients with PD-dementia (PDD) typically have the akinetic/rigid form of the disorder where tremor is less prominent than in idiopathic PD. The course of PDD is more rapid and the management is more difficult than in PD due to the high incidence of cognitive side effects from antiparkinsonian therapy, particularly anticholinergics and amantadine. Central dopaminomimetic toxicity can present in many ways, ranging from sleep disruption with daytime sleepiness, personality changes, depression and mental dullness, episodic confusion, hallucinations, and disruptive behaviors.

DLB is an increasingly recognized form of dementia with prominent parkinsonian features. The dementia may precede or follow the parkinsonian syndrome. In patients presenting with parkinsonian features, the dementia is often heralded by levodopa-induced sedation, myoclonus, and hallucinations. Early on, the phenotype can be indistinguishable from PD. Features that help differentiate this entity from PD include the presence of an action rather than a rest tremor, a rapidly fading response to levodopa, and rapidly fluctuating, spontaneous, and drug-induced problems with arousal. Another feature of DLB is the higher incidence of neuropsychiatric symptoms than in idiopathic PD. These symptoms include apathy, personality changes, depression, fixed delusions, and hallucinations. Finally, patients with DLB exhibit a heightened sensitivity to drug-induced parkinsonism (DIP) when exposed to any dopamine blocker. The progression of symptoms in DLB is intermediate between the PD and PD/AD overlap. →***DLB is discussed in detail in Chap. 350.***

OTHER PARKINSONIAN DISORDERS

PARKINSONIAN DISORDERS ASSOCIATED WITH ABNORMAL METABOLISM OF α-SYNUCLEIN (α-SYNUCLEINOPATHIES) ■ **Multiple System Atrophy** MSA represents a sporadic group of disorders characterized by varying degrees of parkinsonism and cerebellar, corticospinal, and autonomic dysfunction. The average age of onset is 50 years (earlier than in PD), and the median survival 6 to 9 years. The clinical presentation is highly varied and may begin with any of the above clinical signs. The unifying pathologic hallmark is the presence of α-synuclein-positive inclusions located in various brain regions.

CLINICAL PHENOTYPES With disease progression, 90% percent of patients exhibit parkinsonian signs, 80% signs of autonomic failure, and a similarly high percentage exhibit upper motor neuron signs. Tremor is common but, unlike in PD, this and other parkinsonian signs are more likely to present symmetrically. Parkinsonian symptoms are typically poorly responsive to dopaminergic therapy, although some patients may respond favorably for years. Drug-induced dyskinesias typically involve the face and neck rather than the trunk and limbs, as is the case in PD. Corticospinal signs consist of spasticity, involving the legs more than the arms, and pseudobulbar palsy. This aspect of the illness may mimic primary lateral sclerosis with lower motor neurons being occasionally involved. A few patients develop myoclonus.

Signs of autonomic failure include orthostatic hypotension, leg swelling not due to drug therapy, changes in sweating patterns, and autonomic storms with diaphoresis and flushing. Orthostatic hypotension can present with dizziness, faintness, or syncope. Once patients are successfully treated for syncope, they often develop fatigue and lassitude. This is due in part to chronic tissue hypoperfusion caused by marginal blood pressures while sitting or standing. More aggressive management of the blood pressure is warranted but not always successful. Urinary symptoms include urgency, retention, and incontinence. In men impotence is one of the earliest and most prominent signs. The autonomic dysfunction can precede or follow the development of other neurologic signs by several years. Dementia may not be as frequent as in PD.

The clinical phenotype of MSA can fall into one of three broad categories, termed *striatonigral degeneration* (SND), *olivopontocerebellar atrophy* (OPCA), and *progressive autonomic failure* (PAF), either without parkinsonism or with parkinsonism (Shy-Drager syndrome). Patients presenting with a relatively pure form of akinetic rigid parkinsonism and a limited response to levodopa are designated as SND. The diagnosis is difficult. Individuals with other signs such as ataxia, upper motor neuron and corticobulbar involvement, myoclonus, oculomotor abnormalities, peripheral neuropathy, and deafness fit into the category of OPCA. This phenotype is notably heterogeneous, with sporadic and hereditary forms. The sporadic forms are more likely to form part of the spectrum referred to in this section, with the hereditary forms usually representing one of the spinocerebellar ataxias (Chap. 352). Finally, a diagnosis of Shy-Drager syndrome is justified when the parkinsonian features are associated with prominent signs of autonomic dysfunction. Although the above categories remain clinically useful, it should be noted that as disease progresses, there tends to be more clinical and pathologic overlap than separation between these entities.

The spectrum of disease in MSA is determined by the location and density of the LB pathology. For instance, in PD the LBs are confined to neurons in the brainstem, and in DLB to the brainstem, cortex, and hippocampus. In MSA these deposits take the form of glial α-synuclein-positive intracytoplasmic inclusions in the substantia nigra, putamen, inferior olives, pontine nuclei, pigmented nuclei of the brainstem, the intermediolateral nucleus of the spinal cord, and the cerebellum. In addition in MSA there are myelin degeneration and oligodendroglia containing argyrophilic glial cytoplasmic inclusions that are immunoreactive for ubiquitin and α-synuclein. Similar inclusions can be found in neuronal cell bodies and processes.

Several diagnostic tests help differentiate MSA from PD and other parkinsonian syndromes. In OPCA, brain MRI reveals prominent atrophy of the cerebellum, pons, and olivary eminence of the medulla. In SND, prominent volume loss and T2-weighted image hyperintensity in the putamen, globus pallidus, and white matter may be present. Electrodiagnostic studies may reveal rectal sphincter abnormalities with signs of degeneration with reinnervation due to anterior horn cell loss. Commercially available genetic tests are available for many of the spinocerebellar ataxias (Chap. 352) that present with features that overlap OPCA.

TREATMENT

Early in the course of the illness parkinsonian features may respond to dopaminomimetic agents. These have to be used with caution due to their tendency to provoke orthostatic hypotension. →***Treatment of orthostatic hypotension and other autonomic symptoms is discussed in Chap. 354.***

PARKINSONIAN DISORDERS ASSOCIATED WITH ABNORMALITIES OF TAU METABOLISM (TAUOPATHIES) As in the synucleopathies, the discovery that a group of familial and sporadic disorders with pathology involving the microtubule-associated protein tau has helped classify a group of disorders characterized by atypical parkinsonism and dementia. In the less common familial forms, mutations in the *tau* gene have been linked to rare forms of parkinsonism and to frontotemporal dementia, another tauopathy discussed in Chap. 350. This discussion will focus on two entities that typically present with movement disorders. The first, PSP, has not been linked to mutations in the *tau* gene but is associated with overrepresentation of the H1 *tau* gene haplotype. These and other findings support the view that abnormal processing of tau may be directly linked to the pathogenesis of sporadic and familial tauopathies.

Progressive Supranuclear Palsy This is a sporadic neurodegenerative disorder of unknown etiology associated with tau pathology. It presents in the sixth to seventh decades and progresses faster than PD, with

death in 5 to 10 years. Risk factors include head trauma, vascular disease, dietary exposure to benzyl-tetrahydroisoquinolines (TIQ, reticuline), and beta-carbolines (reports from the West Indies).

PSP is characterized by akinetic rigid parkinsonism, dizziness, unsteadiness, slowness, falls, and pseudobulbar dysarthria. Tremor is distinctly uncommon. Supranuclear eye movement abnormalities affecting downgaze occur first, followed by variable limitations of upward and horizontal eye movement. Because the vestibular ocular reflex ("doll's eyes" maneuver) and the Bell's reflex (elevation and abduction of eyes on attempted lid closure) are intact, these abnormalities are termed *supranuclear*. Neurologic examination often reveals prominent stare and furrowed brow, axial (especially nuchal) and proximal distal limb rigidity and dystonia, as well as upper motor neuron and occasional cerebellar signs. Virtually all patients develop frontal-type cognitive dysfunction (Chap. 350), and a significant number may develop dementia with distinct subcortical features (e.g., abulia, mental inflexibility, and defects in memory retrieval). Brain MRI reveals midbrain atrophy (superior colliculus), and PET studies show symmetric frontal and striatal hypometabolism. Although some response may occur to levodopa and other antiparkinson medications, especially early in the course, treatment is generally not highly effective. The diagnosis is made on clinical grounds.

Pathologically, PSP is characterized by deposition of neurofibrillary tangles histochemically positive for tau (mostly 4-repeat tau) and negative for amyloid or α-synuclein. The deposits are associated with varying degrees of degeneration in the brainstem, basal ganglia, and cerebellum. There is loss of dopamine and dopamine receptors due to intrinsic striatal damage. This is thought to account for the poor response to therapy.

Corticobasal Degeneration (CBD) CBD, another sporadic tauopathy, is less common and has a broader range of clinical presentations than PSP. As with most atypical forms of parkinsonism, it begins insidiously in the sixth to seventh decades with varying degrees of asymmetric progressive apraxia, rigidity, dystonia, bradykinesia, and myoclonic jerks with or without cortical sensory loss. Alien limb phenomena is a characteristic sign present in many cases. The disorder progresses to become bilateral over 2 to 5 years, leading to total incapacity with, ultimately, paraplegia in flexion. A significant number of cases present with frontotemporal dementia or progressive aphasia, followed by asymmetric cortical sensory signs, including abnormalities of graphesthesia and astereognosis (Chap. 350). Brain MRI reveals focal cortical loss in the contralateral superior frontal and parietal lobes with corresponding hypometabolic changes on PET scan, as well as hyperintense signal abnormalities in white matter and sometimes atrophy of the corpus callosum. Treatment is largely ineffective.

Grossly, CBD is a focal cortical degenerative process with asymmetric pathology and volume loss in the parietal and frontal regions. Most of the damage is in the dorsal peri-Rolandic, superior frontal, and superior parietal cortices, whereas cases with aphasia show abnormalities in the peri-Sylvian regions. Histologically, gliosis and swollen (ballooned) achromatic neurons and neuronal loss are present in these cortical regions as well as in the nigra, caudate, putamen, and thalamus. Recent clinicopathologic evidence indicates the syndrome can occur in the absence of basal ganglia or nigral degeneration.

SECONDARY PARKINSONISM ■ Drug-Induced Parkinsonism DIP closely resembles PD except for the tremor, which is generally (but not always) less prominent. It is commonly due to neuroleptics, some atypical antipsychotics, lithium carbonate, or antiemetic agents (especially metochlopramide). Less common causes include valproic acid and, more recently, fluoxetine. DIP can be induced as well by the chronic administration of antihypertensive agents such as reserpine and alpha-methyldopa. Exposure to manganese, carbon monoxide or disulfides, cyanide, and methanol can also lead to a parkinsonian state. The severity of the parkinsonian symptoms usually correlates with the dose or exposure to a medication or toxin. If due to medication, the symptoms tend to disappear within days to weeks after stopping the offending agent but may be permanent. Patients with permanent symptoms may have been in the process of developing parkinsonism. DIP may respond to anticholinergic agents, amantadine, and levodopa.

Vascular Parkinsonism The concept of vascular or atherosclerotic parkinsonism remains a topic of controversy. Generally, patients with vascular parkinsonism exhibit an akinetic-rigid syndrome with short mincing steps without tremor. Most have neurologic signs distinguishable from those associated with PD, including upper motor neuron signs, pseudobulbar palsy, or dementia. A poor response to levodopa therapy is characteristic. Imaging studies are heterogeneous and may reveal basal ganglia lacunes or multiple infarcts. The hypertensive and diabetic microangiopathy and diffuse white matter disease (Chap. 349) typically present with patchy, confluent or diffuse white matter in the centrum semiovale. Other causes of microangiopathy can also rarely be a cause. The premortem diagnosis of these disorders is difficult to make with certainty, given the absence of disease markers.

TREMOR

Tremor is defined as an "approximately rhythmic and roughly sinusoidal movement of variable amplitude and frequency" (Elble and Koller). Not all tremors are abnormal; most are involuntary with occasional voluntary tremors occurring in malingerers. Individuals with conversion disorders may show partial control over their tremor symptom. Physiologic tremor is a normal high-frequency, low-amplitude tremor notable only during hyperadrenergic states. Parkinsonian rest tremor is discussed above. Cerebellar kinetic tremor is discussed in Chaps. 21 and 352. Kinetic tremors can be postural, action, or both. Postural tremor is most prominent when the arms are held in front of the chest. Action or intention tremor is most notable when reaching to a target. Most tremor disorders have a predominant tremor type and a variable representation of other tremor types.

ESSENTIAL TREMOR ET is perhaps the most common movement disorder, affecting 5 to 10 million adults and a few children in the United States. It is characterized by a 6- to 12-Hz postural and kinetic tremor affecting the arms in almost all cases. In order of decreasing frequency, other body parts that can also be involved include the head (titubation), legs, the larynx (voice tremor), and the trunk. Diagnosis is made on clinical grounds. An autosomal dominant inheritance pattern is likely; thus a positive family history is very helpful, as is a history of partial response to alcohol consumption. Drugs that can aggravate any tremor include valproic acid, lithium, β-adrenergic agonists, methylxanthines, thyroxin, glucocorticoids, tricyclic antidepressants, and serotonin reuptake blockers. Withdrawal from drugs associated with tolerance, or medical conditions such as thyrotoxicosis and other enhanced adrenergic states, can amplify physiologic tremor, mimic pathologic tremors, or aggravate ET.

Compared to PD, symptoms of ET are generally bilateral from onset and the course slower. A small subset of patients has comorbid PD. ET can nonetheless be associated with significant disability, depending on amplitude of the tremor and the body region involved. Anxiety disorders are comorbid in a significant number of cases, and, as in all movement disorders, symptoms and signs worsen during emotional and physiologic stress. There is no consensus with respect to any pathology associated with ET, and diagnostic imaging of the brain is normal.

TREATMENT

There is no cure for ET, but symptoms can be managed adequately with pharmacologic interventions in ~50% of cases and with surgical interventions in 80% of patients. Primidone and propranolol are the first-line treatments for ET; both have shown efficacy in double-blind, placebo-controlled studies. Primidone (50 to 750 mg/d) is often highly effective. The starting dose should be 25 mg (one-half of a 50-mg tab) at bedtime, with slowly increasing doses to minimize sedation. Propranolol (40 to 320 mg/d) is better tolerated but no more effective and is contraindicated in patients with asthma, bradycardia, and some car-

diac conduction defects. Additional medications with potential efficacy (with or without the primary agents) include benzodiazepines, gabapentin, topiramate, and botulinum toxin injections to affected muscle groups. Approximately 80% of patients resistant or intolerant to pharmacotherapy respond to thalamotomy or to deep brain stimulation of the ventral intermediate nucleus of the thalamus.

HYPERKINETIC DISORDERS

Hyperkinetic movement disorders (Chap. 21) encompass a wide variety of involuntary movements, which may occur in isolation or in combination. Hyperkinesias have a wide spectrum of severity ranging from subtle restlessness to the violent movements of hemiballismus and the highly complex and emotionally laden vocal tics and coprolalia in Tourette syndrome.

HEMIBALLISMUS/HEMICHOREA Hemiballismus, a dramatic disorder, is typically acute in onset and ranges from mild chorea to the wild flinging movements of ballism. Hemiballismus may be viewed as a large-amplitude, violent form of chorea affecting the proximal more than the distal limbs. The most common cause is a lesion of the subthalamic nucleus, most often a hypertensive lacunar stroke (Fig. 351-4). Other cerebral lesions associated with hemiballismus and hemichorea include cortical, thalamic, and basal ganglia infarcts or lesions and demyelinating disease. Medical management of hemiballismus consists of supportive care to avoid injuries, exhaustion, and dehydration. The condition is difficult to treat pharmacologically but the drugs most consistently beneficial are tetrabenazine (not available in the United States), haloperidol, propranolol, phenytoin, clonazepam, and baclofen. Although hemiballismus was once thought to carry a poor prognosis, with proper treatment there is a high likelihood of survival and improvement over weeks to months. In intractable cases, pallidotomy or thalamotomy can be highly effective.

HUNTINGTON'S DISEASE HD is a fatal autosomal dominant disorder characterized by progressive motor, emotional, and cognitive dysfunction. Onset is typically between the ages of 35 and 45 years (range 3 to 70). HD occurs worldwide, with a prevalence of 10 cases per 100,000. It is caused by mutations in the Huntington's gene on the short arm of chromosome 4, specifically an expanding and unstable polyglutamine repeat (CAG) in its coding sequence. The gene encodes the highly conserved cytoplasmic protein huntingtin, which is present in all neurons.

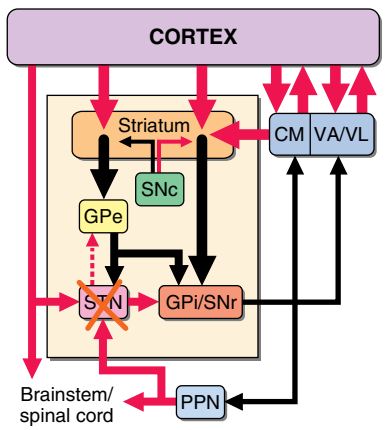

FIGURE 351-4 Schematic diagram of the basal ganglia–thalamocortical circuitry in hemiballismus, a surrogate in this case for other hyperkinetic movement disorders. As in Fig. 351-3, inhibitory connections are shown as black arrows and excitatory connections as red arrows. In hemiballismus the sudden loss of activity in STN neurons or their connections results in the loss of the normal thalamic inhibition by basal ganglia outflow, leading to poorly modulated and excessive thalamic activation of cortex. Clinically the patient exhibits abnormal contralateral choreiform movements. Dopamine antagonists help reduce the violence of the movements by decreasing neuronal activity in the direct pathway and increasing it in the indirect pathway, elevating neuronal activity in GPi/SNr. Parodoxically, surgical lesions of GPi/SNr are also beneficial, suggesting that abnormalities in neuronal discharge patterns are a major factor as well. D, direct pathway; I, indirect pathway; GPe, external segment of the globus pallidus; GPi, internal segment of the globus pallidus; SNr, substantia nigra, pars reticulata; SNc, substantia nigra, pars compacta; STN, subthalamic nucleus; VA/VL, ventral anterior and ventrolateral thalamus; CM, centromedian nucleus; PPN, pedunculopontine nucleus. *(Courtesy of T Wichmann, MD, Emory University School of Medicine.)*

Clinical Features A clinical diagnosis of HD can be made readily in cases with a positive family history and an insidious onset of chorea with variable degrees of dementia and emotional symptoms. The term *chorea* ("dance") refers to arrhythmic involuntary movements that are typically sudden and brief and that seem to flow from one part of the body to another. When combined with slower writhing movements or dystonic posturing, the term *choreoathetosis* is often used. Examples of other involuntary movements that may be confused with chorea include myoclonus and tics. Myoclonic jerks are lightning fast but lack the rhythmic flow of activity seen in chorea. While patients with myoclonic jerks commonly lose motor control and drop objects, this rarely happens with chorea or tics. Unlike chorea and myoclonus, motor tics can be readily suppressed voluntarily.

The clinical course of HD can last 15 to 20 years. In the early stages the chorea is focal and segmental (i.e., increased blinking, grimacing) but progresses to involve multiple body parts. The chorea typically peaks within 10 years and is gradually replaced by bradykinesia, rigidity, and dystonia. In 6 to 10% of cases HD may present with a parkinsonian syndrome rather than with chorea (Westphalt variant). The latter cases typically have an early onset (e.g., $<$ 20 years). The behavioral and cognitive disturbances characteristic of HD most often account for the brunt of the patient's disability and most of the hardship to the family. Approximately one-third develop dysthymia or an affective disorder; one-third an intermittent explosive disorder; and the remaining third substance-abuse problems, sexual dysfunction, antisocial personality traits, or schizophreniform symptoms. Depression with suicidal tendencies is not uncommon. Even the minority who may not manifest behavioral problems ultimately succumb to dementia.

The diagnosis of HD is confirmed with genetic testing, which is also helpful in the differential diagnosis of chorea of unknown etiology and in cases of atypical dementia or psychosis. Genetic testing is also used for genetic counseling in adults but is usually not necessary in symptomatic individuals if there is genetic or pathologic confirmation of HD in other family members. Other conditions important in the differential diagnosis of HD include so-called senile chorea occurring in older individuals, benign hereditary chorea in younger individuals, and neuroacanthocytosis, a progressive autosomal recessive degeneration of the basal ganglia associated with acanthocytosis of red cells in the peripheral smear and normal plasma lipoproteins. Ancillary diagnostic measures include MRI to determine if there is caudate atrophy. Other diagnostic measures may be helpful in atypical cases without a clear family history and in cases where the genetic testing results are indeterminate. These tests include PET, which typically reveals decreased striatal metabolic activity before atrophy is apparent, and neuropsychologic testing.

Pathology and Pathophysiology The neuropathology of HD consists of widespread cerebral atrophy with prominent involvement of the striatum and cerebral cortex. Neuronal loss and gliosis are maximal in the caudate initially, with lesser involvement of the cortex and other subcortical structures. Although the mechanism of cell death in HD remains unclear, there is now experimental evidence to support the hypothesis that abnormal glutamatergic transmission with excitotoxicity of striatal cells bearing glutamate receptors plays a role.

TREATMENT

Treatment should involve a multidisciplinary team that can provide social, medical, neuropsychiatric, and genetic guidance to patients and families throughout the course of the illness. Although dopamine blockers are moderately effective for chorea, they may aggravate bradykinesia and dystonia. Atypical antipsychotics such as clozapine, risperidone, and olanzapine are better tolerated but may not be as effec-

tive. The indications for treating chorea include interference with activities of daily living and social embarrassment.

Depression responds to conventional antidepressant therapy. The therapy needs to be monitored carefully since it can produce mania or precipitate suicide, a particularly serious problem in HD. Anxiety responds to benzodiazepines as well as to effective treatment of depression. Long-acting benzodiazepines are favored over short-acting ones because of the lesser potential for abuse and paradoxical excitation.

Psychosis can be treated with atypical neuroleptics clozapine (50 to 600 mg/d), quetiapine (100 to 600 mg/d), and risperidone (2 to 8 mg/d). These medications control dyskinesias as well as traditional neuroleptics but have fewer extrapyramidal side effects. When these drugs cannot be tolerated, smaller doses combined with tetrabenazine can be tried. There is currently no adequate treatment for the motor and cognitive decline of HD.

DYSTONIA ■ Clinical Features *Dystonia* is a syndrome consisting of involuntary muscular contractions that result in twisting and repetitive movements and/or abnormal postures. Dystonia comprises a large and heterogeneous group of disorders. Although dystonia is one of the more common movement disorders, it is also one of the most frequently under- and misdiagnosed due to its highly variable presentations. The prevalence is not certain because of underreporting but probably exceeds 300,000 cases in the United States, a prevalence equal to that of multiple sclerosis.

Co-contraction of agonist and antagonist muscles is a fundamental feature of dystonia, distinguishing it from chorea, tics, and other dyskinesias. Also, unlike other hyperkinetic movement disorders, dystonia is characteristically present during attempted voluntary movement (so-called action dystonia). It is also associated with "overflow," the abnormal spread of activation to muscles other than those required for the intended movement. As with most movement disorders, dystonia is exacerbated by stress and fatigue. A unique feature of dystonia is that it can often be attenuated by sensory (tactile or proprioceptive) input (so-called sensory tricks). For instance, in patients with torticollis, placing a finger on the chin or the hand on the neck may reduce the twisting movements or abnormal postures. Another common feature of primary dystonia is the presence of dystonic tremor, which may appear in a form resembling essential tremor or as a succession of rapid dystonic movements.

The dystonias can be classified according to: (1) age of onset (childhood vs. adult), (2) region of the body involved, and (3) etiology. Using an etiologic scheme, similar to that used for PD, the dystonias may be divided into primary, secondary, dystonia-plus syndromes, and hereditary degenerative disorders.

PRIMARY DYSTONIA Primary dystonia includes syndromes in which dystonia is the only clinical manifestation of the disease (other than tremor), and no pathologic changes are evident. Primary dystonia is often inherited and a number of genes have been identified. The major childhood disorder in this group is idiopathic torsion dystonia (ITD), or Oppenheim's dystonia. Sporadic adult-onset focal dystonias are the most common forms of primary dystonia.

Oppenheim's Dystonia ITD dystonia is an autosomal dominant hereditary disorder affecting primarily Ashkenazy Jewish families (up to 90% of all cases of dystonia) but also present in non-Jewish families. The gene is located on chromosome 9q34 and results in a loss of glutamic acid in the protein Torsin A. The penetrance is about 30%. Families with ITD dystonia may exhibit either generalized or focal dystonia. The age of onset is typically in childhood for generalized and later for focal dystonia. The first signs of dystonia generally occur in the foot during walking or in the arms during voluntary movement. Dystonia later occurs at rest, leading to postural abnormalities. It usually spreads to the arm on the same side before spreading to the other side of the body. The age of onset is typically later in cases in which the symptoms begin in the arm or neck. In late-onset ITD the dystonia tends to remain focal, in contrast to early-onset forms that usually become generalized.

Focal Dystonias The most common forms of dystonia are the focal dystonias, which present primarily in adults. These may affect (1) the eyelids, causing them to close involuntarily (*blepharospasm*); (2) the neck and shoulders (*cervical dystonia*), causing the neck to twist to the side (*torticollis*), forward (*anterocollis*), or backward (*retrocollis*); (3) the lower face and jaw or a syndrome causing the jaw to move incessantly (*oromandibular dystonia*); and (4) the larynx (*spasmodic dysphonia*), causing the voice to have a strained and discontinuous quality due to involuntary closing of the vocal cords with phonation. The combination of lower facial and jaw dystonia (*Meige's syndrome*) is not uncommon. Another type of task-specific focal dystonia affects the hand and forearm in specific activities such as handwriting (writer's cramp), typing, or playing a musical instrument (musician's cramp). Dystonia can, in fact, occur in almost any situation involving repetitive activities of the hand or other body parts. The focal dystonias are still often misdiagnosed as psychiatric or orthopedic problems.

The role of hereditary and environmental factors in adult-onset focal dystonia is not well understood. There is now mounting evidence that in some cases dystonia can develop from peripheral factors such as trauma to peripheral nerves. In addition to peripheral injury, discrete cerebral lesions, typically involving the basal ganglia but also the thalamus, cortex, or brainstem, can cause unilateral dystonia. The most frequent cause is a cerebral infarction but trauma, tumor, and other lesions may be accountable. In the case of infarction, the onset of dystonia is typically delayed by weeks to months as the associated hemiparesis clears.

SECONDARY DYSTONIAS Secondary dystonias are largely due to drugs and other environmental factors. The drug-induced phenomena include levodopa-induced dystonia as well as acute and tardive dystonia associated with dopamine receptor blockers (see "Drug-Induced Movement Disorders," below). External factors producing dystonia include cerebral palsy (athetoid form), cerebral trauma, peripheral nerve injury, cerebral hypoxia, some infectious and postinfectious states, and toxic exposure to manganese, cyanide, and 3-nitro proprionic acid.

Dystonia-Plus Syndromes Two types of dystonia-plus syndromes deserve mention—dopamine-responsive dystonia (DRD) and myoclonic dystonia. DRD is a dominantly inherited disorder associated with mutations in the gene for cyclohydrolase I (*GTPCH*), the rate-limiting enzyme in the synthesis of the tyrosine hydroxylase cofactor tetrahydrobiopterin. Tyrosine hydroxylase is the rate-limiting enzyme for dopamine synthesis. DRD typically presents in childhood beginning in the legs and spreading to the arms. Marked diurnal fluctuations are common. In the typical case a child aged between 4 and 8 develops a stiff-legged gait that worsens as the day progresses but improves dramatically on awakening from sleep. Some patients exhibit parkinsonism and signs of spasticity. In late-onset cases the presentation may consist of parkinsonism instead of dystonia. Patients have an excellent response to levodopa and a non-progressive course. DRD may be misdiagnosed as "athetoid" cerebral palsy, "spastic" paraplegia, or parkinsonism. Although rare, DRD is so responsive to levodopa that many feel that a trial of levodopa is warranted in all cases of dystonia.

The hereditary syndrome of myoclonic dystonia (also called hereditary dystonia with lightning jerks) is not always easily distinguished from primary dystonia or heredity essential myoclonus. It is distinguished not only by its character but also by its responsiveness to alcohol.

The hereditary degenerative diseases that may manifest dystonia typically present with more prominent parkinsonian features and include Wilson's disease, HD, PD, corticobasal degeneration (CBD), progressive supranuclear palsy (PSP), the Lubag form of dystonia-parkinsonism (DYT3), Leigh's disease, and other mitochondrial encephalopathies.

Pathophysiology There is now considerable evidence for a loss of inhibition at multiple levels in the central nervous system (CNS), in-

cluding the cortex, brainstem, and spinal cord, in patients with both generalized and focal dystonia. Dystonia appears to result primarily from dysfunction within the basal ganglia. As in PD, both ablation and DBS of the internal segment of the globus pallidus are effective in ameliorating the abnormal motor signs. Experimental studies in humans and animals have demonstrated a degradation of sensorimotor representation in the cortex, suggesting a disturbance of neuroplasticity.

TREATMENT

Treatment for dystonia is for the most part symptomatic except in the rare instances such as Wilson's disease (Chap. 339) or DRD, where known mechanisms are present and specific therapies are available. The available treatments include physical and emotional support, physical therapy and neurorehabilitation, drugs, and surgery. The importance of education and supportive care must be recognized. Sensory retraining in humans with focal dystonias has resulted in a substantial recovery of function in some patients. Patients with generalized dystonia benefit from a team approach in a specialized center.

Pharmacotherapy Anticholinergic drugs are the most effective forms of treatment for generalized primary dystonia. Trihexyphenidyl is most commonly used. Doses ≥120 mg/d in children may be necessary, with a usual range of 20 to 50 mg/d. Adults can rarely tolerate these high doses. The limiting factors include constipation, dry mouth, blurred vision, and urinary retention as well as impaired short-term memory, confusion, and hallucinations. Benzodiazepines, including clonazepam or diazepam, are also effective for dystonia, alone or in combination with anticholinergics. Dosages are raised slowly until benefits are obtained or side effects, including sedation, ataxia, and confusion, prevent further escalation. Baclofen, a drug similar to the naturally occurring neurotransmitter γ-aminobutyric acid (GABA), is also effective for treating both focal and generalized dystonia. Relatively high doses are required (60 to 100 mg); however, side effects are often limiting. A baclofen pump for intrathecal infusion may be helpful for such cases. Dystonia involving the legs and trunk is most responsive to this form of therapy. Unfortunately, sustained benefits are not the rule and complications are not infrequent. Dopaminergic drugs are occasionally beneficial in both generalized and focal dystonias, but the most dramatic effects are seen in individuals with DRD, who experience a dramatic and sustained improvement with even a small dose of levodopa. Paradoxically, a fair percentage of patients with generalized dystonia (and craniocervical dystonia) respond to dopaminergic antagonists, such as haloperidol or pimozide. Sometimes the combination of tetrabenazine, pimozide, and trihexyphenidyl is effective.

Botulinum Toxin Although the focal dystonias are generally poorly responsive to drugs, they often respond dramatically to botulinum toxin injected into the affected muscle groups. Botulinum toxin can also be used in generalized dystonia for the occasional treatment of focal problems. Botulinum toxin acts by blocking the release of acetylcholine at the neuromuscular junction, resulting in dose-dependent weakness. Repeated injections are required every 2 to 5 months. Botulinum toxin serotypes A and B are now available, providing an alternative should resistance develop to either serotype.

Surgical Approaches Prior to the introduction of botulinum toxin, peripheral denervation procedures, such as dorsal or anterior cervical rhizotomy and selective peripheral denervation, were commonly performed, primarily for the treatment of cervical dystonia. These are now performed far less frequently, generally in patients with cervical dystonia who fail botulinum toxin injections. Stereotactic surgery is used primarily for severe generalized dystonia unresponsive to other treatments. In recent years following the success in PD, pallidotomy and DBS of the pallidum are being used with promising results. The best candidates for surgery appear to be individuals with primary (DYT1) dystonia. Patients with secondary forms of dystonia are less likely to benefit. Bilateral surgery is usually necessary to obtain control of axial dystonia.

TOURETTE SYNDROME

The most common disorder characterized by tics is Tourette syndrome (TS), a neurodevelopmental disorder with neurologic and behavioral manifestations. The true prevalence of TS disorders is unknown but has been estimated at 0.05%. In addition to tics, approximately half of patients develop comorbidities, specifically obsessive-compulsive disorder (OCD) and attention-deficit hyperactivity disorder (ADHD).

Clinical Features A *tic* is a brief, rapid, repetitive, and seemingly purposeless stereotyped action that may involve one or more muscle groups. Tics are divided into motor or vocal types, depending on the affected muscle group, and into simple and complex, depending on the number of muscle groups involved and the associated behaviors. They can range from the barely detectable and easily rationalized "nervous habits" such as blinking, twitching of the nose, and jerking of the neck, to the complex, emotionally laden, and sometimes offensive utterances of a minority of patients (*coprolalia*). Tics can be associated with brief focal sensory experiences termed *sensory tics* that commonly affect the face, head, and neck areas. Some tics may be difficult to distinguish from other fast "jerky" movements, such as chorea and myoclonus, but are unique in that they can be voluntarily inhibited for a brief period of time.

Developmentally, attentional problems develop before school and tics present during the first years of school. OCD symptoms develop later, just before or during adolescence. Tics and ADHD symptoms tend to stabilize with aging. The OCD symptoms have a more variable course.

The inheritance pattern of TS best fits the model of a major gene or genes with low penetrance, modifier genes, and a phenotype influenced by environmental factors. The risk of a family with one affected child of having another is 25%. No specific gene has been linked to TS, however. In PET studies using selective dopamine D_2-receptor ligands, alleles of this gene have been shown to modify symptom severity.

TREATMENT

Tic symptoms have been ascribed to an overactivity of dopaminergic circuits. Accordingly dopamine blockers have consistently improved symptoms. Tics are not the most disabling feature of the illness, and treatment is generally indicated only when tics interfere with quality of life. The typical antipsychotics, Fluphenazine, haloperidol, and pimozide, thought to be very effective at treating tics, have been associated with extrapyramidal symptoms and school phobias. More recently, selected atypical antipsychotics have been shown to control tic symptoms and to have a lower incidence of these complications compared to typical antipsychotics. Drugs in this category include risperidone (0.5 to 4 mg/d), olanzapine (5 to 30 mg/d), and ziprasidone (80 to 200 mg/d). Other treatments for tics include clonidine (0.1 to 0.4 mg/d or the equivalent as transdermal patch), guanifencine (0.5 to 2 mg/d), and clonazepam (0.5 to 4.0 mg/d). Botulinum toxin injections can be effective in controlling focal tics involving small muscle groups. In general, symptoms of anxiety and OCD should be treated first since their control may preclude the need to treat the tics (Chap. 371).

DRUG-INDUCED HYPERKINETIC DISORDERS

This important group of iatrogenic and mostly reversible movement disorders is primarily associated with drugs that directly or indirectly affect central dopaminergic transmission. CNS stimulants, levodopa, dopamine agonists, and dopamine receptor blockers are the most common offending agents. The mechanism of acute and subacute movement disorders appears to result from idiosyncratic extensions of the intended action of the compound. By contrast, the mechanism of delayed or tardive dyskinesia (TD) syndromes remains more obscure.

DRUG-INDUCED MOVEMENT DISORDERS ■ Acute Reactions in this category include acute dystonia in response to dopamine antagonists,

which appears most frequently in a generalized form in children and in a focal form (e.g., blepharospasm, torticollis, or oromandibular dystonia) in adults. These movements can be readily treated with the parenteral administration of anticholinergics (benztropine or diphenhydramine) or benzodiazepines (lorazepam or diazepam). Other acute movement disorders include dyskinesias, stereotypic behaviors, and tics after exposure to CNS stimulants such as methylphenidate, dextroamphetamine, and pemoline.

Subacute Probably the most common of these reactions is neuroleptic-induced akathisia, a state of motor restlessness with a feeling of restlessness and a need to move, which tends to alleviate the symptoms temporarily. Therapy consists of removing the offending agent(s). When this is not possible, symptoms can be ameliorated with benzodiazepines, anticholinergics, beta blockers, and, in some cases, dopamine agonists.

Tardive Tardive movement disorders such as TD are primarily due to chronic exposure to central dopamine blockers. The movements are most often choreatic, affecting first the mouth, lips, and tongue and later the trunk and limbs. In a fully developed case there can be head nodding, pelvic rocking, and fine movements of the fingers and toes. The diaphragm is affected rarely, producing respiratory distress. Other tardive syndromes include tardive dystonia, which generally presents with more axial than appendicular involvement; tardive akathisia; tardive tics; and even tardive tremor.

Approximately one-third of patients with TD remit within 3 months of stopping neuroleptic therapy, and in most patients the movements will gradually remit within 5 years. Patients at risk of permanent TD include the elderly, the edentulous, and those with underlying organic cerebral dysfunction. Patients with affective illnesses appear more likely to develop TD than patients with schizophrenia. Since treatment of TD is most often unsatisfactory and frustrating for both patient and physician, it is critical that typical antipsychotics be used judiciously and that, once started, their continued need be reassessed periodically. Abrupt drug cessation may result in "withdrawal dyskinesias," which presage the development of frank TD.

Rx TREATMENT

Atypical antipsychotics (clozapine, risperidone, olanzepine, quetiapine, ziprasidone, and aripiprazole) significantly lower the risk of TD compared to typical antipsychotics. Accordingly, if withdrawal of the offending antipsychotic is not possible, replacing traditional with atypical antipsychotics should be tried. Furthermore, it appears that atypical antipsychotics can successfully block the dyskinesias themselves. Elimination of stimulants and anticholinergics will also alleviate dyskinesias. In refractory cases, choreatic TD can be treated with the catecholamine depletors reserpine and tetrabenazine. Reserpine should be started at 0.125 mg/d and escalated slowly as needed up to 6 mg/d. Tetrabenazine should be started at 12.5 mg/d and gradually increased as necessary up to 200 mg/d. The elderly are less likely to tolerate the dose-dependent sedation and orthostatic hypotension associated with these drugs. Approximately 15% of patients on catecholamine depletors develop depression with chronic use of reserpine. Another strategy employs GABAergic medications such as baclofen (40 to 80 mg/d), clonazepam (1 to 8 mg/d), or valproic acid (750 to 3,000 mg/d). The latter strategy is particularly helpful in patients with tardive dystonia, which may also benefit from anticholinergic therapy and botulinum toxin injections.

Neuroleptic Malignant Syndrome (NMS) This serious complication of neuroleptic medications occurs in 1 to 2% of treated individuals; the mortality rate is as high as 20%. Muscle rigidity with myonecrosis; an altered mental status resembling catatonia; and autonomic dysfunction with hyperthermia, tachycardia, and a labile blood pressure constitute the principal manifestations. Symptoms typically evolve subacutely over several days and usually occur in the first few weeks following initial exposure to the drug, but can develop anytime. NMS can also be precipitated by the abrupt withdrawal of antiparkinson medications.

Rx TREATMENT

Treatment begins with immediate cessation of the offending antipsychotic drug as well as lithium and anticholinergic agents, which appear to increase the risk of NMS. Careful monitoring of body temperature, hydration, electrolytes (especially K^+), and blood pressure are essential. Specific pharmacologic agents include dopamine agonists or levodopa, amantadine, and benzodiazepines as well as dantrolene. Supportive measures include antipyretics, cooling blankets, fluids, and measures to maintain blood pressure.

352 ATAXIC DISORDERS

Roger N. Rosenberg

APPROACH TO THE PATIENT

Symptoms and signs of ataxia consist of gait impairment, unclear ("scanning") speech, visual blurring due to nystagmus, hand incoordination, and tremor with movement (Chap. 21). These result from the involvement of the cerebellum and its afferent and efferent pathways, including the spinocerebellar pathways, and the frontopontocerebellar pathway originating in the rostral frontal lobe. True cerebellar ataxia must be distinguished from ataxia associated with vestibular nerve or labyrinthine disease, as the latter results in a disorder of gait associated with a significant degree of dizziness, light-headedness, or the perception of movement (Chap. 20). True cerebellar ataxia is devoid of these vertiginous complaints and is clearly an unsteady gait due to imbalance. Sensory disturbances can also on occasion simulate the imbalance of cerebellar disease; with sensory ataxia, imbalance dramatically worsens when visual input is removed (Romberg sign). Rarely, weakness of proximal leg muscles mimics cerebellar disease. In the patient who presents with ataxia, the rate and pattern of the development of cerebellar symptoms help to narrow the diagnostic possibilities (Table 352-1). A gradual and progressive increase in symptoms with bilateral and symmetric involvement suggests a biochemical, metabolic, immune, or toxic etiology. Conversely, focal, unilateral symptoms with headache and impaired level of consciousness accompanied by ipsilateral cranial nerve palsies and contralateral weakness imply a space-occupying cerebellar lesion.

Symmetric Ataxia Progressive and symmetric ataxia can be classified with respect to onset as acute (over hours or days), subacute (weeks or months), or chronic (months to years). Acute and reversible ataxias include those caused by intoxication with alcohol, phenytoin, lithium, barbiturates, and other drugs. Intoxication caused by toluene exposure, gasoline sniffing, glue sniffing, spray painting, or exposure to methyl mercury or bismuth are additional

TABLE 352-1 *Etiology of Cerebellar Ataxia*

Symmetric and Progressive Signs			Focal and Ipsilateral Cerebellar Signs		
Acute (Hours to Days)	*Subacute (Days to Weeks)*	*Chronic (Months to Years)*	*Acute (Hours to Days)*	*Subacute (Days to Weeks)*	*Chronic (Months to Years)*
Intoxication: alcohol, lithium, diphenylhydantoin, barbiturates (positive history and toxicology screen) Acute viral cerebellitis (CSF supportive of acute viral infection) Postinfection syndrome	Intoxication: mercury, solvents, gasoline, glue; cytotoxic chemotherapeutic drugs Alcoholic-nutritional (vitamin B_1 and B_{12} deficiency) Lyme disease	Paraneoplastic syndrome Anti-gliadin antibody syndrome Hypothyroidism Inherited diseases Tabes dorsalis (tertiary syphilis) Phenytoin toxicity	Vascular: cerebellar infarction, hemorrhage, or subdural hematoma Infectious: cerebellar abscess (positive mass lesion on MRI/CT, positive history in support of lesion)	Neoplastic: cerebellar glioma or metastatic tumor (positive for neoplasm on MRI/CT) Demyelinating: multiple sclerosis (history, CSF, and MRI are consistent) AIDS-related multifocal leukoencephalopathy (positive HIV test and CD4+ cell count for AIDS)	Stable gliosis secondary to vascular lesion or demyelinating plaque (stable lesion on MRI/CT older than several months) Congenital lesion: Chiari or Dandy-Walker malformations (malformation noted on MRI/CT)

Abbreviations: CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging.

causes of acute or subacute ataxia, as is treatment with cytotoxic chemotherapeutic drugs such as fluorouracil and paclitaxel. Patients with a postinfectious syndrome (especially after varicella) may develop gait ataxia and mild dysarthria, both of which are reversible (Chap. 359). Rare infectious causes of acquired ataxia include poliovirus, coxsackievirus, echovirus, Epstein-Barr virus, toxoplasmosis, *Legionella*, and Lyme disease.

The subacute development of ataxia of gait over weeks to months (degeneration of the cerebellar vermis) may be due to the combined effects of alcoholism and malnutrition, particularly with deficiencies of vitamins B_1 and B_{12}. Hyponatremia has also been associated with ataxia. Paraneoplastic cerebellar ataxia is associated with a number of different tumors (and autoantibodies) such as breast and ovarian cancers (anti-Yo), small-cell lung cancer (anti-PQ type voltage-gated calcium channel), and Hodgkin's disease (anti-Tr) (Chap. 87). Another paraneoplastic syndrome associated with myoclonus and opsoclonus occurs with breast (anti-Ri) and lung cancers and neuroblastoma. For all of these paraneoplastic ataxias, the neurologic syndrome may be the presenting symptom of the cancer. Another immune-mediated progressive ataxia is associated with anti-gliadin (and anti-endomysium) antibodies and the HLA DQB1*0201 haplotype; in some affected patients, biopsy of the small intestine reveals villous atrophy consistent with gluten-sensitive enteropathy (Chap. 275). Finally, subacute progressive ataxia may be caused by a prion disorder, especially when an infectious etiology, such as transmission from contaminated human growth hormone, is responsible (Chap. 362).

Chronic symmetric gait ataxia suggests an inherited ataxia (discussed below), a metabolic disorder, or a chronic infection. Hypothyroidism must always be considered as a readily treatable and reversible form of gait ataxia. Infectious diseases that can present with ataxia are meningovascular syphilis and tabes dorsalis due to degeneration of the posterior columns and spinocerebellar pathways in the spinal cord.

Focal Ataxia Acute focal ataxia commonly results from cerebrovascular disease, usually ischemic infarction, or cerebellar hemorrhage. These lesions typically produce cerebellar symptoms ipsilateral to the injured cerebellum and may be associated with an impaired level of consciousness due to brainstem compression and increased intracranial pressure; ipsilateral pontine signs, including sixth and seventh nerve palsies, may be present. Focal and worsening signs of acute ataxia should also prompt consideration of a posterior fossa subdural hematoma, bacterial abscess, or primary or metastatic cerebellar tumor. Computed tomography (CT) or magnetic resonance imaging (MRI) studies will reveal clinically significant processes of this type. Many of these lesions represent true neurologic emergencies, as sudden herniation, either rostrally through the tentorium or caudal herniation of cerebellar tonsils through the foramen magnum, can occur and is usually devastating. Acute surgical decompression may be required (Chap. 258). Lymphoma or progressive multifocal leukoencephalopathy (PML) in a patient with AIDS may present with an acute or subacute focal cerebellar syndrome. Chronic etiologies of progressive ataxia include multiple sclerosis (Chap. 359) and congenital lesions such as a Chiari malformation (Chap. 356) or a congenital cyst of the posterior fossa (Dandy-Walker syndrome).

THE INHERITED ATAXIAS

These may show autosomal dominant, autosomal recessive, or maternal (mitochondrial) modes of inheritance. A genomic classification (Table 352-2) has now largely superseded previous ones based on clinical expression alone.

Although the clinical manifestations and neuropathologic findings of cerebellar disease dominate the clinical picture, there may also be characteristic changes in the basal ganglia, brainstem, spinal cord, optic nerves, retina, and peripheral nerves. In large families with dominantly inherited ataxias, many gradations are observed from purely cerebellar manifestations to mixed cerebellar and brainstem disorders, cerebellar and basal ganglia syndromes, and spinal cord or peripheral nerve disease. Rarely, dementia is present as well. The clinical picture may be homogeneous within a family with dominantly inherited ataxia, but sometimes most affected family members show one characteristic syndrome, while one or several members have an entirely different phenotype.

AUTOSOMAL DOMINANT ATAXIAS The autosomal spinocerebellar ataxias (SCAs) include SCA type 1 through SCA22, dentatorubropallidoluysian atrophy (DRPLA), and episodic ataxia (EA) types 1 and 2 (Table 352-2). SCA1, SCA2, SCA3 [Machado-Joseph disease (MJD)], SCA6, SCA7, and SCA17 are caused by CAG triplet repeat expansions in different genes. SCA8 is due to an untranslated CTG repeat expansion, SCA12 is linked to an untranslated CAG repeat, and SCA10 is caused by an untranslated pentanucleotide repeat. The clinical phenotypes of these SCAs overlap. The genotype has become the "gold standard" for diagnosis and classification. CAG encodes glutamine, and these expanded CAG triplet repeat expansions result in expanded polyglutamine proteins, termed *ataxins*, that produce a toxic gain of function with autosomal dominant inheritance. Although the phenotype is variable for any given disease gene, a pattern of neuronal loss with gliosis is produced that is relatively unique for each ataxia. Immunohistochemical and biochemical studies have shown cytoplasmic (SCA2), neuronal (SCA1, MJD, SCA7), and nucleolar (SCA7) accumulation of the

TABLE 352-2 *Genotype Classification of the Spinocerebellar Ataxias*

Name	Locus	Phenotype
SCA1 (autosomal dominant type 1)	6p22-p23 with CAG repeats (exonic) Ataxin-1	Ataxia with ophthalmoparesis, pyramidal and extrapyramidal findings
SCA2 (autosomal dominant type 2)	12q23-q24.1 with CAG repeats (exonic) Ataxin-2	Ataxia with slow saccades and minimal pyramidal and extrapyramidal findings
Machado-Joseph disease/SCA3 (autosomal dominant type 3)	14q24.3-q32 with CAG repeats (exonic) MJD–ataxin-3	Ataxia with ophthalmoparesis and variable pyramidal, extrapyramidal, and amyotrophic signs
SCA4 (autosomal dominant type 4)	16q24-ter	Ataxia with normal eye movements, sensory axonal neuropathy, and pyramidal signs
SCA5 (autosomal dominant type 5)	Centromeric region of chromosome II	Ataxia and dysarthria
SCA6 (autosomal dominant type 6)	19p13.2 with CAG repeats in α_{1A}-voltage–dependent calcium channel gene (exonic)	Ataxia and dysarthria, nystagmus, mild proprioceptive sensory loss
SCA7 (autosomal dominant type 7)	3p14.1-p21.1 with CAG repeats (exonic) Ataxin-7	Ophthalmoparesis, visual loss, ataxia, dysarthria, extensor plantar response, pigmentary retinal degeneration
SCA8 (autosomal dominant type 8)	13q21 with CTG repeats; noncoding	Gait ataxia, dysarthria, nystagmus, leg spasticity, and reduced vibratory sensation
SCA10 (autosomal dominant type 10)	22q; ATTCT repeat; noncoding	Gait ataxia, dysarthria, nystagmus; partial complex and generalized motor seizures; polyneuropathy
SCA11 (autosomal dominant type 11)	15q14-q21.3 by linkage	Slowly progressive gait and extremity ataxia, dysarthria, vertical nystagmus, hyperreflexia
SCA12 (autosomal dominant type 12)	5q31-q33 by linkage; CAG repeat; protein phosphatase 2A	Tremor, decreased movement, increased reflexes, dystonia, ataxia, dysautonomia, dementia, dysarthria
SCA13 (autosomal dominant type 13)	19q13.3-q14.4	Mutation unknown
SCA14 (autosomal dominant type 14)	19q-13.4	Mutation unknown
SCA15 (autosomal dominant type 15)	Mutation unknown in 1 family; other known loci were excluded	Gait and extremity ataxia, dysarthria
SCA16 (autosomal dominant type 16)	8q22.1-24.1	Mutation unknown; pure cerebellar ataxia and head tremor, gait ataxia, and dysarthria; horizontal gaze–evoked nystagmus
SCA17 (autosomal dominant type 17)	6q27; CAG expansion in the TATA-binding protein (*TBP*) gene	Gait ataxia, dementia, parkinsonism, dystonia, chorea, seizures; MRI shows cerebral & cerebellar atrophy
SCA18 (autosomal dominant type 18)	7q22-q32	Ataxia motor/sensory neuropathy
SCA19 (autosomal dominant type 19)	1p21-q21	Ataxia, tremor, cognitive impairment, myoclonus
SCA20 (assigned but not yet published)	—	—
SCA21 (autosomal dominant type 21)	7p21.3-p15.1	Ataxia, extrapyramidal features of akinesia, rigidity, tremor, cognitive defect
SCA22 (assigned but not yet published)	—	—
Dentatorubropallidoluysian atrophy (autosomal dominant)	12p12-ter with CAG repeats (exonic) Atrophin	Ataxia, choreoathetosis, dystonia, seizures, myoclonus, dementia
Friedreich's ataxia (autosomal recessive)	9q13-q21.1 with intronic GAA repeats Frataxin	Ataxia, areflexia, extensor plantar responses, position sense deficits, cardiomyopathy, diabetes mellitus, scoliosis, foot deformities; defective iron transport from mitochondria
Friedreich's ataxia (autosomal recessive)	8q13.1-q13.3; (α-TTP deficiency)	Same as phenotype that maps to 9q but associated with vitamin E deficiency
Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS)	Chromosome 13; SACS gene; loss of Sacsin peptide activity	Childhood onset of ataxia, spasticity, dysarthria, distal muscle wasting, foot deformity, retinal striations, mitral valve prolapse
Kearns-Sayre syndrome (sporadic)	mtDNA deletion and duplication mutations	Ptosis, ophthalmoplegia, pigmentary retinal degeneration, cardiomyopathy, diabetes mellitus, deafness, heart block, increased CSF protein, ataxia
Myoclonic epilepsy and ragged red fiber syndrome (MERRF) (maternal inheritance)	Mutation in mtDNA of the $tRNA^{lys}$ at 8344; also mutation at 8356	Myoclonic epilepsy, ragged red fiber myopathy, ataxia
Mitochondrial encephalopathy, lactic acidosis, and stroke syndrome (MELAS) (maternal inheritance)	$tRNA^{leu}$ mutation at 3243; also at 3271 and 3252	Headache, stroke, lactic acidosis, ataxia
Leigh's disease; subacute necrotizing encephalopathy (maternal inheritance or autosomal recessive)	mtDNA complex V defect (ATPase gene at 8993) or mitochondrial protein synthesis defect (both maternally inherited); or complex IV defect (autosomal recessive)	Obtundation, hypotonia, cranial nerve defects, respiratory failure, hyperintense signals on T2-weighted MRI in basal ganglia, cerebellum, or brainstem; ataxia
Episodic ataxia, type 1 (EA-1) (autosomal dominant)	12p; potassium channel gene, *KCNA1*	Episodic ataxia for minutes; provoked by startle or exercise; with facial and hand myokymia; cerebellar signs are not progressive; responds to phenytoin
Episodic ataxia, type 2 (EA-2) (autosomal dominant)	19p-13(*CACNA1A*) (allelic with SCA6) (α_{1A}-voltage–dependent calcium channel subunit)	Episodic ataxia for days; provoked by stress, fatigue; with down-gaze nystagmus; cerebellar atrophy results; progressive cerebellar signs; responds to acetazolamide
Ataxia telangiectasia (autosomal recessive)	11q22-23; *ATM* gene for regulation of cell cycle; mitogenic signal transduction and meiotic recombination	Telangiectasia, ataxia, dysarthria, pulmonary infections, neoplasms of lymphatic system; IgA and IgG deficiencies; diabetes mellitus, breast cancer

(continued)

TABLE 352-2—(Continued)

Name	Locus	Phenotype
Infantile-onset spinocerebellar ataxia of Nikali et al (autosomal recessive)	10q23.3-q24.1	Infantile ataxia, sensory neuropathy; athetosis, hearing deficit, ophthalmoplegia, optic atrophy; primary hypogonadism in females
Hypoceruloplasminemia with ataxia and dysarthria (autosomal recessive)	Ceruloplasmin gene; 3q23-q25 (trp 858 ter)	Gait ataxia and dysarthria; hyperreflexia; cerebellar atrophy by MRI; iron deposition in cerebellum, basal ganglia, thalamus, and liver; onset in the 4th decade
Spinocerebellar ataxia with neuropathy (SCAN1) (autosomal recessive)	Tryosyl-DNA phosphodiesterase-1 (TDP-1) 14q31-q32	Onset in 2nd decade; gait ataxia, dysarthria, seizures, cerebellar vermis atrophy on MRI, dysmetria

Abbreviations: MRI, magnetic resonance imaging; CSF, cerebrospinal fluid.

specific mutant polyglutamine containing ataxin proteins. Expanded polyglutamine ataxins with more than ~40 glutamines are potentially toxic to neurons for a variety of reasons including the following: high levels of gene expression for the mutant polyglutamine ataxin in affected neurons; conformational change of the aggregated protein to a β-pleated structure; abnormal transport of the ataxin into the nucleus (SCA1, MJD, SCA7); binding to other polyglutamine proteins, including the TATA-binding transcription protein and the CREB-binding protein, impairing their functions; altering the efficiency of the ubiquitin-proteosome system of protein turnover; and inducing neuronal apoptosis. An earlier age of onset (anticipation) and more aggressive disease in subsequent generations are due to further expansion of the CAG triplet repeat and increased polyglutamine number in the mutant ataxin. The most common disorders are discussed below.

SCA1 SCA1 was previously referred to as *olivopontocerebellar atrophy*, but genomic data have shown that that entity represents several different genotypes with overlapping clinical features.

SYMPTOMS AND SIGNS SCA1 is characterized by the development in early or middle adult life of progressive cerebellar ataxia of the trunk and limbs, impairment of equilibrium and gait, slowness of voluntary movements, scanning speech, nystagmoid eye movements, and oscillatory tremor of the head and trunk. Dysarthria, dysphagia, and oculomotor and facial palsies may also occur. Extrapyramidal symptoms include rigidity, an immobile face, and parkinsonian tremor. The reflexes are usually normal, but knee and ankle jerks may be lost, and extensor plantar responses may occur. Dementia may be noted but is usually mild. Impairment of sphincter function is common, with urinary and sometimes fecal incontinence. Cerebellar and brainstem atrophy are evident on MRI (Fig. 352-1).

Marked shrinkage of the ventral half of the pons, disappearance of the olivary eminence on the ventral surface of the medulla, and atrophy of the cerebellum are evident on gross postmortem inspection of the brain. Variable loss of Purkinje cells, reduced numbers of cells in the molecular and granular layer, demyelination of the middle cerebellar peduncle and the cerebellar hemispheres, and severe loss of cells in the pontine nuclei and olives are found on histologic examination. Degenerative changes in the striatum, especially the putamen, and loss of the pigmented cells of the substantia nigra may be found in cases with extrapyramidal features. More widespread degeneration in the central nervous system (CNS), including involvement of the posterior columns and the spinocerebellar fibers, is often present.

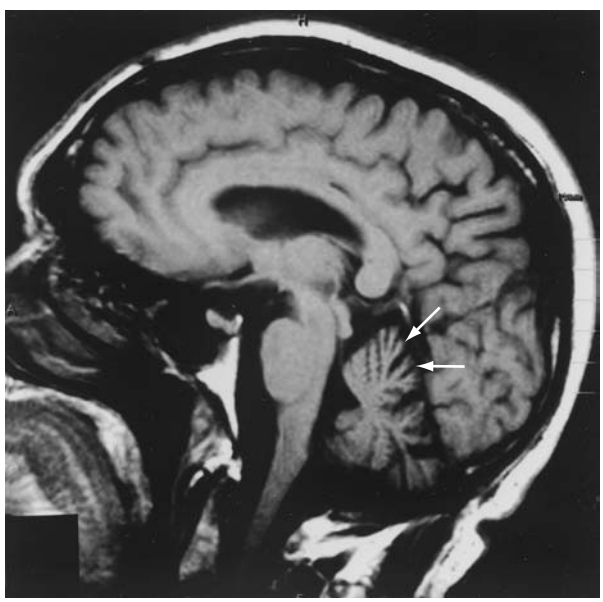

FIGURE 352-1 Sagittal MRI of the brain of a 60-year-old man with gait ataxia and dysarthria due to SCA1, illustrating cerebellar atrophy (*arrows*).

GENETIC CONSIDERATIONS SCA1 encodes a gene product, called ataxin-1, which is a novel protein of unknown function. The mutant allele has 40 CAG repeats located within the coding region, whereas alleles from unaffected individuals have ≤36 repeats. A few patients with 38 to 40 CAG repeats have been described. There is a direct correlation between a larger number of repeats and a younger age of onset for SCA1. Juvenile patients have higher numbers of repeats, and anticipation is present in subsequent generations. Transgenic mice carrying SCA1 developed ataxia and Purkinje cell pathology. Nuclear localization, but not aggregation, of ataxin-1 appears to be required for cell death initiated by the mutant protein.

SCA2 ■ *SYMPTOMS AND SIGNS* Another clinical phenotype, SCA2, has been described in Cubans. These patients probably are descendants of a common ancestor, and the population may be the largest homogeneous group of patients with ataxia yet described. The age of onset ranges from 2 to 65 years, and there is considerable clinical variability within families. Although neuropathologic and clinical findings are compatible with a diagnosis of SCA1, including slow saccadic eye movements, ataxia, dysarthria, parkinsonian rigidity, optic disk pallor, mild spasticity, and retinal degeneration, SCA2 is a unique form of cerebellar degenerative disease.

GENETIC CONSIDERATIONS The gene in SCA2 families also contains CAG repeat expansions coding for a polyglutamine-containing protein, ataxin-2. Normal alleles contain 15 to 32 repeats; mutant alleles have 35 to 77 repeats.

Machado-Joseph Disease/SCA3 MJD was first described among the Portuguese and their descendants in New England and California. Subsequently, MJD has been found in families from Portugal, Australia, Brazil, Canada, China, England, France, India, Israel, Italy, Japan, Spain, Taiwan, and the United States. In most populations, it is the most common autosomal dominant ataxia.

SYMPTOMS AND SIGNS MJD has been classified into three clinical types. In type I MJD (amyotrophic lateral sclerosis–parkinsonism–dystonia type), neurologic deficits appear in the first two decades and involve weakness and spasticity of extremities, especially the legs, often with dystonia of the face, neck, trunk, and extremities. Patellar and ankle clonus are common, as are extensor plantar responses. The gait is slow and stiff, with a slightly broadened base and lurching from side to side; this gait results from spasticity, not true ataxia. There is no truncal

titubation. Pharyngeal weakness and spasticity cause difficulty with speech and swallowing. Of note is the prominence of horizontal and vertical nystagmus, loss of fast saccadic eye movements, hypermetric and hypometric saccades, and impairment of upward vertical gaze. Facial fasciculations, facial myokymia, lingual fasciculations without atrophy, ophthalmoparesis, and ocular prominence are common early manifestations.

In type II MJD (ataxic type), true cerebellar deficits of dysarthria and gait and extremity ataxia begin in the second to fourth decades along with corticospinal and extrapyramidal deficits of spasticity, rigidity, and dystonia. Type II is the most common form of MJD. Ophthalmoparesis, upward vertical gaze deficits, and facial and lingual fasciculations are also present. Type II MJD can be distinguished from the clinically similar disorders SCA1 and SCA2.

Type III MJD (ataxic-amyotrophic type) presents in the fifth to the seventh decades with a pancerebellar disorder that includes dysarthria and gait and extremity ataxia. Distal sensory loss involving pain, touch, vibration, and position senses and distal atrophy are prominent, indicating the presence of peripheral neuropathy. The deep tendon reflexes are depressed to absent, and there are no corticospinal or extrapyramidal findings.

The mean age of onset of symptoms in MJD is 25 years. Neurologic deficits invariably progress and lead to death from debilitation within 15 years of onset, especially in patients with types I and II disease. Usually, patients retain full intellectual function.

The major pathologic findings are variable loss of neurons and glial replacement in the corpus striatum and severe loss of neurons in the pars compacta of the substantia nigra. A moderate loss of neurons occurs in the dentate nucleus of the cerebellum and in the red nucleus. Purkinje cell loss and granule cell loss occur in the cerebellar cortex. Cell loss also occurs in the dentate nucleus and in the cranial nerve motor nuclei. Sparing of the inferior olives distinguishes MJD from other dominantly inherited ataxias.

GENETIC CONSIDERATIONS The gene for MJD maps to 14q24.3-q32. Unstable CAG repeat expansions are present in the MJD gene coding for a polyglutamine-containing protein named ataxin-3, or MJD-ataxin. An earlier age of onset is associated with longer repeats. Alleles from normal individuals have between 12 and 37 CAG repeats, and MJD alleles have 60 to 84 CAG repeats. Polyglutamine-containing aggregates of ataxin-3 (MJD-ataxin) have been described in neuronal nuclei undergoing degeneration.

SCA6 Genomic screening for CAG repeats in other families with autosomal dominant ataxia and vibratory and proprioceptive sensory loss have yielded another locus. Of interest is that different mutations in the same gene for the α_{1A} voltage-dependent calcium channel subunit (CACNLIA4; also referred to as the *CACNA1A* gene) at 19p13 result in different clinical disorders. CAG repeat expansions (21 to 27 in patients; 4 to 16 triplets in normal individuals) result in late-onset progressive ataxia with cerebellar degeneration. Missense mutations in this gene result in familial hemiplegic migraine. Nonsense mutations resulting in termination of protein synthesis of the gene product yield hereditary paroxysmal cerebellar ataxia or EA. Some patients with familial hemiplegic migraine develop progressive ataxia and also have cerebellar atrophy.

SCA7 This disorder is distinguished from all other SCAs by the presence of retinal pigmentary degeneration. The visual abnormalities first appear as blue-yellow color blindness and proceed to frank visual loss with macular degeneration. In almost all other respects, SCA7 resembles several other SCAs in which ataxia is accompanied by various noncerebellar findings, including ophthalmoparesis and extensor plantar responses. The genetic defect is an expanded CAG repeat in the SCA7 gene. The expanded repeat size in SCA7 is highly variable. Consistent with this, the severity of clinical findings varies from essentially asymptomatic to mild late-onset symptoms to severe, aggressive disease in childhood with rapid progression. Marked anticipation has been recorded, especially with paternal transmission. The disease protein, ataxin-7, forms aggregates in nuclei of affected neurons, as has also been described for SCA1 and SCA3/MJD.

SCA8 This form of ataxia is caused by a CTG repeat expansion in an untranslated region of a gene on chromosome 13q21. There is marked maternal bias in transmission, perhaps reflecting contractions of the repeat during spermatogenesis. The mutation is not fully penetrant. Symptoms include slowly progressive dysarthria and gait ataxia beginning at ~40 years of age with a range between 20 and 65 years. Other features include nystagmus, leg spasticity, and reduced vibratory sensation. Severely affected individuals are nonambulatory by the fourth to sixth decades. MRI shows cerebellar atrophy. The mechanism of disease may involve a dominant "toxic" effect occurring at the RNA level, as occurs in myotonic dystrophy.

Dentatorubropallidoluysian Atrophy DRPLA has a variable presentation that may include progressive ataxia, choreoathetosis, dystonia, seizures, myoclonus, and dementia. DRPLA is due to unstable CAG triplet repeats in the open reading frame of a gene named *atrophin* located on chromosome 12p12-ter. Larger expansions are found in patients with earlier onset. The number of repeats is 49 in patients with DRPLA and ≤26 in normal individuals. Anticipation occurs in successive generations, with earlier onset of disease in association with an increasing CAG repeat number in children who inherit the disease from their father. One well-characterized family in North Carolina has a phenotypic variant known as the *Haw River syndrome*, now recognized to be due to the DRPLA mutation.

Episodic Ataxia EA types 1 and 2 are two rare dominantly inherited disorders that have been mapped to chromosomes 12p (a potassium channel gene) for type 1 and 19p for type 2. Patients with EA-1 have brief episodes of ataxia with myokymia and nystagmus that last only minutes. Startle, sudden change in posture, and exercise can induce episodes. Acetazolamide or anticonvulsants may be therapeutic. Patients with EA-2 have episodes of ataxia with nystagmus that can last for hours or days. Stress, exercise, or excessive fatigue may be precipitants. Acetazolamide may be therapeutic and can reverse the relative intracellular alkalosis detected by magnetic resonance spectroscopy. Stop codon, nonsense mutations causing EA-2 have been found in the *CACNA1A* gene, encoding the α_{1A} voltage-dependent calcium channel subunit (see "SCA6," above).

AUTOSOMAL RECESSIVE ATAXIAS ■ Friedreich's Ataxia This is the most common form of inherited ataxia, comprising one-half of all hereditary ataxias. It can occur in a classic form or in association with a genetically determined vitamin E deficiency syndrome; the two forms are clinically indistinguishable.

SYMPTOMS AND SIGNS Friedreich's ataxia presents before 25 years of age with progressive staggering gait, frequent falling, and titubation. The lower extremities are more severely involved than the upper ones. Dysarthria occasionally is the presenting symptom; rarely, progressive scoliosis, foot deformity, nystagmus, or cardiopathy is the initial sign.

The neurologic examination reveals nystagmus, loss of fast saccadic eye movements, truncal titubation, dysarthria, dysmetria, and ataxia of trunk and limb movements. Extensor plantar responses (with normal tone in trunk and extremities), absence of deep tendon reflexes, and weakness (greater distally than proximally) are usually found. Loss of vibratory and proprioceptive sensation occurs. The median age of death is 35 years. Women have a significantly better prognosis than men.

Cardiac involvement occurs in 90% of patients. Cardiomegaly, symmetric hypertrophy, murmurs, and conduction defects are reported. Moderate mental retardation or psychiatric syndromes are present in a small percentage of patients. A high incidence of diabetes mellitus (20%) is found and is associated with insulin resistance and pancreatic β-cell dysfunction. Musculoskeletal deformities are com-

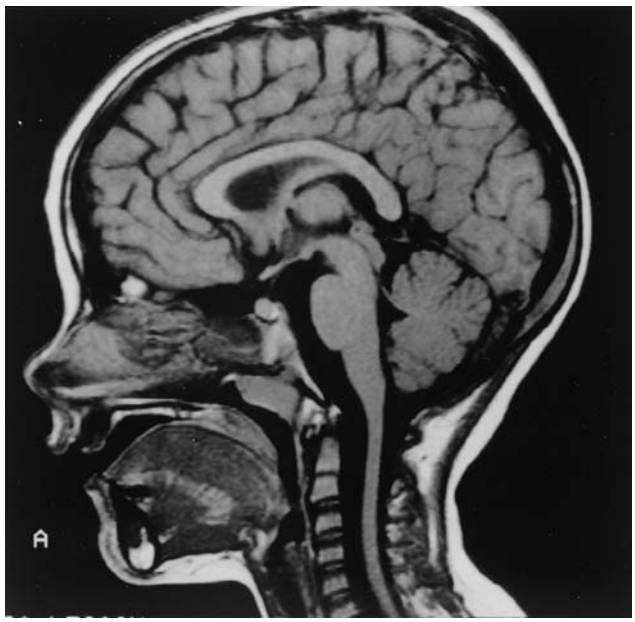

FIGURE 352-2 Sagittal MRI of the brain and spinal cord of a patient with Friedreich's ataxia, demonstrating spinal cord atrophy.

mon and include pes cavus, pes equinovarus, and scoliosis. MRI of the spinal cord shows atrophy (Fig. 352-2).

The primary sites of pathology are the spinal cord, dorsal root ganglion cells, and the peripheral nerves. Slight atrophy of the cerebellum and cerebral gyri may occur. Sclerosis and degeneration occur predominantly in the spinocerebellar tracts, lateral corticospinal tracts, and posterior columns. Degeneration of the glossopharyngeal, vagus, hypoglossal, and deep cerebellar nuclei is described. The cerebral cortex is histologically normal except for loss of Betz cells in the precentral gyri. The peripheral nerves are extensively involved, with a loss of large myelinated fibers. Cardiac pathology consists of myocytic hypertrophy and fibrosis, focal vascular fibromuscular dysplasia with subintimal or medial deposition of periodic acid–Schiff (PAS)–positive material, myocytopathy with unusual pleomorphic nuclei, and focal degeneration of nerves and cardiac ganglia.

GENETIC CONSIDERATIONS The classic form of Friedreich's ataxia has been mapped to 9q13-q21.1, and the mutant gene, *frataxin*, contains expanded GAA triplet repeats in the first intron. There is homozygosity for expanded GAA repeats in >95% of patients. Normal persons have 7 to 22 GAA repeats, and patients have 200 to 900 GAA repeats. A more varied clinical syndrome has been described in compound heterozygotes who have one copy of the GAA expansion and the other copy a point mutation in the *frataxin* gene. When the point mutation is located in the region of the gene that encodes the amino-terminal half of frataxin, the phenotype is milder, often consisting of a spastic gait, retained or exaggerated reflexes, no dysarthria, and mild or absent ataxia.

Patients with Friedreich's ataxia have undetectable or extremely low levels of *frataxin* mRNA, as compared with carriers and unrelated individuals; thus, disease appears to be caused by a loss of expression of the frataxin protein. Frataxin is a mitochondrial protein involved in iron homeostasis. Mitochondrial iron accumulation due to loss of the iron transporter coded by the mutant *frataxin* gene results in oxidized intramitochondrial iron. Excess oxidized iron results in turn in the oxidation of cellular components and irreversible cell injury.

Two forms of hereditary ataxia associated with abnormalities in the interactions of vitamin E (α-tocopherol) with very low density lipoprotein (VLDL) have been delineated. These are abetalipoproteinemia (Bassen-Kornzweig syndrome) and ataxia with vitamin E deficiency (AVED). Abetalipoproteinemia is caused by mutations in the gene coding for the larger subunit of the microsomal triglyceride transfer protein (MTP). Defects in MTP result in impairment of formation and secretion of VLDL in liver. This defect results in a deficiency of delivery of vitamin E to tissues, including the central and peripheral nervous system, as VLDL is the transport molecule for vitamin E and other fat-soluble substitutes. AVED is due to mutations in the gene for α-tocopherol transfer protein (α-TTP). These patients have an impaired ability to bind vitamin E into the VLDL produced and secreted by the liver, resulting in a deficiency of vitamin E in peripheral tissues. Hence, either absence of VLDL (abetalipoproteinemia) or impaired binding of vitamin E to VLDL (AVED) causes an ataxic syndrome. Once again, a genotype classification has proved to be essential in sorting out the various forms of the Friedreich's disease syndrome, which may be clinically indistinguishable.

Ataxia Telangiectasia ■ *SYMPTOMS AND SIGNS* Patients with ataxia telangiectasia (AT) present in the first decade of life with progressive telangiectatic lesions associated with deficits in cerebellar function and nystagmus. The neurologic manifestations correspond to those in Friedreich's disease, which should be included in the differential diagnosis. Truncal and limb ataxia, dysarthria, extensor plantar responses, myoclonic jerks, areflexia, and distal sensory deficits may develop. There is a high incidence of recurrent pulmonary infections and neoplasms of the lymphatic and reticuloendothelial system in patients with AT. Thymic hypoplasia with cellular and humoral (IgA and IgG2) immunodeficiencies, premature aging, and endocrine disorders such as type 1 diabetes mellitus are described. There is an increased incidence of lymphomas, Hodgkin's disease, acute leukemias of the T cell type, and breast cancer.

The most striking neuropathologic changes include loss of Purkinje, granule, and basket cells in the cerebellar cortex as well as of neurons in the deep cerebellar nuclei. The inferior olives of the medulla may also have neuronal loss. There is a loss of anterior horn neurons in the spinal cord and of dorsal root ganglion cells associated with posterior column spinal cord demyelination. A poorly developed or absent thymus gland is the most consistent defect of the lymphoid system.

GENETIC CONSIDERATIONS The gene for AT (the *ATM* gene) encodes a protein that is similar to several yeast and mammalian phosphatidylinositol-3′-kinases involved in mitogenic signal transduction, meiotic recombination, and cell cycle control. Defective DNA repair in AT fibroblasts exposed to ultraviolet light has been demonstrated. The discovery of *ATM* will make possible the identification of heterozygotes who are at risk for cancer (e.g., breast cancer) and permit early diagnosis.

Mitochondrial Ataxias Spinocerebellar syndromes have been identified with mutations in mitochondrial DNA (mtDNA). Thirty pathogenic mtDNA point mutations and 60 different types of mtDNA deletions are known, several of which cause or are associated with ataxia (Chap. 368).

TREATMENT

The most important goal in management of patients with ataxia is to identify treatable disease entities. Mass lesions must be recognized promptly and treated appropriately. Paraneoplastic disorders can often be identified by the clinical patterns of disease that they produce, measurement of specific autoantibodies, and uncovering the primary cancer; these disorders are often refractory to therapy, but some patients improve following removal of the tumor or immunotherapy (Chap. 87). Ataxia with anti-gliadin antibodies and gluten-sensitive enteropathy may improve with a gluten-free diet. Malabsorption syndromes leading to vitamin E deficiency may lead to ataxia. The vitamin E deficiency form of Friedreich's ataxia must be considered, and serum vitamin E levels measured. Vitamin E therapy is indicated for these

rare patients. Vitamin B_1 and B_{12} levels in serum should be measured, and the vitamins administered to patients having deficient levels. Hypothyroidism is easily treated. The cerebrospinal fluid should be tested for a syphilitic infection in patients with progressive ataxia and other features of tabes dorsalis. Similarly, antibody titers for Lyme disease and *Legionella* should be measured, and appropriate antibiotic therapy should be instituted in antibody-positive patients. Aminoacidopathies, leukodystrophies, urea-cycle abnormalities, and mitochondrial encephalomyopathies may produce ataxia, and some dietary or metabolic therapies are available for these disorders. The deleterious effects of diphenylhydantoin and alcohol on the cerebellum are well known and these exposures should be avoided in patients with ataxia of any cause.

There is no proven therapy for any of the autosomal dominant ataxias (SCA1 to 22). There is preliminary evidence that idebenone, a free-radical scavenger, can improve myocardial hypertrophy in patients with classic Friedreich ataxia; there is no current evidence, however, that it improves neurologic function. Iron chelators and antioxidant drugs are potentially harmful in Friedreich's patients as they may increase heart muscle injury. Acetazolamide can reduce the duration of symptoms of episodic ataxia. At present, identification of an at-risk person's genotype, together with appropriate family and genetic counseling, can reduce the incidence of these cerebellar syndromes in future generations (Chap. 58).

353 AMYOTROPHIC LATERAL SCLEROSIS AND OTHER MOTOR NEURON DISEASES

Robert H. Brown, Jr.

AMYOTROPHIC LATERAL SCLEROSIS Amyotrophic lateral sclerosis (ALS) is the most common form of progressive motor neuron disease. It is a prime example of a neurodegenerative disease and is arguably the most devastating of the neurodegenerative disorders.

Pathology The pathologic hallmark of motor neuron degenerative disorders is death of lower motor neurons (consisting of anterior horn cells in the spinal cord and their brainstem homologues innervating bulbar muscles) and upper, or corticospinal, motor neurons (originating in layer five of the motor cortex and descending via the pyramidal tract to synapse with lower motor neurons, either directly or indirectly via interneurons) (Chap. 21). Although at its onset ALS may involve selective loss of function of only upper or lower motor neurons, it ultimately causes progressive loss of both categories of motor neurons. Indeed, in the absence of clear involvement of both motor neuron types, the diagnosis of ALS is questionable.

Other motor neuron diseases involve only particular subsets of motor neurons (Tables 353-1 and 353-2). Thus, in bulbar palsy and spinal muscular atrophy (SMA; also called progressive muscular atrophy), the lower motor neurons of brainstem and spinal cord, respectively, are most severely involved. By contrast, pseudobulbar palsy, primary lateral sclerosis (PLS), and familial spastic paraplegia (FSP) affect only upper motor neurons innervating the brainstem and spinal cord.

In each of these diseases, the affected motor neurons undergo shrinkage, often with accumulation of the pigmented lipid (lipofuscin) that normally develops in these cells with advancing age. In ALS, the motor neuron cytoskeleton is typically affected early in the illness. Focal enlargements are frequent in proximal motor axons; ultrastructurally, these "spheroids" are composed of accumulations of neurofilaments. Also seen is proliferation of astroglia and microglia, the inevitable accompaniment of all degenerative processes in the central nervous system (CNS).

The death of the peripheral motor neurons in the brainstem and spinal cord leads to denervation and consequent atrophy of the corresponding muscle fibers. Histochemical and electrophysiologic evidence indicates that in the early phases of the illness denervated muscle can be reinnervated by sprouting of nearby distal motor nerve terminals, although reinnervation in this disease is considerably less extensive than in most other disorders affecting motor neurons (e.g., poliomyelitis, peripheral neuropathy). As denervation progresses, muscle atrophy is readily recognized in muscle biopsies and on clinical examination. This is the basis for the term *amyotrophy*. The loss of cortical motor neurons results in thinning of the corticospinal tracts that travel via the internal capsule (Fig. 353-1) and brainstem to the lateral and anterior white matter columns of the spinal cord. The loss of fibers in the lateral columns and resulting fibrillary gliosis impart a particular firmness (*lateral sclerosis*). A remarkable feature of the disease is the selectivity of neuronal cell death. By light microscopy, the entire sensory apparatus, the regulatory mechanisms for the control and coordination of movement, and the components of the brain that are needed for cognitive processes, remain intact. However, immunostaining indicates that neurons bearing ubiquitin, a marker for degeneration, are also detected in nonmotor systems. Moreover, studies of glucose metabolism in the illness also indicate that there is neuronal dysfunction outside of the motor system. Within the motor system, there is some selectivity of involvement. Thus, motor neurons required for ocular motility remain unaffected, as do the parasympathetic neurons in the sacral spinal cord (the nucleus of Onufrowicz, or Onuf) that innervate the sphincters of the bowel and bladder.

Clinical Manifestations The manifestations of ALS are somewhat variable depending on whether corticospinal neurons or lower motor neurons in the brainstem and spinal cord are more prominently involved. With lower motor neuron dysfunction and early denervation, typically the first evidence of the disease is insidiously developing asymmetric weakness, usually first evident distally in one of the limbs. A detailed history often discloses recent development of cramping with volitional movements, typically in the early hours of the morning (e.g., while stretching in bed). Weakness caused by denervation is associated with progressive wasting and atrophy of muscles and, particularly early in the illness, spontaneous twitching of motor units, or fasciculations. In the hands, a preponderance of extensor over flexor weakness is common. When the initial denervation involves bulbar rather than limb muscles, the problem at onset is difficulty with chewing, swallowing, and movements of the face and tongue. Early involvement of the muscles of respiration may lead to death before the disease is far advanced elsewhere. With prominent corticospinal involvement, there is hyperactivity of the muscle-stretch reflexes (tendon jerks) and, often, spastic resistance to passive movements of the affected limbs. Patients with significant reflex hyperactivity complain of muscle stiffness often out of proportion to weakness. Degeneration of the corticobulbar projections innervating the brainstem results in dysarthria and exaggeration of the motor expressions of emotion. The latter leads to involuntary excess in weeping or laughing (so-called pseudobulbar affect).

Virtually any muscle group may be the first to show signs of disease, but, as time passes, more and more muscles become involved until ultimately the disorder takes on a symmetric distribution in all regions. It is characteristic of ALS that, regardless of whether the initial disease involves upper or lower motor neurons, both will eventually be implicated. Even in the late stages of the illness, sensory, bowel

TABLE 353-1 *Etiology and Investigation of Motor Neuron Disorders*

Diagnostic Category	Investigations
Structural lesions	MRI scan of head (including foramen magnum), cervical spine[a]
Parasagittal or foramen magnum tumors	
Cervical spondylosis	
Chiari malformation or syrinx	
Spinal cord arteriovenous malformation	
Infections	CSF exam, culture[a]
Bacterial—tetanus, Lyme	Lyme antibody titer[a]
Viral—poliomyelitis, herpes zoster	Antiviral antibody titers
Retroviral myelopathy	HTLV-1 titers
Intoxications, physical agents	
Toxins—lead, aluminum, others	24-h urine for heavy metals[a]
Drugs—strychnine, phenytoin	Serum for lead level[a]
Electric shock, x-irradiation	
Immunologic mechanisms	Complete blood count[a]
Plasma cell dyscrasias	Sedimentation rate[a]
Autoimmune polyradiculoneuropathy	Protein immunoelectrophoresis[a]
Motor neuropathy with conduction block	Anti-GM1 antibodies[a]
Paraneoplastic	Anti-Hu antibody
Paracarcinomatous/lymphoma	MRI scan, bone marrow biopsy
Metabolic	
Hypoglycemia	Fasting blood sugar (FBS), routine chemistries including calcium[a]
Hyperparathyroidism	PTH, calcium, phosphate
Hyperthyroidism	Thyroid function[a]
Deficiency of folate, vitamin B_{12}, vitamin E	Vitamin B_{12}, vitamin E, folate levels[a]
Malabsorption	24-h stool fat, carotene, prothrombin time
Mitochondrial dysfunction	Fasting lactate, pyruvate, ammonia Consider mtDNA analysis
Hereditary biochemical disorders	
Superoxide dismutase 1 gene mutation	White blood cell DNA analysis
Androgen receptor defect (Kennedy's disease)	Abnormal CAG insert in androgen receptor gene
Hexosaminidase deficiency	Lysosomal enzyme screen
Infantile (α-glucosidase deficiency/Pompe's disease)	
Hyperlipidemia	Lipid electrophoresis
Hyperglycinuria	Urine and serum amino acids
Methylcrotonylglycinuria	CSF amino acids

[a] Denotes studies that should be obtained in all cases.
Note: CSF, cerebrospinal fluid; HTLV, human T cell lymphotropic virus; MRI, magnetic resonance imaging.

and bladder, and cognitive functions are preserved. Even when there is severe brainstem disease, ocular motility is spared until the very late stages of the illness. Dementia is not a component of sporadic ALS. In some families, ALS is co-inherited with frontotemporal dementia, characterized by early behavioral abnormalities with prominent behavioral features indicative of frontal lobe dysfunction.

A committee of the World Federation of Neurology has established diagnostic guidelines for ALS. Essential for the diagnosis is simultaneous upper and lower motor neuron involvement with progressive weakness, and the exclusion of all alternative diagnoses. The disorder is ranked as "definite" ALS when three or four of the following are involved: bulbar, cervical, thoracic, and lumbosacral motor neurons. When two sites are involved, the diagnosis is "probable," and when only one site is implicated, the diagnosis is "possible." An exception is made for those who have progressive upper and lower motor neuron signs at only one site and a mutation in the gene encoding superoxide dismutase (SOD1; below).

Epidemiology The illness is relentlessly progressive, leading to death from respiratory paralysis; the median survival is from 3 to 5 years. There are very rare reports of stabilization or even regression of ALS. In most societies there is an incidence of 1 to 3 per 100,000 and a prevalence of 3 to 5 per 100,000. Several endemic foci of higher prevalence exist in the western Pacific (e.g., in specific regions of Guam or Papua New Guinea). In the United States and Europe, males are somewhat more frequently affected than females. While ALS is overwhelmingly a sporadic disorder, some 5 to 10% of cases are inherited as an autosomal dominant trait.

Familial ALS Several forms of selective motor neuron disease are inheritable (Table 353-3). Two involve both corticospinal and lower motor neurons. The most common is familial ALS (FALS). Apart from its inheritance as an autosomal dominant trait, it is clinically indistinguishable from sporadic ALS. Genetic studies have identified mutations in the gene encoding the cytosolic, copper- and zinc-binding enzyme SOD1 as the cause of one form of FALS. However, this accounts for only 20% of inherited cases of ALS. Rare mutations in other genes are also clearly implicated in ALS-like diseases. Thus, a familial, predominantly lower motor neuron disease with bulbar predominance has been ascribed to mutations in the gene encoding the cellular motor protein dynactin. Another familial, adult-onset disorder that may mimic aspects of ALS is Kennedy's syndrome; as described below, this arises from distinctive mutations in the androgen receptor. Genetic

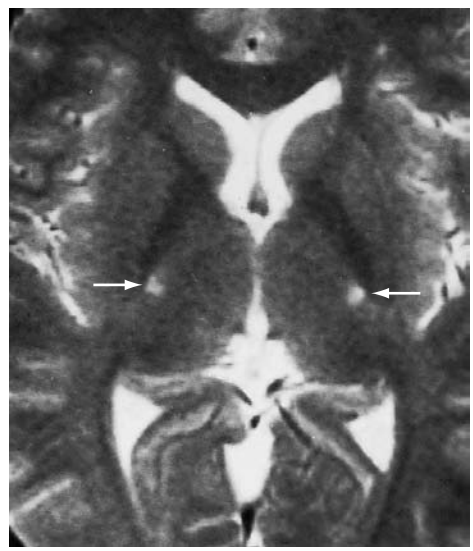

FIGURE 353-1 Amyotrophic lateral sclerosis. Axial T2-weighted MRI scan through the lateral ventricles of the brain reveals abnormal high signal intensity within the corticospinal tracts (*arrows*). This MRI feature represents an increase in water content in myelin tracts undergoing Wallerian degeneration secondary to cortical motor neuronal loss. This finding is commonly present in ALS, but can also be seen in AIDS-related encephalopathy, infarction, or other disease processes that produce corticospinal neuronal loss in a symmetric fashion.

TABLE 353-3 *Genetic Motor Neuron Diseases*

Disease	Locus	Gene
I. Upper and lower motor neurons (familial ALS)		
A. Autosomal dominant	2p	Dynactin
	21q	Superoxide dismutase
	22q	Neurofilament heavy subunit
	9q	Unknown
	16q	Unknown
	20p	Unknown
	X_{cent}	Unknown
B. Autosomal recessive (juvenile)	2q	Alsin
	15q	Unknown
C. Mitochondrial	mtDNA	Cytochrome c oxidase
II. Lower motor neurons		
A. Spinal muscular atrophies	5q	Survival motor neuron protein
B. X-linked spinobulbar muscular atrophy	Xq	Androgen receptor
C. G_{M2} gangliosidosis		
1. Adult Tay-Sach's disease	15q	Hexosaminidase A
2. Sandhoff disease	5q	Hexosaminidase B
3. AB variant	5q	G_{M2} activator protein
III. Upper motor neurons/selected FSPs		
A. Autosomal dominant	2p	Spastin
	2q	Mitochondrial heat shock protein
	12q	Kinesin heavy chain KIF5A
	14q	Unknown
B. Autosomal recessive	16q	Paraplegin
C. X-linked	Xq21	Proteolipid protein
	Xq28	L1 CAM
D. Adrenomyeloneuropathy	Xq21	Adrenoleukodystrophy protein
IV. ALS-plus syndromes		
A. ALS with frontotemporal dementia	9q	Unknown
B. Amyotrophy with behavioral disorder and parkinsonian features	17q	Tau protein

Note: ALS, amyotrophic lateral sclerosis; FSP, familial spastic paraplegia.

analyses are also beginning to illuminate the pathogenesis of some childhood-onset motor neuron diseases. For example, a slowly disabling degenerative, predominantly upper motor neuron disease that starts in the first decade is caused by mutations in a gene that expresses a novel signaling molecule with properties of a guanine-exchange factor, termed *alsin*. In other instances, chromosomal locations for motor neuron diseases, but not the causative genes themselves, have been identified. Typical FALS has been genetically mapped to chromosomes 16 and 20 in several families, and a juvenile-onset, dominantly inherited form of ALS has been mapped to the long-arm of chromosome 9.

Differential Diagnosis Because ALS is currently untreatable, it is imperative that potentially remediable causes of motor neuron dysfunction be excluded (Table 353-1). This is particularly true in cases that are atypical by virtue of (1) restriction to either upper or lower motor neurons, (2) involvement of neurons other than motor neurons, and (3) evidence of motor neuronal conduction block on electrophysiologic testing. Compression of the cervical spinal cord or cervicomedullary junction from tumors in the cervical regions or at the foramen magnum or from cervical spondylosis with osteophytes projecting into the vertebral canal can produce weakness, wasting, and fasciculations in the upper limbs and spasticity in the legs, closely resembling ALS. The absence of cranial nerve involvement may be helpful in differentiation, although some foramen magnum lesions may compress the twelfth cranial (hypoglossal) nerve, with resulting paralysis of the tongue. Absence of pain or of sensory changes, normal bowel and bladder function, normal roentgenographic studies of the spine, and normal cerebrospinal fluid (CSF) all favor ALS. Where doubt exists, magnetic resonance imaging (MRI) scans and contrast myelography should be performed to visualize the cervical spinal cord.

Another important entity in the differential diagnosis of ALS is *multifocal motor neuropathy with conduction block* (MMCB), discussed below. A diffuse, lower motor axonal neuropathy mimicking ALS sometimes evolves in association with hematopoietic disorders such as lymphoma. In this clinical setting, the presence of an M-component in serum should prompt consideration of a bone marrow biopsy. Lyme disease (Chap. 157) may also cause an axonal, lower motor neuropathy.

Other treatable disorders that occasionally mimic ALS are chronic lead poisoning and thyrotoxicosis. These disorders may be suggested by the patient's social or occupational history or by unusual clinical features. When the family history is positive, disorders involving the genes encoding cytosolic SOD1, hexosaminidase A, or α-glucosidase deficiency must be excluded (Chap. 340). These are readily identified by appropriate laboratory tests. Benign fasciculations are occasionally a source of concern because on inspection they resemble the fascicular twitchings that accompany motor neuron degeneration. The absence of weakness, atrophy, or denervation phenomena on electrophysiologic examination usually excludes ALS or other serious neurologic disease. Patients who have recovered from poliomyelitis may experience a delayed deterioration of motor neurons that presents clinically with progressive weakness, atrophy, and fasciculations. Its cause is unknown, but it is thought to reflect sublethal prior injury to motor neurons by poliovirus (Chap. 175).

Rarely, ALS develops concurrently with features indicative of more widespread neurodegeneration. Thus, one infrequently encounters otherwise typical ALS patients with a parkinsonian movement disorder or dementia. It remains unclear whether this reflects the unlikely simultaneous occurrence of two disorders or a primary defect triggering two forms of neurodegeneration. The latter is suggested by the observation that multisystem neurodegenerative diseases may be inherited. For example, prominent amyotrophy has been described as a dominantly inherited disorder in individuals with bizarre behavior and a movement disorder suggestive of parkinsonism; many such cases have now been ascribed to mutations that alter the expression of tau protein in brain (Chap. 350). In other cases, ALS develops simultaneously with a striking frontotemporal dementia. These disorders may be dominantly co-inherited; in some families, this trait is linked to a locus on chromosome 9q, although the underlying genetic defect is not established.

Pathogenesis The cause of sporadic ALS is not well defined. Several mechanisms that impair motor neuron viability have been elucidated in mice and rats induced to develop motor neuron disease by SOD1 transgenes with ALS-associated mutations. It is evident that excitotoxic neurotransmitters such as glutamate participate in the death of motor neurons in ALS. This may be a consequence of diminished uptake of synaptic glutamate by an astroglial glutamate transporter, EAAT2. It is striking that one cellular defense against such excitotoxicity is the enzyme SOD1, which detoxifies the free radical superoxide anion (Chap. 345). Because SOD1 is mutated in some familial cases of ALS, it may be that glutamate excitotoxicity and ALS result from free radical accumulations in motor neurons. Precisely why the SOD1 mutations are toxic to motor nerves is not established, although it is clear the effect is not simply loss of normal scavenging of the superoxide anion. The mutant protein is conformationally unstable and prone to aberrant catalytic reactions. In turn, these features lead to aggregation of SOD1 protein, impairment of axonal transport, reduced production of ATP and other perturbations of mitochondrial function, activation of cyclo-oxygenase within the ALS spinal cord, and ultimately induction of cell death via pathways that are at least partially

dependent on caspases. Recent studies have raised the hypothesis that genetic variants in the vascular endothelial growth factor gene (VEGF) that reduce VEGF expression increase the risk of ALS; whether this is a consequence of spinal cord hypoxia or diminished neurotrophic influence of VEGF remains to be established.

TREATMENT

No treatment arrests the underlying pathologic process in ALS. The drug riluzole (100 mg/d) was approved for ALS because it produces a modest lengthening of survival. In one trial, the survival rate at 18 months with riluzole was similar to placebo at 15 months. The mechanism of this effect is not known with certainty; riluzole may reduce excitotoxicity by diminishing glutamate release. Riluzole is generally well tolerated; nausea, dizziness, weight loss, and elevated liver enzymes occur occasionally. Several agents have failed in clinical trials in human ALS including brain-derived neurotrophic factor, glial-derived neurotrophic factor, the anti-glutamate compound topiramate, and creatine. The latter was somewhat surprising as creatine was proven to be beneficial in transgenic ALS mice, perhaps by augmenting intracellular ATP stores. Insulin-like growth factor 1 (IGF-1) produced inconsistent results in ALS patients and is undergoing further clinical trials. The finding that cyclo-oxygenase activity is enhanced in the spinal cords of ALS mice led to a preclinical study of the COX-2 inhibitor, celecoxib, which significantly increased life span in that model. As a consequence, celecoxib is currently being tested in human ALS. Analogously, because minocycline produced a modest benefit in ALS mice, presumably by inhibiting late stages of the apoptotic cascade, it is now being tested in a multicenter ALS trial.

In the absence of a primary therapy for ALS, a variety of rehabilitative aids may substantially assist ALS patients. Foot-drop splints facilitate ambulation by obviating the need for excessive hip flexion and by preventing tripping on a floppy foot. Finger extension splints can potentiate grip. Respiratory support may be life-sustaining. For patients electing against long-term ventilation by tracheostomy, positive-pressure ventilation by mouth or nose provides transient (several weeks) relief from hypercarbia and hypoxia. Also extremely beneficial for some patients is a respiratory device (In-exsufflator or Cough Assist Device) that produces an artificial cough. This is highly effective in clearing airways and preventing aspiration pneumonia. When bulbar disease prevents normal chewing and swallowing, gastrostomy is uniformly helpful, restoring normal nutrition and hydration. Fortunately, an increasing variety of speech synthesizers are now available to augment speech when there is advanced bulbar palsy. These facilitate oral communication and may be effective for telephone use.

In contrast to ALS, several of the disorders (Tables 353-1 and 353-3) that bear some clinical resemblance to ALS are treatable. For this reason, a careful search for causes of secondary motor neuron disease is warranted.

SELECTED LOWER MOTOR NEURON DISORDERS In these motor neuron diseases, the peripheral motor neurons are affected without evidence of involvement of the corticospinal motor system (Tables 353-1 to 353-3).

X-Linked Spinobulbar Muscular Atrophy (Kennedy's Disease) This is an X-linked lower motor neuron disorder in which progressive weakness and wasting of limb and bulbar muscles begins in males in mid-adult life and is conjoined with androgen insensitivity manifested by gynecomastia and reduced fertility (Chap. 325). In addition to gynecomastia, which may be subtle, two findings distinguishing this disorder from ALS are the absence of signs of pyramidal tract disease (spasticity) and the presence of a subtle sensory neuropathy in some patients. The underlying molecular defect is an expanded trinucleotide repeat (-CAG-) in the first exon of the androgen receptor gene on the X chromosome. DNA testing is available. An inverse correlation appears to exist between the number of -CAG- repeats and the age of onset of the disease.

Adult Tay-Sach's Disease Several reports have described adult-onset, predominantly lower motor neuropathies arising from deficiency of the enzyme β-hexosaminidase (hex A). These tend to be distinguishable from ALS because they are very slowly progressive; dysarthria and radiographically evident cerebellar atrophy may be prominent. In rare cases, spasticity may also be present, although it is generally absent (Chap. 340).

Spinal Muscular Atrophy The SMAs are a family of selective lower motor neuron diseases of early onset. Despite some phenotypic variability (largely in age of onset), the defect in the majority of families with SMA maps to a locus on chromosome 5 encoding a putative motor neuron survival protein (SMN, for survival motor neuron) that is important in the formation and trafficking of RNA complexes across the nuclear membrane. Neuropathologically these disorders are characterized by extensive loss of large motor neurons; muscle biopsy reveals evidence of denervation atrophy. Several clinical forms exist.

Infantile SMA (SMA I, Werdnig-Hoffmann Disease) has the earliest onset and most rapidly fatal course. In some instances it is apparent even before birth, as indicated by decreased fetal movements late in the third trimester. Though alert, afflicted infants are weak and floppy (hypotonic) and lack muscle stretch reflexes. Death generally ensues within the first year of life. *Chronic childhood SMA* (SMA II) begins later in childhood and evolves with a more slowly progressive course. *Juvenile SMA* (SMA III, Kugelberg-Welander disease) manifests during late childhood and runs a slow, indolent course. Unlike most denervating diseases, in this chronic disorder weakness is greatest in the proximal muscles; indeed, the pattern of clinical weakness can suggest a primary myopathy such as limb-girdle dystrophy. Electrophysiologic and muscle biopsy evidence of denervation distinguish SMA III from the myopathic syndromes.

Multifocal Motor Neuropathy with Conduction Block In this disorder lower motor neuron function is regionally and chronically disrupted by remarkably focal blocks in conduction. Many cases have elevated serum titers of mono- and polyclonal antibodies to ganglioside GM1; it is hypothesized that the antibodies produce selective, focal, paranodal demyelination of motor neurons. MMCB is not typically associated with corticospinal signs. In contrast with ALS, MMCB may respond dramatically to therapy such as intravenous immunoglobulin or chemotherapy; it is thus imperative that MMCB be excluded when considering a diagnosis of ALS.

Other Forms of Lower Motor Neuron Disease In individual families, other syndromes characterized by selective lower motor neuron dysfunction in an SMA-like pattern have been described. There are rare X-linked and autosomal dominant forms of apparent SMA. There is an ALS variant of juvenile onset, the Fazio-Londe syndrome, that involves mainly the musculature innervated by the brainstem. A component of lower motor neuron dysfunction is also found in degenerative disorders such as Machado-Joseph disease and the related olivopontocerebellar degenerations (Chap. 352).

SELECTED DISORDERS OF THE UPPER MOTOR NEURON ■ Primary Lateral Sclerosis This exceedingly rare disorder arises sporadically in adults in mid- to late life. Clinically PLS is characterized by progressive spastic weakness of the limbs, preceded or followed by spastic dysarthria and dysphagia, indicating combined involvement of the corticospinal and corticobulbar tracts. Fasciculations, amyotrophy, and sensory changes are absent; neither electromyography nor muscle biopsy shows denervation. On neuropathologic examination there is selective loss of the large pyramidal cells in the precentral gyrus and degeneration of the corticospinal and corticobulbar projections. The peripheral motor neurons and other neuronal systems are spared. The course of PLS is variable; while long-term survival is documented, the course may be as aggressive as in ALS, with ~3-year survival from onset to death. Early in its course, PLS raises the question of multiple sclerosis or other demyelinating diseases such as adrenoleukodystrophy as diag-

nostic considerations (Chap. 359). A myelopathy suggestive of PLS is infrequently seen with infection with the retrovirus human T cell lymphotropic virus (HTLV-I) (Chap. 356). The clinical course and laboratory testing will distinguish these possibilities.

Familial Spastic Paraplegia In its pure form, FSP is usually transmitted as an autosomal trait; most adult-onset cases are dominantly inherited. It arises in the third or fourth decade and is characterized by progressive spastic weakness beginning in the distal lower extremities. FSP typically has a long survival, presumably because respiratory function is spared. Late in the illness there may be urinary urgency and incontinence and sometimes fecal incontinence; sexual function tends to be preserved. In pure forms of FSP, ataxia, posterior column sensory loss, and amyotrophy are absent or minimal; however, in some patients, minor sensory changes (impaired vibration and position sense) may be observed in late stages. Some family members may have spasticity without clinical symptoms. Neuropathologically, in FSP there is degeneration of the corticospinal tracts, which appear nearly normal in the brainstem but show increasing atrophy at more caudal levels in the spinal cord. It is now apparent that defects at numerous loci underlie both dominantly and recessively inherited forms of FSP (Table 353-3). An infantile-onset form of X-linked, recessive FSP arises from mutations in the gene for myelin proteolipid protein (Chap. 345). This is an example of rather striking allelic variation, as most other mutations in the same gene cause not FSP but Pelizaeus-Merzbacher disease, a widespread disorder of CNS myelin. Defects in genes encoding the proteins spastin and paraplegin have been associated respectively with dominantly and recessively inherited FSP. The latter gene is of particular interest as it has homology to metalloproteases that are important in mitochondrial function in yeast. Defects in the gene *spartin*, a protein with homology to spastin, are associated with recessively inherited spasticity and distal weakness of early childhood onset. A kinesin heavy chain protein implicated in microtubule motor function was found to be defective in a family with dominantly inherited FSP of variable onset age.

Rarely, FSP may arise concomitantly with significant involvement of other regions of the nervous system. Thus, it has been described concurrently with amyotrophy, mental retardation, mental retardation with skin thickening, optic atrophy, and sensory neuropathy. In some cases there is loss of fibers in the ascending posterior columns and the spinocerebellar tracts, features reminiscent of Friedreich's ataxia (Chap. 352). These complicated forms of FSP emphasize the challenge inherent in classifying the neurodegenerative disorders; there may be considerable overlap of the clinical phenotypes in diseases otherwise classified as distinct. Fortunately, it is likely that increasingly available genetic testing will clarify these nosologic difficulties.

WEB SITES Several web sites provide valuable information on ALS including those offered by the Muscular Dystrophy Association (www.mdausa.org), the Amyotrophic Lateral Sclerosis Association (www.alsa.org), and the World Federation of Neurology and the Neuromuscular Unit At Washington University in St. Louis (www.neuro.wustl.edu/neuromuscular).

354 DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM

Phillip A. Low, John W. Engstrom

The autonomic nervous system (ANS) innervates the entire neuraxis and permeates all organ systems. It regulates blood pressure (BP), heart rate, sleep, and bladder and bowel function. It operates in the background, so that its full importance becomes recognized only when ANS function is compromised, resulting in dysautonomia. →***Hypothalamic disorders that cause disturbances in homeostasis are discussed in Chaps. 16 and 318.***

ANATOMIC ORGANIZATION The activity of the autonomic nervous system is regulated by central neurons responsive to diverse afferent inputs. After central integration of afferent information, autonomic outflow is adjusted to permit the functioning of the major organ systems in accordance with the needs of the organism as a whole. Connections between the cerebral cortex and the autonomic centers in the brainstem coordinate autonomic outflow with higher mental functions.

The preganglionic neurons of the parasympathetic nervous system leave the central nervous system (CNS) in the third, seventh, ninth, and tenth cranial nerves as well as the second and third sacral nerves, while the preganglionic neurons of the sympathetic nervous system exit the spinal cord between the first thoracic and the second lumbar segments (Fig. 354-1). The postganglionic neurons, located in ganglia outside the CNS, give rise to the postganglionic autonomic nerves that innervate organs and tissues throughout the body. Responses to sympathetic and parasympathetic stimulation are frequently antagonistic (Table 354-1), reflecting highly coordinated interactions within the CNS; the resultant changes in parasympathetic and sympathetic activity provide more precise control of autonomic responses than could be achieved by the modulation of a single system.

Acetylcholine (ACh) is the preganglionic neurotransmitter for both divisions of the ANS as well as the postganglionic neurotransmitter of the parasympathetic neurons. Norepinephrine (NE) is the neurotransmitter of the postganglionic sympathetic neurons, except for cholinergic neurons innervating the eccrine sweat glands and perhaps some blood vessels supplying skeletal muscle.

CLINICAL EVALUATION ■ Classification Disorders of the ANS may result from pathology of either the CNS or the peripheral nervous system (PNS) (Table 354-2). Signs and symptoms may result from interruption of the afferent limb, CNS processing centers, or efferent limb of reflex arcs controlling autonomic responses. For example, a lesion of the medulla produced by a posterior fossa tumor can impair BP responses to postural changes and result in orthostatic hypotension (OH). OH can also be caused by lesions of the spinal cord or peripheral vasomotor nerve fibers (e.g., diabetic autonomic neuropathy). The site of reflex interruption is usually established by the clinical context in which the dysautonomia arises, combined with judicious use of ANS testing and neuroimaging studies. Important elements of the clinical context include the presence or absence of CNS signs (pathophysiology and prognosis differ), association with sensory or motor polyneuropathy, family history, and pathologic findings. Some syndromes do not fit easily into any classification scheme.

Symptoms of Autonomic Dysfunction Clinical manifestations result from a loss of function (e.g., impaired baroreflexes leading to OH), overactivity (e.g., hyperhidrosis, hypertension, tachycardia), or loss of regulation (e.g., autonomic storms, autonomic dysreflexia) of autonomic circuits. The disorder may be widespread or regional in distribution.

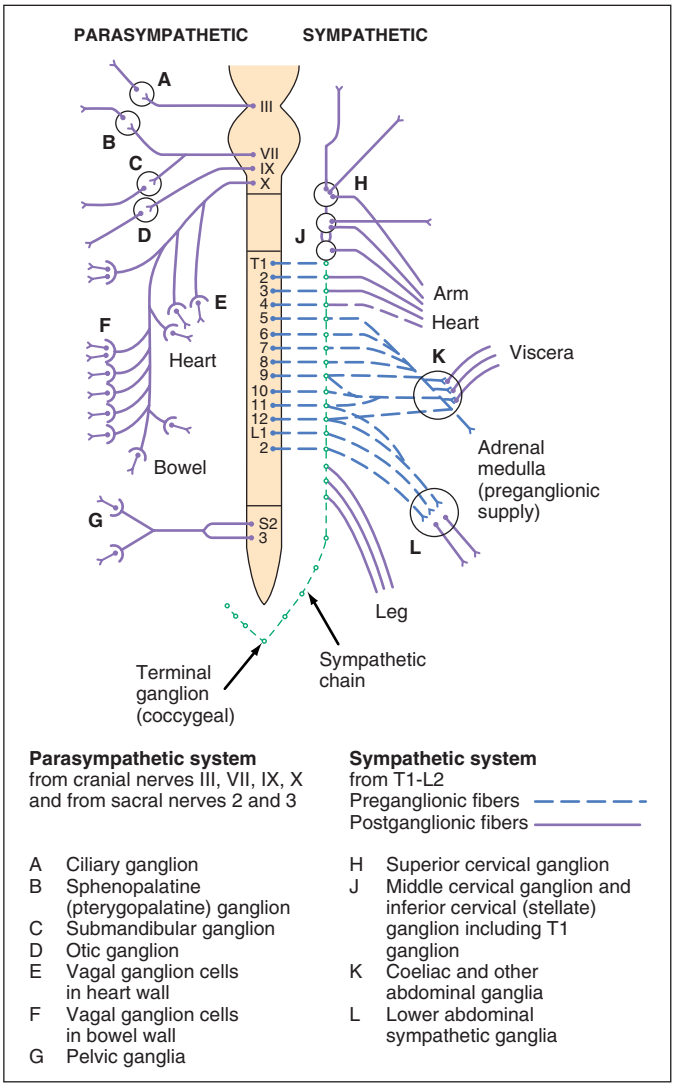

FIGURE 354-1 Schematic representation of the autonomic nervous system. (*From M Moskowitz: Clin Endocrinol Metab 6:77, 1977.*)

An autonomic history focuses on systemic functions (BP, heart rate, sleep, thermoregulation) and individual organ systems (pupils, bowel, bladder, sexual function). More formal assessment is possible using a standardized instrument such as the autonomic symptom profile. It is also important to recognize the modulating effects of age and gender. For instance, OH commonly results in lightheadedness in the young, whereas cognitive slowing is much more important in the elderly. Specific symptoms of orthostatic intolerance are quite diverse (Table 354-3). Autonomic symptoms may vary dramatically, reflecting the dynamic nature of autonomic control over homeostatic function. For example, OH might be manifest only in the early morning, following a

TABLE 354-1 *Functional Consequences of Normal ANS Activation*

	Sympathetic	Parasympathetic
Heart rate	Increased	Decreased
Blood pressure	Increased	Mildly decreased
Bladder	Increased sphincter tone	Voiding (decreased tone)
Bowel motility	Decreased motility	Increased
Lung	Bronchodilation	Bronchoconstriction
Sweat glands	Sweating	—
Pupils	Dilation	Constriction
Adrenal glands	Catecholamine release	—
Sexual function	Ejaculation, orgasm	Erection
Lacrimal glands	—	Tearing
Parotid glands	—	Salivation

TABLE 354-2 *Classification of Clinical Autonomic Disorders*

I. Autonomic disorders with brain involvement
  A. Associated with multisystem degeneration
    1. Multisystem degeneration: autonomic failure clinically prominent
      a. Multiple system atrophy (MSA)
      b. Parkinson's disease with autonomic failure
      c. Diffuse Lewy body disease (some cases)
    2. Multisystem degeneration: autonomic failure clinically not usually prominent
      a. Parkinson's disease
      b. Other extrapyramidal disorders (inherited spinocerebellar atrophies, progressive supranuclear palsy, corticobasal degeneration, Machado-Joseph disease)
  B. Unassociated with multisystem degeneration
    1. Disorders mainly due to cerebral cortex involvement
      a. Frontal cortex lesions causing urinary/bowel incontinence
      b. Partial complex seizures
    2. Disorders of the limbic and paralimbic circuits
      a. Shapiro's syndrome (agenesis of corpus callosum, hyperhidrosis, hypothermia)
      b. Autonomic seizures
    3. Disorders of the hypothalamus
      a. Wernicke-Korsakoff syndrome
      b. Diencephalic syndrome
      c. Neuroleptic malignant syndrome
      d. Serotonin syndrome
      e. Fatal familial insomnia
      f. Antidiuretic hormone (ADH) syndromes (diabetes insipidus, inappropriate ADH)
      g. Disturbances of temperature regulation (hyperthermia, hypothermia)
      h. Disturbances of sexual function
      i. Disturbances of appetite
      j. Disturbances of BP/HR and gastric function
      k. Horner's syndrome
    4. Disorders of the brainstem and cerebellum
      a. Posterior fossa tumors
      b. Syringobulbia and Arnold-Chiari malformation
      c. Disorders of BP control (hypertension, hypotension)
      d. Cardiac arrhythmias
      e. Central sleep apnea
      f. Baroreflex failure
      g. Horner's syndrome
II. Autonomic disorders with spinal cord involvement
  A. Traumatic tetraplegia
  B. Syringomyelia
  C. Subacute combined degeneration
  D. Multiple sclerosis
  E. Amyotrophic lateral sclerosis
  F. Tetanus
  G. Stiff-man syndrome
  H. Spinal cord tumors
III. Autonomic neuropathies
  A. Acute/subacute autonomic neuropathies
    1. Subacute autoimmune autonomic neuropathy (panautonomic neuropathy, pandysautonomia)
      a. Subacute paraneoplastic autonomic neuropathy
      b. Guillain-Barré syndrome
      c. Botulism
      d. Porphyria
      e. Drug induced autonomic neuropathies
      f. Toxic autonomic neuropathies
  B. Chronic peripheral autonomic neuropathies
    1. Distal small fiber neuropathy
    2. Combined sympathetic and parasympathetic failure
      a. Amyloid
      b. Diabetic autonomic neuropathy
      c. Autoimmune autonomic neuropathy (paraneoplastic and idiopathic)
      d. Sensory neuronopathy with autonomic failure
      e. Familial dysautonomia (Riley-Day syndrome)

Note: BP, blood pressure; HR, heart rate.

TABLE 354-3 *Symptoms of Orthostatic Intolerance*

Lightheadedness (dizziness)	88%
Weakness or tiredness	72%
Cognitive difficulty (thinking/concentrating)	47%
Blurred vision	47%
Tremulousness	38%
Vertigo	37%
Pallor	31%
Anxiety	29%
Palpitations	26%
Clammy feeling	19%
Nausea	18%

Source: From Low et al.

meal, or with exercise, depending upon the regional vascular bed affected by dysautonomia.

Early symptoms may be overlooked. Impotence, although not specific for autonomic failure, often heralds autonomic failure in men and may precede other symptoms by years (Chap. 43). A decrease in the frequency of spontaneous early morning erections may occur months before loss of nocturnal penile tumescence and development of total impotence. Bladder dysfunction may appear early in men and women, particularly in those with CNS involvement. Brain and spinal cord disease above the level of the lumbar spine results first in urinary frequency and small bladder volumes, and eventually in incontinence (upper motor neuron or spastic bladder). Disease of PNS autonomic nerve fibers to and from the bladder results in large bladder volumes, urinary frequency, and overflow incontinence (lower motor neuron bladder or flaccid bladder). Measurement of bladder volume (postvoid residual) is a useful bedside test for distinguishing between upper and lower motor neuron bladder dysfunction in the early stages of dysautonomia. Gastrointestinal autonomic dysfunction typically presents as severe constipation. Diarrhea occurs occasionally (as in diabetes mellitus) due to rapid transit of contents or uncoordinated small-bowel motor activity, or on an osmotic basis from bacterial overgrowth associated with small-bowel stasis. Impaired glandular secretory function may cause difficulty with food intake due to decreased salivation or with eye irritation due to decreased lacrimation. Occasionally, temperature elevation and vasodilation can result from anhidrosis because sweating is normally important for heat dissipation (Chap. 16).

OH (also called "postural hypotension") is perhaps the most disabling feature of autonomic dysfunction. The prevalence of OH is relatively high, especially when OH associated with aging is included (Table 354-4). OH can cause a variety of symptoms including dimming or loss of vision, lightheadedness, diaphoresis, diminished hearing, pallor, and weakness. Syncope results when the drop in BP impairs cerebral perfusion. Other manifestations of impaired baroreflexes are supine hypertension, a heart rate that is fixed regardless of posture, postprandial hypotension, and an excessively high nocturnal BP. Many patients with OH have a preceding diagnosis of hypertension, reflecting the great importance of baroreflexes in maintaining postural and supine normotension. The most common causes of OH are not neurologic in origin; these must be distinguished from the neurogenic causes. →***Neurocardiogenic and cardiac syncope are considered in Chap. 20.***

APPROACH TO THE PATIENT

The first step in the evaluation of symptomatic OH is the exclusion of treatable causes. The history should include a review of medications that may cause OH (e.g., diuretics, antihypertensives, antidepressants, phenothiazines, ethanol, narcotics, insulin, barbiturates, and calcium channel blocking agents). However, the precipitation of OH by medications may also be the first sign of an underlying autonomic disorder. The history may reveal an underlying cause for symptoms (e.g., diabetes, Parkinson's disease) or specific underlying mechanisms (e.g., cardiac pump failure, reduced intravascular volume). The relationship of symptoms to meals (splanchnic pooling), standing on awakening in the morning (intravascular volume depletion), ambient warming (vasodilatation), or exercise (muscle arteriolar vasodilatation) should be sought.

TABLE 354-4 *Prevalence of Orthostatic Hypotension in Different Disorders*

Disorder	Prevalence
Aging	14–20%
Diabetic neuropathy	10%
Other autonomic neuropathies	10–50 per 100,000
Multiple system atrophy	5–15 per 100,000
Pure autonomic failure	10–30 per 100,000

Physical examination includes measurement of supine and standing pulse and BP. OH is defined as a sustained drop in systolic (≥20 mmHg) or diastolic (≥10 mmHg) BP within 3 min of standing up. In nonneurogenic causes of OH (such as hypovolemia), the BP drop is accompanied by a compensatory increase in heart rate of >15 beats/min. An important clinical clue that the patient has neurogenic OH is the aggravation or precipitation of OH by autonomic stressors (such as a meal, hot tub/hot bath, and exercise). Neurologic evaluation should include a mental status examination (to exclude neurodegenerative disorders), cranial nerve examination (impaired downgaze is found with progressive supranuclear palsy), abnormal pupils (Horner's or Adie's pupils), motor examination (Parkinson's disease and parkinsonian syndromes), and sensory examination (polyneuropathies). In patients without a clear initial diagnosis, follow-up neurologic examinations and repeat laboratory evaluations over 1 to 2 years may reveal an evolution of findings that enables a specific diagnosis to be made.

Disorders of autonomic function should be considered in patients with symptoms of altered sweating (hyperhidrosis or hypohidrosis), gastroparesis (bloating, nausea, vomiting of old food), constipation, impotence, or bladder dysfunction (urinary frequency, hesitancy, or incontinence).

Autonomic Testing Autonomic function tests (Table 354-5) are helpful when the history and physical examination findings are inconclusive, when detection of subclinical involvement is important to evaluate the extent and severity of abnormalities, or to follow the course of an autonomic disorder or its response to therapy.

HEART RATE VARIATION WITH DEEP BREATHING This is a test of parasympathetic influence on cardiovascular function. Results are influenced by the subject's posture, rate and depth of respiration [6 breaths per minute and a forced vital capacity (FVC) >1.5 L are optimal], age, medications, and hypocapnea. Interpretation of results requires comparison of test data with results from normal individuals collected under the same test conditions. For example, the lower limit of normal heart rate variation with deep breathing

TABLE 354-5 *Neural Pathways Underlying Some Standardized Autonomic Tests*

Test Evaluated	Procedure	Autonomic Function
HRBD	6 deep breaths/min	Cardiovagal function
Valsalva ratio	Expiratory pressure, 40 mmHg for 10–15 s	Cardiovagal function
QSART	Axon-reflex test 4 limb sites	Postganglionic sudomotor function
BP_{BB} to VM	BP_{BB} response to VM	Adrenergic function: baroreflex adrenergic control of vagal and vasomotor function
HUT	BP_{BB} and heart rate response to HUT	Adrenergic and cardiovagal responses to HUT

Note: HRDB, heart rate response to deep breathing; BP_{BB}, beat-to-beat blood pressure; QSART, quantitative sudomotor axon-reflex test; VM, Valsalva maneuver; HUT, head-up tilt.

in persons <20 years is >15 to 20 beats/min, but for persons over age 60 it is 5 to 8 beats/min. Heart rate variation with deep breathing (respiratory sinus arrhythmia) is abolished by the administration of atropine.

VALSALVA RESPONSE This response (Table 354-5) assesses integrity of the baroreflex control of heart rate (parasympathetic) and BP (adrenergic). The response is obtained with the subject supine. A constant expiratory pressure of 40 mmHg is maintained for 15 s while measuring changes in heart rate and beat-to-beat BP. There are four phases of BP and heart rate response to the Valsalva maneuver. Phases I and III are mechanical and related to changes in intrathoracic and intraabdominal pressure. In early phase II, reduced venous return results in a fall in stroke volume and BP, counteracted by a combination of reflex tachycardia and increased total peripheral resistance. Increased total peripheral resistance arrests the BP drop ~5 to 8 s after the onset of the maneuver. Late phase II begins with a progressive rise in BP to or above baseline. Venous return and cardiac output return to normal in phase IV. Persistent peripheral arteriolar vasoconstriction and increased cardiac adrenergic tone results in a temporary BP overshoot and phase IV bradycardia (mediated by the baroreceptor reflex).

Autonomic function during the Valsalva maneuver can be measured using beat-to-beat blood pressure or heart rate changes. The Valsalva ratio is defined as the maximum phase II tachycardia divided by the minimum phase IV bradycardia. The ratio reflects cardiovagal function.

SUDOMOTOR FUNCTION Sweating is induced by release of ACh from sympathetic postganglionic fibers. The quantitative sudomotor axon reflex test (QSART) is a measure of regional autonomic function mediated by ACh-induced sweating. A reduced or absent response indicates a lesion of the postganglionic sudomotor axon. For example, sweating may be reduced in the legs as a result of peripheral neuropathy (e.g., in diabetes) before other signs of autonomic dysfunction emerge. The thermoregulatory sweat test (TST) is a qualitative measure of regional sweat production in response to an elevation of body temperature. An indicator powder placed on the anterior body surface changes color with sweat production during temperature elevation. The pattern of color changes is a measure of regional sweat secretion. Combining TST and QSART results will determine the site of the lesion. A postganglionic lesion is present if both QSART and TST show absent sweating. In a preganglionic lesion, QSART is intact but TST shows anhidrosis. Measurement of galvanic skin responses in the limbs after an induced electrical potential is another qualitative test for detecting the presence or absence of sweating.

ORTHOSTATIC BP RECORDINGS Beat-to-beat BP measurements determined in supine, 70° tilt, and tilt-back positions are useful to quantitate orthostatic failure of BP control. It is important to allow a 20-min period of supine rest before assessing changes in BP during tilting. The BP change combined with heart rate monitoring can be useful for the evaluation of patients with suspected OH or unexplained syncope or to detect vagally mediated syncope.

PHARMACOLOGIC TESTS Pharmacologic assessments can help localize an autonomic defect to the CNS or the PNS. A useful method to evaluate the systemic adrenergic response is the measurement of plasma NE, first with the patient supine and then after standing for at least 5 min. Supine values are reduced in postganglionic disorders (such as autonomic neuropathy or pure autonomic failure) and may fail to increase in preganglionic or postganglionic disorders (e.g., multiple system atrophy).

Administration of tyramine (releases NE from postganglionic terminals) and phenylephrine (denervation supersensitivity—directly acting α_1-agonist) is often used to evaluate postganglionic adrenergic function. In a postganglionic lesion, the response to tyramine is reduced and there is an excessive response to subthreshold doses of phenylephrine. Other strategies include ganglionic blockade with trimethaphan (greater fall in resulting BP with a preganglionic lesion) or administration of arginine vasopressin (to evaluate afferent central pathways).

SPECIFIC SYNDROMES OF ANS DYSFUNCTION

Multiple System Atrophy

Multiple system atrophy (MSA) is an uncommon entity that comprises autonomic failure (OH and/or a neurogenic bladder are required for diagnosis) combined with either striatonigral degeneration (Shy-Drager syndrome) or sporadic olivopontocerebellar atrophy (Chap. 351). The parkinsonism is usually unassociated with rest tremor and is not responsive to levodopa. Levodopa-induced dyskinesia is also uncommon. Autonomic function tests can usually differentiate MSA from Parkinson's disease in that the severity and distribution of autonomic failure is more severe and generalized in MSA. Cardiac postganglionic adrenergic innervation, measured as labeled metaiodobenzylguanidine (MIBG) uptake on single photon emission computed tomography or fluorodopamine on positron emission tomography (PET), is markedly impaired in the dysautonomia of Parkinson's disease but is normal in MSA.

MSA generally progresses relentlessly to death 7 to 10 years after onset. Neuropathologic changes include primary neuronal degeneration with loss of neurons and gliosis in many CNS regions, including the brainstem, the cerebellum, the striatum, and the intermediolateral cell column of the thoracolumbar spinal cord.

Spinal Cord Spinal cord lesions from any cause may result in focal autonomic deficits or autonomic hyperreflexia. Spinal cord transection or hemisection may be attended by autonomic hyperreflexia affecting bowel, bladder, sexual, temperature-regulation, or cardiovascular functions. Dangerous increases or decreases in body temperature may result from inability to experience the sensory accompaniments of heat or cold exposure below the level of the injury. Quadriparetic patients exhibit both supine hypertension and OH after upward tilting. Markedly increased autonomic discharge can be elicited by bladder pressure or stimulation of the skin or muscles; suprapubic palpation of the bladder, a distended bladder, catheter insertion, catheter obstruction, or urinary infection are common and correctable precipitants. This phenomenon, termed *autonomic dysreflexia*, affects 85% of patients with a traumatic spinal cord lesion above the C6 level. In patients with supine hypertension, BP can be lowered by tilting the head upward. Vasodilator drugs may be used to treat acute elevations in BP. Clonidine is used prophylactically to reduce the hypertension resulting from bladder stimulation. Sudden, dramatic increases in BP can lead to intracranial hemorrhage and death.

Peripheral Nerve and Neuromuscular Junction Disorders Peripheral neuropathies (Chap. 363) are the most common cause of chronic autonomic insufficiency. Neuropathies that affect small myelinated and unmyelinated fibers of the sympathetic and parasympathetic nerves occur in diabetes mellitus, amyloidosis, chronic alcoholism, porphyria, and Guillain-Barré syndrome. Neuromuscular junction disorders include botulism and Lambert-Eaton syndrome.

DIABETES MELLITUS Autonomic neuropathy typically begins ~10 years after the onset of diabetes (Chap. 323) and slowly progresses. The earliest autonomic abnormalities, typically asymptomatic, consist of vagal disturbances, which can be detected as reduced heart rate variation with deep breathing, and loss of distal sudomotor function, detected by QSART. Loss of small myelinated and unmyelinated nerve fibers in the splanchnic distribution, carotid sinus, and vagus nerves is characteristic. In advanced disease, widespread enteric neuropathy can cause profound disturbances in gut motility (*gastroparesis*), nausea and vomiting, malnutrition, achlorhydria, and bowel incontinence. Other symptoms can include impotence, urinary incontinence, pupillary abnormalities, and OH. Typical symptoms and signs of hypoglycemia may fail to appear because damage to the sympathetic innervation of the adrenal gland can result in a lack of epinephrine

release. Insulin increases flow through arteriovenous shunts and may also aggravate OH. Autonomic dysfunction may lengthen the QT interval, increasing the risk of sudden death due to cardiac arrhythmia. There is postganglionic cardiac denervation with some proximal segments showing increased uptake of labeled hydroxyephedrine, indicative of hyperadrenergic innervation, on PET scanning. This finding is of interest in that these areas could be potentially arrhythmogenic. Hyperglycemia appears to be a direct risk factor for autonomic involvement in diabetes. Biochemical and pharmacologic studies in diabetic neuropathy are compatible with autonomic failure localized to the PNS. Supine plasma NE levels can be reduced, and a minority of patients experience a phase of hyperadrenegic autonomic function characterized by exaggerated orthostatic pressor responsiveness.

AMYLOIDOSIS Autonomic neuropathy occurs in both sporadic and familial forms of amyloidosis (Chap. 310). The AL (immunoglobulin light chain) type is associated with primary amyloidosis or amyloidosis secondary to multiple myeloma. The ATTR type, with transthyretin as the primary protein component, is responsible for the most common form of inherited amyloidosis. Although patients usually present with a distal painful neuropathy accompanied by sensory loss, autonomic insufficiency can precede the development of the polyneuropathy or occur in isolation. Death is usually due to cardiac or renal impairment. Postmortem studies reveal amyloid deposition in many organs, including two sites that contribute to autonomic failure: intraneural blood vessels and autonomic ganglia. Pathologic examination reveals a loss of unmyelinated and myelinated nerve fibers.

ALCOHOLIC NEUROPATHY Abnormalities in parasympathetic vagal and efferent sympathetic function are usually mild in individuals with alcoholic neuropathy. Pathologic changes can be demonstrated in the parasympathetic (vagus) and sympathetic fibers and in ganglia. OH is usually due to brainstem involvement. Impotence is a major problem, but concurrent gonadal hormone abnormalities may obscure the parasympathetic component. Clinical symptoms of autonomic failure generally appear when the polyneuropathy is severe and there is usually coexisting Wernicke's encephalopathy (Chap. 258). Autonomic involvement may contribute to the high mortality rates associated with alcoholism (Chap. 372).

PORPHYRIA Although each of the porphyrias can cause autonomic dysfunction, the condition is most extensively documented in the acute intermittent type (Chap. 337). Autonomic symptoms include tachycardia, sweating, urinary retention, and hypertension, or, less commonly, hypotension. Other prominent symptoms include anxiety, abdominal pain, nausea, and vomiting. Abnormal autonomic function can occur both during acute attacks and during remissions. Elevated catecholamine levels during acute attacks correlate with the degree of tachycardia and hypertension that are present.

GUILLAIN-BARRÉ SYNDROME BP fluctuations and arrhythmias can be severe (Chap. 365). It is estimated that 2 to 10% of patients seriously ill with Guillain-Barré syndrome suffer fatal cardiovascular collapse. Gastrointestinal autonomic involvement is common. Abnormal sweating, sphincter disturbance, and pupillary dysfunction also occur. Demyelination has been described in the vagus and glossopharyngeal nerves, the sympathetic chain, and the white rami communicantes. The presence of autonomic involvement is not clearly related to the severity of motor or sensory involvement.

AUTOIMMUNE AUTONOMIC NEUROPATHY The development of serologic testing for the ganglionic ACh receptor (A_3 AChR) autoantibody, which is a putative effector of autoimmune dysautonomia, now allows definition of the entity of autoimmune autonomic neuropathy (AAN). This disorder presents as the subacute development of autonomic failure with OH, enteric neuropathy (gastroparesis, ileus, constipation/diarrhea), and cholinergic failure; the latter consists of loss of sweating, sicca complex, and a tonic pupil. In general, the antibody titer correlates with the severity of autonomic failure. Symptoms of cholinergic failure are also predictive of a high antibody titer. Onset of the neuropathy follows a viral infection in approximately half of cases. Some patients appear to respond to immunotherapy. The spectrum of AAN is broader than originally thought, and some antibody-positive cases have an insidious onset and slow progression with a pure autonomic failure (see below) phenotype. An experimental autonomic neuropathy has recently been produced by immunization of rabbits with this receptor.

AAN can have a paraneoplastic basis (Chap. 87). The clinical features of the autonomic neuropathy may be indistinguishable from the nonparaneoplastic form, or a coexisting paraneoplastic syndrome, such as cerebellar involvement or dementia, may be present (Tables 87-2 and 87-3). The neoplasm may be truly occult, possibly suppressed by the autoantibody.

BOTULISM Botulinum toxin binds presynaptically to cholinergic nerve terminals and, after uptake into the cytosol, blocks ACh release. Manifestations consist of motor paralysis and autonomic disturbances that include blurred vision, dry mouth, nausea, unreactive or sluggishly reactive pupils, constipation, and urinary retention (Chap. 125).

Pure Autonomic Failure (PAF) This sporadic syndrome consists of postural hypotension, impotence, bladder dysfunction, and defective sweating. The disorder begins in the middle decades and occurs in women more often than men. The symptoms can be disabling, but the disease does not shorten life span. The clinical and pharmacologic characteristics suggest primary involvement of postganglionic sympathetic neurons. There is a severe reduction in the density of neurons within sympathetic ganglia that results in low supine plasma NE levels and noradrenergic supersensitivity. Recent studies have questioned the specificity of PAF as a distinct clinical entity. Some cases are ganglionic antibody–positive and thus represent a type of AAN. Between 10 and 15% of cases evolve into MSA.

Postural Orthostatic Tachycardia Syndrome (POTS) This syndrome is characterized by symptomatic orthostatic intolerance (not OH) and by either an increase in heart rate to >120 beats/min or an increase of 30 beats/min with standing that subsides on sitting or lying down. Women are affected approximately five times more often than men, and most develop the syndrome between the ages of 15 and 50 years. Approximately half of affected patients report an antecedent viral infection. Syncopal symptoms (lightheadedness, weakness, blurred vision) combined with those of autonomic overactivity (palpitations, tremulousness, nausea) are common. Recurrent unexplained episodes of dysautonomia and fatigue also occur. The pathogenesis is unclear in most cases; hypovolemia, venous pooling, impaired brainstem regulation, or β-receptor supersensitivity may play a role. In one affected individual, a mutation in the NE transporter, which resulted in impaired NE clearance from synapses, was responsible. Some cases are due to an underlying limited autonomic neuropathy. Although ~80% of patients improve, only one-quarter eventually resume their usual daily activities (including exercise and sports). Expansion of fluid volume and postural training (see "Treatment") are initial approaches to treatment. When these approaches are inadequate, midodrine, fludrocortisone, phenobarbital, beta blockers, and clonidine have been used with some success.

Inherited Disorders There are five known hereditary sensory and autonomic neuropathies (HSAN I–V). The most important ones are HSAN I and HSAN III (Riley-Day syndrome; familial dysautonomia). HSAN I is dominantly inherited and often presents as a distal small-fiber neuropathy (burning feet syndrome). The responsible gene, on chromosome 9q, is designated *SPTLC1*. SPTLC is an important enzyme in the regulation of ceramide. Cells from HSAN I patients affected by mutation of *SPTLCI* produce higher-than-normal levels of glucosyl ceramide, perhaps triggering apoptosis.

HSAN III, an autosomal recessive disorder of infants and children that occurs among Ashkenazi Jews, is much less prevalent than HSAN I. Decreased tearing, hyperhidrosis, reduced sensitivity to pain, areflexia, absent fungiform papillae on the tongue, and labile BP may be present. Episodic abdominal crises and fever are common. Patho-

logic examination of nerves reveals a loss of small myelinated and unmyelinated nerve fibers. The defective gene, named *IKBKAP*, is also located on the long arm of chromosome 9. Pathogenic mutations may prevent normal transcription of important molecules in neural development.

Primary Hyperhidrosis This syndrome presents with excess sweating of the palms of the hands and soles of the feet. The disorder affects 0.6 to 1.0% of the population; the etiology is unclear but there may be a genetic component. While not dangerous, the condition can be socially embarrassing (e.g., shaking hands) or disabling (e.g., inability to write without soiling the paper). Onset of symptoms is usually in adolescence; the condition tends to improve with age. Topical antiperspirants are occasionally helpful. More useful are potent anticholinergic drugs such as glycopyrrolate, 1 to 2 mg tid. T2 ganglionectomy or sympathectomy is successful in >90% of patients with palmar hyperhidrosis. The advent of endoscopic transaxillary T2 sympathectomy has lowered the complication rate of the procedure. The most common postoperative complication is compensatory hyperhidrosis, which improves spontaneously over months; other potential complications include recurrent hyperhidrosis (16%), Horner's syndrome (<2%), gustatory sweating, wound infection, hemothorax, and intercostal neuralgia. Local injection of botulinum toxin has also been used to block cholinergic, postganglionic sympathetic fibers to sweat glands in patients with palmar hyperhidrosis. This approach is limited by the need for repetitive injections (the effect usually lasts 4 months before waning), pain with injection, the high cost of botulinum toxin, and the possibility of temporary intrinsic hand muscle weakness. Tap water iontophoresis has been successful for some patients.

Miscellaneous Other conditions associated with autonomic failure include infections, poisoning (organophosphates), malignancy, and aging. Disorders of the hypothalamus can affect autonomic function and produce abnormalities in temperature control, satiety, sexual function, and circadian rhythms (Chap. 318).

Reflex Sympathetic Dystrophy and Causalgia The failure to identify a primary role of the ANS in the pathogenesis of these disorders has resulted in a change of nomenclature. Complex regional pain syndrome (CRPS) types I and II are now used in place of reflex sympathetic dystrophy (RSD) and causalgia, respectively.

CRPS type I is a regional pain syndrome that usually develops after tissue trauma. Examples of associated trauma include myocardial infarction, minor shoulder or limb injury, and stroke. *Allodynia* (the perception of a nonpainful stimulus as painful), *hyperpathia* (an exaggerated pain response to a painful stimulus), and spontaneous pain occur. The symptoms are unrelated to the severity of the initial trauma and are not confined to the distribution of a single peripheral nerve. CRPS type II is a regional pain syndrome that develops after injury to a peripheral nerve, usually a major nerve trunk. Spontaneous pain initially develops within the territory of the affected nerve but eventually may spread outside the nerve distribution.

Pain is the primary clinical feature of CRPS. Vasomotor dysfunction, sudomotor abnormalities, or focal edema may occur alone or in combination but must be present for diagnosis. Limb pain syndromes that do not meet these criteria are best classified as "limb pain—not otherwise specified." In CRPS, localized sweating (increased resting sweat output) and changes in blood flow may produce temperature differences between affected and unaffected limbs.

CRPS type I (RSD) has classically been divided into three clinical phases but is now considered to be more variable. Phase I consists of pain and swelling in the distal extremity occurring within weeks to 3 months after the precipitating event. The pain is diffuse, spontaneous, and either burning, throbbing, or aching in quality. The involved extremity is warm and edematous, and the joints are tender. Increased sweating and hair growth develop. In phase II (3 to 6 months after onset), thin, shiny, cool skin appears. After an additional 3 to 6 months (phase III), atrophy of the skin and subcutaneous tissue plus flexion contractures complete the clinical picture.

The natural history of typical CRPS may be more benign than reflected in the literature. A variety of surgical and medical treatments have been developed, with conflicting reports of efficacy. Clinical trials suggest that early mobilization with physical therapy or a brief course of glucocorticoids may be helpful for CRPS type I. Other medical treatments include the use of adrenergic blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), calcium channel blockers, phenytoin, opioids, and calcitonin. Stellate ganglion blockade is a commonly used invasive therapeutic technique that often provides temporary pain relief, but the efficacy of repetitive blocks is uncertain.

TREATMENT

Management of autonomic failure is aimed at specific treatment of the cause and alleviation of symptoms. Of particular importance is the removal of drugs or amelioration of underlying conditions that cause or aggravate the autonomic symptom. For instance, OH can be caused or aggravated by angiotensin-converting enzyme inhibitors, calcium channel blocking agents, tricyclic antidepressants, levodopa, alcohol, or insulin.

Patient Education OH can be asymptomatic or symptomatic. Neurogenic OH requires treatment, but only a minority of patients require pharmacologic treatment. All patients should be taught the mechanisms of postural normotension (volume status, resistance and capacitance bed, autoregulation) and the nature of orthostatic stressors (time of day and the influence of meals, heat, standing, and exercise). Patients should learn to recognize orthostatic symptoms early in their evolution (especially subtle cognitive symptoms, weakness, and fatigue) and to modify activities that provoke episodes. Other helpful measures may include keeping a BP log, dietary education (salt/fluids), monitoring urine volume and sodium excretion, or recognizing medications and situations to avoid. Learning physical countermaneuvers that reduce standing OH, practicing postural and resistance training, and learning to manage worsening OH in specific situations and at specific times are helpful measures.

Symptomatic Treatment Nonpharmacologic approaches are summarized in Table 354-6. Adequate intake of salt and fluids to produce a voiding volume between 1.5 to 2.5 L of urine (containing >170 meq of Na^+) each 24 h is essential. Sleeping with the head of the bed elevated will minimize the effects of supine nocturnal hypertension. Prolonged recumbency should be avoided when possible. Patients are advised to sit with legs dangling over the edge of the bed for several minutes before attempting to stand in the morning; other postural stresses should be similarly approached in a gradual manner. Physical countermaneuvers that can reduce OH include leg-crossing, with maintained contraction of leg muscles for 30 s. Such maneuvers compress leg veins and increase systemic resistance. Compressive garments such as compression stockings and abdominal binders may be helpful; some patients find these uncomfortable. Anemia should be corrected, if necessary, with erythropoietin, administered subcutaneously at doses of 25 to 75 U/kg three times per week. The hematocrit increases after 2 to 6 weeks. A weekly maintenance dose is usually necessary. The increased intravascular volume that accompanies the rise in hematocrit can exacerbate supine hypertension.

If these measures are not sufficient, drug treatment might be nec-

essary. Midodrine is effective but can aggravate supine hypertension at higher doses. The drug is a directly acting α_1-agonist that does not cross the blood-brain barrier. It has a duration of action of 2 to 4 h. The usual dose is 5 to 10 mg orally tid, but some patients respond best to a decremental dose (e.g., 15 mg on awakening, 10 mg at noon, and 5 mg in the afternoon). Midodrine should not be taken after 6 P.M. Side effects include pruritus, uncomfortable piloerection, and supine hypertension. Pyridostigmine appears to improve OH without aggravating supine hypertension by enhancing ganglionic transmission (maximal when orthostatic, minimal supine). Fludrocortisone will reduce OH, but it aggravates supine hypertension. At doses between 0.1 mg/d and 0.3 mg bid orally, it enhances renal sodium conservation and increases the sensitivity of arterioles to NE. Susceptible patients may develop fluid overload, congestive heart failure, supine hypertension, or hypokalemia. Potassium supplements are often necessary with chronic administration of fludrocortisone. Sustained elevations of supine BP >180/110 mmHg should be avoided.

Postprandial OH may respond to several measures. Frequent, small, low-carbohydrate meals may diminish splanchnic shunting of blood after meals and reduce postprandial OH. Prostaglandin inhibitors (ibuprofen or indomethacin) taken with meals or midodrine (10 mg with the meal) can be helpful. The somatostatin analogue octreotide can be useful in the treatment of postprandial syncope by inhibiting the release of gastrointestinal peptides that have vasodilator and hypotensive effects. The subcutaneous dose ranges from 25 μg bid to 100 to 200 μg tid.

The patient should be taught to self-treat transient worsening of OH. Drinking two 250-mL (8-oz) glasses of water can raise standing BP 20 to 30 mmHg for about 2 h, beginning ~20 min after the fluid load. The patient can increase intake of salt and fluids (bouillon treatment), increase use of physical countermaneuvers, temporarily resort to a full-body stocking (compression pressure 30 to 40 mmHg), or increase the dose of midodrine. Supine hypertension (>180/110 mmHg) can be self-treated by avoiding the supine position and reducing fludrocortisone. A daily glass of wine, if requested by the patient, can be taken shortly before bedtime. If these simple measures are not adequate, drugs to be considered include oral hydralazine (25 mg qhs), oral procardia (10 mg qhs), or a nitroglycerin patch.

ACKNOWLEDGMENT

In the previous edition, Lewis Landsberg and James B. Young contributed the section on the anatomic organization of the autonomic nervous system.

355 TRIGEMINAL NEURALGIA, BELL'S PALSY, AND OTHER CRANIAL NERVE DISORDERS

M. Flint Beal, Stephen L. Hauser

Symptoms and signs of cranial nerve pathology are common in internal medicine. They often develop in the context of a widespread neurologic disturbance, and in such situations cranial nerve involvement may represent the initial manifestation of the illness. In other disorders, involvement is largely restricted to one or several cranial nerves; these distinctive disorders are reviewed in this chapter. Disorders of ocular movement are discussed in Chap. 25; disorders of smell, taste, and hearing in Chap. 26; and vertigo and disorders of vestibular function in Chap. 20.

FACIAL PAIN OR NUMBNESS

ANATOMIC CONSIDERATIONS The trigeminal (fifth cranial) nerve supplies sensation to the skin of the face and anterior half of the head (Fig. 355-1). Its motor part innervates the masseter and pterygoid masticatory muscles.

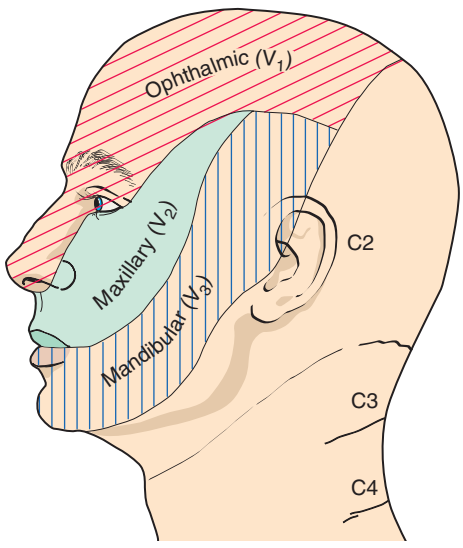

FIGURE 355-1 The three major sensory divisions of the trigeminal nerve consist of the ophthalmic, maxillary, and mandibular nerves.

TRIGEMINAL NEURALGIA (TIC DOULOUREUX) ■ Clinical Manifestations Trigeminal neuralgia is characterized by excruciating paroxysms of pain in the lips, gums, cheek, or chin and, very rarely, in the distribution of the ophthalmic division of the fifth nerve. The pain seldom lasts more than a few seconds or a minute or two but may be so intense that the patient winces, hence the term *tic*. The paroxysms, experienced as single jabs or clusters, tend to recur frequently, both day and night, for several weeks at a time. They may occur spontaneously or with movements of affected areas evoked by speaking, chewing, or smiling. Another characteristic feature is the presence of trigger zones, typically on the face, lips, or tongue, that provoke attacks; patients may report that tactile stimuli—e.g. washing the face, brushing the teeth, or exposure to a draft of air—generate excruciating pain. *An essential feature of trigeminal neuralgia is that objective signs of sensory loss cannot be demonstrated on examination.*

Trigeminal neuralgia is relatively common, with an estimated annual incidence of 4.5 per 100,000 individuals. Middle-aged and elderly persons are affected primarily, and ~60% of cases occur in women. Onset is typically sudden, and bouts tend to persist for weeks or months before remitting spontaneously. Remissions may be longlasting, but in most patients the disorder ultimately recurs.

Pathophysiology Symptoms result from ectopic generation of action potentials in pain-sensitive afferent fibers of the fifth cranial nerve root just before it enters the lateral surface of the pons. Compression or other pathology in the nerve leads to demyelination of large myelinated fibers that do not themselves carry pain sensation but become hyperexcitable and electrically coupled with smaller unmyelinated or poorly myelinated pain fibers in close proximity; this may explain why tactile stimuli, conveyed via the large myelinated fibers, can stimulate paroxysms of pain. Compression of the trigeminal nerve root by a blood vessel, most often the superior cerebellar artery or on occasion a tortuous vein, is the source of trigeminal neuralgia in a substantial

proportion of patients. In cases of vascular compression, age-related brain sagging and increased vascular thickness and tortuosity may explain the prevalence of trigeminal neuralgia in later life.

Differential Diagnosis Trigeminal neuralgia must be distinguished from other causes of face and head pain (Chap. 14) and from pain arising from diseases of the jaw, teeth, or sinuses. Pain from migraine or cluster headache tends to be deep seated and steady, unlike the superficial stabbing quality of trigeminal neuralgia; rarely, cluster headache is associated with trigeminal neuralgia, a syndrome known as *cluster-tic*. In temporal arteritis, superficial facial pain is present but is not typically shock-like, the patient frequently complains of myalgias and other systemic symptoms and an elevated erythrocyte sedimentation rate (ESR) is usually present (Chap. 306). When trigeminal neuralgia develops in a young adult or is bilateral, multiple sclerosis is a key consideration, and in such cases the cause is a demyelinating plaque at the root entry zone of the fifth nerve in the pons; often, evidence of facial sensory loss can be found on careful examination. Cases that are secondary to mass lesions—such as aneurysms, neurofibromas, or meningiomas—also usually produce objective signs of sensory loss in the trigeminal nerve distribution (trigeminal neuropathy, see below).

Laboratory Evaluation An ESR is indicated if temporal arteritis is suspected. In typical cases of trigeminal neuralgia, neuroimaging studies are not necessary.

℞ TREATMENT

Drug therapy with carbamazepine is effective in ~50 to 75% of patients. Carbamazepine should be started as a single daily dose of 100 mg taken with food, and increased gradually (by 100 mg daily every 1 to 2 days) until substantial (>50%) pain relief is achieved. Most patients require a maintenance dose of 200 mg qid. Doses >1200 mg daily provide no additional benefit. Dizziness, imbalance, sedation, and rare cases of agranulocytosis are the most important side effects of carbamazepine. If treatment is effective, it is usually continued for approximately 1 month and then tapered as tolerated. If carbamazepine is not well tolerated or is ineffective, phenytoin, 300 to 400 mg daily, can be tried. Baclofen may also be administered, either alone or in combination with carbamazepine or phenytoin. The initial dose is 5 to 10 mg tid, gradually increasing as needed to 20 mg qid.

If drug treatment fails, surgical therapy should be offered. The most widely applied procedure creates a heat lesion of the trigeminal (gasserian) ganglion or nerve, a method termed *radiofrequency thermal rhizotomy*. Injection of glycerol in Meckel's cave is a method preferred by some surgeons. Either procedure produces short-term relief in >95% of patients; however, long-term studies indicate that pain recurs in a substantial percentage of treated patients. Complications are infrequent in experienced hands. These procedures result in partial numbness of the face and carry a risk of corneal denervation with secondary keratitis when used for first-division trigeminal neuralgia.

A third treatment, microvascular decompression, requires a suboccipital craniotomy. This procedure has a >70% efficacy rate and a low rate of pain recurrence in responders; in a small number of cases, there is perioperative damage to the eighth or seventh nerve. High-resolution magnetic resonance angiography may be useful preoperatively to visualize the relationships between the fifth cranial nerve root and nearby blood vessels.

TRIGEMINAL NEUROPATHY A variety of diseases may affect the trigeminal nerve (Table 355-1). Most present with sensory loss on the face or with weakness of the jaw muscles. Deviation of the jaw on opening indicates weakness of the pterygoids on the side to which the jaw deviates. Some cases are due to Sjögren's syndrome or a collagen-vascular disease such as systemic lupus erythematosus, scleroderma, or mixed connective tissue disease. Among infectious causes, herpes zoster and leprosy should be considered. Tumors of the middle cranial fossa (meningiomas), of the trigeminal nerve (schwannomas), or of the base of the skull (metastatic tumors) may cause a combination of motor and sensory signs. Lesions in the cavernous sinus can affect the first and second divisions of the trigeminal nerve, and lesions of the superior orbital fissure can affect the first (ophthalmic) division; the accompanying corneal anesthesia increases the risk of ulceration (neurokeratitis).

Loss of sensation over the chin (mental neuropathy) can be the only manifestation of systemic malignancy. Rarely, an idiopathic form of trigeminal neuropathy is observed. It is characterized by numbness and paresthesia, sometimes bilaterally, with loss of sensation in the territory of the trigeminal nerve but without weakness of the jaw. Gradual recovery is the rule. Tonic spasm of the masticatory muscles, known as *trismus*, is symptomatic of tetanus (Chap. 124) or may occur in patients treated with phenothiazine drugs.

TABLE 355-1 Trigeminal Nerve Disorders

Nuclear (brainstem) lesions	Peripheral nerve lesions
Multiple sclerosis	Nasopharyngeal carcinoma
Stroke	Trauma
Syringobulbia	Guillain-Barré syndrome
Glioma	Sjögren's syndrome
Lymphoma	Collagen-vascular diseases
Preganglionic lesions	Sarcoidosis
Acoustic neuroma	Leprosy
Meningioma	Drugs (stilbamidine, trichloroethylene)
Metastasis	Idiopathic trigeminal neuropathy
Chronic meningitis	
Cavernous carotid aneurysm	
Gasserian ganglion lesions	
Trigeminal neuroma	
Herpes zoster	
Infection (spread from otitis media or mastoiditis)	

FACIAL WEAKNESS

ANATOMIC CONSIDERATIONS (Fig. 355-2) The seventh cranial nerve supplies all the muscles concerned with facial expression. The sensory component is small (the nervus intermedius); it conveys taste sensation from the anterior two-thirds of the tongue and probably cutaneous impulses from the anterior wall of the external auditory canal. The motor nucleus of the seventh nerve lies anterior and lateral to the abducens nucleus. After leaving the pons, the seventh nerve enters the internal auditory meatus with the acoustic nerve. The nerve continues its course in its own bony channel, the facial canal, and exits from the

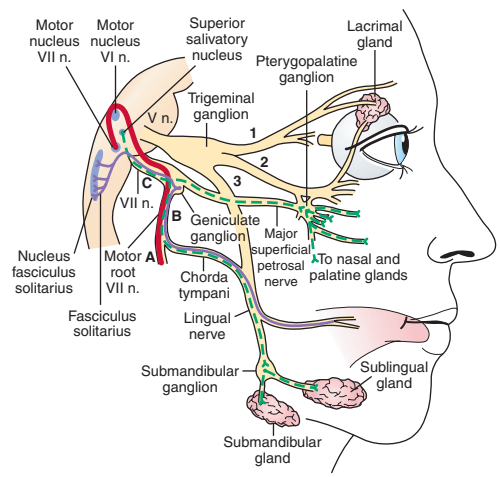

FIGURE 355-2 The facial nerve. A, B, and C denote lesions of the facial nerve at the stylomastoid foramen, distal and proximal to the geniculate ganglion, respectively. Green lines indicate the parasympathetic fibers, red line indicates motor fibers, and purple lines indicate visceral afferent fibers (taste). (*Adapted from Carpenter, 1978.*)

skull via the stylomastoid foramen. It then passes through the parotid gland and subdivides to supply the facial muscles.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression. The corner of the mouth droops, the creases and skin folds are effaced, the forehead is unfurrowed, and the eyelids will not close. Upon attempted closure of the lids, the eye on the paralyzed side rolls upward (*Bell's phenomenon*). The lower lid sags and falls away from the conjunctiva, permitting tears to spill over the cheek. Food collects between the teeth and lips, and saliva may dribble from the corner of the mouth. The patient complains of a heaviness or numbness in the face, but sensory loss is rarely demonstrable and taste is intact.

If the lesion is in the middle ear portion, taste is lost over the anterior two-thirds of the tongue on the same side. If the nerve to the stapedius is interrupted, there is hyperacusis (sensitivity to loud sounds). Lesions in the internal auditory meatus may affect the adjacent auditory and vestibular nerves, causing deafness, tinnitus, or dizziness. Intrapontine lesions that paralyze the face usually affect the abducens nucleus as well, and often the corticospinal and sensory tracts.

If the peripheral facial paralysis has existed for some time and recovery of motor function is incomplete, a continuous diffuse contraction of facial muscles may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Attempts to move one group of facial muscles may result in contraction of all (associated movements, or *synkinesis*). Facial spasms, initiated by movements of the face, may develop (*hemifacial spasm*). Anomalous regeneration of seventh nerve fibers may result in other troublesome phenomena. If fibers originally connected with the orbicularis oculi come to innervate the orbicularis oris, closure of the lids may cause a retraction of the mouth, or if fibers originally connected with muscles of the face later innervate the lacrimal gland, anomalous tearing ("crocodile tears") may occur with any activity of the facial muscles, such as eating. Another facial synkinesia is triggered by jaw opening, causing closure of the eyelids on the side of the facial palsy (jaw-winking).

BELL'S PALSY The most common form of facial paralysis is *Bell's palsy*. The annual incidence of this idiopathic disorder is between 11 and 40 per 100,000 annually, or about 1 in 60 persons in a lifetime.

Clinical Manifestations The onset of Bell's palsy is fairly abrupt, maximal weakness being attained by 48 h as a general rule. Pain behind the ear may precede the paralysis for a day or two. Taste sensation may be lost unilaterally, and hyperacusis may be present. In some cases there is mild cerebrospinal fluid lymphocytosis. Magnetic resonance imaging (MRI) may reveal swelling and uniform enhancement of the geniculate ganglion and facial nerve, and, in some cases, entrapment of the swollen nerve in the temporal bone. Approximately 80% of patients recover within a few weeks or months. Electromyography may be of some prognostic value; evidence of denervation after 10 days indicates that there has been axonal degeneration and that there will be a long delay (3 months, as a rule) before regeneration occurs and that it may be incomplete. The presence of incomplete paralysis in the first week is the most favorable prognostic sign.

Pathophysiology Bell's palsy is associated with the presence of herpes simplex virus type 1 DNA in endoneurial fluid and posterior auricular muscle, suggesting that a reactivation of this virus in the geniculate ganglion may be responsible. However, a causal role for herpes simplex virus in Bell's palsy is unproven.

Differential Diagnosis There are many other causes of facial palsy that must be considered in the differential diagnosis of Bell's palsy. Tumors that invade the temporal bone (carotid body, cholesteatoma, dermoid) may produce a facial palsy, but the onset is insidious and the course progressive. The *Ramsay Hunt syndrome*, presumably due to herpes zoster of the geniculate ganglion, consists of a severe facial palsy associated with a vesicular eruption in the pharynx, external auditory canal, and other parts of the cranial integument; often the eighth cranial nerve is affected as well. *Acoustic neuromas* frequently involve the facial nerve by local compression. Infarcts, demyelinating lesions of multiple sclerosis, and tumors are the common pontine lesions that interrupt the facial nerve fibers; other signs of brainstem involvement are usually present. Bilateral facial paralysis (facial diplegia) occurs in *Guillain-Barré syndrome* (Chap. 365) and also in a form of sarcoidosis known as *uveoparotid fever* (*Heerfordt syndrome*). Lyme disease is a frequent cause of facial palsies in endemic areas. The rare *Melkersson-Rosenthal syndrome* consists of a triad of recurrent facial paralysis, recurrent—and eventually permanent—facial (particularly labial) edema, and less constantly, plication of the tongue; its cause is unknown. Leprosy frequently involves the facial nerve, and facial neuropathy may also occur in diabetes mellitus.

All these forms of nuclear or peripheral facial palsy must be distinguished from the supranuclear type. In the latter, the frontalis and orbicularis oculi muscles are involved less than those of the lower part of the face, since the upper facial muscles are innervated by corticobulbar pathways from both motor cortices, whereas the lower facial muscles are innervated only by the opposite hemisphere. In supranuclear lesions there may be a dissociation of emotional and voluntary facial movements, and often some degree of paralysis of the arm and leg or an aphasia (in dominant hemisphere lesions) is conjoined.

Laboratory Evaluation The diagnosis of Bell's palsy can usually be made clinically in patients with (1) a typical presentation, (2) no risk factors or preexisting symptoms for other causes of facial paralysis, (3) absence of cutaneous lesions of herpes zoster in the external ear canal, and (4) a normal neurologic examination with the exception of the facial nerve. Particular attention to the eighth cranial nerve, which courses near to the facial nerve in the pontomedullary junction and in the temporal bone, and to other cranial nerves is essential. In atypical or uncertain cases, an ESR, testing for diabetes mellitus, a Lyme titer, angiotensin-converting enzyme and chest x-ray for possible sarcoidosis, or MRI scanning may be indicated.

℞ TREATMENT

Symptomatic measures include (1) the use of paper tape to depress the upper eyelid during sleep and prevent corneal drying, and (2) massage of the weakened muscles. A course of glucocorticoids, given as prednisone 60 to 80 mg daily during the first 5 days and then tapered over the next 5 days, appears to shorten the recovery period and modestly improve the functional outcome. In one double-blind study, patients treated within 3 days of onset with both prednisone and acyclovir (400 mg five times daily for 10 days) had a better outcome than patients treated with prednisone alone.

OTHER MOTOR DISORDERS OF THE FACE *Hemifacial spasm* consists of painless irregular involuntary contractions on one side of the face. Symptoms may develop as a sequela to Bell's palsy but may also be due to an irritative lesion of the facial nerve (e.g., an acoustic neuroma, an aberrant artery that compresses the nerve, or a basilar artery aneurysm). However, in the most common form of hemifacial spasm, the cause and pathology are unknown. Hemifacial spasm can be treated successfully with carbamazepine or, if this drug fails, with baclofen. Refractory cases due to vascular compression usually respond to surgical decompression of the facial nerve. *Blepharospasm* is an involuntary recurrent spasm of both eyelids that occurs in elderly persons as an isolated phenomenon or with varying degrees of spasm of other facial muscles. Severe, persistent cases of blepharospasm can be treated by local injection of botulinum toxin into the orbicularis oculi; the spasms are relieved for 3 to 4 months, and the injections can be repeated. *Facial myokymia* refers to a fine rippling activity of the facial muscles; it may be caused by multiple sclerosis or follow Guillain-Barré syndrome (Chap. 365).

Facial hemiatrophy occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one side of the face. It usually begins in adolescence or early adult

years and is slowly progressive. In its advanced form, the affected side of the face is gaunt, and the skin is thin, wrinkled, and rather brown. The facial hair may turn white and fall out, and the sebaceous glands become atrophic. The muscles and bones are not involved as a rule. Sometimes the atrophy becomes bilateral. The condition is a form of lipodystrophy. Treatment is cosmetic, consisting of transplantation of skin and subcutaneous fat.

OTHER CRANIAL NERVE DISORDERS

GLOSSOPHARYNGEAL NEURALGIA This form of neuralgia involves the ninth (glossopharyngeal) and sometimes portions of the tenth (vagus) cranial nerves. It resembles trigeminal neuralgia in many respects but is much less common. The pain is intense and paroxysmal; it originates on one side of the throat, approximately in the tonsillar fossa. In some cases the pain is localized in the ear or may radiate from the throat to the ear because of involvement of the tympanic branch of the glossopharyngeal nerve. Spasms of pain may be initiated by swallowing or coughing. There is no demonstrable motor or sensory deficit; the glossopharyngeal nerve supplies taste sensation to the posterior third of the tongue and, together with the vagus nerve, sensation to the posterior pharynx. Cardiac symptoms—bradycardia, hypotension, and fainting—have been reported. Medical therapy is similar to that for trigeminal neuralgia, and carbamazepine is generally the first choice. If drug therapy is unsuccessful, surgical procedures, including microvascular decompression if vascular compression is evident, or rhizotomy of glossopharyngeal and vagal fibers in the jugular bulb is frequently successful.

Very rarely, herpes zoster involves the glossopharyngeal nerve. Glossopharyngeal neuropathy in conjunction with vagus and accessory nerve palsies may also occur with a tumor or aneurysm in the posterior fossa or in the jugular foramen. Hoarseness due to vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the intact side, anesthesia of the posterior wall of the pharynx, and weakness of the upper part of the trapezius and sternocleidomastoid muscles make up the jugular foramen syndrome (Table 355-2).

DYSPHAGIA AND DYSPHONIA When the intracranial portion of one vagus (tenth cranial) nerve is interrupted, the soft palate droops ipsilaterally and does not rise in phonation. There is loss of the gag reflex on the affected side, as well as of the "curtain movement" of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying "ah." The voice is hoarse and slightly nasal, and the vocal cord lies immobile midway between abduction and adduction. Loss of sensation at the external auditory meatus and the posterior pinna may also be present.

The pharyngeal branches of both vagal nerves may be affected in diphtheria; the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

The vagus nerve may be involved at the meningeal level by neoplastic and infectious processes and within the medulla by tumors, vascular lesions (e.g., the lateral medullary syndrome), and motor neuron disease. This nerve may be involved by infection with herpes zoster virus. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, may be confused with diseases of the vagus nerves. Also, dysphagia is a symptom in some patients with myotonic dystrophy. →***See Chap. 33 for discussion of nonneurologic forms of dysphagia.***

The recurrent laryngeal nerves, especially the left, are most often damaged as a result of intrathoracic disease. Aneurysm of the aortic arch, an enlarged left atrium, and tumors of the mediastinum and bronchi are much more frequent causes of an isolated vocal cord palsy than are intracranial disorders. However, a substantial number of cases of recurrent laryngeal palsy remain idiopathic.

When confronted with a case of laryngeal palsy, the physician must attempt to determine the site of the lesion. If it is intramedullary, there are usually other signs, such as ipsilateral cerebellar dysfunction, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Horner syndrome. If the lesion is extramedullary, the glossopharyngeal and spinal accessory nerves are frequently involved (jugular foramen syndrome). If it is extracranial in the posterior laterocondylar or retroparotid space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial nerve palsies and a Horner syndrome (Table 355-2). If there is no sensory loss over the palate and pharynx and no palatal weakness or dysphagia, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region; the usual site of disease is then the mediastinum.

NECK WEAKNESS Isolated involvement of the accessory (eleventh cranial) nerve can occur anywhere along its route, resulting in partial or complete paralysis of the sternocleidomastoid and trapezius muscles. More commonly, involvement occurs in combination with deficits of the ninth and tenth cranial nerves in the jugular foramen or after exit from the skull (Table 355-2). An idiopathic form of accessory neuropathy, akin to Bell's palsy, has been described, and it may be recurrent in some cases. Most but not all patients recover.

TONGUE PARALYSIS The hypoglossal (twelfth cranial) nerve supplies the ipsilateral muscles of the tongue. The nucleus of the nerve or its fibers of exit may be involved by intramedullary lesions such as tumor, poliomyelitis, or most often motor neuron disease. Lesions of the basal meninges and the occipital bones (platybasia, invagination of occipital condyles, Paget's disease) may compress the nerve in its extramedullary course or in the hypoglossal canal. Isolated lesions of unknown cause can occur. Atrophy and fasciculation of the tongue develop weeks to months after interruption of the nerve.

MULTIPLE CRANIAL NERVE PALSIES

Several cranial nerves may be affected by the same disease process. In this situation, the main clinical problem is to determine whether the lesion lies within the brainstem or outside it. Lesions that lie on the surface of the brainstem are characterized by involvement of adjacent cranial nerves (often occurring in succession) and late and rather slight involvement of the long sensory and motor pathways and segmental structures lying within the brainstem. The opposite is true of primary lesions within the brainstem. The extramedullary lesion is more likely

TABLE 355-2 Cranial Nerve Syndromes

Site	Cranial Nerves	Usual Cause
Sphenoid fissure (superior orbital)	III, IV, first division V, VI	Invasive tumors of sphenoid bone; aneurysms
Lateral wall of cavernous sinus	III, IV, first division V, VI, often with proptosis	Infection, thrombosis, aneurysm, or fistula of cavernous sinus; invasive tumors from sinuses and sella turcica; benign granuloma responsive to glucocorticoids
Retrosphenoid space	II, III, IV, V, VI	Large tumors of middle cranial fossa
Apex of petrous bone	V, VI	Petrositis; tumors of petrous bone
Internal auditory meatus	VII, VIII	Tumors of petrous bone (dermoids, etc.); infectious processes; acoustic neuroma
Pontocerebellar angle	V, VII, VIII, and sometimes IX	Acoustic neuroma; meningioma
Jugular foramen	IX, X, XI	Tumors and aneurysms
Posterior laterocondylar space	IX, X, XI, XII	Tumors of parotid gland and carotid body and metastatic tumors
Posterior retroparotid space	IX, X, XI, XII and Horner syndrome	Tumors of parotid gland, carotid body, lymph nodes; metastatic tumor; tuberculous adenitis

to cause bone erosion or enlargement of the foramens of exit of cranial nerves. The intramedullary lesion involving cranial nerves often produces a crossed sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side).

Involvement of multiple cranial nerves outside the brainstem is frequently the result of diabetes or trauma, localized infections such as herpes zoster, infectious and noninfectious (especially carcinomatous) causes of meningitis (Chap. 361), granulomatous diseases such as Wegener's granulomatosis, Behçet's disease, enlarging saccular aneurysms, or tumors. Among the tumors, nasopharyngeal cancers, lymphomas, neurofibromas, meningiomas, chordomas, cholesteatomas, carcinomas, and sarcomas have all been observed to involve a succession of lower cranial nerves. Owing to their anatomic relationships, the multiple cranial nerve palsies form a number of distinctive syndromes, listed in Table 355-2. Sarcoidosis is the cause of some cases of multiple cranial neuropathy, and chronic glandular tuberculosis the cause of a few others. Platybasia, basilar invagination of the skull, and the adult Chiari malformation are additional causes. A purely motor disorder without atrophy always raises the question of myasthenia gravis (Chap. 366). As noted above, Guillain-Barré syndrome commonly affects the facial nerves bilaterally. In the Fisher variant of the Guillain-Barré syndrome, oculomotor paresis occurs with ataxia and areflexia in the limbs (Chap. 365). Wernicke encephalopathy can cause a severe ophthalmoplegia combined with other brainstem signs.

The *cavernous sinus syndrome* (Fig. 355-3) is a distinctive and frequently life-threatening disorder. It often presents as orbital or facial pain; orbital swelling and chemosis due to occlusion of the ophthalmic veins; fever; oculomotor neuropathy affecting the third, fourth, and sixth cranial nerves; and trigeminal neuropathy affecting the ophthalmic (V_1) and occasionally the maxillary (V_2) divisions of the trigeminal nerve. Cavernous sinus thrombosis, often secondary to infection from orbital cellulitis (frequently *Staphylococcus aureus*), a cutaneous source on the face, or sinusitis (especially with mucormycosis in diabetic patients), is the most frequent cause; other etiologies include aneurysm of the carotid artery, a carotid-cavernous fistula (orbital bruit may be present), meningioma, nasopharyngeal carcinoma, other tumors, or an idiopathic granulomatous disorder (Tolosa-Hunt syndrome). The two cavernous sinuses directly communicate via intercavernous channels, thus involvement on one side may extend to become bilateral. Early diagnosis is essential, especially when due to infection, and treatment depends upon the underlying etiology. In infectious cases, prompt administration of broad-spectrum antibiotics, drainage of any abscess cavities, and identification of the offending organism is essential. Anticoagulant therapy may benefit cases of primary thrombosis. Repair or occlusion of the carotid artery may be required for treatment of fistulas or aneurysms. The Tolosa-Hunt syndrome generally responds to glucocorticoids.

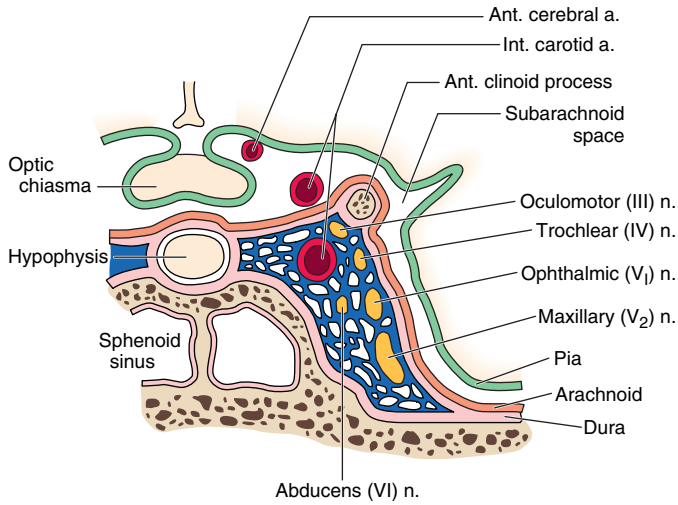

FIGURE 355-3 Anatomy of the cavernous sinus in coronal section, illustrating the location of the cranial nerves in relation to the vascular sinus, internal carotid artery (which loops anteriorly to the section), and surrounding structures.

An idiopathic form of multiple cranial nerve involvement on one or both sides of the face is occasionally seen. The syndrome consists of a subacute onset of boring facial pain, followed by paralysis of motor cranial nerves. The clinical features overlap those of the Tolosa-Hunt syndrome and appear to be due to idiopathic inflammation of the dura mater, which may be visualized by MRI. The syndrome is frequently responsive to glucocorticoids.

ACKNOWLEDGMENT

The authors acknowledge the contributions of Dr. Joseph B. Martin to this chapter in previous editions.

356 DISEASES OF THE SPINAL CORD

Stephen L. Hauser, Allan H. Ropper

Diseases of the spinal cord are frequently devastating. They can produce quadriplegia, paraplegia, and sensory deficits far beyond the damage they would inflict elsewhere in the nervous system because the spinal cord contains, in a small cross-sectional area, almost the entire motor output and sensory input of the trunk and limbs. Many spinal cord diseases are reversible if recognized and treated at an early stage (Table 356-1); thus, they are among the most critical of neurologic emergencies. The efficient use of diagnostic procedures, guided by a knowledge of the anatomy and the clinical features of common spinal cord diseases, is required for a successful outcome.

APPROACH TO THE PATIENT

SPINAL CORD ANATOMY RELEVANT TO CLINICAL SIGNS The spinal cord is a thin, tubular extension of the central nervous system contained within the bony spinal canal. It originates at the medulla and continues caudally to the conus medullaris at the lumbar level; its fibrous extension, the filum terminale, terminates at the coccyx. The adult spinal cord is ~46 cm (18 in.) long, oval or round in shape, and enlarged in the cervical and lumbar regions, where neurons that innervate the upper and lower extremities, respectively, are located. The white matter tracts containing ascending sensory and descending motor pathways are located peripherally, whereas nerve cell bodies are clustered in an inner region shaped like a four-leaf clover that surrounds the central canal (anatomically an extension

TABLE 356-1 *Some Treatable Spinal Cord Disorders*

Compressive
Epidural, intradural, or intramedullary neoplasm
Epidural abscess
Epidural hemorrhage
Cervical spondylosis
Herniated disc
Posttraumatic compression by fractured or displaced vertebra or hemorrhage
Vascular
Arteriovenous malformation
Antiphospholipid syndrome and other hypercoagulable states
Inflammatory
Multiple sclerosis including neuromyelitis optica
Transverse myelitis
Sarcoidosis
Vasculitis
Infectious
Viral: VZV, HSV-1 and -2, CMV, HIV, HTLV-I, others
Bacterial and mycobacterial: *Borrelia*, *Listeria*, syphilis, others
Mycoplasma pneumoniae
Parasitic: schistosomiasis, toxoplasmosis
Developmental
Syringomyelia
Meningomyelocoele
Tethered cord syndrome
Metabolic
Vitamin B_{12} deficiency (subacute combined degeneration)
Adrenomyeloneuropathy

Note: VZV, varicella-zoster virus; HSV, herpes simplex virus; CMV, cytomegalovirus; HTLV, human T cell lymphotropic virus.

of the fourth ventricle). The membranes that cover the spinal cord—the pia, arachnoid, and dura—are continuous with those of the brainstem and cerebral hemispheres.

The spinal cord has 31 segments, each defined by an exiting ventral motor root and entering dorsal sensory root. During embryologic development, growth of the cord lags behind that of the vertebral column, and in the adult the spinal cord (conus segments) ends at approximately the first lumbar vertebral body. The lower spinal nerves take an increasingly downward course to exit via intervertebral foramina. The first seven pairs of cervical spinal nerves exit above the same-numbered vertebral bodies, whereas all the subsequent nerves exit below the same-numbered vertebral bodies; this situation is due to the presence of eight cervical spinal cord segments but only seven cervical vertebrae. The relationship between spinal cord segments and the corresponding vertebral bodies is shown in Table 356-2. These relationships assume particular importance for localization of lesions that cause spinal cord compression; a T10 spinal cord level, for example, indicates involvement of the cord adjacent to the seventh or eighth thoracic vertebral body. In addition, at every level the main ascending and descending tracts are somatotopically organized with a laminated distribution that reflects the origin or destination of nerve fibers.

Level of the Lesion (Fig. 356-1) The presence of a horizontally defined level below which sensory, motor, and/or autonomic function is impaired is a hallmark of spinal cord disease. A sensory level is sought by asking the patient to identify a pinprick or cold stimulus (i.e., a dry tuning fork after immersion in cold water) applied to the low back and sequentially moved up toward the neck on each side. The presence of a sensory level indicates damage to the spinothalamic tract, but the lesion is located one to two segments above the perceived level of a unilateral spinal cord lesion and at the level of the lesion when bilateral. That is the result of the ascent of second-order sensory fibers, which originate in the dorsal horn, proceed to cross anterior to the central canal, and join the opposite spinothalamic tract. Lesions that transect the descending corticospinal and other motor tracts cause paraplegia or quadriplegia, with increased muscle tone, exaggerated deep tendon reflexes, and extensor plantar signs (the upper motor neuron syndrome). Such lesions also typically produce autonomic disturbances consisting of disturbed sweating and bladder, bowel, and sexual dysfunction.

TABLE 356-2 *Spinal Cord Levels Relative to the Vertebral Bodies*

Spinal Cord Level	*Corresponding Vertebral Body*
Upper cervical	Same as cord level
Lower cervical	1 level higher
Upper thoracic	2 levels higher
Lower thoracic	2 to 3 levels higher
Lumbar	T10-T12
Sacral	T12-L1
Coccygeal	L1
